Fig. 103.2: Mean inflation and the equilibrium gain as the government becomes more patient

```
     δ        C       ν
  0.95   0.0790    2.00
  0.96   0.0738    1.80
  0.97   0.0673    1.57
  0.98   0.0588    1.29
  0.99   0.0463    0.90
 0.995   0.0361    0.61

formula (sc_nu) at the book's δ = 0.99 entry, C = 0.019:  ν = 1.74
```

Mean inflation lies far below the Nash value at every discount factor and declines toward the Ramsey value of zero as $\delta \to 1$.

The values of C and ν match footnote 14 of chapter 7 of Sargent [1999] for $\delta = 0.95, 0.96$, and 0.98.

The book's entry for $\delta = 0.99$ ($C = 0.019$, mean inflation 0.25) is inconsistent with (103.8), which, as printed above, gives a much higher mean inflation at $C = 0.019$.

103.7.2 The role of ρ

Every number above was computed with the public's perceived root $\rho = 0.995$.

How the equilibrium depends on \rho showed that in Bray's model the equilibrium gain vanishes as $\rho \to 1$.

The next cell asks what happens here, for both values of σ_2, again using a finer frequency grid.

```
print(f"{'ρ':>7} {'C (σ2=1)':>10} {'ν (σ2=1)':>10} {'C (σ2=.3)':>11} {'ν (σ2=.3)':>11}
 ↪")
for ρ in [0.99, 0.995, 0.999, 0.9995]:
    row = []
    for σ2 in [1.0, 0.3]:
        C, ν, _ = MisspecifiedPhillips(δ=0.97, σ2=σ2, ρ=ρ, N=2**14).solve()
        row += [C, ν]
    print(f"{ρ:>7} {row[0]:>10.4f} {row[1]:>10.3f} {row[2]:>11.4f} {row[3]:>11.3f}")

m1 = MisspecifiedPhillips(δ=0.97, ρ=1.0, N=2**14)
ratio = max(m1.best_estimate(C) / C for C in np.linspace(0.005, 0.3, 30))
print(f"\nρ = 1: largest value of B(C)/C on the grid = {ratio:.3f}")
```

```
      ρ   C (σ2=1)    ν (σ2=1)    C (σ2=.3)    ν (σ2=.3)
   0.99     0.0918       1.260       0.1527       0.842
  0.995     0.0673       1.574       0.1138       1.069
  0.999     0.0316       2.474       0.0558       1.783
 0.9995     0.0223       2.905       0.0404       2.169

ρ = 1: largest value of B(C)/C on the grid = 0.311
```

Mean inflation rises toward the Nash value as $\rho \to 1$, for both values of σ_2.

With the exact unit root, $B(C) < C$ for every C, so the equilibrium gain is zero, the public's expectations stop moving, and by (103.8) mean inflation is the Nash rate θU^*.

So the better-than-Nash outcomes hold for each fixed $\rho < 1$, and vanish as $\rho \to 1$.

For each fixed $\rho < 1$ they approach Ramsey as $\delta \to 1$, but for each fixed $\delta < 1$ they disappear as $\rho \to 1$ (Exercise 103.8.3 studies the two limits).

The reason is the one given in *How the equilibrium depends on \rho*: the pull toward a large gain comes from the mean bias that a perceived model with $\rho < 1$ would leave, and it disappears with the unit root that the public's forecasting rule actually embodies.

103.7.3 Spectra and impulse responses

Let's compare the true and approximating inflation processes at the equilibrium, as in Figures 7.2 and 7.3 of Sargent [1999].

```
ν_star, F, _ = mp.true_process(C_star)
c_star = mp.best_estimate(C_star)
σ_ε2 = forecast_mse(F, ν_star, c_star, mp.ρ, mp.z)
H = np.abs((1 - (1 - c_star) * mp.z) / (1 - mp.ρ * mp.z))**2
G = H * σ_ε2

half = mp.N // 2
fig, ax = plt.subplots(figsize=(8, 5))
ax.plot(mp.ω[:half], np.log(F[:half]), 'C0', label='true model', lw=2)
ax.plot(mp.ω[:half], np.log(G[:half]), 'C1--', label='approximating model', lw=2)
```

(continues on next page)

(continued from previous page)

```
ax.set_xlabel(r'angular frequency $\omega$')
ax.set_ylabel('log spectral density')
ax.legend()
plt.show()
```

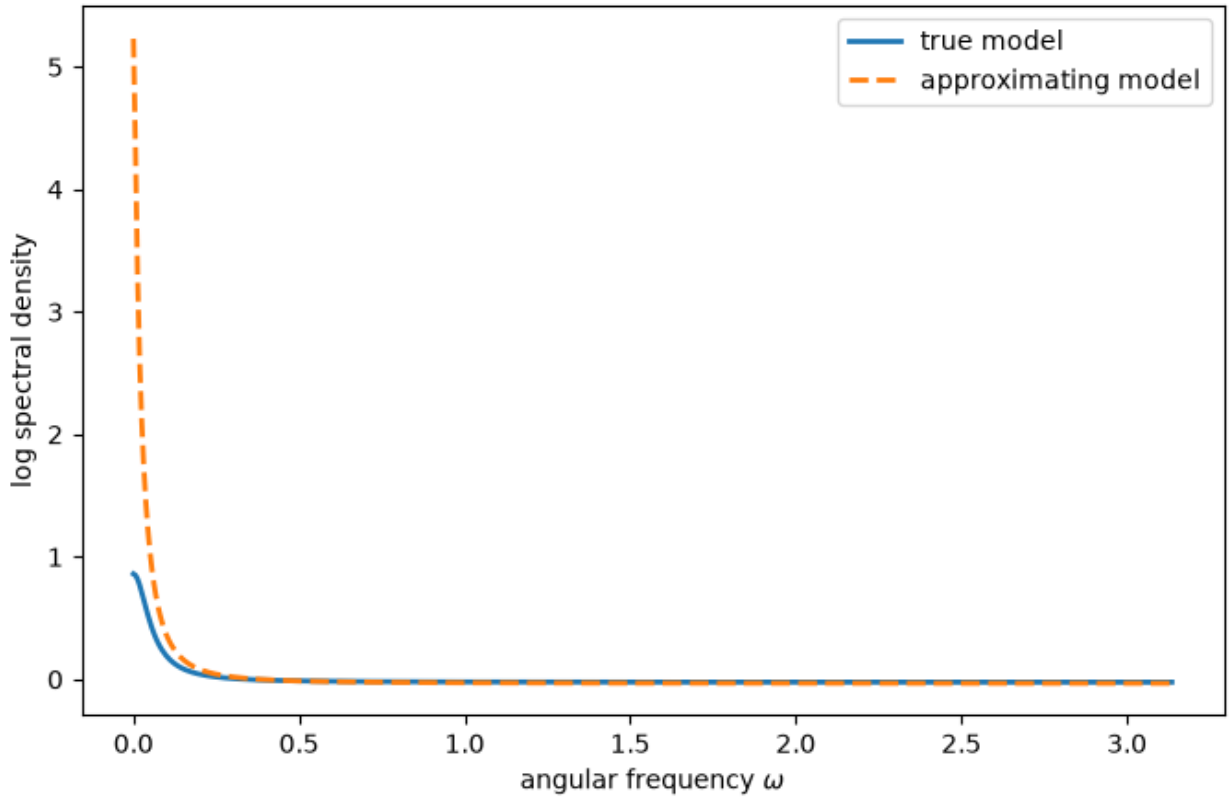

Fig. 103.3: Spectral densities of the true and approximating inflation processes at the equilibrium

The true and approximating spectral densities match well at all but the lowest frequencies.

The true inflation rate is only moderately serially correlated, and — as in the Bray model of *Optimal Misspecified Beliefs* — the approximating model uses a near unit root to simulate a mean, capturing first moments with second moments.

```
def ima_impulse(num, den, T=25):
    "IRF of (1 - num L)/(1 - den L)."
    h = np.empty(T)
    h[0] = 1.0
    for k in range(1, T):
        h[k] = den * h[k - 1]
    h[1:] -= num * h[:-1]
    return h

ψ = 1 - C_star * (1 - f2)
irf_true = ima_impulse(1 - C_star, ψ)
irf_approx = ima_impulse(1 - c_star, mp.ρ)
```

(continues on next page)

(continued from previous page)

```
lags = np.arange(len(irf_true))
fig, axes = plt.subplots(1, 2, figsize=(11, 4.5))
for ax, start in zip(axes, [0, 1]):
    ax.plot(lags[start:], irf_true[start:], 'C0o-', ms=4, label='true model', lw=2)
    ax.plot(lags[start:], irf_approx[start:], 'C1s--', ms=4,
            label='approximating model', lw=2)
    ax.set_xlabel('lag')
    ax.set_ylabel('response')
axes[0].set_title('all lags')
axes[1].set_title('lags 1 and beyond')
axes[0].legend()
plt.tight_layout()
plt.show()
```

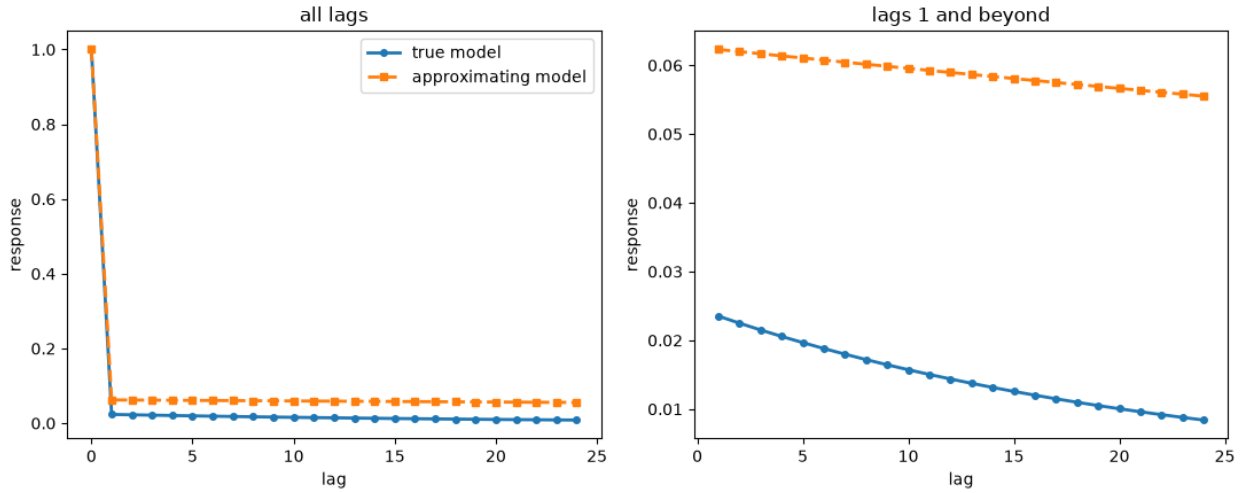

Fig. 103.4: Impulse responses of the true and approximating inflation processes

Here both models respond to a unit one-step-ahead forecast error, since $f(0) = g(0) = 1$.

The near unit root of the approximating model shows up as a response that dies out only at rate ρ, which over the horizon plotted looks like a nonzero asymptote.

103.7.4 Grounds for optimism

After the disappointments of the self-confirming equilibria, the equilibrium with forecast misspecification is heartening: it supports better-than-Nash outcomes.

The equilibrium concept is not self-confirming, but it has that spirit — it embodies a type of self-confirmation with a *wrong* model.

The approximation error is small.

```
print(f"one-step RMSE of the approximating model / true innovation s.d. = "
      f"{np.sqrt(σ_ε2) / mp.σ2:.4f}")
```

```
one-step RMSE of the approximating model / true innovation s.d. = 1.0155
```

The approximating model's one-step forecast errors are only slightly larger than the true innovations, so there is a nearly self-confirming model with much better than Nash outcomes.

But the optimism is conditional.

The good outcomes rest on the public's perceived model having a root ρ strictly below one; with the exact unit root that its forecasting rule embodies, the equilibrium gain is zero and the outcome is Nash.

What the example shows is that a small, hard-to-detect misspecification in the public's model can matter a great deal for outcomes.

The next lectures in this suite — *Adaptive Learning and Escape Dynamics*, *Escaping Nash Inflation*, and *Priors, Escapes, and Learning Cycles* — build adaptive, real-time versions of these models in which the government estimates its Phillips curve recursively from the most recent data.

There the classical (Nash) self-confirming equilibrium becomes the attractor of the learning dynamics.

With a constant gain, the government escapes from it recurrently toward Ramsey and is pulled back, and better-than-Nash outcomes reappear during the escapes.

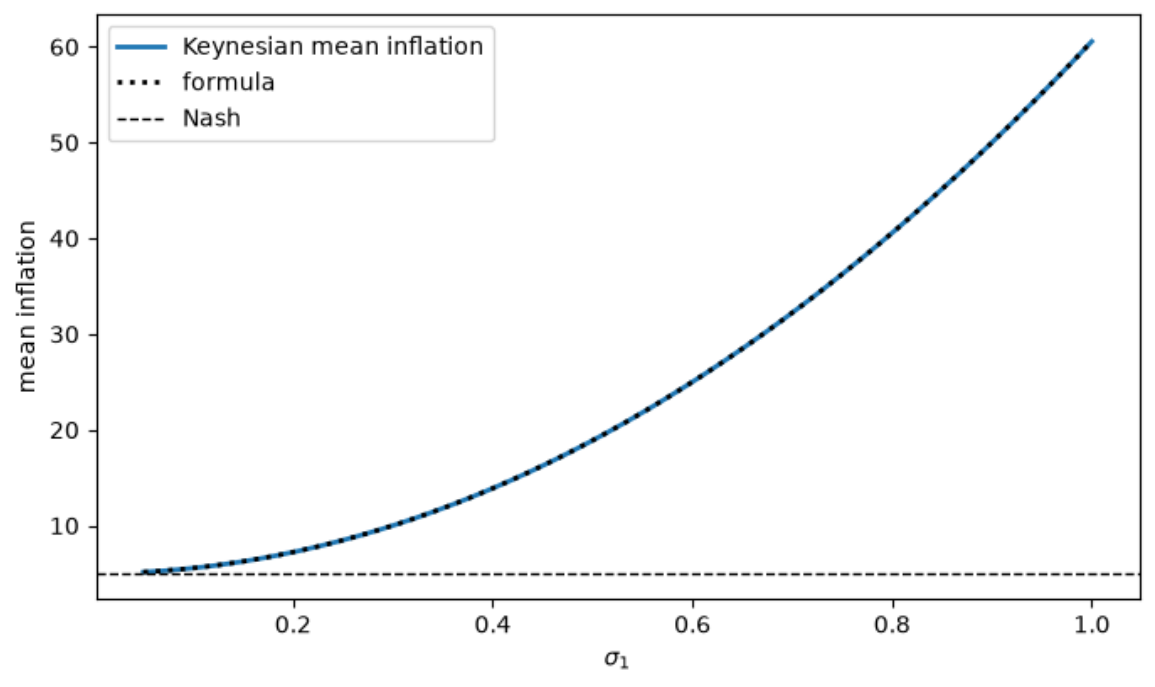
Those escapes run through the *government's* beliefs, not through a misspecification of the public's.

103.8 Exercises

Exercise 103.8.1

The gap between the two static self-confirming equilibria is driven by the variances σ_1^2 (of the Phillips curve shock) and σ_2^2 (of the inflation surprise).

The classical equilibrium always delivers mean inflation equal to the Nash value θU^*, but the Keynesian mean inflation depends on the ratio σ_1/σ_2.



Fixing $\sigma_2 = 0.3$, $\theta = 1$, $U^* = 5$, plot Keynesian mean inflation as a function of $\sigma_1 \in [0.05, 1.0]$, and compare it with formula (103.5).

What happens as $\sigma_1 \to 0$, and why?

Solution

```
σ1_grid = np.linspace(0.05, 1.0, 50)
y_keynes = [SelfConfirmingStatic(σ1=σ1, σ2=0.3).keynesian()[2]
            for σ1 in σ1_grid]
y_formula = 5.0 * (1 + σ1_grid**2 / 0.3**2)

fig, ax = plt.subplots(figsize=(8, 4.5))
ax.plot(σ1_grid, y_keynes, lw=2, label='Keynesian mean inflation')
ax.plot(σ1_grid, y_formula, 'k:', lw=2, label='formula')
ax.axhline(5.0, color='k', ls='--', lw=1, label='Nash')
ax.set_xlabel(r'$\sigma_1$')
ax.set_ylabel('mean inflation')
ax.legend()
plt.show()
```

The computed values lie on the formula $\theta U^*(1 + \sigma_1^2/(\theta^2\sigma_2^2))$.

As $\sigma_1 \to 0$ the Phillips curve becomes nearly deterministic, the Keynesian slope $\beta_1 \to -1/\theta$, and the two directions of fit agree, so Keynesian mean inflation approaches the Nash value.

As σ_1 grows, unemployment becomes noisier, the Keynesian regression of y on U flattens, and the government perceives a more exploitable tradeoff, raising mean inflation quadratically in σ_1.

Exercise 103.8.2

Self-confirming equilibria are rest points of least squares learning.

Here is what decreasing-gain learning does in the static model, in which the government re-estimates its Phillips curve every period.

Each period the government sets $\hat{y}_t$ by (103.3) at its current beliefs, the public expects $x_t = \hat{y}_t$, (U_t, y_t) are generated by the actual Phillips curve with $\rho_1 = \rho_2 = 0$, and the government updates its regression by recursive least squares with gain $1/(t + t_0)$.

The value $t_0 = 100$ represents a prior sample of 100 observations, and the regression's moment matrix starts at its population value in the self-confirming equilibrium.

1. For each direction of fit, simulate 500 paths of 20,000 periods, starting at the respective self-confirming equilibrium.
2. For the Keynesian fit, show that the root mean square deviation of $\hat{y}_t$ from its equilibrium value 10 shrinks roughly like $t^{-0.2}$, as its E-stability eigenvalue predicts.
3. For the classical fit, compute the fraction of paths whose target ends more than one point away from the Nash value 5.
4. Explain the difference, using the moments of (U_t, y_t) when the target $\hat{y}_t$ moves over time.

Solution

```
def rls_static(direction, n_paths=500, T=20_000, t0=100,
               θ=1.0, U_star=5.0, σ1=0.3, σ2=0.3, seed=0):
    """
    Decreasing-gain recursive least squares in the static model.
    Beliefs are (intercept, slope).  Returns the targets ŷ_t, shape
    (n_paths, T), and the target in the self-confirming equilibrium.
    """
    rng = np.random.default_rng(seed)
    if direction == 'classical':                    # regress U on (1, y)
        y_sce = θ * U_star
        b0 = np.array([(1 + θ**2) * U_star, -θ])
        R0 = np.array([[1.0, y_sce], [y_sce, y_sce**2 + σ2**2]])
    else:                                           # regress y on (1, U)
        β1 = -θ * σ2**2 / (σ1**2 + θ**2 * σ2**2)
        y_sce = -U_star / β1
        b0 = np.array([(1 + β1**2) * y_sce, β1])
        R0 = np.array([[1.0, U_star],
                       [U_star, U_star**2 + θ**2 * σ2**2 + σ1**2]])
    b = np.tile(b0, (n_paths, 1))
    R = np.tile(R0, (n_paths, 1, 1))
    targets = np.empty((n_paths, T))
    ones = np.ones(n_paths)

    for t in range(T):
        intercept, slope = b[:, 0], b[:, 1]
        if direction == 'classical':
            y_hat = -slope * intercept / (1 + slope**2)
        else:
            y_hat = intercept / (1 + slope**2)
        targets[:, t] = y_hat

        v1 = σ1 * rng.standard_normal(n_paths)
        v2 = σ2 * rng.standard_normal(n_paths)
        y = y_hat + v2
        U = U_star - θ * v2 + v1
        if direction == 'classical':
            X, lhs = np.column_stack([ones, y]), U
        else:
            X, lhs = np.column_stack([ones, U]), y

        g = 1 / (t + 1 + t0)
        R = R + g * (X[:, :, None] * X[:, None, :] - R)
        err = lhs - np.sum(X * b, axis=1)
        b = b + g * np.linalg.solve(R, (X * err[:, None])[:, :, None])[:, :, 0]

    return targets, y_sce

results = {d: rls_static(d) for d in ['classical', 'keynesian']}
t_axis = np.arange(1, 20_001)

fig, axes = plt.subplots(1, 2, figsize=(11, 4.5))
for d, color in [('classical', 'C0'), ('keynesian', 'C1')]:
    targets, y_sce = results[d]
    axes[0].plot(t_axis, targets[:15].T, color=color, lw=0.6, alpha=0.7)
    axes[0].axhline(y_sce, color=color, ls='--', lw=1.5, label=f'{d.capitalize()}␣
↪SCE')
```

```
    far = np.mean(np.abs(targets - y_sce) > 1.0, axis=0)
    axes[1].plot(t_axis, far, color=color, lw=2, label=d.capitalize())
axes[0].set_xlabel('$t$')
axes[0].set_ylabel(r'target inflation $\hat y_t$')
axes[0].legend()
axes[1].set_xlabel('$t$')
axes[1].set_ylabel('fraction of paths more than 1 from the SCE')
axes[1].legend()
plt.tight_layout()
plt.show()

targets, y_sce = results['keynesian']
rms = np.sqrt(np.mean((targets - y_sce)**2, axis=0))
keep = slice(200, None)
slope = np.polyfit(np.log(t_axis[keep] + 100), np.log(rms[keep]), 1)[0]
print(f"Keynesian: slope of log RMS deviation on log t = {slope:.2f}  (eigenvalue -
↪0.2)")
for d in ['classical', 'keynesian']:
    targets, y_sce = results[d]
    print(f"{d}: fraction of paths more than 1 from the SCE at the end = "
          f"{np.mean(np.abs(targets[:, -1] - y_sce) > 1.0):.2f}")
```

```
Keynesian: slope of log RMS deviation on log t = -0.17  (eigenvalue -0.2)
classical: fraction of paths more than 1 from the SCE at the end = 0.85
keynesian: fraction of paths more than 1 from the SCE at the end = 0.00
```

The Keynesian learner converges slowly, at roughly the rate its eigenvalue predicts.

The classical learner, whose eigenvalue $-1/2$ promises faster convergence, does much worse: a large fraction of its paths escape toward Ramsey and are still far from Nash after 20,000 periods.

The reason lies in what the data show when the target moves.

Since only surprises move unemployment, a change in $\hat{y}_t$ moves y_t but not U_t.

In a regression of U on y, that variation adds to the variance of the regressor but not to its covariance with U, so it flattens the estimated slope toward zero.

A flatter perceived curve makes the Phelps rule (103.3) recommend lower inflation, which moves the target further and flattens the slope again: a self-reinforcing escape toward Ramsey.

In a regression of y on U, the same variation adds only to the variance of the dependent variable, and leaves the slope alone.

E-stability is a statement about small deviations from the equilibrium; escapes are large deviations, studied in *Adaptive Learning and Escape Dynamics* and *Escaping Nash Inflation*.

With a decreasing gain, least squares still converges to the equilibrium asymptotically, but an escape that starts early can last a long time, because the falling gain also slows the return (*Least squares learning: a decreasing gain*).

Exercise 103.8.3

Formula (103.8) shows that mean inflation in the equilibrium with misspecified beliefs depends on δ and on the equilibrium gain C, which depends on δ and on the public's perceived root ρ.

1. Compute the equilibrium C and mean inflation ν for $\delta \in \{0.97, 0.99, 0.999\}$ and $\rho \in \{0.995, 0.9995, 1\}$, with $\sigma_2 = 1$.
2. What happens as $\delta \to 1$ with ρ fixed, and as $\rho \to 1$ with δ fixed?
3. What does this imply for the claim that the equilibrium approaches Ramsey as the government becomes patient?

Solution

```
def v_closed(C, δ, θ=1.0, U_star=5.0):
    "Mean inflation (sc_nu) given the public's gain C."
    return θ * U_star * (1 - δ) / (1 - δ + δ * C)

print(f"{'δ':>6} {'ρ':>7} {'C':>8} {'ν':>7}")
for δ in [0.97, 0.99, 0.999]:
    for ρ in [0.995, 0.9995]:
        C, ν, _ = MisspecifiedPhillips(δ=δ, ρ=ρ, N=2**14).solve()
        print(f"{δ:>6} {ρ:>7} {C:>8.4f} {ν:>7.3f}")
    m1 = MisspecifiedPhillips(δ=δ, ρ=1.0, N=2**14)
    ratio = max(m1.best_estimate(C) / C for C in np.linspace(0.005, 0.3, 20))
    print(f"{δ:>6} {1:>7} {0:>8.4f} {v_closed(0.0, δ):>7.3f}"
          f"   (largest B(C)/C = {ratio:.2f})")
```

```
     δ       ρ        C       ν
  0.97   0.995   0.0673   1.574
  0.97  0.9995   0.0223   2.905
  0.97       1   0.0000   5.000   (largest B(C)/C = 0.31)
  0.99   0.995   0.0463   0.896
  0.99  0.9995   0.0166   1.894
  0.99       1   0.0000   5.000   (largest B(C)/C = 0.23)
 0.999   0.995   0.0199   0.239
 0.999  0.9995   0.0075   0.587
 0.999       1   0.0000   5.000   (largest B(C)/C = 0.04)
```

For fixed $\rho < 1$, mean inflation falls toward zero as δ rises, because the equilibrium gain falls much more slowly than $1 - \delta$ in (103.8).

For fixed δ, mean inflation rises toward the Nash value as $\rho \to 1$, because the equilibrium gain falls to zero, and at $\rho = 1$ it is exactly θU^* for every $\delta < 1$.

The two limits do not commute.

The claim that the equilibrium approaches Ramsey as the government becomes patient holds for each fixed $\rho < 1$, but it is not uniform in ρ: the closer the public's perceived root is to the unit root that its rule embodies, the more

patient the government must be to get close to Ramsey.

104.1 Overview

This lecture is the culmination of the theory built by Sargent [1999].

It follows chapter 8, the most ambitious chapter of the book.

Everything after it in this suite builds on it:

- *Escaping Nash Inflation* and *Priors, Escapes, and Learning Cycles* sharpen its analytics;
- *Econometric Policy Evaluation* follows the book's chapter 9 in taking the adaptive models to data;
- *Drifts and Volatilities* and *Drifts and Volatilities after 2000* put its central claim to an empirical test; and
- *The Lost Conquest: Fed Policy in the 2020s* carries its tools to a later episode.

In *Self-Confirming Equilibria* a government held *fixed* beliefs about the Phillips curve — beliefs that were confirmed by the data those beliefs generated.

Here we make the government a real-time econometrician.

Each period it

- re-estimates its Phillips curve by recursive least squares from the data seen so far, and
- sets inflation at the first-period recommendation of the *Phelps problem* for its *current* estimate.

We ask whether such an adaptive government converges to a self-confirming equilibrium.

The answer depends on a single parameter — the **gain** that governs how fast old data are discounted:

- With a *decreasing* gain that implements least squares, the mean dynamics pull the economy toward a self-confirming equilibrium *asymptotically*, and in the limit we get nothing new: the system is stuck near the Nash outcome.
- With a *constant* gain, agents discount past data, convergence is arrested, and **new outcomes emerge** as the system recurrently *escapes* the self-confirming equilibrium toward the Ramsey (zero-inflation) outcome, in spontaneous stabilizations that resemble the arrival of Volcker.

The word "asymptotically" matters.

In a finite sample a falling gain also slows the journey *back* to the self-confirming equilibrium, so a least squares government whose prior is not tight can escape early and then stay near Ramsey for a very long time (*Least squares learning: a decreasing gain*).

These escapes are the heart of the *vindication of econometric policy evaluation* story from *The Rise and Fall of U.S. Inflation*: an adaptive government, learning a Solow-Tobin distributed-lag version of the natural-rate hypothesis, is led by chance observations to stabilize inflation.

This lecture replicates, analyzes, and reinterprets simulations like those of Christopher Sims and Heetaik Chung [Chung, 1990, Sims, 1988].

Their governments ran **Kalman filters** on Phillips-curve coefficients that they believed drift as random walks (see *A First Look at the Kalman Filter*).

Sims's government fit a *static* Phillips curve, and Chung's fit a distributed lag.

In their simulations the government escaped from Nash once and stayed near Ramsey, apparently indefinitely.

Chung's filter had a gain that did not vanish, which let him estimate the government's learning rule from post-war U.S. data (*The econometricians did return the compliment*; Exercise **??** poses a stripped-down version of his problem).

Following Sargent [1999], we instead give the government **constant-gain recursive least squares**, which produces *recurrent* escapes: the mean dynamics keep pulling the beliefs back toward the self-confirming equilibrium, and the economy keeps escaping again.

Sargent and Williams [2005] trace the difference to the government's prior about coefficient drift, and *Priors, Escapes, and Learning Cycles* reproduces their account.

Because Sims's government fit a static curve, the induction-hypothesis mechanism studied below does not apply to his simulations (chapter 8, footnote 15 of Sargent [1999]).

Here we study the escapes by *simulation*; *Escaping Nash Inflation* then characterizes them analytically as a second, deterministic ODE, and *Priors, Escapes, and Learning Cycles* asks how the government's prior about coefficient drift reshapes both forces.

Let's import what we need:

```
import matplotlib.pyplot as plt
import numpy as np
from scipy.integrate import solve_ivp
from scipy.linalg import solve_discrete_are, solve_discrete_lyapunov
```

104.2 A primer on recursive algorithms

This section is a self-contained primer.

It develops the two analytical objects — **mean dynamics** and **escape routes** — that organize everything that follows, and it explains the sense in which one and the same recursion can be read either as an *algorithm* for computing a self-confirming equilibrium or as a *model* of a government adapting in real time.

The material is technical, and readers who want the punchline can skip to the simulations below and refer back as needed.

Readers arriving from the Bounded Rationality lectures have seen the scalar version of the mean dynamics, together with the T-map and E-stability, in *One recursion, many learners*, and *Least Squares Learning in Self-Referential Models* proves the convergence theorems for linear self-referential models.

This primer holds the general large-deviation theory for the whole suite; *Escaping Nash Inflation* applies it to a static version of the model.

104.2.1 Beliefs, moment conditions, and self-confirming equilibria

A self-confirming equilibrium under the classical identification is pinned down by the government's beliefs about some population moments and the regression coefficients they imply.

Under the classical identification these beliefs are measured by the triple $(\gamma,\ EX_C X_C^\top,\ EUX_C)$, where γ is the vector of Phillips-curve coefficients.

In the adaptive models of this lecture the *time-t values* of these objects are among the economy's state variables; they disappear as state variables in a self-confirming equilibrium only because there they are constants.

A self-confirming equilibrium under the classical identification satisfies the moment conditions

$$\begin{aligned} \mathbb{E}\, R_{XC}^{-1}(\gamma)\left[U_t X_{Ct}^\top - (X_{Ct}X_{Ct}^\top)\,\gamma\right] &= 0, \\ \mathbb{E}\, X_{Ct}X_{Ct}^\top - R_{XC}(\gamma) &= 0, \end{aligned} \tag{104.1}$$

where the mathematical expectation is taken with respect to a distribution of (U_t, X_{Ct}) that depends on γ through the solution $h(\gamma)$ of the Phelps problem.

Self-reference surfaces precisely in this dependence of the distribution on γ: the government's beliefs shape its policy, which shapes the data on which the beliefs are then checked.

The first line of (104.1) is the least squares normal equations for γ, pre-multiplied by the inverse second-moment matrix; the second line defines R_{XC} as the second-moment matrix of the regressors.

It is convenient to assemble all the unknowns into a single vector

$$\phi = \begin{bmatrix} \gamma \\ \mathrm{col}(R_{XC}) \end{bmatrix}, \tag{104.2}$$

where $\mathrm{col}(R_{XC})$ stacks the columns of R_{XC}.

The moment conditions (104.1) then take the compact form

$$\mathbb{E}\left[F(\phi,\zeta)\right] = 0, \qquad b(\phi) \equiv \mathbb{E}\left[F(\phi,\zeta)\right], \tag{104.3}$$

where ζ is a random vector and the expectation is over its distribution (which, again, depends on ϕ).

A self-confirming equilibrium is a set of beliefs ϕ_f that is a zero of b,

$$b(\phi_f) = 0. \tag{104.4}$$

The rest of this section describes recursive algorithms for finding such a zero, and a change of perspective that converts each computational algorithm into a model of real-time adaptation.

104.2.2 Iteration

The simplest algorithm computes a sequence $\{\phi_k\}$ of estimates from

$$\phi_{k+1} = \phi_k + a\, b(\phi_k), \tag{104.5}$$

where the distribution used to evaluate the expectation defining $b(\phi_k)$ in (104.3) is itself evaluated at the current estimate ϕ_k, and $a > 0$ is a step size.

This is the relaxation algorithm used to compute self-confirming equilibria in *Self-Confirming Equilibria*.

Each step requires evaluating the mathematical expectation $b(\phi) = \mathbb{E}[F(\phi, \zeta)]$ — which is exactly why we needed the moment (Lyapunov) formulas there.

104.2.3 Stochastic approximation

A random version of (104.5) is obtained by replacing the mean $b(\phi_n)$ by a single random draw $F(\phi_n, \zeta_n)$ and letting the *step size* do the averaging:

$$\phi_{n+1} = \phi_n + a_n F(\phi_n, \zeta_n), \qquad a_n > 0, \quad \sum_{n=0}^{\infty} a_n = +\infty. \tag{104.6}$$

To study the limiting behavior of (104.6), define **artificial time**

$$t_n = \sum_{k=0}^{n} a_k, \tag{104.7}$$

form the sampled process $\phi(t_n) = \phi_n$, and interpolate (typically piecewise-linearly) to obtain a continuous-time process $\phi^o(t)$.

One then approximates $\phi^o(t)$ by a continuous-time process as $n \to \infty$ and uses it to characterize the tail of the original sequence.

Different rates of decrease of the gain sequence $\{a_n\}$ produce different approximating processes, because they change the mapping (104.7) from real time n to artificial time t_n.

Note

Recursive stochastic approximation originates with Robbins and Monro [1951], who devised (104.6) to find the root of a regression function observed with noise, and with Kiefer and Wolfowitz [1952], who adapted it to find the maximum of a regression function (the "K-W" algorithms referred to below).

The "ODE method" for analyzing such recursions — approximating the interpolated process by the solution of a differential equation — is due to Ljung [1977]; book-length treatments are Benveniste *et al.* [1990] and Kushner and Yin [2003].

Its use to study learning in self-referential macroeconomic models is developed by Marcet and Sargent [1989] and, comprehensively, by Evans and Honkapohja [2001].

104.2.4 Mean dynamics

The classic stochastic approximation algorithms of Kushner and Clark [1978] and Ljung [1977] set the gain to decrease like $a_n \sim 1/n$ (at least for $t \geq N$ for some $N > 0$).

This permits strong statements about the almost sure convergence of (104.6) to a zero of $b(\phi)$.

For $a_n \sim 1/n$, as $n \to \infty$ the interpolated process $\phi^o(t)$ approaches the solution of the ordinary differential equation

$$\frac{d\phi^o(t)}{dt} = b\left(\phi^o(t)\right), \tag{104.8}$$

which we call the **mean dynamics** — the vector generalization of the scalar least-squares-learning ODE of *Least squares learning converges to Nash*.

A law of large numbers makes the random term in the continuous-time approximation vanish fast enough that the mean dynamics (104.8) describe the *tail* behavior of the stochastic process (104.6).

Consequently:

- if the algorithm converges (almost surely), it converges to a zero of the mean dynamics, $b(\phi) = 0$ — a self-confirming equilibrium; and
- the ODE (104.8) carries the information about local and global stability of the algorithm.

Local stability is governed by the eigenvalues of the Jacobian of b at a rest point: if all eigenvalues have negative real parts the rest point is locally stable.

This is the condition called **E-stability** (*One recursion, many learners*).

For least squares the Jacobian has a simple structure, established by the Jacobian-reduction proposition (*Proposition 139.4.2*) of *Least Squares Learning in Self-Referential Models*:

- the block belonging to the second-moment matrix contributes repeated eigenvalues equal to -1; and
- the remaining eigenvalues are those of $DT - I$, where the map T sends a belief to the population regression coefficients that the belief induces.

Under a decreasing gain the eigenvalue of largest real part also governs the *rate* of convergence.

A necessary condition for the usual $\sqrt{t}$ rate, with asymptotically normal estimates, is that every eigenvalue have real part below $-\frac{1}{2}$.

Mean dynamics near the self-confirming equilibrium computes these eigenvalues for our model; one of them, repeated five times, sits exactly at the $-\frac{1}{2}$ boundary.

That boundary concerns the asymptotic distribution of a decreasing-gain estimator.

It does not govern how often a constant-gain government escapes; the large-deviation objects introduced below do.

> **Note**
>
> Brock and Hommes [1997] build models whose global behavior is driven by stable mean dynamics far from rational expectations equilibria together with local instability of adaptation near them — a complementary mechanism for generating endogenous fluctuations from learning.

104.2.5 Constant gain and convergence in distribution

We are equally interested in versions of (104.6) with a *constant* gain $a_n = \epsilon > 0$ for all n.

Limit theorems for constant-gain algorithms use a weaker notion of convergence — convergence *in distribution* — than the almost-sure convergence available when $a_n \sim 1/n$.

They concern small-noise limits, taken as $\epsilon \to 0$ and $n\epsilon \to +\infty$ simultaneously.

Again using artificial time (104.7), form the family of processes

$$\phi^{\epsilon}_{n+1} = \phi^{\epsilon}_n + \epsilon\, F(\phi^{\epsilon}_n, \zeta_n), \tag{104.9}$$

interpolate to obtain $\phi^{\epsilon}(t)$, and study its small-ϵ limit.

Dupuis and Kushner, Kushner and Yin [2003], and others verified conditions under which, as $\epsilon \to 0$ and $\epsilon n \to \infty$, the process ϕ^{ϵ}_n converges *in distribution* to the zeros of the same mean dynamics (104.8); the restrictions on the mean dynamics needed for convergence match those from the classic $a_n \sim 1/n$ theory.

Unlike the decreasing-gain algorithm, a constant-gain algorithm does not settle down: (γ, R_{XC}) converges to a *stationary stochastic process*, perpetually fluctuating around — and occasionally far from — the self-confirming equilibrium.

104.2.6 Escape routes and the theory of large deviations

The feature of the constant-gain apparatus that matters most for this lecture is not convergence toward ϕ_f but the *excursions away from it*.

We are as interested in movements away from a self-confirming equilibrium as in those toward one, because the recurrent stabilizations in the simulations are precisely such excursions.

The **theory of large deviations** characterizes these excursions through three objects.

First, the log moment generating function of (an averaged version of) the innovation process $F(\phi_n, \zeta_n)$: for a vector α conformable to F,

$$H(\alpha, \phi) = \log \mathbb{E} \exp\left(\alpha^{\top} F(\phi, \zeta)\right), \tag{104.10}$$

where the expectation is over the distribution of ζ.

Note

Equation (104.10) is a heuristic shorthand.

The object that actually enters the theory is a *time-averaged* limit; Dupuis and Kushner [1987] and Kushner and Yin [2003] assume that for each block width $\Delta > 0$ the following limit exists uniformly in ϕ_i, α_i on any compact set: $$\sum_{i=0}^{T/\Delta-1} \Delta\, H(\alpha_i, \phi_i) = \lim_{N\to\infty} \frac{\Delta}{N} \log \mathbb{E} \exp \sum_{i=0}^{T/\Delta-1} \alpha_i^{\top} \sum_{j=iN}^{iN+N-1} F(\phi_i, \zeta_j).$$ *The inner sum averages the innovations over a block of length* N; the double limit lets us treat serially dependent innovations.

Second, the **Legendre transform** of H, which plays the role of a rate function:

$$L(\xi, \phi) = \sup_{\alpha} \left[\alpha^{\top}\xi - H(\alpha, \phi)\right]. \tag{104.11}$$

Third, the **action functional**, which measures the "cost" of a candidate escape path $\phi(\cdot)$:

$$S(T, \phi) = \begin{cases} \displaystyle\int_0^T L\big(\tfrac{d}{ds}\phi(s),\, \phi(s)\big)\, ds & \text{if } \phi(s) \text{ is absolutely continuous and } \phi(0) = \phi_f, \\ \infty & \text{otherwise.} \end{cases} \tag{104.12}$$

Dupuis and Kushner turn the search for the most likely escape into a *deterministic control problem*.

Let D be a compact set containing ϕ_f, with boundary ∂D, and let $C[0,T]$ be the continuous functions on $[0,T]$.

The escape route is the path $\tilde{\phi}(\cdot)$ that solves

$$\inf_{T>0} \inf_{\phi \in A} S(T,\phi), \qquad A = \{\phi(\cdot) \in C[0,T] : \phi(T) \in \partial D\}. \tag{104.13}$$

Assuming the minimizer $\tilde{\phi}(\cdot)$ is unique, and letting t_D^ϵ be the first time the constant-gain process $\phi^\epsilon(t)$ leaves D, Dupuis and Kushner [1987] show that for every $\eta > 0$

$$\lim_{\epsilon \to 0} \mathbb{P}\left(\left|\phi^\epsilon(t_D^\epsilon) - \tilde{\phi}(T)\right| > \eta\right) = 0. \tag{104.14}$$

In words: *conditional on escaping the set D, the system leaves it near the terminal point of the least-action path* — so the escape has a deterministic direction and shape, even though it is triggered by chance.

This is the sense in which the escapes below, though they require no large shock, "seem purposeful": they follow the least-action route dictated by (104.13).

The same theory delivers the *mean time* to escape.

Let $\bar{S}$ be the minimized value of (104.13); then $\epsilon \log \mathbb{E}\, t_D^\epsilon \to \bar{S}$ as $\epsilon \to 0$.

So escapes become exponentially rare as the gain shrinks.

That is a small-gain statement.

When $\bar{S}$ is small relative to ϵ, as it is at the gains used in this suite, escapes are *frequent*: mean escape times grow roughly like $1/\epsilon$, not like $\exp(\bar{S}/\epsilon)$ (*Simulating escapes* measures them), and in the simulations below the government spends most of its time near the Ramsey outcome.

A crucial contrast with the mean dynamics: the mean dynamics (104.8) do *not* depend on the noise around them, whereas the escape routes *do* — the noise not only adds random fluctuations around (104.8), it also carves out this second family of paths.

Note

The mathematical foundations are the large-deviation theory for randomly perturbed dynamical systems of Freidlin and Wentzell [1998] (especially their chapter 4), specialized to stochastic approximation by Dupuis and Kushner [1987] and Dupuis and Kushner [1989]; a weak-convergence treatment is Dupuis and Ellis [1997].

104.2.7 A tractable action functional

The escape-route calculation promises cheap information about central tendencies of the algorithm, but the action functional (104.12) is generally hard to compute.

An important special case simplifies it dramatically.

Suppose the innovation is additive and Gaussian,

$$F(\phi, \zeta) = b(\phi) + \sigma(\phi)\,\zeta,$$

where ζ_n is stationary and Gaussian but not necessarily serially uncorrelated, and define $\Omega = \sum_j \mathbb{E}\,\zeta_t \zeta_{t-j}^\top$.

Then the action functional takes the quadratic form

$$S(T,\phi) = \frac{1}{2}\int_0^T \left(\tfrac{d}{ds}\phi - b(\phi)\right)^\top \left[\sigma(\phi)\,\Omega\,\sigma(\phi)^\top\right]^+ \left(\tfrac{d}{ds}\phi - b(\phi)\right) w(s)\,ds, \tag{104.15}$$

where $(\cdot)^+$ is the Moore-Penrose generalized inverse (used to handle possible stochastic singularity of $\sigma\Omega\sigma^\top$).

The weight $w(s)$ depends on the gain: $w(s) = \exp(s)$ when $p = 1$ in $a_n = a_0/n^p$, and $w(s) = 1$ when $p < 1$.

Read (104.15) as a cost that penalizes departures of the *realized drift* $\frac{d}{ds}\phi$ from the *mean drift* $b(\phi)$, weighting each direction by the inverse of the local noise covariance $\sigma\Omega\sigma^\top$.

The least-action escape therefore threads the beliefs through regions where the mean dynamics are weak and the noise is large — which, in our model, is the direction of the *induction hypothesis*.

Our model does not satisfy the assumptions behind (104.15) exactly.

Its innovation F contains products such as $X_{C,t}X_{C,t}^\top$ and $X_{C,t}U_t$, so it is quadratic in the shocks rather than additive and Gaussian.

Note

Cho *et al.* [2002], the published treatment of the model of this lecture, reduce the escape problem to minimizing a quadratic cost of the form (104.15), with a weighting matrix that is a fourth-moment matrix computed from Lyapunov equations.

The reduction draws on an early version of Williams's work, [Williams, 2001].

Williams [2019], the published version, notes that the early version misapplied a large-deviation theorem, a discrepancy that matters only for dynamic models like the one in this lecture, so the CWS calculations for the dynamic model rest on that shortcut.

They solve the control problem (104.13) *numerically* for the Nash self-confirming equilibrium of the dynamic model and find (their Figure 3) that along the dominant escape path the sum of weights on inflation rises from -1 to nearly zero, the value that activates the induction hypothesis — that is, the escape heads toward the Ramsey outcome.

Sargent and Williams [2005] replace recursive least squares with a Kalman filter whose drift covariance V is fixed, and study how V reshapes the escape (*Priors, Escapes, and Learning Cycles*).

The constant-gain algorithm of this lecture is a Kalman filter whose drift covariance is proportional to the current P_{t-1} (see below); a fixed V reproduces it only asymptotically.

Kasa [2004] applies the same large-deviation machinery to recurrent currency crises.

104.2.8 From computation to adaptation

The preceding recursions were introduced as *algorithms* to approximate a self-confirming equilibrium.

The same mathematics tells us what happens when we instead *modify* our self-confirming-equilibrium models to incorporate real-time adaptation — simply by reading ϕ_n as the government's time-n beliefs rather than as the n-th iterate of a solver.

Two facts organize everything below:

1. gain sequences that implement least squares (decreasing like $1/t$) make the mean dynamics pull the economy *toward* self-confirming equilibria, at least asymptotically; while
2. gain sequences that fall off more slowly — in the limit, constant gains that discount the past — *arrest* that pull and increase the frequency with which the escape dynamics influence outcomes.

Note

A brief intellectual history.

Lucas and Prescott [1971] dismissed iterating on the moment conditions (104.4) as a computational strategy, but Townsend [1983] used it.

DeCanio [1979] and Evans [1985], Evans [1989] used the map from perceived to actual laws of motion to define expectational stability.

Woodford [1990] and Marcet and Sargent [1989], Marcet and Sargent [1989] used the mean dynamics (104.8) to establish conditions for the convergence of least squares learning to rational expectations in models with self-reference, both requiring continuity of $b(\phi)$.

In-Koo Cho studied problems with *discontinuous* $b(\phi)$ inherited from discontinuous decision rules (trigger strategies in credibility and search problems); to make least squares learning approach rational expectations he used gains satisfying $\frac{1}{\sqrt{n}} < a_n < \frac{1}{\log n}$, which yield a *diffusion* approximation to (104.6) that promotes enough experimentation to discover an equilibrium (footnote 8 of chapter 8 of Sargent [1999] prints the two bounds the other way round, which describes an empty set because $\log n < \sqrt{n}$).

Kandori *et al.* [1993] use related mathematics to select long-run equilibria in games via mutation, and Roger Myerson applied an escape-route calculation to a voting problem.

The modern synthesis of these learning methods is Evans and Honkapohja [2001].

104.3 The adaptive model

We now build the classical adaptive model.

104.3.1 Government beliefs and behavior

The government believes in a distributed-lag Phillips curve

$$U_t = \gamma^\top X_{C,t} + \varepsilon_{C,t}, \qquad X_{C,t} = \begin{bmatrix} y_t & U_{t-1} & U_{t-2} & y_{t-1} & y_{t-2} & 1 \end{bmatrix}^\top. \tag{104.16}$$

Arriving at time t with an estimate γ_{t-1}, it sets the systematic part of inflation by solving the Phelps problem *as if* γ_{t-1} will govern the Phillips curve forever:

$$y_t = h(\gamma_{t-1}) X_{t-1} + v_{2t}, \qquad X_{t-1} = \begin{bmatrix} U_{t-1} & U_{t-2} & y_{t-1} & y_{t-2} & 1 \end{bmatrix}^\top. \tag{104.17}$$

It then updates its beliefs by **recursive least squares** (RLS):

$$\begin{aligned} \gamma_t &= \gamma_{t-1} + g_t R_{XC,t}^{-1} X_{C,t} \left(U_t - \gamma_{t-1}^\top X_{C,t} \right), \\ R_{XC,t} &= R_{XC,t-1} + g_t \left(X_{C,t} X_{C,t}^\top - R_{XC,t-1} \right), \end{aligned} \tag{104.18}$$

where $\{g_t\}$ is the gain sequence.

Least squares sets $g_t = 1/t$; a constant-gain algorithm sets $g_t = g_0 > 0$ and discounts past observations, which is sensible if the government suspects the Phillips curve wanders over time.

Readers arriving from *A government learning the Phillips curve* should note a change of letters: there, and throughout the Bounded Rationality lectures (*Notation across the series*), γ is the gain and α the beliefs, whereas here, following the book, γ denotes the beliefs and g_t, or $1-\lambda$ below, the gain (see also *A note on notation*).

The public is assumed to know the government's rule, so its inflation forecast is $x_t = h(\gamma_{t-1}) X_{t-1}$, the systematic part of (104.17).

Unemployment is generated by the actual Phillips curve of *Self-Confirming Equilibria* with $\rho_1 = \rho_2 = 0$:

$$U_t = U^* - \theta(y_t - x_t) + v_{1t} = U^* - \theta v_{2t} + v_{1t}.$$

104.3.2 The Phelps problem with lags

Given a belief γ, the decision rule $h(\gamma)$ solves an LQ control problem.

Write the believed Phillips curve as $U_t = \gamma_0 y_t + c^\top s_t$, where γ_0 is the coefficient on current inflation and c collects the coefficients on the state $s_t = X_{t-1}$.

The government minimizes $\mathbb{E}\sum_t \delta^t (U_t^2 + y_t^2)$, so the per-period loss is $s_t^\top (cc^\top) s_t + (\gamma_0^2 + 1) y_t^2 + 2\gamma_0\, y_t\, c^\top s_t$, and the state evolves as $s_{t+1} = A s_t + B y_t$ with

$$s_{t+1} = \begin{bmatrix} U_t \\ U_{t-1} \\ y_t \\ y_{t-1} \\ 1 \end{bmatrix}, \qquad U_t = c^\top s_t + \gamma_0 y_t.$$

This is the Phelps problem of *Adaptive Expectations and the Phelps Problem*, now with a distributed-lag Phillips curve.

We solve the discounted LQ problem with `scipy`'s discrete algebraic Riccati equation.

To fold the discount factor into an undiscounted problem we scale A and B by $\sqrt{\delta}$.

The cross-product term $2\gamma_0\, y_t\, c^\top s_t$ in the loss (`N` in the code) is a per-period cost, like the other two terms, so it is not scaled.

```

We use the Kalman-filter implementation of RLS from Appendix A of Sargent [1999].

The government treats γ as a hidden state that follows a random walk, $\tilde{\gamma}_t = \tilde{\gamma}_{t-1} + w_t$, and observes it through the regression $U_t = \tilde{\gamma}_t^\top X_{C,t} + \varepsilon_{C,t}$; the Kalman filter of *A First Look at the Kalman Filter* then updates its estimate γ_t and the estimate's covariance matrix P_t.

A forgetting factor $\lambda \in (0, 1]$ maps to the gain:

- $\lambda = 1$ sets the drift covariance $\mathbb{E} w_t w_t^\top$ to zero and gives least squares ($g_t \to 1/t$);
- $\lambda < 1$ sets $\mathbb{E} w_t w_t^\top = (1/\lambda - 1) P_{t-1}$, a drift covariance proportional to the government's current uncertainty, and gives a constant gain $g_0 = 1 - \lambda$.

The prior is initialized as if the government had already seen T_0 periods of self-confirming-equilibrium data, through $P_0 = (\sigma_C^2 / T_0)\, M^{-1}$; larger T_0 (`T_prior` in the code) means a tighter prior.

The function also returns the final beliefs and covariance matrix, which we use below.

```
def simulate(model, λ, T_prior, n=1000, seed=0):
    "Simulate the adaptive system. λ=1 is least squares; λ<1 is constant gain."
    rng = np.random.default_rng(seed)

        y_path[t], U_path[t] = y, U
        sumweights[t] = γ[0] + γ[3] + γ[4]                # weights on current+lagged y
        constant[t] = γ[5]
        U2, U1 = U1, U
        y2, y1 = y1, y

    return dict(y=y_path, U=U_path, sumweights=sumweights, constant=constant,
                γ=γ, P=P)
```

Let's check the decision rule at the self-confirming belief.

```
model = AdaptivePhillips()
h_sce = model.phelps_h(model.γ_sce)
print("decision rule at the self-confirming belief:")
print(f"  h(γ_sce) = {np.round(h_sce, 3) + 0.0}  (a constant rule of "
      f"{h_sce[-1]:.1f} = Nash inflation)")
```

```
decision rule at the self-confirming belief:
  h(γ_sce) = [0. 0. 0. 0. 5.]  (a constant rule of 5.0 = Nash inflation)
```

At the self-confirming belief the Phelps rule is a constant equal to the Nash inflation rate, and the beliefs reproduce themselves — the adaptive system's rest point is the self-confirming equilibrium of *Self-Confirming Equilibria*.

We follow Sargent [1999] in setting the true data-generating parameters to the classical example at the end of *Self-Confirming Equilibria*: $U^* = 5$, $\theta = 1$, $\sigma_1 = \sigma_2 = 0.3$, $\rho_1 = \rho_2 = 0$, $\delta = 0.98$.

The classical self-confirming equilibrium has serially uncorrelated (U, y) fluctuating around means $(5, 5)$.

104.4 Mean dynamics near the self-confirming equilibrium

Before simulating, we compute the mean dynamics (104.8) for this model and their behavior near the self-confirming equilibrium.

Substituting the government's rule (104.17) and the public's forecast into the true Phillips curve gives

$$U_t = -\theta y_t + \theta\, h(\gamma) X_{t-1} + U^* + v_{1t}.$$

The shock v_{1t} is independent of every regressor in $X_{C,t}$.

So when the government uses the rule $h(\gamma)$, the population regression of U_t on $X_{C,t}$ is exactly

$$T(\gamma) = \begin{bmatrix} -\theta & \theta h_1(\gamma) & \theta h_2(\gamma) & \theta h_3(\gamma) & \theta h_4(\gamma) & U^* + \theta h_5(\gamma) \end{bmatrix}^\top, \tag{104.19}$$

where $h_j(\gamma)$ is the j-th entry of $h(\gamma)$.

This is the T-map of *One recursion, many learners* for our model: it sends the government's perceived Phillips curve to the actual one that its policy generates.

Applied to the recursive least squares algorithm (104.18), stochastic approximation delivers the mean dynamics (equation (89) of the book)

$$\frac{d\gamma}{d\tau} = R_{XC}^{-1} M(\gamma)\,[T(\gamma) - \gamma]\,, \qquad \frac{dR_{XC}}{d\tau} = M(\gamma) - R_{XC}, \tag{104.20}$$

where τ is artificial time and $M(\gamma) = \mathbb{E} X_{C,t} X_{C,t}^\top$ is computed from the stationary distribution of the system when the government's beliefs are frozen at γ.

A rest point has $T(\gamma) = \gamma$ and $R_{XC} = M(\gamma)$: it is a self-confirming equilibrium.

At a rest point the Jacobian of (104.20) is block triangular.

Its eigenvalues are therefore those of $DT - I$, together with repeated eigenvalues of -1 from the R_{XC} block (*Proposition 139.4.2* of *Least Squares Learning in Self-Referential Models*).

We compute DT at the self-confirming belief by finite differences.

```
def T_map(model, γ):
    "Population regression of U_t on X_C,t when the government uses h(γ)."
    θ, h = model.θ, model.phelps_h(γ)
    return np.concatenate([[-θ], θ * h[:4], [model.U_star + θ * h[4]]])

def jacobian_T(model, ε=1e-5):
    "Finite-difference Jacobian of T at the self-confirming belief."
    J = np.empty((6, 6))
    for j in range(6):
        d = np.zeros(6)
        d[j] = ε
        J[:, j] = (T_map(model, model.γ_sce + d)
                   - T_map(model, model.γ_sce - d)) / (2 * ε)
    return J

DT_I = jacobian_T(model) - np.eye(6)
print("DT - I at the self-confirming belief:")
print(np.round(DT_I, 3) + 0.0)
print("eigenvalues:", np.round(np.sort(np.linalg.eigvals(DT_I).real), 4))
print(f"-1/(1 + θ²) = {-1 / (1 + model.θ**2)}")
```

```
DT - I at the self-confirming belief:
[[-1.     0.     0.     0.     0.     0.   ]
 [ 0.    -0.5    0.     0.     0.     0.   ]
 [ 0.     0.    -0.5    0.     0.     0.   ]
 [ 0.     0.     0.    -0.5    0.     0.   ]
 [ 0.     0.     0.     0.    -0.5    0.   ]
 [ 0.     2.45   2.401 -2.45  -2.401 -0.5  ]]
eigenvalues: [-1.  -0.5 -0.5 -0.5 -0.5 -0.5]
-1/(1 + θ²) = -0.5
```

The matrix $DT - I$ is lower triangular, so its eigenvalues are its diagonal entries.

- The first, -1, belongs to the coefficient on current inflation: T assigns that coefficient $-\theta$ whatever the government believes.
- The other five all equal $-1/(1+\theta^2) = -\frac{1}{2}$.

The second group has a simple source.

At the self-confirming equilibrium the lags carry no weight, and to first order the Phelps rule responds to a small believed coefficient c_j on a lagged variable as the static first-order condition $y_t = \theta\, c^\top X_{t-1}/(1+\theta^2)$ prescribes.

That makes the diagonal entry of DT equal to $\theta^2/(1+\theta^2)$.

The off-diagonal entries all sit in the last row: a believed coefficient on a lag also shifts the constant in the rule, through the dynamic part of the Phelps problem.

The repeated eigenvalue $-1/(1+\theta^2)$ is the same number as the slope $\mathcal{M}$ of the scalar mean dynamics in *Least squares learning converges to Nash*, where the public learned a single number, and as the classical E-stability eigenvalue of *Uniqueness and E-stability*.

Sargent [1999] reports a repeated eigenvalue of $-.5$ "of multiplicity 6", together with repeated eigenvalues of -1 for R_{XC}.

The computation shows that the multiplicity is five; the sixth eigenvalue for the beliefs, the one for the coefficient on current inflation, is -1.

All eigenvalues are negative, so the self-confirming equilibrium is E-stable.

At $\theta = 1$ the repeated eigenvalue sits exactly on the $-\frac{1}{2}$ boundary, so least squares converges more slowly than the usual $\sqrt{t}$ rate, as in the scalar case of *Least squares learning converges to Nash*.

As noted in the primer, that boundary concerns the asymptotic distribution of the least squares estimates; how often a constant-gain government escapes is governed instead by the minimized action $\bar{S}$.

Exercise 104.12.3 asks how the eigenvalues change with θ.

104.5 Least squares learning: a decreasing gain

First, least squares (a decreasing gain), with a tight prior worth $T_0 = 5000$ periods of data.

```
ls = simulate(model, λ=1.0, T_prior=5000, n=1000, seed=1)

fig, ax = plt.subplots(figsize=(9, 4.5))
ax.plot(ls['y'], lw=0.8)
ax.axhline(5, color='k', ls='--', lw=1, label='self-confirming (Nash)')
ax.axhline(0, color='C2', ls=':', lw=1, label='Ramsey')
ax.set_xlabel('$t$')
ax.set_ylabel('inflation $y_t$')
ax.legend()
plt.show()
```

In Fig. 104.1 inflation hugs the self-confirming value of 5, and the simulation looks like a draw from the self-confirming equilibrium itself.

This is the outcome the book describes: least squares gets us nothing new, and the government is stuck near Nash.

But the result depends on the prior.

The book's Figure 8.1 uses a looser prior, $T_0 = 800$, and shows 400 periods in which inflation stays near 5.

Let's compare eight paths of 1000 periods under each prior.

To see through the noise we plot a 20-period moving average of inflation, and we call the first date at which that average falls below 1 the government's *first escape*.

```
def moving_average(y, k=20):
    return np.convolve(y, np.ones(k) / k, mode='valid')
```

(continues on next page)

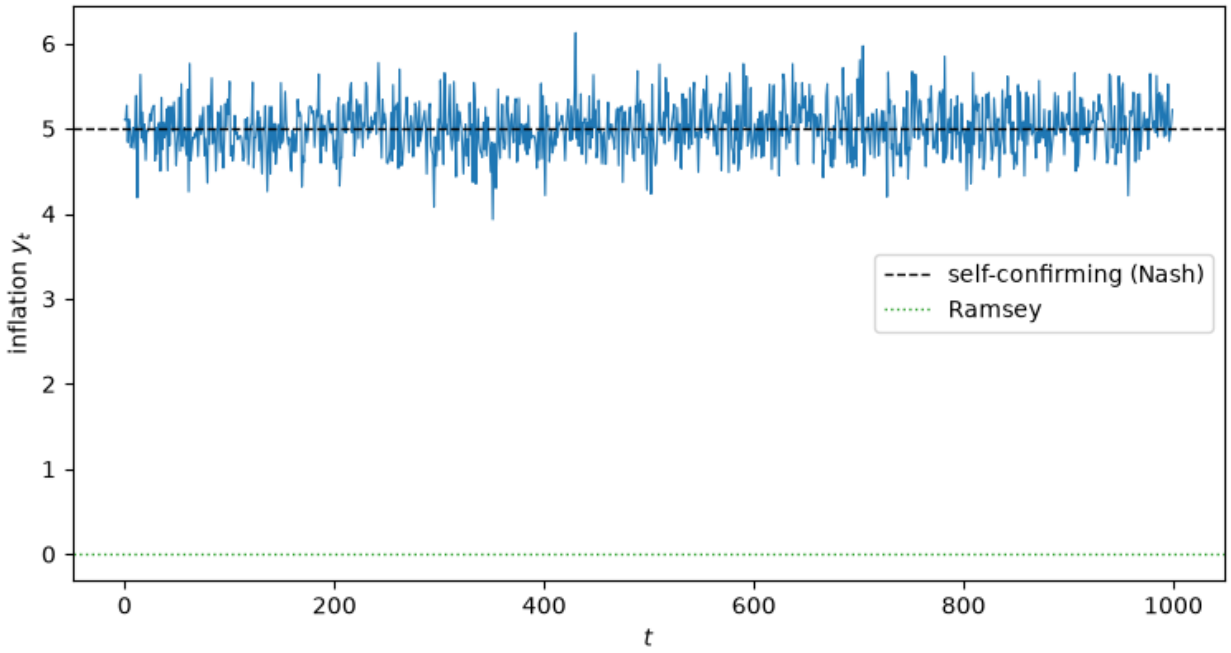

Fig. 104.1: Classical adaptive model under least squares with a tight prior: inflation hugs the self-confirming value

(continued from previous page)

```
def first_escape(y, k=20, level=1.0):
    "First date at which the k-period moving average of y falls below level."
    below = moving_average(y, k) < level
    return int(np.argmax(below)) if below.any() else None

def returns_to_nash(y, k=20, level=4.0):
    "Whether the moving average climbs back above level after the first escape."
    t = first_escape(y, k)
    return t is not None and bool((moving_average(y, k)[t:] > level).any())

ls_runs = {T0: [simulate(model, λ=1.0, T_prior=T0, n=1000, seed=s)
                for s in range(8)]
           for T0 in (5000, 800)}

fig, axes = plt.subplots(1, 2, figsize=(11, 4), sharey=True)
for ax, (T0, runs) in zip(axes, ls_runs.items()):
    for sim in runs:
        ax.plot(np.arange(19, 1000), moving_average(sim['y']), lw=0.8)
    ax.axhline(5, color='k', ls='--', lw=1)
    ax.axhline(0, color='C2', ls=':', lw=1)
    ax.set_title(rf'$T_0 = {T0}$')
    ax.set_xlabel('$t$')
axes[0].set_ylabel('20-period moving average of $y_t$')
plt.tight_layout()
plt.show()

for T0, runs in ls_runs.items():
```

(continues on next page)

(continued from previous page)

```
    escapes = [first_escape(sim['y']) for sim in runs]
    print(f"T_0 = {T0}: {sum(e is not None for e in escapes)} of {len(runs)} "
          f"paths escape; {sum(returns_to_nash(sim['y']) for sim in runs)} "
          f"of them return above 4")
```

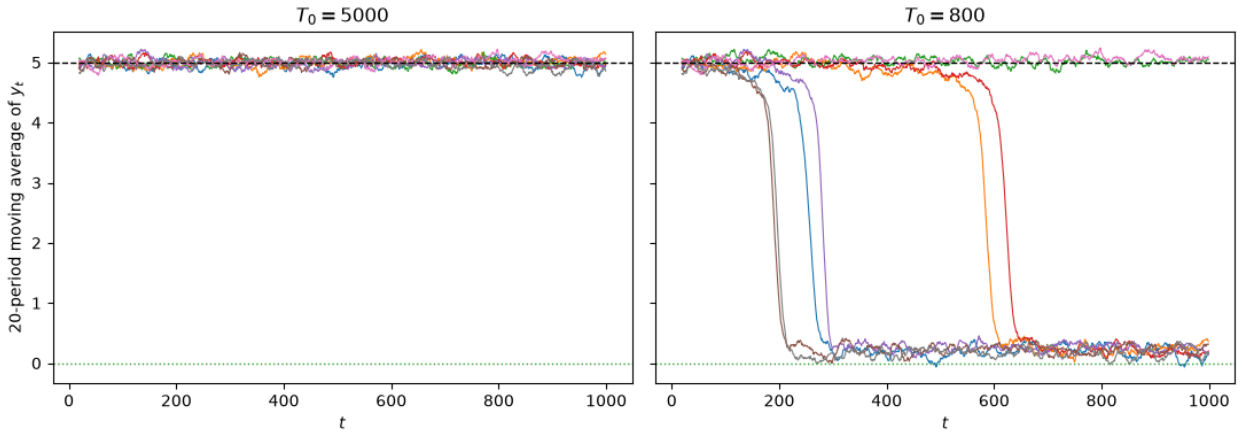

Fig. 104.2: Least squares under a tight and a looser prior: escapes under the looser prior stick

```
T_0 = 5000: 0 of 8 paths escape; 0 of them return above 4
T_0 = 800: 6 of 8 paths escape; 0 of them return above 4
```

Under the looser prior, Fig. 104.2 shows least squares escaping toward Ramsey, and every path that escapes stays there.

Why, if least squares converges to the self-confirming equilibrium?

Because the convergence theorems are about the limit.

With a prior worth T_0 periods, the least squares gain is $1/(T_0 + t)$, so after t periods artificial time (104.7) has advanced by about $\tau = \log\left((T_0 + t)/T_0\right)$.

The clock slows as it runs: each additional unit of τ costs $e \approx 2.7$ times as many periods as the one before.

A constant gain g_0, by contrast, advances τ by g_0 every period.

That explains both panels.

A tight prior slows the clock from the start: 1000 periods supply only $\log(6000/5000) \approx 0.18$ units of artificial time when $T_0 = 5000$, against $\log(1800/800) \approx 0.81$ when $T_0 = 800$.

And once the government has escaped, the slowing clock also delays the return.

To see how much artificial time the return needs, we integrate the mean dynamics (104.20) from the beliefs $(\gamma_t, R_{XC,t})$ that one escaped path holds at $t = 1000$.

We obtain $M(\gamma)$ from the stationary distribution of (y_t, U_t) under the frozen rule $h(\gamma)$, using a discrete Lyapunov equation.

Under least squares, $R_{XC,t} = \sigma_C^2 P_t^{-1}/(T_0 + t)$.

```
def stationary_moments(model, γ):
    """
    Mean inflation and M(γ) = E[X_C X_C'] in the stationary distribution
    of the true system when the government's beliefs are frozen at γ.

mean inflation is back to 2.5 at τ = 12.6: after 5.6e+08 more periods of least␣
↪squares, or 506 periods at a gain of 0.025
```

The last two columns count periods after $t = 1000$.

The mean dynamics do carry the beliefs back toward the self-confirming equilibrium: the sum of weights on inflation falls back toward -1, and mean inflation climbs back toward 5.

So least squares converges, but only asymptotically.

Near the induction hypothesis the mean dynamics are weak, and the return needs many units of artificial time.

A constant gain of 0.025 supplies them within several hundred periods.

Least squares supplies them only over a span of time that dwarfs any historical sample, because a falling gain slows the return as well as the departure.

In a finite sample, then, a decreasing gain can turn an early escape into an escape that sticks.

Paths of this kind, one escape followed by a long stay near Ramsey, resemble what Sims and Chung found with their Kalman filters, although the mechanism here differs from theirs; *Priors, Escapes, and Learning Cycles* (*Sims's nonconvergence*) explains their outcome through the prior in their filters.

Exercise 104.12.2 measures how often least squares escapes under three priors.

104.6 Constant gain and escape dynamics

Now give the government a *constant* gain $g_0 = 1 - \lambda = 0.025$, so it discounts past data.

We use the book's Figure 8.2 settings, $\lambda = 0.975$ and $T_0 = 300$; other lectures in this suite use other gains, each taken from its own source.

```
cg = simulate(model, λ=0.975, T_prior=300, n=1000, seed=1)

fig, ax = plt.subplots(figsize=(9, 4.5))
ax.plot(cg['y'], lw=0.8)
ax.axhline(5, color='k', ls='--', lw=1, label='self-confirming (Nash)')
ax.axhline(0, color='C2', ls=':', lw=1, label='Ramsey')
ax.set_xlabel('$t$')
ax.set_ylabel('inflation $y_t$')
ax.legend()
plt.show()
```

In Fig. 104.3 inflation starts near the self-confirming value of 5 and within a few dozen periods drops almost to zero.

Over the next several hundred periods it drifts back up, but only part of the way toward 5, before a second stabilization sends it back toward zero.

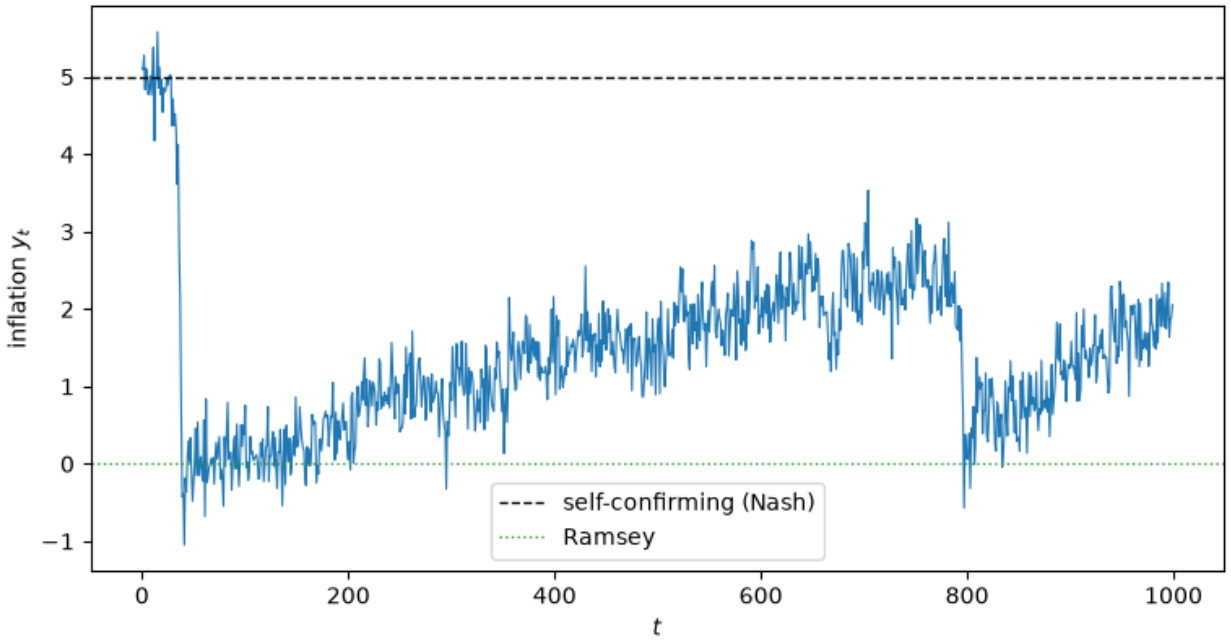

Fig. 104.3: Classical adaptive model under a constant gain: recurrent escapes toward Ramsey

The mean dynamics that pull the system toward the self-confirming equilibrium are opposed by a recurrent force that sends inflation close to the Ramsey outcome.

The drift back up is the slow return computed in *Least squares learning: a decreasing gain*, now run on a clock that does not slow down: the mean dynamics pull the beliefs back, and the noise launches a new escape before they get there.

Sargent [1999] checked that no large shocks trigger these stabilizations: they are an *endogenous* feature of the constant-gain learning dynamics.

One path can mislead, so we repeat the simulation for 24 seeds.

For each path we record the date of the first escape, the fraction of periods with inflation below 2, and whether the moving average of inflation ever climbs back above 4 after the first escape.

We also record the lowest value that the sum of weights on current and lagged inflation reaches after the first escape; we return to that sum below.

```
cg_runs = [simulate(model, λ=0.975, T_prior=300, n=1000, seed=s)
           for s in range(24)]

firsts = [first_escape(sim['y']) for sim in cg_runs]
frac_low = [(sim['y'] < 2).mean() for sim in cg_runs]
low_sw = [sim['sumweights'][t + 20:].min()
          for sim, t in zip(cg_runs, firsts) if t is not None]

print(f"paths that escape: {sum(t is not None for t in firsts)} of {len(cg_runs)}")
escaped = [t for t in firsts if t is not None]
print(f"first escape: median t = {np.median(escaped):.0f}, latest t = {max(escaped)}")
print(f"fraction of periods with y < 2: {min(frac_low):.0%} to "
      f"{max(frac_low):.0%} across seeds (mean {np.mean(frac_low):.0%})")
print(f"paths that return above 4 after escaping: "
      f"{sum(returns_to_nash(sim['y']) for sim in cg_runs)}")
print(f"lowest sum of weights after the first escape: {min(low_sw):.2f}")
```

```
paths that escape: 24 of 24
first escape: median t = 56, latest t = 145
fraction of periods with y < 2: 74% to 95% across seeds (mean 83%)
paths that return above 4 after escaping: 0
lowest sum of weights after the first escape: -0.71
```

Every path escapes early, inflation is below 2 in most periods, and no path's moving average climbs back above 4 within 1000 periods.

At this gain escapes are *frequent*, not rare.

The large-deviation statement that escapes become exponentially rare is a small-gain limit; *Simulating escapes* measures how escape times grow as the gain shrinks.

104.7 The escape route and the induction hypothesis

Why does the system escape toward Ramsey rather than in some other direction?

The answer is the **induction hypothesis** of *Adaptive Expectations and the Phelps Problem*: when the sum of the weights on current and lagged inflation in the estimated Phillips curve approaches zero, the Phelps problem advises the government to *reduce* inflation.

Let's plot inflation together with that sum of weights.

```
fig, axes = plt.subplots(2, 1, figsize=(9, 7), sharex=True)

axes[0].plot(cg['y'], lw=0.8)
axes[0].axhline(0, color='C2', ls=':', lw=1)
axes[0].set_ylabel('inflation $y_t$')

axes[1].plot(cg['sumweights'], lw=0.8, color='C1')
axes[1].axhline(-1, color='k', ls='--', lw=1, label='self-confirming value')
axes[1].axhline(0, color='C3', ls=':', lw=1, label='induction hypothesis')
axes[1].set_xlabel('$t$')
axes[1].set_ylabel('sum of weights on $y$')
axes[1].legend()

plt.tight_layout()
plt.show()
```

In Fig. 104.4 the first stabilization coincides with the sum of weights jumping from its self-confirming value of -1 to about zero.

The sum of weights never goes back to -1, here or in any of the 24 runs above.

As inflation drifts back up, the sum of weights falls only part of the way toward -1, and the next stabilization coincides with its rising back toward zero.

When it reaches zero, the induction hypothesis is (temporarily) satisfied, the Phelps problem calls for near-Ramsey inflation, and the resulting data briefly *reinforce* the induction hypothesis — a situation that is not self-confirming in the technical sense but is nonetheless self-reinforcing.

We can see the escape route directly by plotting the joint path of the constant and the sum of weights in the estimated Phillips curve.

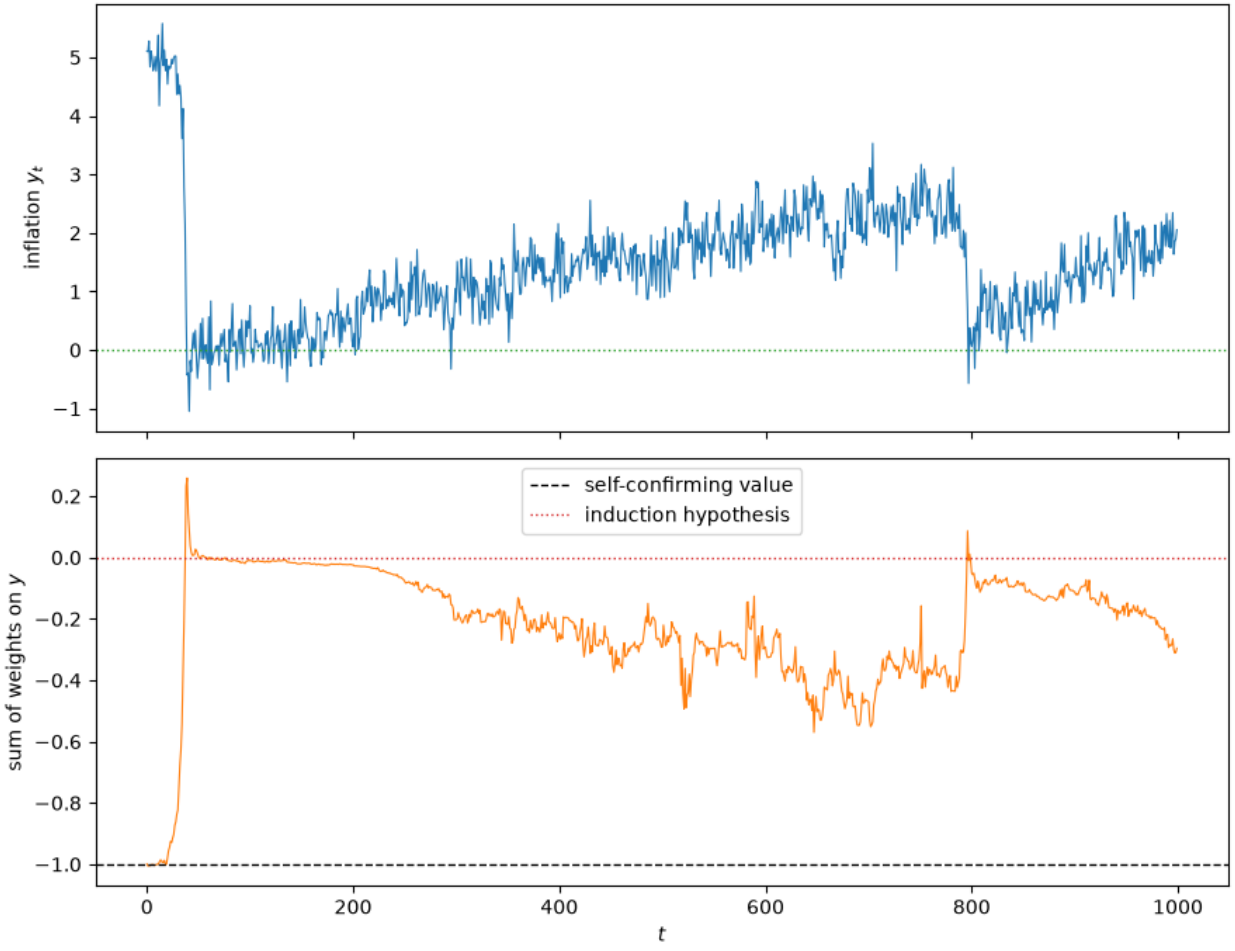

Fig. 104.4: Stabilizations coincide with the sum of weights on inflation rising toward zero

```
fig, ax = plt.subplots(figsize=(8, 6))
sc = ax.scatter(cg['constant'], cg['sumweights'], c=np.arange(len(cg['y'])),
                cmap='viridis', s=6)
ax.axhline(0, color='C3', ls=':', lw=1.5, label='induction hypothesis')
ax.axhline(-1, color='k', ls='--', lw=1, label='self-confirming value')
ax.set_xlabel('constant in estimated Phillips curve')
ax.set_ylabel('sum of weights on $y$')
ax.legend()
plt.colorbar(sc, label='time $t$')
plt.show()
```

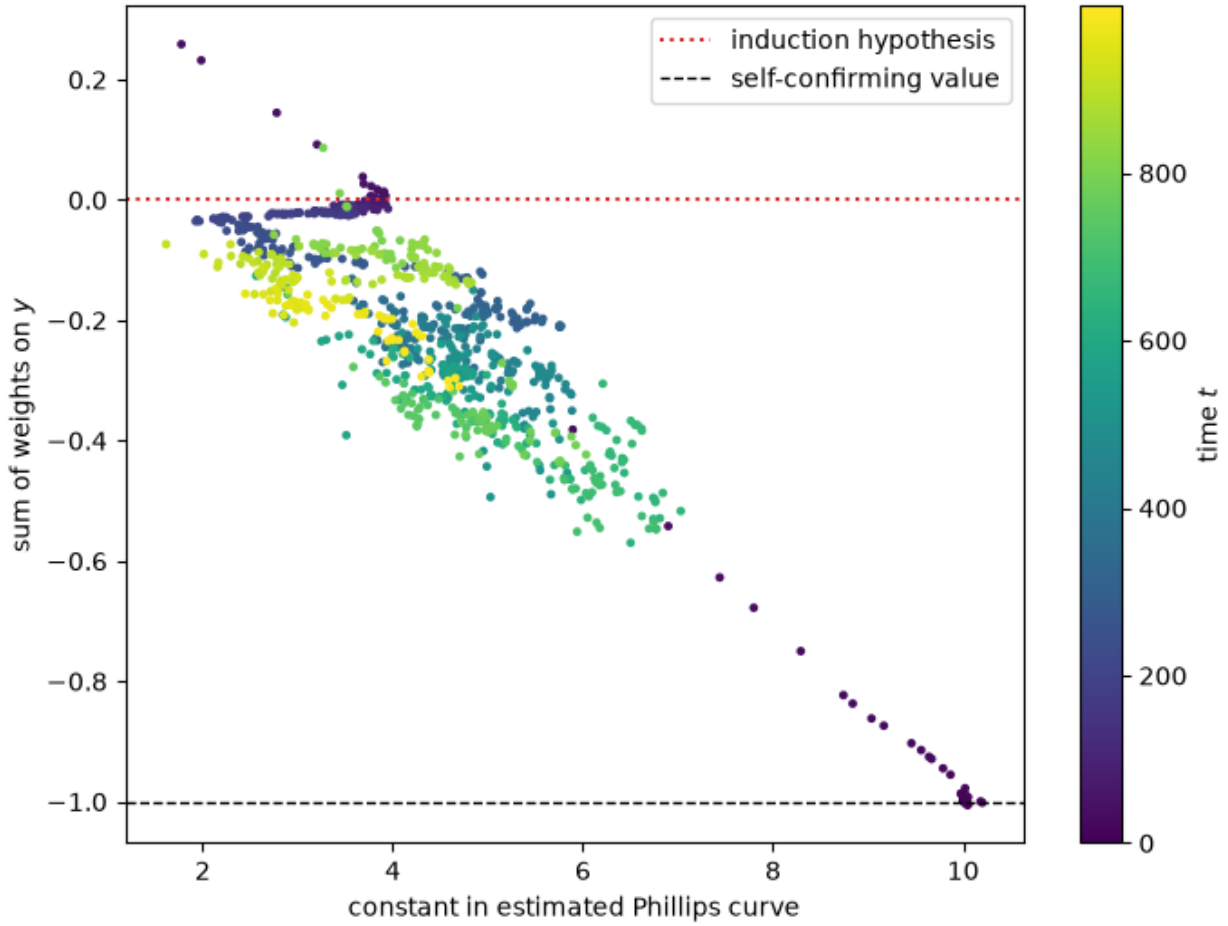

Fig. 104.5: The escape route in belief space, coloured by time

In Fig. 104.5 the beliefs leave the self-confirming point (constant 10, sum of weights -1) early and do not come back to it.

Afterwards they move back and forth below the induction line: as inflation drifts up, the sum of weights falls and the constant rises, and each stabilization sends the beliefs back up toward the induction line (sum of weights $= 0$).

That line is the end of the escape route along which the government learns a Solow-Tobin version of the natural-rate hypothesis and stabilizes inflation.

104.8 Relation to equilibria under forecast misspecification

The near-Ramsey episodes are reminiscent of the equilibria with optimal misspecified forecasts of *Optimal Misspecified Beliefs* and *Self-Confirming Equilibria*.

There, a forecasting model *without a constant but with a unit root* could closely approximate a true model that *includes* a constant.

Here an approximation with a similar flavor operates during the near-Ramsey episodes: the government's estimated Phillips curve, by driving the sum of weights toward zero, uses the induction hypothesis to approximate a constant — except that the approximated model is not fixed but changes as the government's own beliefs feed back through the Phelps problem.

104.9 Role of the discount factor

Sargent [1999] reports two findings about the government's discount factor δ:

- the recurrent stabilizations toward Ramsey depend on δ being near one; and
- lowering δ raises the inflation rate observed during the low-inflation episodes.

The book does not report the simulations behind them, so let's run some.

We simulate 16 seeds for each of three discount factors, reusing the first 16 constant-gain runs above for $\delta = 0.98$.

```
δ_runs = {0.98: cg_runs[:16]}
for δ in (0.90, 0.95):
    m = AdaptivePhillips(δ=δ)
    δ_runs[δ] = [simulate(m, λ=0.975, T_prior=300, n=1000, seed=s)
                 for s in range(16)]

for δ in sorted(δ_runs):
    runs = δ_runs[δ]
    firsts = [first_escape(sim['y']) for sim in runs]
    eig = np.linalg.eigvals(jacobian_T(AdaptivePhillips(δ=δ)) - np.eye(6)).real
    print(f"δ = {δ}: {sum(t is not None for t in firsts)} of {len(runs)} escape, "
          f"median first escape t = {np.median([t for t in firsts if t is not None]):.
↪0f}, "
          f"mean inflation for t ≥ 200 = {np.mean([sim['y'][200:].mean() for sim in␣
↪runs]):.2f}, "
          f"eig(DT − I) = {np.unique(np.round(eig, 4))}")
```

```
δ = 0.9: 16 of 16 escape, median first escape t = 56, mean inflation for t ≥ 200 =␣
↪1.70, eig(DT − I) = [-1.  -0.5]
δ = 0.95: 16 of 16 escape, median first escape t = 55, mean inflation for t ≥ 200␣
↪= 1.44, eig(DT − I) = [-1.  -0.5]
δ = 0.98: 16 of 16 escape, median first escape t = 54, mean inflation for t ≥ 200␣
↪= 1.24, eig(DT − I) = [-1.  -0.5]
```

Over this range of discount factors the second finding holds, but the first does not.

The timing of the first escape hardly depends on δ; what changes is how low inflation goes once the government has escaped.

That makes sense.

At the self-confirming equilibrium the Phelps rule is a constant, Nash inflation, for every δ, and the eigenvalues computed in *Mean dynamics near the self-confirming equilibrium* do not depend on δ either, so the forces that govern the escape are much the same.

Once the induction hypothesis is active, though, the government believes it faces a vertical long-run Phillips curve and a short-run tradeoff, and *Adaptive Expectations and the Phelps Problem* showed that a discounted Phelps problem of that kind stops short of zero inflation, more so the less patient the government is.

```
fig, ax = plt.subplots(figsize=(9, 4.5))
for δ in sorted(δ_runs):
    ax.plot(np.arange(19, 1000), moving_average(δ_runs[δ][1]['y']),
            lw=0.9, label=rf'$\delta = {δ}$')
ax.axhline(0, color='k', lw=0.5)
ax.set_xlabel('$t$')
ax.set_ylabel('20-period moving average of $y_t$')
ax.legend()
plt.show()
```

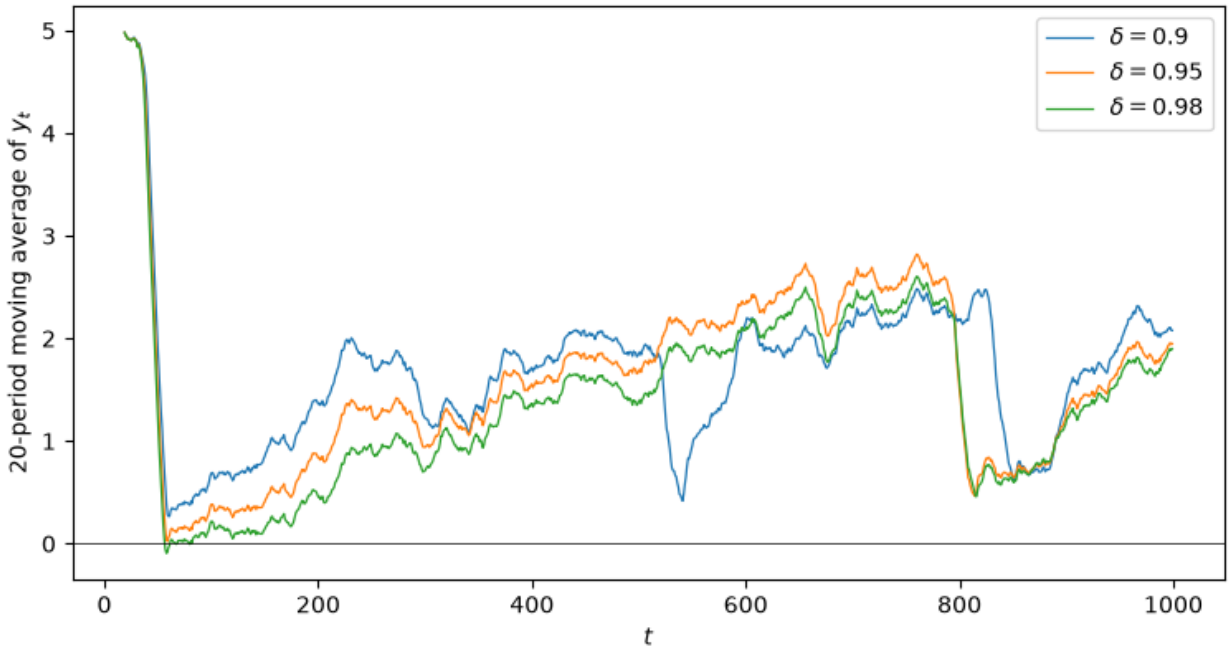

Fig. 104.6: The government's discount factor shifts the level of inflation after an escape, not the escape's timing

Fig. 104.6 shows one seed: the three governments escape at about the same date, and right after the escape the less patient ones settle at higher inflation.

104.10 Anticipated utility

The adaptive model is an example of what David Kreps calls an **anticipated utility** model [Kreps, 1998].

The government adapts a temporarily misspecified model — a Phillips curve with fixed coefficients — to incorporate the most recent observations, and reoptimizes along the way.

In forming decisions at t, it acts as if its current estimate γ_{t-1} will govern the Phillips curve forever, using the same policy functional $h(\cdot)$ that would be optimal if γ were truly time-invariant.

This is a small departure from rational expectations: calendar time enters only through the drifting beliefs γ_t.

The government treats coefficient drift in two different ways.

When it *estimates*, it allows for drift: the constant gain discounts old data precisely because the government suspects that the Phillips curve wanders, and in the Kalman-filter form of (104.18) it attributes a positive covariance to the drift.

When it *decides*, it ignores drift: it acts as if γ_{t-1} will never change.

Anticipated utility thus stretches a property of linear-quadratic problems.

Certainty equivalence (*Certainty Equivalence*) lets a decision maker who faces *additive* uncertainty replace random variables by their expectations.

The anticipated-utility government does the same with its uncertain coefficients γ, which enter multiplicatively, where certainty equivalence no longer holds.

A Bayesian decision maker would instead take into account, when choosing y_t, that its beliefs will change (*Rational Learning and Rational Expectations*), and a robust one would guard against misspecification of its model.

Yet, as the simulations show, this modest departure from rationality is enough to generate a rich account of the rise and fall of U.S. inflation, and to supply underpinnings for the vindication of econometric policy evaluation.

104.11 Conclusions

For long stretches, an adaptive government learns to generate *better than Nash* outcomes.

These results come from the recurrent dynamics of adaptation: the mean dynamics that under least squares pull the system toward a self-confirming equilibrium continue to operate, but under a constant gain the noise lets the system recurrently escape toward the Ramsey outcome.

Starting from a self-confirming equilibrium, the adaptive algorithm gradually makes the government put enough weight on the induction hypothesis that chance observations eventually promote a stabilization.

With a decreasing gain the same forces operate on a clock that keeps slowing down: least squares converges to the self-confirming equilibrium only asymptotically, and in a finite sample an early escape can stick.

Adaptation makes the government's beliefs a hidden state that imparts serial correlation into inflation — so that an outside forecaster would do well to use a random-coefficients model, or to make the constant adjustments that Lucas noted in his Critique [Lucas, 1976].

(Unemployment stays serially uncorrelated in this model, because the public knows the government's rule and only inflation surprises move unemployment.)

In this sense the adaptive models contain the underpinnings for vindicating econometric policy evaluation — the second of the two stories of *The Rise and Fall of U.S. Inflation*.

That last observation is a testable one, and it is worth recording what the model predicts before anyone looks.

If the government's beliefs really are a hidden drifting state, then a reduced-form description of post-war inflation and unemployment ought to show *drifting coefficients*, not merely drifting shock variances.

The model also predicts how the persistence of inflation should move with its level.

At the self-confirming equilibrium inflation is serially uncorrelated, while after a constant-gain escape it is persistent (Exercise 104.12.4), so low inflation should come with high persistence.

Drifts and Volatilities fits a drifting-coefficients model to the data and reports the verdict: persistence rose and fell with the level of inflation, and it fell during the Volcker disinflation, the opposite of this prediction.

Before that, the suite continues with the theory.

Escaping Nash Inflation characterizes the escape route analytically, *Priors, Escapes, and Learning Cycles* shows how the government's prior about coefficient drift shapes both the mean dynamics and the escapes, and *Econometric Policy Evaluation* follows the book's chapter 9 in estimating the adaptive models on U.S. data.

104.12 Exercises

Exercise 104.12.1

Everything above hinges on the constant gain, so it is worth seeing how much.

Simulate the classical adaptive model with $\lambda \in \{0.99, 0.975, 0.95\}$ and $T_0 = 300$, for 24 seeds each, and measure how often inflation escapes toward Ramsey.

Use two statistics that measure *frequency*:

- the median date of the first escape, defined as in *Least squares learning: a decreasing gain*; and
- the number of escape episodes per 1000 periods, where an episode starts when the sum of weights on current and lagged inflation rises above -0.1, and the sum must fall back below -0.3 before another episode can start.

Also compute the fraction of periods with $y_t < 2$.

How does a larger gain (smaller λ, faster discounting of the past) affect each statistic?

Why is the fraction of periods with low inflation a poor measure of how often the government escapes?

Note

A more ambitious version of this exercise is to build the **Keynesian** adaptive model, in which the government fits the Phillips curve in the reverse direction, regressing inflation on unemployment.
The regressors are $X_{K,t} = [U_t \quad U_{t-1} \quad U_{t-2} \quad y_{t-1} \quad y_{t-2} \quad 1]^\top$; the government estimates β in $y_t = \beta^\top X_{K,t} + \varepsilon_{K,t}$, then inverts to γ using the inversion formulas $\gamma_1 = \beta_1^{-1}$, $\gamma_{-1} = -\beta_{-1}/\beta_1$ of *Self-Confirming Equilibria* before solving the Phelps problem.
The Keynesian self-confirming inflation rate is 10.
In the book's simulation ($\lambda = 0.99$, $T_0 = 300$, Figures 8.3a–8.3d), the Keynesian system "spends much time away from the self-confirming equilibrium, and, like the classical system, recurrently escapes to the Ramsey outcome" [Sargent, 1999].
Its Jacobian has a repeated eigenvalue of $-.2$, which makes the mean dynamics slow and, in the book's words, "sustains long episodes near the Ramsey outcome".

Solution

We count episodes with a small function and reuse the 24 runs with $\lambda = 0.975$ from above.

```
def escape_episodes(sw, up=-0.1, down=-0.3):
    "Upcrossings of `up` by the sum of weights, re-armed only below `down`."
    count, armed = 0, True
    for v in sw:
        if armed and v > up:
            count, armed = count + 1, False
        elif not armed and v < down:
            armed = True
    return count

gain_runs = {0.975: cg_runs}
for λ in (0.99, 0.95):
    gain_runs[λ] = [simulate(model, λ=λ, T_prior=300, n=1000, seed=s)
                    for s in range(24)]

print(f"{'λ':>6} {'median first escape':>20} {'episodes per 1000':>18} "
      f"{'fraction y < 2':>15}")
for λ in (0.99, 0.975, 0.95):
    runs = gain_runs[λ]
    firsts = [first_escape(sim['y']) for sim in runs]
    episodes = [escape_episodes(sim['sumweights']) * 1000 / len(sim['y'])
                for sim in runs]
    print(f"{λ:>6} {np.median([t for t in firsts if t is not None]):20.0f} "
          f"{np.mean(episodes):18.2f} "
          f"{np.mean([(sim['y'] < 2).mean() for sim in runs]):15.2f}")
```

```
     λ  median first escape  episodes per 1000  fraction y < 2
  0.99                   90               1.00            0.89
 0.975                   56               2.62            0.83
  0.95                   38               6.08            0.85
```

A larger gain makes escapes come sooner and more often: the median first escape comes earlier, and the number of episodes per 1000 periods rises, as λ falls.

The fraction of periods with $y_t < 2$ barely moves, and it need not move monotonically.

The reason is that a larger gain also speeds the return trip, since the clock of *Least squares learning: a decreasing gain* runs faster.

Each near-Ramsey spell is therefore shorter, and inflation within it is noisier.

The fraction of time spent near Ramsey mixes how often the government escapes with how long it stays, and as the gain rises those two move in opposite directions.

Exercise 104.12.2

Fig. 104.1 and Fig. 104.2 show that whether least squares escapes depends on the tightness of the prior.

Simulate the least squares system ($\lambda = 1$) for $T_0 \in \{300, 800, 5000\}$, with 24 seeds and 1000 periods each.

1. For each T_0, report how many paths escape, the median date of the first escape, and how many of the escaped paths return above 4.
2. For the paths that escape, compute the artificial time $\tau = \log\left((T_0 + t)/T_0\right)$ at the first escape. Use the answer to explain why the tight prior rarely escapes within 1000 periods.
3. Explain why no escaped path returns, although least squares converges to the self-confirming equilibrium. Is the eigenvalue $-\frac{1}{2}$ of *Mean dynamics near the self-confirming equilibrium*, which sits at the boundary of $\sqrt{t}$

convergence, the reason?

Solution

```
ls_prior_runs = {T0: [simulate(model, λ=1.0, T_prior=T0, n=1000, seed=s)
                      for s in range(24)]
                 for T0 in (300, 800, 5000)}

for T0, runs in ls_prior_runs.items():
    firsts = np.array([t for t in (first_escape(sim['y']) for sim in runs)
                       if t is not None])
    line = f"T_0 = {T0:>4}: {len(firsts):>2} of {len(runs)} escape"
    if len(firsts):
        τ = np.log((T0 + firsts) / T0)
        line += (f", median first escape t = {np.median(firsts):.0f} "
                 f"(τ = {np.median(τ):.2f}), "
                 f"{sum(returns_to_nash(sim['y']) for sim in runs)} return")
    else:
        line += f"; τ at t = 1000 is only {np.log((T0 + 1000) / T0):.2f}"
    print(line)
```

```
T_0 =  300: 21 of 24 escape, median first escape t = 132 (τ = 0.36), 0 return
T_0 =  800: 15 of 24 escape, median first escape t = 270 (τ = 0.29), 0 return
T_0 = 5000:  0 of 24 escape; τ at t = 1000 is only 0.18
```

A looser prior escapes more often and sooner, and no escaped path returns.

Measured in artificial time, first escapes under the two looser priors come after a few tenths of a unit.

With $T_0 = 5000$, 1000 periods supply only $\log(6000/5000) \approx 0.18$ units of artificial time, fewer than most escaping paths under the looser priors needed.

No escaped path returns because, as *Least squares learning: a decreasing gain* showed, the return needs many units of artificial time, and the least squares clock slows down exponentially.

The eigenvalue $-\frac{1}{2}$ is not the reason.

It governs how fast decreasing-gain estimates converge, and their asymptotic distribution, once they are near the self-confirming equilibrium.

It says nothing special about the probability of leaving the self-confirming equilibrium, which the large-deviation objects of the primer govern, or about the speed of the return from far away, which depends on the global mean dynamics; those are slow near the induction hypothesis.

Priors, Escapes, and Learning Cycles shows how, in a Kalman filter with a gain that does not vanish, the government's prior produces escapes that stick, and the bullets on decreasing and constant gains in *One recursion, many learners* summarize the general theory.

Exercise 104.12.3

Mean dynamics near the self-confirming equilibrium computed the eigenvalues of $DT - I$ at $\theta = 1$.

1. Check that (104.19) is exact away from the self-confirming equilibrium. Freeze the government's beliefs at those that one of the constant-gain runs holds at $t = 1000$, simulate the economy for 50,000 periods under the frozen rule, regress U_t on $X_{C,t}$, and compare the coefficients with `T_map`.

2. Compute the eigenvalues of $DT - I$ at the self-confirming equilibrium for $\theta \in \{0.5, 1, 2\}$, holding the other parameters fixed, and compare them with $-1/(1+\theta^2)$.
3. For which of these θ do least squares estimates converge at the usual $\sqrt{t}$ rate? Compare with *Least squares learning converges to Nash* and *Uniqueness and E-stability*.

Solution

For the first part we freeze the rule and simulate.

```
y_frozen = cg_runs[1]['y']
h = model.phelps_h(y_frozen)
rng = np.random.default_rng(0)
N = 50_000
v1 = model.σ1 * rng.standard_normal(N)
v2 = model.σ2 * rng.standard_normal(N)
U = model.U_star - model.θ * v2 + v1
y = np.zeros(N)
y[:2] = h[4]
for t in range(2, N):
    y[t] = h @ [U[t-1], U[t-2], y[t-1], y[t-2], 1.0] + v2[t]

X_C = np.column_stack([y[2:], U[1:-1], U[:-2], y[1:-1], y[:-2], np.ones(N - 2)])
coef = np.linalg.lstsq(X_C, U[2:], rcond=None)[0]
print("regression of U on X_C:", np.round(coef, 3))
print("T(y) from the formula: ", np.round(T_map(model, y_frozen), 3))
```

```
regression of U on X_C: [-0.998  0.007  0.056  0.044  0.124  6.186]
T(y) from the formula:  [-1.     0.011  0.054  0.049  0.126  6.169]
```

The two agree up to sampling error, because v_{1t} is independent of every regressor.

Now the eigenvalues.

```
for θ in (0.5, 1.0, 2.0):
    m = AdaptivePhillips(θ=θ)
    eig = np.sort(np.linalg.eigvals(jacobian_T(m) - np.eye(6)).real)
    print(f"θ = {θ}: eig(DT - I) = {np.round(eig, 4)}, "
          f"-1/(1 + θ²) = {-1 / (1 + θ**2):.4f}")
```

```
θ = 0.5: eig(DT - I) = [-1.  -0.8 -0.8 -0.8 -0.8 -0.8], -1/(1 + θ²) = -0.8000
θ = 1.0: eig(DT - I) = [-1.  -0.5 -0.5 -0.5 -0.5 -0.5], -1/(1 + θ²) = -0.5000
θ = 2.0: eig(DT - I) = [-1.  -0.2 -0.2 -0.2 -0.2 -0.2], -1/(1 + θ²) = -0.2000
```

For every θ the eigenvalues are -1 once and $-1/(1+\theta^2)$ five times.

The $\sqrt{t}$ rate requires $-1/(1+\theta^2) < -\frac{1}{2}$, that is, $\theta < 1$.

So least squares converges at the usual rate when $\theta = 0.5$, sits on the boundary when $\theta = 1$, and converges more slowly when $\theta = 2$, with the slow mean dynamics of a repeated eigenvalue -0.2.

These are the same numbers as the slope $\mathcal{M} = -1/(1+\theta^2)$ of the scalar mean dynamics in *Least squares learning converges to Nash* and the classical E-stability eigenvalues of *Uniqueness and E-stability*.

A steeper Phillips curve makes the static Phelps rule respond more strongly to a believed coefficient on a lag, which pushes the diagonal of DT, $\theta^2/(1+\theta^2)$, toward one and weakens the pull of the mean dynamics.

Exercise 104.12.4

The conclusions claim that inflation is serially uncorrelated at the self-confirming equilibrium but persistent after a constant-gain escape.

Check the claim, measuring persistence by the slope coefficient in a least squares regression of y_t on a constant and y_{t-1}.

1. For the least squares economy with $T_0 = 5000$, which stays near the self-confirming equilibrium, compute it over the first 200 periods of each path of Exercise 104.12.2.
2. For the constant-gain economies of Exercise 104.12.1, compute it over the 200 periods that begin 20 periods after the first escape.
3. Do the same for the least squares paths with $T_0 = 800$ that escape.
4. What relation between the level of inflation and its persistence does the model predict? Compare with *Drifts and Volatilities*.

Solution

```
def ar1(z):
    "Slope of a least squares regression of z_t on a constant and z_{t-1}."
    X = np.column_stack([np.ones(len(z) - 1), z[:-1]])
    return np.linalg.lstsq(X, z[1:], rcond=None)[0][1]

def after_escape(runs, start=20, length=200):
    "AR(1) coefficients over a window that starts `start` periods after the first␣
 ↪escape."
    out = []
    for sim in runs:
        t = first_escape(sim['y'])
        if t is not None and t + start + length <= len(sim['y']):
            out.append(ar1(sim['y'][t + start:t + start + length]))
    return np.array(out)

def summarize(label, values):
    print(f"{label:28s} median {np.median(values):+.2f}, "
          f"range {values.min():+.2f} to {values.max():+.2f} ({len(values)} paths)
 ↪")

summarize("least squares, T_0 = 5000:",
          np.array([ar1(sim['y'][:200]) for sim in ls_prior_runs[5000]]))
for λ in (0.99, 0.975, 0.95):
    summarize(f"constant gain, λ = {λ}:", after_escape(gain_runs[λ]))
summarize("least squares, T_0 = 800:", after_escape(ls_prior_runs[800]))
```

```
least squares, T_0 = 5000:   median +0.01, range -0.14 to +0.21 (24 paths)
constant gain, λ = 0.99:     median +0.10, range -0.11 to +0.29 (24 paths)
constant gain, λ = 0.975:    median +0.38, range +0.06 to +0.70 (24 paths)
constant gain, λ = 0.95:     median +0.73, range +0.58 to +0.88 (24 paths)
least squares, T_0 = 800:    median +0.06, range -0.02 to +0.21 (15 paths)
```

Near the self-confirming equilibrium the AR(1) coefficient is centered on zero.

After a constant-gain escape inflation is persistent, and more so the larger the gain; at $\lambda = 0.99$ the effect is small.

After a least squares escape that sticks, persistence is small again.

So the persistence comes from the motion of the government's beliefs, which a constant gain keeps alive, not from low inflation as such.

Under a constant gain the model therefore predicts that persistence should be high when inflation is low and low when inflation is high, with the transition from high to low inflation raising persistence.

Drifts and Volatilities (*Inflation persistence*) finds the reverse in U.S. data: persistence rose and fell with the level of inflation, and it fell during the Volcker disinflation.

105.1 Overview

> If an unlikely event occurs, it is very likely to occur in the most likely way.
>
> – Michael Harrison

This lecture is the analytical companion to *Adaptive Learning and Escape Dynamics*.

It follows Cho *et al.* [2002] (CWS), who give a *deterministic characterization* of the escape dynamics that chapter 8 of Sargent [1999] found by simulation.

In *Adaptive Learning and Escape Dynamics* we watched a constant-gain government recurrently escape the Nash self-confirming equilibrium and spend long spells near the Ramsey outcome, but we described those escapes only informally and by simulation.

CWS show that the escapes are governed by their own ordinary differential equation, obtained from the **theory of large deviations**.

The picture that emerges has two deterministic pieces:

- the **mean dynamics**, an ODE that pulls the government's beliefs *toward* the self-confirming equilibrium; and
- the **escape dynamics**, a second ODE that, driven by a "most likely unlikely" sequence of shocks, pushes beliefs *away* from it, toward the beliefs that support the Ramsey outcome.

The remarkable finding is that the escape has a *dominant path*: conditional on escaping, the government's beliefs follow a nearly deterministic route along which it temporarily learns a version of the natural-rate hypothesis and cuts inflation.

These escapes recur because the government uses constant-gain least squares, as in Sargent [1999] and CWS.

The governments of Sims [1988] and Chung [1990] instead ran Kalman filters on drifting coefficients; in their simulations a government that escaped did so once and then stayed near Ramsey, apparently indefinitely, and *Priors, Escapes, and Learning Cycles* traces the difference to the government's prior.

The large-deviation results are statements about small gains.

Simulating escapes simulates the model and finds that, at the gains used in this suite, escapes are frequent rather than rare.

We work with the analytically tractable **static** model, in which the government regresses unemployment on current inflation and a constant.

Adaptive Learning and Escape Dynamics simulates CWS's richer *dynamic* model, in which the government's regression also includes lags; we compare the two near the end of the lecture.

A government learning the Phillips curve presents the same static model, with the same calibration, in condensed form.

Readers arriving from there should note that it writes the beliefs as α (intercept first) and the gain as γ, while here γ denotes the beliefs and ε the gain.

The next lecture, *Priors, Escapes, and Learning Cycles*, asks how the government's *prior* about parameter drift reshapes both the mean dynamics and the escape dynamics.

Let's start with our imports:

```
import matplotlib.pyplot as plt
import numpy as np
from scipy.integrate import solve_ivp
from scipy.linalg import solve_discrete_are
```

105.2 The model

The true economy is the natural-rate model of Kydland and Prescott [1977],

$$U_n = u - \theta(\pi_n - \hat{x}_n) + \sigma_1 W_{1n}, \qquad \pi_n = x_n + \sigma_2 W_{2n}, \qquad \hat{x}_n = x_n, \tag{105.1}$$

with $\theta, u > 0$ and $W_n = (W_{1n}, W_{2n})^\top$ IID standard Gaussian.

The government does not know (105.1).

In the static model it fits a non-expectational Phillips curve by regressing unemployment on inflation and a constant,

$$U_n = \gamma_1 \pi_n + \gamma_{-1} + \eta_n, \tag{105.2}$$

with beliefs $\gamma = (\gamma_1, \gamma_{-1})$ (slope and intercept), and it treats η_n as exogenous.

Note

We keep the ordering of Cho *et al.* [2002]: the slope comes first, and the regressors are $\Phi = (\pi, 1)$.

This also matches the γ_1, γ_{-1} convention of *Self-Confirming Equilibria*.

Priors, Escapes, and Learning Cycles and *A government learning the Phillips curve* follow Sargent and Williams [2005] and put the intercept first.

Each lecture follows its source paper; the warning box in *Priors, Escapes, and Learning Cycles* translates between the two.

Believing (105.2), the government solves the *Phelps problem*, whose static best response sets inflation to the constant

$$x(\gamma) = -\frac{\gamma_{-1}\,\gamma_1}{1+\gamma_1^2}. \tag{105.3}$$

Three beliefs are worth naming, following CWS:

- **Belief 1 (Nash):** $\gamma_1 = -\theta$ with an intercept that makes $x = \theta u$, the time-consistent outcome of Kydland and Prescott [1977].
- **Belief 2 (Ramsey):** $\gamma_1 = 0$, so the government perceives no tradeoff and sets $x = 0$.
- **Belief 3 (induction):** in CWS's dynamic model, coefficients on current and lagged inflation that sum to zero, which for a patient government also sends inflation to 0.

In the static model there is only one coefficient on inflation, so Belief 3 coincides with Belief 2: a vertical perceived Phillips curve "trivially satisfies the induction property" (CWS, section 6.2).

```
class EscapeModel:
    "CWS 2002 static model. γ = (γ₁ slope, γ₋₁ intercept), regressors Φ = (π, 1)."

    def __init__(self, θ=1.0, u=5.0, σ1=0.3, σ2=0.3):
        self.θ, self.u, self.σ1, self.σ2 = θ, u, σ1, σ2

    def γ_sce(self):
        "Self-confirming beliefs (slope -θ, intercept u(1+θ²))."
        return np.array([-self.θ, self.u * (1 + self.θ**2)])

    def x(self, γ):
        γ1, γm1 = γ
        return -γm1 * γ1 / (1 + γ1**2)

    def M(self, γ):
        "E[ΦΦ'] with Φ = (π, 1)."
        x = self.x(γ)
        return np.array([[x**2 + self.σ2**2, x], [x, 1.0]])

    def g_bar(self, γ):
        "Mean-dynamics forcing E[Φ(U - Φ'γ)] = M(T(γ) - γ)."
        x = self.x(γ)
        E_ΦU = np.array([x * self.u - self.θ * self.σ2**2, self.u])
        return E_ΦU - self.M(γ) @ γ
```

105.3 The self-confirming equilibrium

A self-confirming equilibrium is a belief that reproduces itself: the population regression coefficients of (105.2), computed on the data the government generates by acting on γ, equal γ.

Writing $T(\gamma)$ for those population coefficients and $\bar{M}(\gamma) = \mathbb{E}\,\Phi\Phi^\top$ for the population moment matrix of the regressors, CWS show

$$\bar{g}(\gamma) \equiv \mathbb{E}\left[\Phi(U - \Phi^\top\gamma)\right] = \bar{M}(\gamma)\,(T(\gamma) - \gamma)\,,$$

so a self-confirming equilibrium solves $\bar{g}(\gamma) = 0$.

Under a constant policy x, only the surprise $\sigma_2 W_{2n}$ moves inflation, so $T(\gamma) = (-\theta,\ u + \theta x(\gamma))$.

For the static model the equilibrium is therefore the intersection of the line $\gamma_1 = -\theta$ with the parabola $\gamma_{-1} = u(1+\gamma_1^2)$, a unique point that supports the Nash outcome of *The Credibility Problem*.

It is the same self-confirming equilibrium constructed in *Self-Confirming Equilibria*, written here in the static (constant-plus-slope) special case that *Priors, Escapes, and Learning Cycles* also uses, and it is what Kydland and Prescott [1977] call a *consistent* equilibrium (*A government learning the Phillips curve*).

```
model = EscapeModel(θ=1.0, u=5.0, σ1=0.3, σ2=0.3)
γ_sce = model.γ_sce()

print(f"self-confirming beliefs γ = {γ_sce}  (slope -θ, intercept u(1+θ²))")
print(f"self-confirming inflation x = {model.x(γ_sce):.2f}  (= Nash = θu)")
print(f"check g_bar = {model.g_bar(γ_sce)}")
```

```
self-confirming beliefs γ = [-1. 10.]  (slope -θ, intercept u(1+θ²))
self-confirming inflation x = 5.00  (= Nash = θu)
check g_bar = [0. 0.]
```

The figure plots the two loci whose intersection is the equilibrium.

```
γ1_grid = np.linspace(-2, 1, 200)
fig, ax = plt.subplots(figsize=(7, 6))
ax.plot(γ1_grid, model.u * (1 + γ1_grid**2), label=r'$\gamma_{-1} = u(1+\gamma_1^2)$',
 ↪ lw=2)
ax.axvline(-model.θ, color='C1', ls='--', label=r'$\gamma_1 = -\theta$')
ax.plot(γ_sce[0], γ_sce[1], 'ko', ms=8)
ax.annotate('SCE (Nash)', γ_sce, (γ_sce[0] + 0.1, γ_sce[1] + 1))
ax.set_xlabel(r'slope $\gamma_1$')
ax.set_ylabel(r'intercept $\gamma_{-1}$')
ax.set_ylim(0, 25)
ax.legend()
plt.show()
```

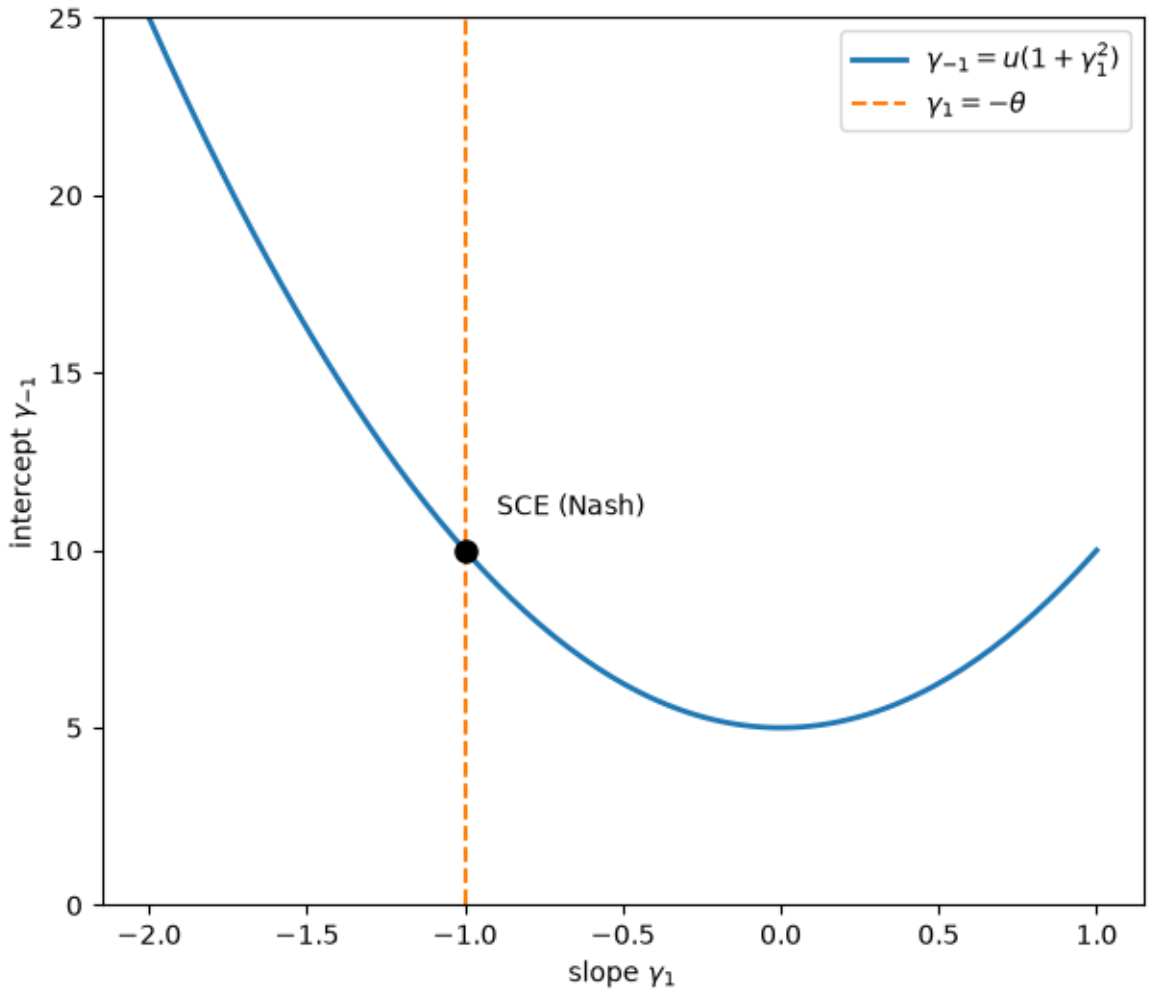

Fig. 105.1: The unique self-confirming equilibrium in belief space

105.4 Adaptation and the mean dynamics

We make the government adaptive.

Each period it sets $x_n = x(\gamma_n)$, observes (π_n, U_n), and updates its estimates by constant-gain recursive least squares,

$$R_n = R_{n-1} + \varepsilon\left(\Phi_n\Phi_n^\top - R_{n-1}\right), \qquad \gamma_{n+1} = \gamma_n + \varepsilon R_n^{-1}\Phi_n\left(U_n - \Phi_n^\top\gamma_n\right), \tag{105.4}$$

where $\Phi_n = (\pi_n, 1)^\top$ and $\varepsilon > 0$ is the gain.

This is the recursion of `constant_gain` in *A government learning the Phillips curve*, with the regressors in CWS's order.

CWS's equations (4.24)–(4.25) date R one period earlier, which makes no difference as $\varepsilon \to 0$.

Because the government acts on its current estimate as if it were permanent, this is an *anticipated-utility* model in the sense of Kreps [1998].

The literature on least squares learning in self-referential models [Evans and Honkapohja, 2001, Marcet and Sargent, 1989, Woodford, 1990] shows that, as $\varepsilon \to 0$ with time measured as $t = n\varepsilon$, the beliefs are approximated by the **mean-dynamics** ODE

$$\dot\gamma = R^{-1}\bar g(\gamma), \qquad \dot R = \bar M(\gamma) - R. \tag{105.5}$$

One recursion, many learners derives this kind of ODE for a scalar recursion and connects its stability to E-stability.

> **Note**
>
> **Notation across lectures.** *A primer on recursive algorithms* stacks the beliefs as $\phi = (\gamma, \mathrm{col}(R))$ and writes the mean dynamics as $\dot\phi = b(\phi)$.
>
> In the static model $b(\phi) = \left(R^{-1}\bar g(\gamma),\ \mathrm{col}(\bar M(\gamma) - R)\right)$, so (105.5) is that ODE written out.
>
> The escape dynamics below add a forcing v to the γ block only.
>
> *Priors, Escapes, and Learning Cycles* replaces the scaled inverse moment matrix εR^{-1} by the covariance matrix P of a Kalman filter, and orders γ intercept first.

A rest point of (105.5) is a self-confirming equilibrium, and CWS show that this ODE is *globally stable* about it.

Locally, with $R = \bar M(\bar\gamma)$, the γ block has eigenvalues -1 and $-1/(1+\theta^2)$: these are the E-stability eigenvalues of *Uniqueness and E-stability* and *Mean dynamics near the self-confirming equilibrium*.

```
R_bar = model.M(γ_sce)                          # moment matrix at the SCE
h = 1e-6
J = np.column_stack([(model.g_bar(γ_sce + h * e) - model.g_bar(γ_sce - h * e)) / (2 *␣
 ↪h)
                     for e in np.eye(2)])
print("eigenvalues of R̄⁻¹ Dḡ at the SCE:", np.linalg.eigvals(np.linalg.solve(R_bar,␣
 ↪J)).round(4))
print("-1/(1+θ²) =", -1 / (1 + model.θ**2))
```

```
eigenvalues of R̄⁻¹ Dḡ at the SCE: [-1.  -0.5]
-1/(1+θ²) = -0.5
```

So under the mean dynamics alone, the adaptive government is drawn to Nash inflation.

But the route can be circuitous.

The next figure starts the beliefs part of the way toward Ramsey, at $\gamma(0) = \bar{\gamma} + (0.4, -3)$, in two ways.

In the first, the moment matrix R starts at its Nash-era value $\bar{M}(\bar{\gamma})$; in the second, it starts at the moments $\bar{M}(\gamma(0))$ that the new beliefs would generate.

```
def mean_ode(t, z, model):
    y, R = z[:2], z[2:].reshape(2, 2)
    return np.concatenate([np.linalg.solve(R, model.g_bar(y)),
                           (model.M(y) - R).ravel()])

y0 = y_sce + np.array([0.4, -3.0])
fig, ax = plt.subplots(figsize=(8, 4.5))
starts = [(R_bar, r'$R(0) = \bar M(\bar\gamma)$ (Nash-era moments)', 'R(0) = M(SCE)'),
          (model.M(y0), r'$R(0) = \bar M(\gamma(0))$', 'R(0) = M(y(0))')]
for R0, label, short in starts:
    sol = solve_ivp(mean_ode, [0, 60], np.concatenate([y0, R0.ravel()]), args=(model,
 ↪),
                    max_step=0.1, rtol=1e-9, atol=1e-11)
    x_path = -sol.y[1] * sol.y[0] / (1 + sol.y[0]**2)
    ax.plot(sol.t, x_path, label=label)
    k = np.argmin(x_path)
    print(f"{short:15s}: x(0) = {x_path[0]:.2f}, min x = {x_path[k]:.2f} "
          f"at t = {sol.t[k]:.2f}, x(60) = {x_path[-1]:.2f}")
ax.axhline(model.θ * model.u, color='k', ls='--', lw=1, label='Nash')
ax.set_xlabel('time $t = n\\varepsilon$')
ax.set_ylabel('inflation $x$')
ax.legend()
plt.show()
```

```
R(0) = M(SCE)  : x(0) = 3.09, min x = 1.68 at t = 1.33, x(60) = 5.00
R(0) = M(y(0)) : x(0) = 3.09, min x = 3.09 at t = 0.00, x(60) = 5.00
```

Both paths return to Nash, but they get there differently.

When R starts at the Nash-era moments, inflation first *falls* further, from about 3.1 to about 1.7, before it climbs back.

When R starts at $\bar{M}(\gamma(0))$, inflation rises monotonically.

The dip is the circuitous route of CWS (section 6.4) made visible, and it comes from R lagging behind $\bar{M}(\gamma)$.

We return to this lag in *Mean dynamics reinforce the escape*, where it turns out to drive the escape.

The mean dynamics alone cannot explain the recurrent visits to low inflation in the simulations of *Adaptive Learning and Escape Dynamics*.

For that we need a second force.

105.5 Escape dynamics as a control problem

Although the impact of the noise vanishes as $\varepsilon \to 0$, for a fixed positive gain unusual sequences of shocks can push beliefs a long way from the self-confirming equilibrium.

A primer on recursive algorithms sets out the general theory.

It builds the log moment-generating function H of the innovations, its Legendre transform L, and an **action functional** $S(T, \gamma) = \int_0^T L\, ds$ that measures how improbable a path of beliefs is.

The **dominant escape path** minimizes the action among paths that leave a neighbourhood G of $\bar{\gamma}$.

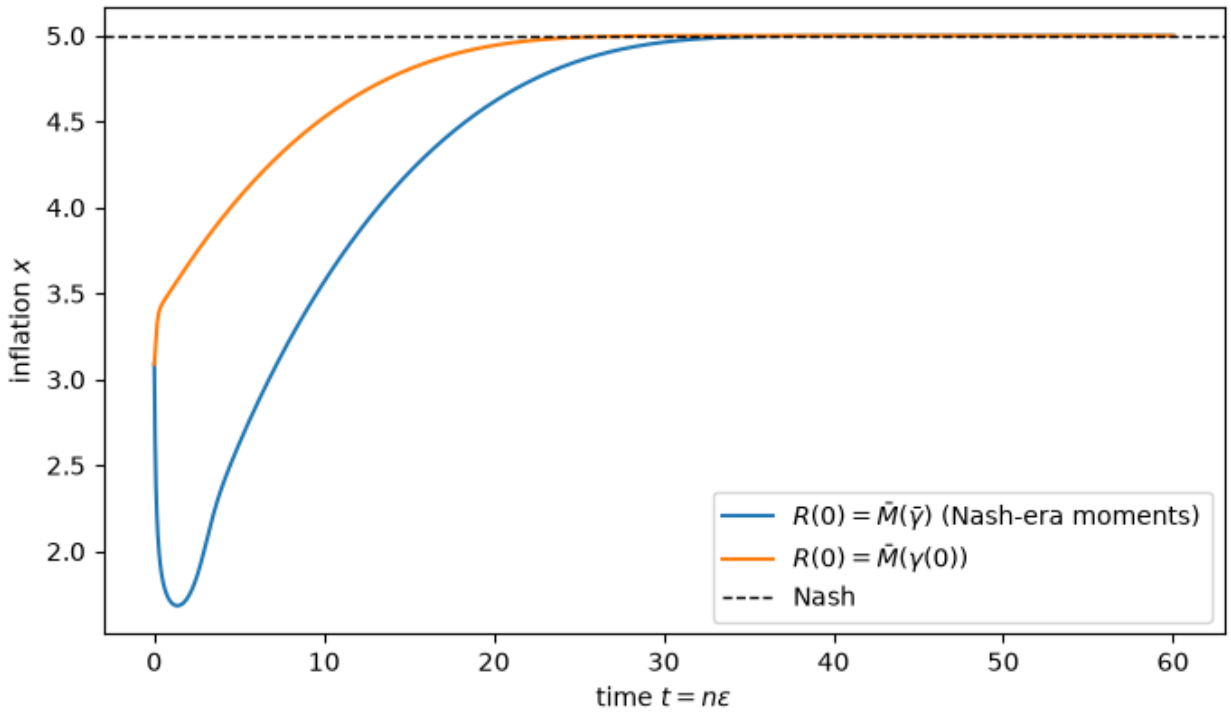

Fig. 105.2: Mean dynamics from a perturbed start: when R starts at its Nash-era value, inflation first dips

Here we need only the operational version.

CWS draw on Noah Williams's dissertation [Williams, 2001], published in corrected form as Williams [2019], to reduce the problem to a clean control problem.

The H-functional becomes a quadratic form with a normalizing matrix Q (a fourth-moment matrix obtained from Lyapunov equations), and the escape path solves

$$\bar{S} = \inf_{v(\cdot),\,T} \frac{1}{2} \int_0^T v(s)^\top Q(\gamma(s), R(s))^{-1} v(s)\, ds \tag{105.6}$$

subject to the *perturbed* mean dynamics

$$\dot{\gamma} = R^{-1}\bar{g}(\gamma) + v, \qquad \dot{R} = \bar{M}(\gamma) - R, \qquad \gamma(0) = \bar{\gamma},\ \gamma(T) \notin G. \tag{105.7}$$

Read (105.6) as a least squares problem: v is the extra "forcing" that the mean dynamics would need to escape, Q plays the role of a covariance matrix, and the least-cost forcing is the most likely unusual shock sequence.

Williams [2019] (p. 892) reports that the 2001 version computed H by misapplying a theorem of Worms (1999).

The discrepancy matters only for dynamic models; for the static model CWS computed H directly.

So the static-model results below stand, while CWS's rate for the dynamic model rests on the earlier shortcut.

Let τ^ε be the first time, measured as $t = n\varepsilon$, at which the beliefs leave G.

Two consequences (CWS, Theorem 5.3) tie the control problem to the stochastic model:

- $\varepsilon \log \mathbb{P}(\text{escape before } T) \to -\bar{S}$ and $\varepsilon \log \mathbb{E}\,\tau^\varepsilon \to \bar{S}$ as $\varepsilon \to 0$; and
- conditional on escaping, beliefs follow the dominant escape path with probability approaching one.

The first is a statement about the limit $\varepsilon \to 0$.

Williams [2019] (footnote 16) writes it as $\log \mathbb{E}\,\tau^{\varepsilon} \approx S_0 + \bar{S}/\varepsilon$ for some constant S_0 that the theory does not pin down.

So $\bar{S}$ governs how fast escape times grow as the gain shrinks, not their level.

For the static model CWS (Table 1) find $\bar{S} \approx 5 \times 10^{-4}$.

At the gains of *Adaptive Learning and Escape Dynamics* and *A government learning the Phillips curve* (0.025 and 0.02), $e^{\bar{S}/\varepsilon} \approx 1.02$, so the large-deviation factor by itself does not make escapes rare.

Simulating escapes measures how often they occur.

The escape dynamics, like the mean dynamics, are *deterministic*.

105.6 The changed-measure escape path

Solving (105.6) requires the matrix Q and a two-point boundary-value problem.

For the static model with binomial shocks, CWS (section 7) identify the escape route by a different and simpler argument.

They change the probability measure on the shocks to the most likely unusual distribution that pushes beliefs away from $\bar{\gamma}$, and average the least squares update under that measure.

The resulting escape forcing is strikingly simple:

$$v = R^{-1} \begin{bmatrix} \sigma_1 \sigma_2 \\ 0 \end{bmatrix}, \tag{105.8}$$

so the changed-measure escape path solves

$$\dot{\gamma} = R^{-1} \left(\bar{g}(\gamma) + \begin{bmatrix} \sigma_1 \sigma_2 \\ 0 \end{bmatrix} \right), \qquad \dot{R} = \bar{M}(\gamma) - R. \tag{105.9}$$

This path shares the dominant escape path's exit point, but it gets there faster.

CWS (footnote 14) warn that the transformed measure underestimates the time to escape.

In their Figure 7, the changed-measure path is shorter than even the shortest of 1,000 simulated escapes.

Let's integrate (105.9) from the self-confirming equilibrium until beliefs leave a circle of radius 5, the escape set CWS use for the static model.

```
def escape_ode(t, z, model):
    γ, R = z[:2], z[2:].reshape(2, 2)
    force = np.array([model.σ1 * model.σ2, 0.0])
    return np.concatenate([np.linalg.solve(R, model.g_bar(γ) + force),
                           (model.M(γ) - R).ravel()])

def left_circle(t, z, *args):
    "Terminal event: beliefs leave the radius-5 circle around the SCE."
    return 5.0 - np.linalg.norm(z[:2] - γ_sce)
left_circle.terminal = True
left_circle.direction = -1

z0 = np.concatenate([γ_sce, R_bar.ravel()])
esc = solve_ivp(lambda t, z: escape_ode(t, z, model), [0, 200], z0,
                events=left_circle, max_step=0.02, rtol=1e-9, atol=1e-11)

slope, intercept = esc.y[0], esc.y[1]
infl = -intercept * slope / (1 + slope**2)
```

The figure plots the two coefficients and the inflation rate they imply.

```
fig, axes = plt.subplots(1, 2, figsize=(12, 5))

axes[0].plot(esc.t, intercept, label='intercept $\\gamma_{-1}$')
axes[0].plot(esc.t, slope, label='slope $\\gamma_1$')
axes[0].axhline(0, color='C3', ls=':', lw=1, label='vertical curve ($\\gamma_1 = 0$)')
axes[0].set_xlabel('time $t = n\\varepsilon$')
axes[0].set_ylabel('coefficient')
axes[0].set_title('Changed-measure escape path (cf. CWS Figures 4 and 7)')
axes[0].legend()

axes[1].plot(esc.t, infl)
axes[1].axhline(model.θ * model.u, color='k', ls='--', lw=1, label='Nash')
axes[1].axhline(0, color='C2', ls=':', lw=1, label='Ramsey')
axes[1].set_xlabel('time $t = n\\varepsilon$')
axes[1].set_ylabel('inflation $x$')
axes[1].set_title('Inflation along the escape')
axes[1].legend()

plt.tight_layout()
plt.show()
```

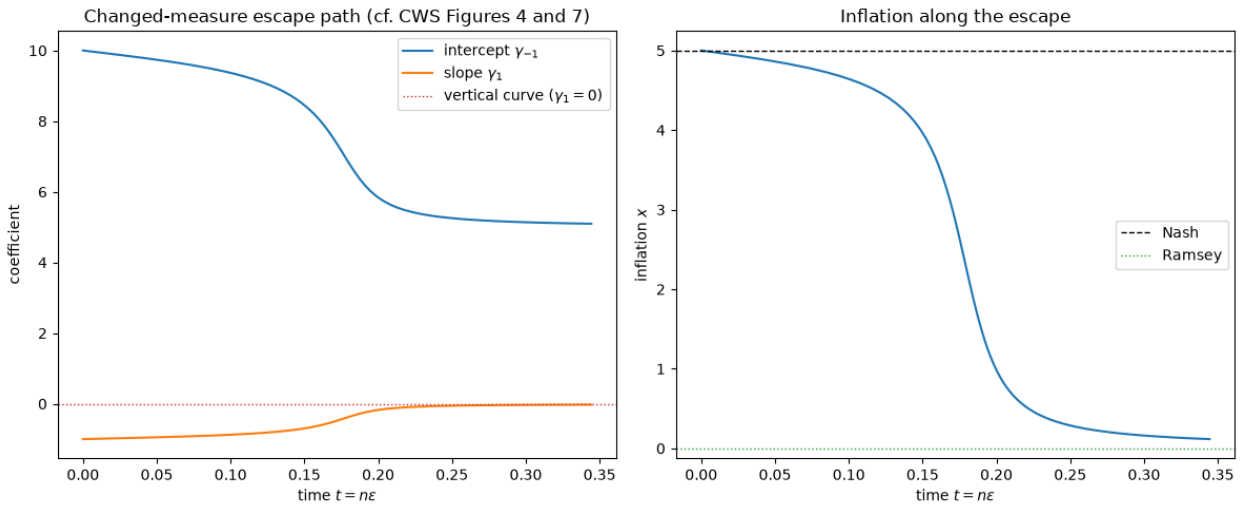

Fig. 105.3: The changed-measure escape path and the inflation rate along it

Here are the start and end points of the path.

```
print(f"exit time : t = {esc.t[-1]:.3f}")
print(f"slope     : {slope[0]:.2f} → {slope[-1]:.3f}   (CWS Table 1, radius 5: -0.025)
↪")
print(f"intercept : {intercept[0]:.1f} → {intercept[-1]:.2f}")
print(f"inflation : {infl[0]:.2f} → {infl[-1]:.2f}   (Nash {model.θ*model.u:.0f} →␣
↪Ramsey 0)")
```

```
exit time : t = 0.344
slope     : -1.00 → -0.023   (CWS Table 1, radius 5: -0.025)
```

(continues on next page)

(continued from previous page)

```
intercept : 10.0 → 5.10
inflation : 5.00 → 0.12   (Nash 5 → Ramsey 0)
```

Along the escape path the slope rises from its self-confirming value of -1 toward zero, and inflation falls from the Nash value toward Ramsey.

The path leaves the circle at a slope of about -0.023, close to the -0.025 that CWS (Table 1) report for the dominant path at the same radius.

It leaves at $t \approx 0.34$, while the dominant path in CWS's Figure 4 needs until about $t = 3$: the two paths share a route but not a timetable.

In the static model, a slope near zero means a vertical perceived Phillips curve, which trivially satisfies the induction hypothesis.

The dynamic model that *Adaptive Learning and Escape Dynamics* simulates escapes differently.

There the *sum* of the coefficients on current and lagged inflation rises toward zero, while the coefficient on current inflation stays negative, so a short-run Phillips curve survives while the long-run curve becomes vertical (CWS, section 6.2 and Figure 3).

In both models the government, by chance, generates enough inflation *experiments* to discover a good-enough version of the natural-rate hypothesis, and acts on it.

105.7 The race of four ODEs

Where does the escape forcing (105.8) come from?

With binomial shocks $W_{in} \in \{-1, +1\}$, each period brings one of four shock realizations $w \in \{-1, 1\}^2$, each with probability $1/4$.

An escape needs a run of updates that push beliefs consistently in one direction.

CWS show that the most efficient runs draw repeatedly from just two realizations whose updates lie in the same half-space, each with probability $1/2$; four such pairs exist.

Averaging the update over a pair gives a *conditional* mean ODE,

$$\dot{\gamma} = R^{-1}\left(\bar{g}(\gamma) + f_j(\gamma)\right), \qquad \dot{R} = \bar{M}(\gamma) - R, \tag{105.10}$$

with forcings

$$f_1 = \begin{bmatrix}\sigma_1\sigma_2\\ 0\end{bmatrix}, \quad f_2 = \begin{bmatrix}-\sigma_1\sigma_2\\ 0\end{bmatrix}, \quad f_3 = \sigma_1\begin{bmatrix}x(\gamma)\\ 1\end{bmatrix}, \quad f_4 = -\sigma_1\begin{bmatrix}x(\gamma)\\ 1\end{bmatrix}$$

for the pairs $\{(1,1),(-1,-1)\}$, $\{(1,-1),(-1,1)\}$, $\{(1,1),(1,-1)\}$ and $\{(-1,1),(-1,-1)\}$.

R follows the unconditional mean dynamics because $\bar{M}$ depends only on W_2, which takes each value with probability $1/2$ within every pair.

Each conditional ODE is a candidate escape route.

Every shock realization has probability $1/4$, so the probability of a run falls geometrically with its length, and the candidate that reaches the boundary first gives the most likely exit point (CWS, section 7.2).

We first compare the candidates' speeds at the self-confirming equilibrium, and then run the race.

```
def cond_ode(t, z, model, f):
    "Conditional mean dynamics for one shock pair with forcing f(y)."
    y, R = z[:2], z[2:].reshape(2, 2)
    return np.concatenate([np.linalg.solve(R, model.g_bar(y) + f(y, model)),
                           (model.M(y) - R).ravel()])

pairs = {
    "1: {(1,1),(-1,-1)}":  lambda y, m: np.array([m.σ1 * m.σ2, 0.0]),
    "2: {(1,-1),(-1,1)}":  lambda y, m: np.array([-m.σ1 * m.σ2, 0.0]),
    "3: {(1,1),(1,-1)}":   lambda y, m: m.σ1 * np.array([m.x(y), 1.0]),
    "4: {(-1,1),(-1,-1)}": lambda y, m: -m.σ1 * np.array([m.x(y), 1.0]),
}

race = {}
print(f"{'pair':22s} {'speed at SCE':>12s} {'exit time':>10s} {'exit y':>17s} {'exit x
↪':>7s}")
for name, f in pairs.items():

4: {(-1,1),(-1,-1)}            0.30      0.473   (-0.043,  5.09)    0.22
```

At the self-confirming equilibrium itself, pairs 1 and 2 tie: their initial velocities are equal and opposite, and much faster than those of pairs 3 and 4.

Speed at the starting point therefore cannot settle the race, so we integrate the four ODEs.

Pair 1 reaches the boundary first, near the Ramsey belief.

Pair 4 also exits near the Ramsey belief, but later.

Pair 2, the mirror image of pair 1, heads toward *higher* inflation and needs far longer to reach the boundary.

Pair 3 never exits: it settles at a rest point inside the circle.

So pair 1 wins the race, and the escape forcing it induces is the $R^{-1}(\sigma_1\sigma_2, 0)^\top$ of (105.8).

CWS describe the winner's velocity as substantially larger than the other three; the table shows that this holds along the route, not at its start.

105.8 Mean dynamics reinforce the escape

Why does the Ramsey-ward escape succeed so quickly while its mirror image crawls?

Near the self-confirming equilibrium the mean dynamics point *toward* it, opposing any escape.

But CWS (section 6.4, Figures 8–9) show that once beliefs have moved a little way along the escape route, the mean dynamics themselves point *toward* Ramsey, reinforcing the escape.

The reason is that R lags $\bar{M}(\gamma)$.

During an escape the beliefs γ move fast, while R adjusts toward $\bar{M}(\gamma)$ only at rate one, so R still holds roughly the moments of the Nash era, $\bar{R} = \bar{M}(\bar{\gamma})$.

At the self-confirming equilibrium inflation barely varies, so $\det \bar{R} = \sigma_2^2$ is small and $\bar{R}^{-1}$ is large.

Premultiplying the drift $\bar{g}(\gamma) = \bar{M}(\gamma)(T(\gamma) - \gamma)$ by $\bar{R}^{-1}$ instead of $\bar{M}(\gamma)^{-1}$ both rotates and amplifies it.

CWS (section 6.5) describe the same self-reinforcement in words, adding that "overweighting recent observations helps this process along."

To see this, we plot the normalized mean-dynamics drift $R^{-1}\bar{g}(\gamma)$ in belief space, once with R held at its Nash-era value $\bar{R}$ and once with R caught up at $\bar{M}(\gamma)$.

```
gs = np.linspace(-1.2, 0.1, 16)       # slope
gi = np.linspace(4.5, 10.5, 16)       # intercept
GS, GI = np.meshgrid(gs, gi)

fig, axes = plt.subplots(1, 2, figsize=(13, 5.5), sharey=True)
titles = [r'$R = \bar M(\bar\gamma)$: $R$ lags', r'$R = \bar M(\gamma)$: $R$ caught up
 ↪']
for ax, lagging, title in zip(axes, [True, False], titles):
    DS, DI = np.zeros_like(GS), np.zeros_like(GI)
    for i in range(GS.shape[0]):
        for j in range(GS.shape[1]):
            y = np.array([GS[i, j], GI[i, j]])
            R = R_bar if lagging else model.M(y)
            d = np.linalg.solve(R, model.g_bar(y))
            DS[i, j], DI[i, j] = d / np.linalg.norm(d)
    ax.quiver(GS, GI, DS, DI, angles='xy', alpha=0.7)
    ax.plot(*y_sce, 'ko', ms=8, label='SCE (Nash)')
    ax.plot(0, model.u, 'C2s', ms=8, label='Ramsey belief')
    ax.plot(slope, intercept, 'C3', lw=2, label='escape path')
    ax.set_xlabel(r'slope $\gamma_1$')
    ax.set_title(title)
axes[0].set_ylabel(r'intercept $\gamma_{-1}$')
axes[0].legend(loc='lower left')
plt.tight_layout()
plt.show()
```

In the left panel, with R at its Nash-era value, the arrows along the escape route sweep toward the Ramsey belief.

In the right panel, where R has caught up, they point back toward slope $-\theta$ everywhere.

There the drift is $T(\gamma) - \gamma$, whose slope component $-\theta - \gamma_1$ is negative whenever $\gamma_1 > -\theta$.

So the reinforcement is a property of the *joint* dynamics of γ and R; it is the same lag that produced the dip in Fig. 105.2.

Along the escape path itself R moves only part of the way toward $\bar{M}(\gamma)$, because the escape takes only a fraction of a unit of time; Exercise 105.13.2 measures the alignment with the path's own R.

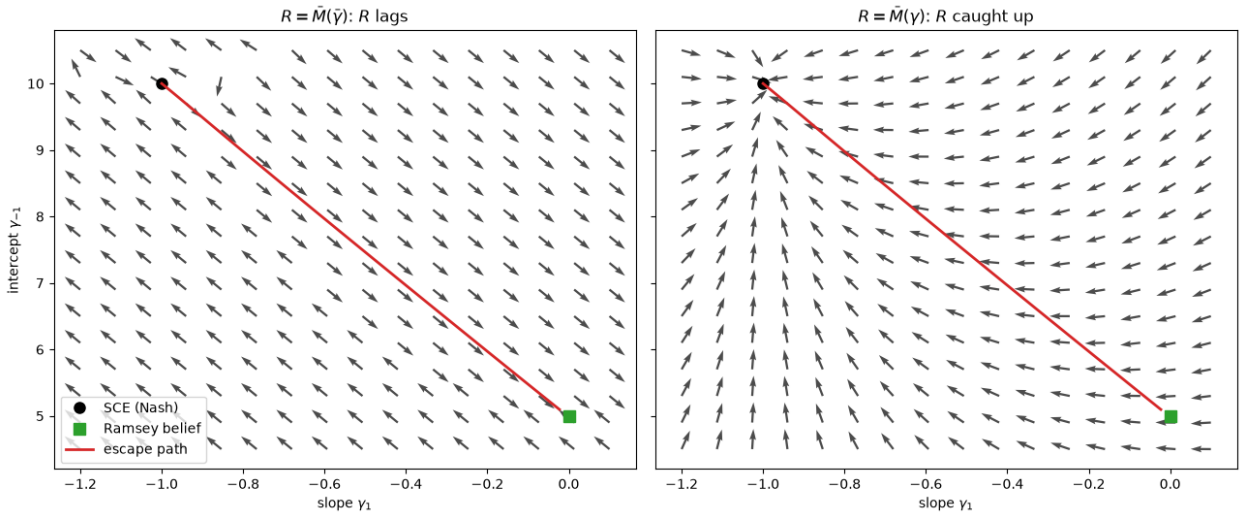

Fig. 105.4: Mean-dynamics drift with R lagging (left) and with R caught up (right), and the escape path

The escape dynamics only need to *start* the departure; the mean dynamics finish the job.

This is the sense in which the mean dynamics trace a *circuitous* route: pushed off the equilibrium along the escape path, the system travels near Ramsey before R catches up, the residual short-run Phillips curve is rediscovered, and the mean dynamics eventually carry beliefs back to Nash.

105.9 The experimentation trap

The escape has a compelling behavioural interpretation.

Within its approximating model, the government can only detect the natural-rate hypothesis if there is enough *dispersion* in inflation.

But inside a self-confirming equilibrium the government sets a constant systematic inflation rate, so it generates no such dispersion: it is caught in an **experimentation trap**.

Only an unusual run of shocks makes the government vary inflation enough to steepen its estimated Phillips curve; a steeper perceived curve leads it (through the best response) to cut inflation, which generates further influential observations that steepen the curve further.

As CWS note, overweighting recent observations helps this process along.

This self-reinforcing process halts when the perceived Phillips curve is vertical, and inflation is near Ramsey.

The system cannot stay there forever: in truth there *is* a short-run Phillips curve, which the government eventually rediscovers, rekindling the mean dynamics that carry it back to Nash.

105.10 Simulating escapes

The large-deviation results describe the limit $\varepsilon \to 0$.

To see what they imply at the gains this suite actually uses, we simulate the static model under the constant-gain recursion (105.4).

Every path starts at the self-confirming equilibrium, with $R_0 = \bar{M}(\bar{\gamma})$.

```
def simulate_path(model, ε, n_periods, seed=0):
    "One path of the static model under constant-gain RLS (en_rls), started at the␣
↪SCE."
    rng = np.random.default_rng(seed)
    θ, u, σ1, σ2 = model.θ, model.u, model.σ1, model.σ2
    γ = model.γ_sce()
    R = model.M(γ)
    x_path, γ_path = np.empty(n_periods), np.empty((n_periods, 2))
    for n in range(n_periods):
        x = model.x(γ)
        w1, w2 = rng.standard_normal(2)
        π = x + σ2 * w2
        U = u - θ * σ2 * w2 + σ1 * w1
        Φ = np.array([π, 1.0])
        R = R + ε * (np.outer(Φ, Φ) - R)
        γ = γ + ε * np.linalg.solve(R, Φ * (U - Φ @ γ))
        x_path[n], γ_path[n] = x, γ
    return x_path, γ_path
```

We use $\varepsilon = 0.02$, the gain of *A government learning the Phillips curve*; *Adaptive Learning and Escape Dynamics* uses 0.025, the book's $\lambda = .975$.

```
ε = 0.02
x_path, γ_path = simulate_path(model, ε, 4_000, seed=1)

fig, axes = plt.subplots(2, 1, figsize=(10, 6), sharex=True)
axes[0].plot(x_path, lw=0.8)
axes[0].axhline(model.θ * model.u, color='k', ls='--', lw=1, label='Nash')
axes[0].axhline(0, color='C2', ls=':', lw=1, label='Ramsey')
axes[0].set_ylabel('target inflation $x_n$')
axes[0].legend(loc='upper right')
axes[1].plot(γ_path[:, 0], lw=0.8, color='C1')
axes[1].axhline(-model.θ, color='k', ls='--', lw=1)
axes[1].set_ylabel(r'slope $\gamma_{1n}$')
axes[1].set_xlabel('period $n$')
plt.tight_layout()
plt.show()
```

Like the long simulation in *A government learning the Phillips curve*, the path is a recurrent sawtooth: abrupt escapes toward zero inflation, each followed by a slow climb back toward Nash, often interrupted by the next escape.

A longer run shows how little time the government spends near Nash.

```
x_long, _ = simulate_path(model, ε, 20_000, seed=2)
print(f"ε = {ε}, 20,000 periods:")
print(f"  share of periods with x > 4: {np.mean(x_long > 4):.2f}")
print(f"  share of periods with x < 2: {np.mean(x_long < 2):.2f}")
```

(continues on next page)

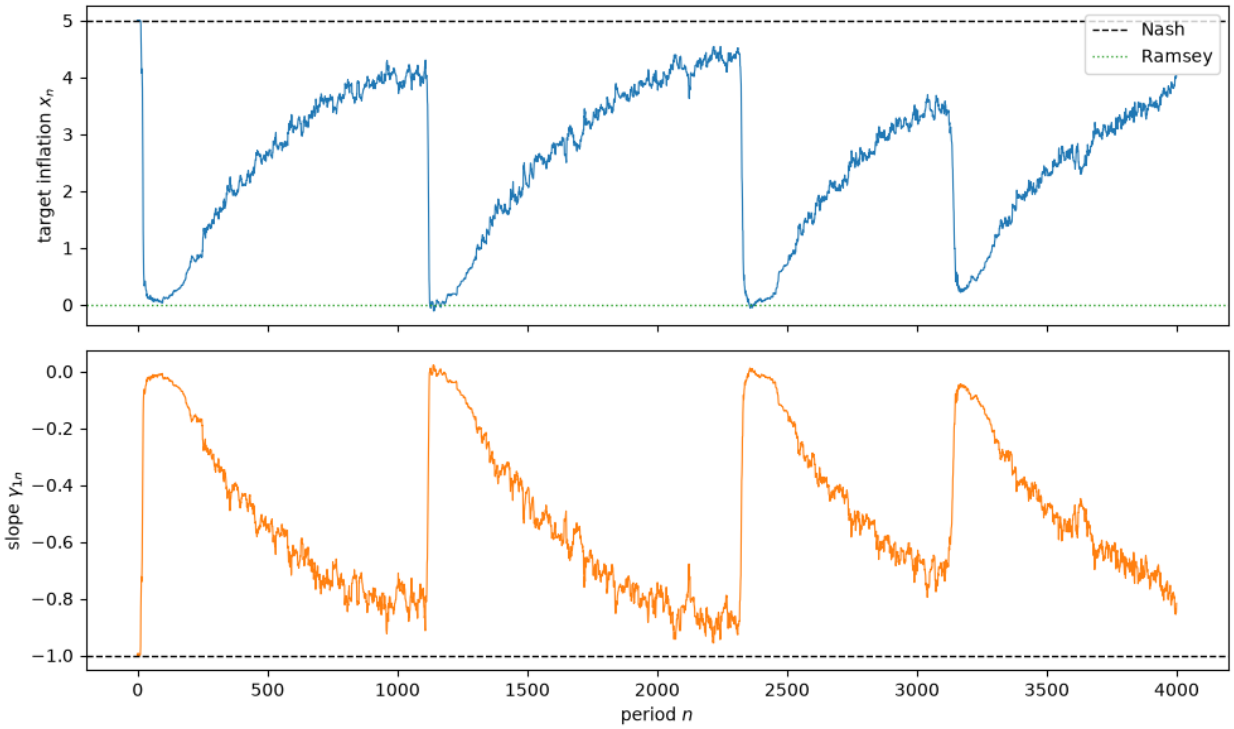

Fig. 105.5: A simulated path of the static model with gain 0.02

(continued from previous page)

```
print(f"  mean target inflation:       {x_long.mean():.2f}   (Nash {model.θ * model.
↪u:.0f})")
```

```
ε = 0.02, 20,000 periods:
  share of periods with x > 4: 0.10
  share of periods with x < 2: 0.34
  mean target inflation:       2.47   (Nash 5)
```

Target inflation is above 4 in only a small minority of periods.

To connect with the theorem, we measure the first exit time from the radius-5 circle, starting at the self-confirming equilibrium, for many independent paths.

```
def first_exits(model, ε, n_paths=400, radius=5.0, seed=0):
    """
    Simulate n_paths independent copies of (en_rls) from the SCE.  Return each
    path's first exit period from the circle of the given radius and its beliefs
    at exit (NaN if it has not exited after 100/ε periods).
    """
    rng = np.random.default_rng(seed)
    θ, u, σ1, σ2 = model.θ, model.u, model.σ1, model.σ2
    γ_bar = model.γ_sce()
    γ = np.tile(γ_bar, (n_paths, 1))
    R = np.tile(model.M(γ_bar), (n_paths, 1, 1))
    τ = np.full(n_paths, np.nan)
    γ_exit = np.full((n_paths, 2), np.nan)
    alive = np.ones(n_paths, dtype=bool)
```

(continues on next page)

(continued from previous page)

```
    n = 0
    while alive.any() and n < 100 / ε:
        n += 1
        x = -y[:, 1] * y[:, 0] / (1 + y[:, 0]**2)
        w1, w2 = rng.standard_normal((2, n_paths))
        π = x + σ2 * w2
        U = u - θ * σ2 * w2 + σ1 * w1
        Φ = np.stack([π, np.ones(n_paths)], axis=1)
        R += ε * (Φ[:, :, None] * Φ[:, None, :] - R)
        e = U - (Φ * y).sum(axis=1)
        y += ε * np.linalg.solve(R, (Φ * e[:, None])[:, :, None])[:, :, 0]
        out = alive & (np.linalg.norm(y - y_bar, axis=1) > radius)
        τ[out], y_exit[out] = n, y[out]
        alive &= ~out
    return τ, y_exit

S_bar = 4.987e-4        # CWS Table 1: static model, normal shocks, radius 5

```

Mean first exit times run from about 16 periods at $\varepsilon = 0.1$ to about 400 at $\varepsilon = 0.005$.

At $\varepsilon = 0.01$ and 0.005 they are close to the 165.7 and 409.6 periods that Sargent and Williams [2005] (Table 1) report for constant-gain least squares.

Every path exits on the Ramsey side, near the exit point of the escape path.

The product $\varepsilon\times$ mean stays between about 1.4 and 2, so mean exit times scale roughly like $1/\varepsilon$.

The factor $e^{\bar{S}/\varepsilon}$, by contrast, never exceeds 1.11 in the table.

At these gains the large-deviation factor plays almost no role; exit times are set by the constant S_0, that is, by how long beliefs take to wander off the equilibrium and travel the route.

At the gains this suite uses, escapes are frequent, not rare.

Starting from the self-confirming equilibrium, a government with gain ε escapes on average after roughly $1.5/\varepsilon$ to $2/\varepsilon$ periods, and between escapes it seldom gets all the way back to Nash.

Rarity is a small-gain statement.

Only for gains of the order of $\bar{S}$ itself does the exponential factor bite: at $\varepsilon = 0.0002$, five times smaller than the smallest gain in Table 1 of Sargent and Williams [2005], $e^{\bar{S}/\varepsilon} \approx 12$.

The simulated exit times also bear out CWS's footnote 14.

Measured in units of $t = n\varepsilon$, they are several times the 0.34 that the changed-measure path takes; Exercise 105.13.5 compares the two in detail.

105.11 Escape frequency and model richness

The minimized action $\bar{S}$ sets the exponential rate at which escape times grow as the gain shrinks.

A striking finding of CWS is that escapes are *more frequent* when the government's model is richer.

CWS's Table 1 gives the dynamic model of *Adaptive Learning and Escape Dynamics*, with lagged unemployment and inflation, a rate $\bar{S} \approx 9.7 \times 10^{-6}$, about fifty times smaller than the static model's 5.0×10^{-4}, even though the two share the same self-confirming equilibrium.

That dynamic-model number needs a caveat: it was computed with the 2001 shortcut that Williams [2019] corrected, which matters for dynamic models.

The comparison does not rest on that number alone, though.

In CWS's simulations (their Figure 5), mean escape times are shorter in the dynamic model at every gain, and Exercise 105.13.6 finds the same for median first-escape times.

A richer model lets the government detect the subtler distributed-lag ("induction-hypothesis") version of the natural-rate hypothesis, so it escapes toward Ramsey more readily.

Note

The escape dynamics inherit the same "near determinism" that makes the mean dynamics useful: for small gains, simulated escapes cluster around the deterministic escape route, in the dynamic model (CWS, Figure 6) and in the static model (Exercise 105.13.5; CWS, Figure 7).

The next lecture, *Priors, Escapes, and Learning Cycles*, shows that the government's *prior* about how its coefficients drift reshapes both dynamics, and can even make the escape a deterministic *cycle*.

105.12 Escaping volatile inflation

The escape delivers a fall in the *level* of inflation.

Ellison and Yates [2007] extend the model to explain a second post-war fact: inflation *volatility* rose and fell together with the level.

Their device is to give the government a reason to stabilize.

Following Phelps and Taylor [1977], they add an unemployment shock W_3 that the government, but not the price-setting private sector, can react to.

Now a government that believes in an exploitable Phillips curve is tempted to *lean against* W_3 by varying inflation, so the perceived effectiveness of policy, $|\gamma_1|$, drives the volatility of inflation as well as its level.

In their model the expected inflation volatility a private agent faces is

$$\mathbb{E}(\sigma_\pi \mid \gamma) = \left[\sigma_2^2 + \left(\frac{\gamma_1}{1+\gamma_1^2}\right)^2 \sigma_3^2\right]^{1/2}. \tag{105.11}$$

At the self-confirming equilibrium $\gamma_1 = -\theta$, the government believes policy is effective and leans against W_3 aggressively, so inflation is *volatile*.

Along an escape, $\gamma_1 \to 0$: the government stops believing it can exploit the Phillips curve, abandons stabilization, and the volatility term collapses to the control error σ_2.

As an approximation, we apply (105.11) to the belief path computed above for $\sigma_3 = 0$.

In Ellison and Yates's model a positive σ_3 also changes the escape itself, as we discuss below, but the approximation shows the level and volatility of inflation escaping *in tandem*.

```
σ3 = 0.9                                    # size of the stabilizable shock
infl_vol = np.sqrt(model.σ2**2 + (slope / (1 + slope**2))**2 * σ3**2)

fig, axes = plt.subplots(1, 2, figsize=(12, 4.5))
axes[0].plot(esc.t, infl)
axes[0].axhline(model.θ * model.u, color='k', ls='--', lw=1, label='Nash')
axes[0].axhline(0, color='C2', ls=':', lw=1, label='Ramsey')
axes[0].set_xlabel('time $t = n\\varepsilon$'); axes[0].set_ylabel('inflation level')
axes[0].set_title('level escapes'); axes[0].legend()

axes[1].plot(esc.t, infl_vol, 'C1')
axes[1].axhline(model.σ2, color='k', ls='--', lw=1, label=r'control error $\sigma_2$')
axes[1].set_xlabel('time $t = n\\varepsilon$'); axes[1].set_ylabel('inflation␣
↪volatility')
axes[1].set_title('volatility escapes too'); axes[1].legend()

plt.tight_layout()
plt.show()
```

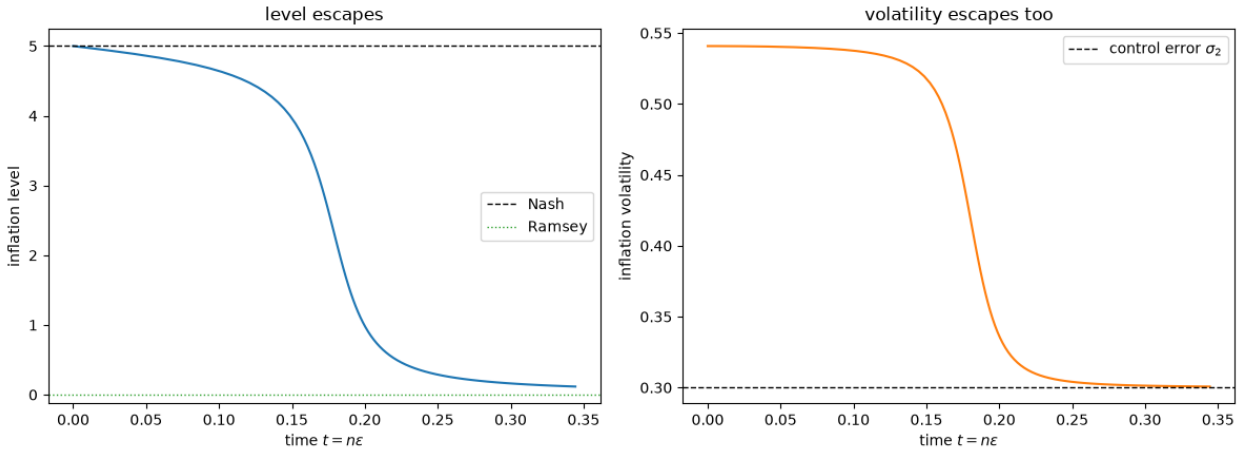

Fig. 105.6: The level and volatility of inflation escape in tandem

Both fall as beliefs escape, because both spring from the same source: the government's belief in an exploitable tradeoff.

Ellison and Yates [2007] draw a further, subtler lesson about the *timing* of escapes.

A larger stabilizable shock σ_3 makes an escape *harder to trigger*: to create the illusion that inflation moves while unemployment stays put, an unusual sequence of shocks must now offset not only the control errors but also the government's own stabilizing reaction to W_3.

The more shocks the government can offset, the more complex the escape-triggering sequence, and the longer the wait.

Ellison and Yates conclude that an escape to low inflation is more likely in a period with relatively few shocks that policy can offset.

It is tempting, and it is our extrapolation rather than theirs, to read the calm of the mid-1980s as such a period, and to link it to the disinflation.

The timing does not fit easily.

In the estimates of *Drifts and Volatilities*, core inflation fell in 1980–82, while most of the decline in the variance of shocks came in the mid-1980s.

The disinflation came first, during a period of unusually large shocks.

That lecture builds a statistical model with room for both *shrinking shocks* and *shifting dynamics* and lets the data apportion them.

Before turning to data, *Priors, Escapes, and Learning Cycles* returns to the static model and asks how the government's prior about drifting coefficients changes everything above.

105.13 Exercises

Exercise 105.13.1

At the self-confirming equilibrium the moment matrix is $\bar{R} = \bar{M}(\bar{\gamma})$, with $\det \bar{R} = \sigma_2^2$.

1. Show that the escape velocity at the self-confirming equilibrium is $\bar{R}^{-1}(\sigma_1\sigma_2, 0)^\top = (\sigma_1/\sigma_2)(1, -\bar{x})^\top$, where $\bar{x} = \theta u$. So with $\sigma_1 = \sigma_2$ it does not depend on the size of the shocks.
2. Integrate the escape ODE (105.9) for $\sigma_1 = \sigma_2 = \sigma \in \{0.1, 0.2, 0.3, 0.4, 0.5\}$ and report the exit time from the radius-5 circle.
3. Exit times nonetheless rise with σ. Explain why. Hint: write $\bar{M}(\gamma) = \bar{R} + \Delta(\gamma)$ and look at how Δ and $\bar{R}^{-1}$ depend on σ_2.
4. Now vary one shock at a time: $\sigma_2 \in \{0.2, 0.3, 0.45\}$ with $\sigma_1 = 0.3$, and $\sigma_1 \in \{0.2, 0.3, 0.45\}$ with $\sigma_2 = 0.3$.

Solution

For part 1, $\bar{R} = \begin{bmatrix} \bar{x}^2 + \sigma_2^2 & \bar{x} \\ \bar{x} & 1 \end{bmatrix}$ has determinant σ_2^2 and inverse $\sigma_2^{-2} \begin{bmatrix} 1 & -\bar{x} \\ -\bar{x} & \bar{x}^2 + \sigma_2^2 \end{bmatrix}$, so $\bar{R}^{-1}(\sigma_1\sigma_2, 0)^\top = (\sigma_1/\sigma_2)(1, -\bar{x})^\top$.

For parts 2 and 4, we integrate the escape ODE for each pair of shock sizes.

```
def exit_time(σ1, σ2):
    m = EscapeModel(θ=1.0, u=5.0, σ1=σ1, σ2=σ2)
    y0 = m.y_sce()

    def leave(t, z):
        return 5.0 - np.linalg.norm(z[:2] - y0)
    leave.terminal = True
```

```
    leave.direction = -1

    v0 = np.linalg.solve(m.M(y0), np.array([σ1 * σ2, 0.0]))
    s = solve_ivp(lambda t, z: escape_ode(t, z, m), [0, 500],
                  np.concatenate([y0, m.M(y0).ravel()]),
                  events=leave, max_step=0.02, rtol=1e-9, atol=1e-11)
    return v0, s.t[-1]

for σ in [0.1, 0.2, 0.3, 0.4, 0.5]:
    v0, T = exit_time(σ, σ)
    print(f"σ1 = σ2 = {σ}: velocity at SCE = {v0.round(3)}, exit time = {T:.3f}")
print()
for σ2 in [0.2, 0.3, 0.45]:
    print(f"σ1 = 0.3, σ2 = {σ2}: exit time = {exit_time(0.3, σ2)[1]:.3f}")
for σ1 in [0.2, 0.3, 0.45]:
    print(f"σ1 = {σ1}, σ2 = 0.3: exit time = {exit_time(σ1, 0.3)[1]:.3f}")
```

```
σ1 = σ2 = 0.1: velocity at SCE = [ 1. -5.], exit time = 0.083
σ1 = σ2 = 0.2: velocity at SCE = [ 1. -5.], exit time = 0.201
σ1 = σ2 = 0.3: velocity at SCE = [ 1. -5.], exit time = 0.344
σ1 = σ2 = 0.4: velocity at SCE = [ 1. -5.], exit time = 0.503
σ1 = σ2 = 0.5: velocity at SCE = [ 1. -5.], exit time = 0.671

σ1 = 0.3, σ2 = 0.2: exit time = 0.171
σ1 = 0.3, σ2 = 0.3: exit time = 0.344
σ1 = 0.3, σ2 = 0.45: exit time = 0.740
σ1 = 0.2, σ2 = 0.3: exit time = 0.411
σ1 = 0.3, σ2 = 0.3: exit time = 0.344
σ1 = 0.45, σ2 = 0.3: exit time = 0.285
```

With $\sigma_1 = \sigma_2$ the starting velocity is the same for every σ, yet the exit time rises steadily with σ.

The speed comes from the R-lag amplification of *Mean dynamics reinforce the escape*.

During the escape R stays near $\bar{R}$, so the mean drift is $\bar{R}^{-1}\bar{M}(\gamma)(T(\gamma)-\gamma) = (T(\gamma)-\gamma) + \bar{R}^{-1}\Delta(\gamma)(T(\gamma)-\gamma)$.

Here $\Delta(\gamma) = \begin{bmatrix} x^2 - \bar{x}^2 & x - \bar{x} \\ x - \bar{x} & 0 \end{bmatrix}$ depends only on how far inflation has moved, not on σ_2, while $\bar{R}^{-1}$ is of order $1/\sigma_2^2$.

So the smaller the control error, the more strongly the lagging moment matrix amplifies any move away from Nash, and the faster beliefs travel the route.

That is why σ_2 matters so much in part 4, while a larger σ_1 speeds the escape only through the initial push σ_1/σ_2.

None of this concerns the *frequency* of escapes, which *Simulating escapes* measures; a noisier economy travels the deterministic route more slowly once an escape is under way.

Exercise 105.13.2

Make the reinforcement in the vector-field plot quantitative.

At several points *along* the escape path, evaluate the mean-dynamics drift $R^{-1}\bar{g}(\gamma)$, with the path's own R, and measure its cosine alignment with the direction from the current beliefs toward the Ramsey belief $(0, u)$.

A cosine near $+1$ means the mean dynamics are pushing beliefs *toward* Ramsey, reinforcing the escape.

Solution

We evaluate the drift at five points along the escape path.

```
y_ramsey = np.array([0.0, model.u])            # Belief 2

def cosine_toward_ramsey(y, R):
    drift = np.linalg.solve(R, model.g_bar(y))
    to_ramsey = y_ramsey - y
    denom = np.linalg.norm(drift) * np.linalg.norm(to_ramsey)
    return np.nan if denom < 1e-9 else drift @ to_ramsey / denom

for frac in [0.0, 0.25, 0.5, 0.75, 0.95]:
    k = min(int(frac * len(esc.t)), len(esc.t) - 1)
    y, R = esc.y[:2, k], esc.y[2:, k].reshape(2, 2)
    print(f"frac {frac:.2f}:  y = ({y[0]:+.2f}, {y[1]:.1f}),  "
          f"cos(drift, →Ramsey) = {cosine_toward_ramsey(y, R):+.2f},  "
          f"with R = M(y): {cosine_toward_ramsey(y, model.M(y)):+.2f}")
```

```
frac 0.00:  y = (-1.00, 10.0),  cos(drift, →Ramsey) = +nan,  with R = M(y): +nan
frac 0.25:  y = (-0.65, 8.2),  cos(drift, →Ramsey) = +1.00,  with R = M(y): -0.
↪93
frac 0.50:  y = (-0.23, 6.1),  cos(drift, →Ramsey) = +1.00,  with R = M(y): -0.
↪47
frac 0.75:  y = (-0.07, 5.3),  cos(drift, →Ramsey) = +1.00,  with R = M(y): -0.
↪25
frac 0.95:  y = (-0.03, 5.1),  cos(drift, →Ramsey) = +1.00,  with R = M(y): -0.
↪25
```

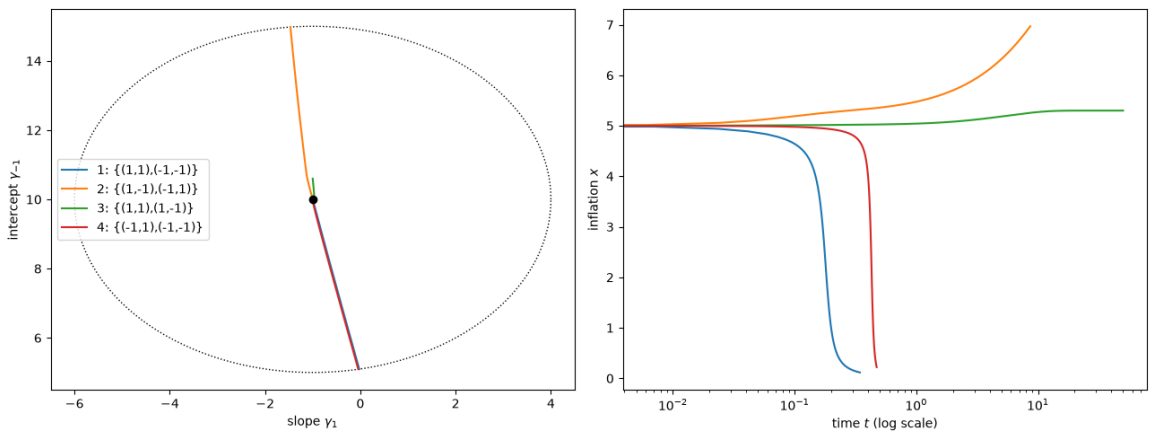
Right at the self-confirming equilibrium the drift vanishes (the cosine is undefined), so the mean dynamics neither help nor hinder.

But once beliefs have moved even slightly along the escape route, the mean-dynamics drift points almost exactly toward the Ramsey belief (cosine $\approx +1$): the mean dynamics reinforce the escape all the way to Ramsey.

The last column replaces the path's R by $\bar{M}(\gamma)$, and the cosine turns negative: the reinforcement comes from R lagging behind.

The opposition that CWS emphasize is confined to a *tiny* neighbourhood of the equilibrium; the escape dynamics only need to nudge beliefs out of it, after which the mean dynamics finish the job.

Exercise 105.13.3



Look more closely at the race of four ODEs.

1. Plot the four conditional paths `race` in the (γ_1, γ_{-1}) plane, together with the radius-5 circle, and plot inflation along each.
2. CWS give the rest points of the conditional ODEs for pairs 3 and 4 as $(-\theta,\ (u \pm \sigma_1)(1+\theta^2))$, both well inside the circle. Pair 3 settles there. Why does pair 4 escape instead?
3. Rerun the race with R held equal to $\bar{M}(\gamma)$, as if the moment matrix adjusted instantly. Which pair wins now, and where does it exit?

Solution

We first plot the four paths computed in the text.

```
fig, axes = plt.subplots(1, 2, figsize=(13, 5))
ψ = np.linspace(0, 2 * np.pi, 200)
axes[0].plot(y_sce[0] + 5 * np.cos(ψ), y_sce[1] + 5 * np.sin(ψ), 'k:', lw=1)
for name, s in race.items():
    axes[0].plot(s.y[0], s.y[1], label=name)
    axes[1].plot(s.t, -s.y[1] * s.y[0] / (1 + s.y[0]**2), label=name)
axes[0].plot(*y_sce, 'ko')
axes[0].set_xlabel(r'slope $\gamma_1$')
axes[0].set_ylabel(r'intercept $\gamma_{-1}$')
axes[1].set_xscale('log')
axes[1].set_xlabel('time $t$ (log scale)')
axes[1].set_ylabel('inflation $x$')
axes[0].legend()
plt.tight_layout()
plt.show()
```

Next we rerun the race with $R = \bar{M}(\gamma)$ imposed, which reduces each conditional ODE to $\dot{\gamma} = T(\gamma) - \gamma + \bar{M}(\gamma)^{-1} f_j(\gamma)$.

```
def cond_ode_no_lag(t, y, model, f):
    return np.linalg.solve(model.M(y), model.g_bar(y) + f(y, model))

def left_circle_y(t, y, *args):
    return 5.0 - np.linalg.norm(y - y_sce)
left_circle_y.terminal = True
left_circle_y.direction = -1

for name, f in pairs.items():
    s = solve_ivp(cond_ode_no_lag, [0, 50], y_sce, args=(model, f), events=left_
 ↪circle_y,
                  max_step=0.02, rtol=1e-9, atol=1e-11)
    y_end = s.y[:, -1]
    status = f"exits at t = {s.t[-1]:.3f}" if s.status == 1 else "never exits"
    print(f"{name:22s} {status:22s} y_end = ({y_end[0]:+.3f}, {y_end[1]:.2f}), "
          f"x = {model.x(y_end):.2f}")
```

```
1: {(1,1),(-1,-1)}      exits at t = 3.941      y_end = (-0.019, 5.10), x = 0.10
2: {(1,-1),(-1,1)}      exits at t = 1.194      y_end = (-1.697, 14.95), x = 6.54
3: {(1,1),(1,-1)}       never exits             y_end = (-1.000, 10.60), x = 5.30
4: {(-1,1),(-1,-1)}     never exits             y_end = (-1.000, 9.40), x = 4.70
```

With $R = \bar{M}(\gamma)$ the rest point of each conditional ODE is a fixed point of a shifted T-map.

For pair 4 it is $(-\theta, (u-\sigma_1)(1+\theta^2))$; the Jacobian of the drift there again has eigenvalues -1 and $-1/(1+\theta^2)$, so the path converges to it.

With the true, lagging R, the same forcing first lowers the intercept and inflation a little; the lagging moment matrix then amplifies the move into a full escape to Ramsey.

Without the lag, the race changes completely.

Pair 1 still heads for Ramsey but only drifts there slowly, while pair 2 now exits first, toward *higher* inflation.

So the R lag decides both the direction and the speed of the escape: it is what makes the Ramsey-ward route the most likely one.

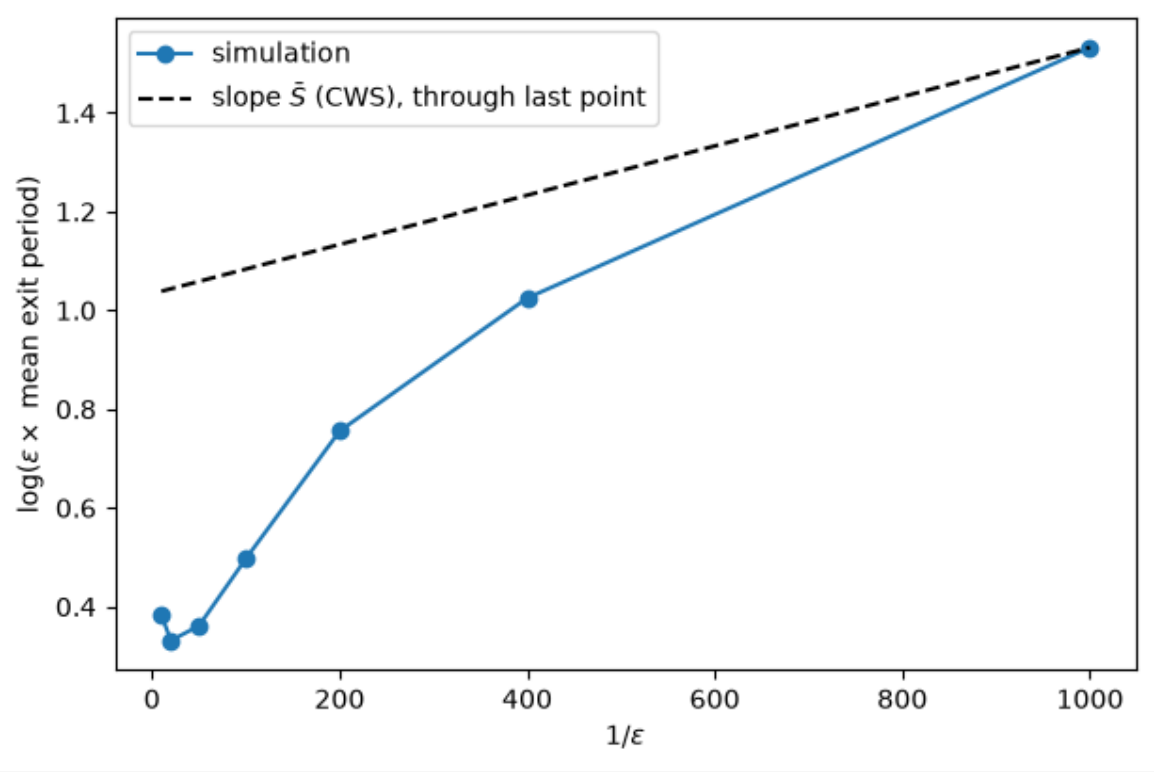
Exercise 105.13.4

The theorem says $\varepsilon \log \mathbb{E}\,\tau^\varepsilon \to \bar{S}$, where $\tau^\varepsilon = n\varepsilon$ is the exit time on the ODE time scale; equivalently $\log \mathbb{E}\,\tau^\varepsilon \approx S_0 + \bar{S}/\varepsilon$.

1. Use `first_exits` to compute the mean exit period for $\varepsilon \in \{0.1, 0.05, 0.02, 0.01, 0.005, 0.0025, 0.001\}$.
2. Plot $\log(\varepsilon \times \text{mean exit period})$ against $1/\varepsilon$, and compare the slope with CWS's $\bar{S}$.
3. Compare the mean exit periods with Sargent and Williams [2005] (Table 1), who report 20.6, 165.7, 409.6, 2414.8 and 4486.7 periods at $\varepsilon = 0.05, 0.01, 0.005, 0.002, 0.001$.

Solution

We compute the mean exit period on a finer grid of small gains.



```
gains = np.array([0.1, 0.05, 0.02, 0.01, 0.005, 0.0025, 0.001])
mean_exit = np.array([np.nanmean(first_exits(model, ε, seed=1)[0]) for ε in gains])
log_scaled = np.log(gains * mean_exit)

for ε, m, l in zip(gains, mean_exit, log_scaled):
    print(f"ε = {ε:6.4f}: mean exit period = {m:7.0f},  ε·mean = {ε * m:5.2f}")
local_slope = np.diff(log_scaled) / np.diff(1 / gains)
print("\nlocal slopes of log(ε·mean) in 1/ε:", local_slope.round(5))
print(f"CWS S̄ = {S_bar:.5f}")

fig, ax = plt.subplots(figsize=(7, 4.5))
ax.plot(1 / gains, log_scaled, 'o-', label='simulation')
ax.plot(1 / gains, log_scaled[-1] + S_bar * (1 / gains - 1 / gains[-1]), 'k--',
        label=r'slope $\bar S$ (CWS), through last point')
ax.set_xlabel(r'$1/\varepsilon$')
ax.set_ylabel(r'$\log(\varepsilon \times$ mean exit period$)$')
ax.legend()
plt.show()
```

```
ε = 0.1000: mean exit period =      15,  ε·mean =  1.47
ε = 0.0500: mean exit period =      28,  ε·mean =  1.39
ε = 0.0200: mean exit period =      72,  ε·mean =  1.43
ε = 0.0100: mean exit period =     164,  ε·mean =  1.64
ε = 0.0050: mean exit period =     426,  ε·mean =  2.13
ε = 0.0025: mean exit period =    1114,  ε·mean =  2.79
ε = 0.0010: mean exit period =    4629,  ε·mean =  4.63

local slopes of log(ε·mean) in 1/ε: [-0.00525  0.001    0.00272  0.00259  0.
↪00135  0.00085]
CWS S̄ = 0.00050
```

The scaled mean $\varepsilon\times$ mean stays between about 1.4 and 4.6 over a hundredfold range of gains.

Over that range $\bar{S}/\varepsilon$ rises only from 0.005 to 0.5, so the level of $\log \mathbb{E}\,\tau^{\varepsilon}$ is dominated by the constant S_0.

At large gains the curve even slopes down, and only at the smallest gains does its slope approach the order of magnitude of $\bar{S}$: the asymptotic regime of the theorem lies at gains far smaller than those this suite uses.

The simulated means agree closely with SW's at $\varepsilon = 0.01$, 0.005 and 0.001.

Exercise 105.13.5

CWS's Figure 7 compares simulated escapes with the dominant and changed-measure paths.

1. Simulate 50 paths at $\varepsilon = 0.005$ from the self-confirming equilibrium, recording beliefs until each first leaves the radius-5 circle.
2. Plot the slope and intercept of each path against $\log n$, together with the changed-measure path at $n = t/\varepsilon$.
3. Compare the exit points, the total time to exit, and the duration of the final run, measured from the last period in which the slope is below -0.9.

Solution

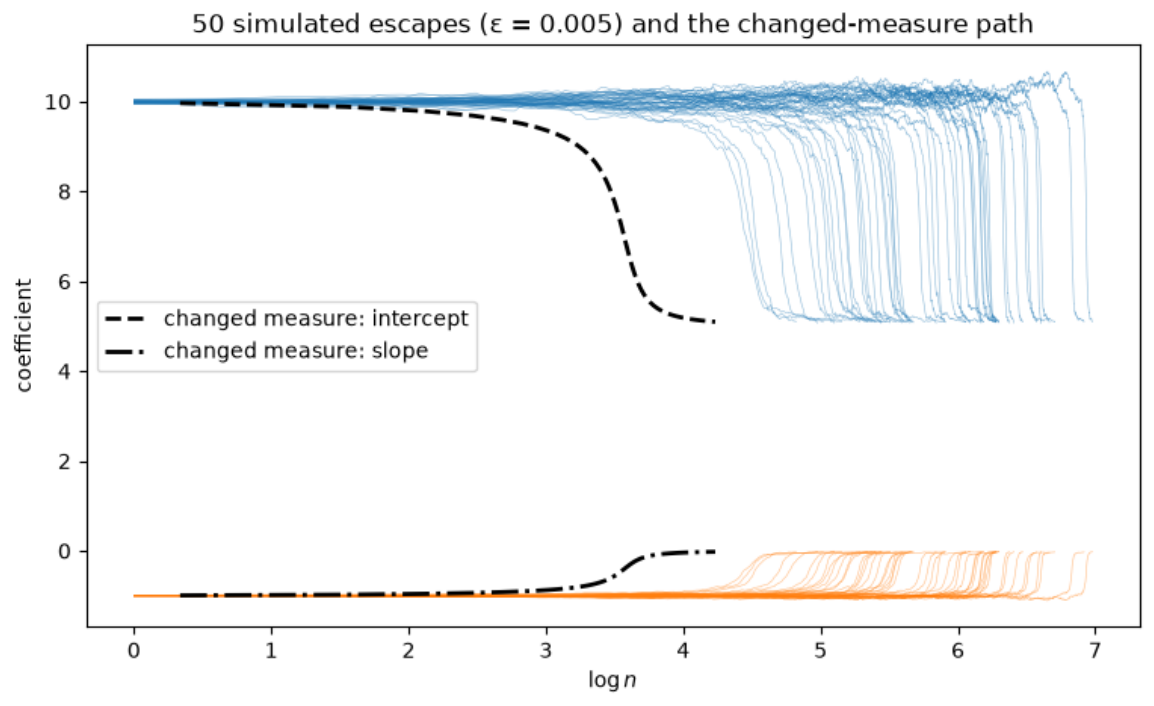
We record the full belief history of each path until it exits.

```
def escape_histories(model, ε, n_paths=50, n_max=10_000, radius=5.0, seed=0):
    rng = np.random.default_rng(seed)
    θ, u, σ1, σ2 = model.θ, model.u, model.σ1, model.σ2
    y_bar = model.y_sce()
```

```
    γ = np.tile(γ_bar, (n_paths, 1))
    R = np.tile(model.M(γ_bar), (n_paths, 1, 1))
    hist = np.full((n_max + 1, n_paths, 2), np.nan)
    hist[0] = γ
    τ = np.zeros(n_paths, dtype=int)
    alive = np.ones(n_paths, dtype=bool)
    for n in range(1, n_max + 1):
        x = -γ[:, 1] * γ[:, 0] / (1 + γ[:, 0]**2)
        w1, w2 = rng.standard_normal((2, n_paths))
        π = x + σ2 * w2
        U = u - θ * σ2 * w2 + σ1 * w1
        Φ = np.stack([π, np.ones(n_paths)], axis=1)
        R += ε * (Φ[:, :, None] * Φ[:, None, :] - R)
        e = U - (Φ * γ).sum(axis=1)
        γ += ε * np.linalg.solve(R, (Φ * e[:, None])[:, :, None])[:, :, 0]
        hist[n, alive] = γ[alive]
        out = alive & (np.linalg.norm(γ - γ_bar, axis=1) > radius)
        τ[out] = n
        alive &= ~out
        if not alive.any():
            break
    return hist[:n + 1], τ

ε = 0.005
hist, τ = escape_histories(model, ε, seed=3)
print(f"all exited: {np.all(τ > 0)}")
print(f"simulated exit periods: min {τ.min()}, median {np.median(τ):.0f}, max {τ.
↪max()}")
print(f"changed-measure path:   exits at n = t/ε = {esc.t[-1] / ε:.0f}")

γ_end = hist[τ, np.arange(len(τ))]
print(f"exit slope: simulated mean {γ_end[:, 0].mean():+.3f}, "
      f"changed-measure {slope[-1]:+.3f}")



final_run = np.array([(τ[i] - np.where(hist[:τ[i] + 1, i, 0] < -0.9)[0].max()) * ε
                      for i in range(len(τ))])
k_cm = np.where(slope < -0.9)[0].max()
print(f"final run (in t = nε): simulated median {np.median(final_run):.2f}, "
      f"changed-measure {esc.t[-1] - esc.t[k_cm]:.2f}")
```

```
all exited: True
simulated exit periods: min 124, median 366, max 1072
changed-measure path:   exits at n = t/ε = 69
exit slope: simulated mean -0.024, changed-measure -0.023
final run (in t = nε): simulated median 0.35, changed-measure 0.26
```

Next we plot the paths on CWS's log time scale.

```
fig, ax = plt.subplots(figsize=(9, 5))
for i in range(len(τ)):
    n_i = np.arange(1, τ[i] + 1)
    ax.plot(np.log(n_i), hist[1:τ[i] + 1, i, 1], color='C0', lw=0.4, alpha=0.5)
    ax.plot(np.log(n_i), hist[1:τ[i] + 1, i, 0], color='C1', lw=0.4, alpha=0.5)
n_cm = esc.t[1:] / ε
ax.plot(np.log(n_cm), intercept[1:], 'k--', lw=2, label='changed measure: intercept
↪')
ax.plot(np.log(n_cm), slope[1:], 'k-.', lw=2, label='changed measure: slope')
ax.set_xlabel(r'$\log n$')
ax.set_ylabel('coefficient')
```

```
ax.set_title(f'50 simulated escapes (ε = {ε}) and the changed-measure path')
ax.legend()
plt.show()
```

The simulated escapes leave the circle at almost exactly the changed-measure path's exit point, as Theorem 5.3 predicts for the dominant path.

But the changed-measure path exits before even the fastest simulated escape, as CWS found.

Most of the difference is waiting time: a simulated path spends a long spell near the self-confirming equilibrium before its final run.

Once that run is under way, it takes a time of the same order as the changed-measure path.

Exercise 105.13.6

CWS find escapes more frequent in their dynamic model than in the static one.

Check this by simulation.

In the dynamic model of *Adaptive Learning and Escape Dynamics* (which writes y for inflation), the government regresses U_n on $(\pi_n, U_{n-1}, U_{n-2}, \pi_{n-1}, \pi_{n-2}, 1)$ and sets inflation by solving the discounted Phelps problem with $\delta = 0.98$.

1. Simulate the dynamic model with the recursion (105.4), now with six regressors, starting at its self-confirming equilibrium with R_0 equal to the self-confirming moment matrix.
2. Define the first escape as the first period in which the 20-period average of inflation falls below 1.
3. Report the median first escape over many paths for both models, for $\varepsilon \in \{0.002, 0.005, 0.01, 0.02\}$.

Solution

The government's decision rule uses the same Phelps solver as *Adaptive Learning and Escape Dynamics*.

The state is $(U_{n-1}, U_{n-2}, \pi_{n-1}, \pi_{n-2}, 1)$, and the cross term of the discounted Riccati equation enters unscaled.

```
def phelps_rule(γ, δ=0.98):

 0.005            286             102   (not escaped: 0/200, 0/24)
 0.010            121              52   (not escaped: 0/200, 0/24)
 0.020             62              32   (not escaped: 0/200, 0/24)
```

At every gain the dynamic model escapes sooner, and the gap widens as the gain falls, as CWS's smaller $\bar{S}$ for the dynamic model suggests.

The government with lags can find the induction hypothesis while keeping a short-run Phillips curve, so it needs a less unusual run of shocks to begin the escape.

The comparison holds even though the two models share the same self-confirming equilibrium.

106.1 Overview

> The Bourbons remember everything and learn nothing.
>
> – Charles Maurice de Talleyrand

This lecture is a sequel to *Adaptive Learning and Escape Dynamics* and *Escaping Nash Inflation*.

It follows Sargent and Williams [2005], which generalizes the adaptive model of chapter 8 of Sargent [1999] and of Cho *et al.* [2002] (CWS), whose escape dynamics we derived in *Escaping Nash Inflation*.

In *Adaptive Learning and Escape Dynamics* the government estimated its Phillips curve by constant-gain recursive least squares.

That is a very particular way to learn.

In large samples, a constant-gain least squares learner behaves as if it believed that the coefficients of its model follow a random walk with one specific innovation covariance matrix.

Here we free the government to hold *any* prior about how its coefficients drift, encoded in a covariance matrix V, and we ask how that prior affects the two forces that drive the model:

- the **mean dynamics**, which pull the government's beliefs *toward* a self-confirming (Nash) equilibrium; and
- the **escape dynamics**, which recurrently push beliefs *away* from it, toward the low-inflation Ramsey outcome.

We will find three things.

1. Some priors make the self-confirming equilibrium *unstable*, so that the mean dynamics themselves produce recurrent disinflations: a **learning cycle**, born in a Hopf bifurcation, rather than a stochastic escape.
2. The prior shapes the *direction* and the *speed* of escapes, but in every case we study an escape heads toward the Ramsey outcome.
3. The prior resolves a puzzle in the literature: why the simulated governments of Sims [1988] and Chung [1990] escape Nash inflation once and stay near Ramsey, apparently indefinitely, while those of Sargent [1999] and CWS escape only to be pulled back, again and again.

Throughout we work with the analytically tractable **static** model of *Escaping Nash Inflation* and *A government learning the Phillips curve*, in which the government regresses unemployment on inflation and a constant.

Let's start with our imports:

```
import matplotlib.pyplot as plt
import numpy as np
from scipy.linalg import sqrtm
from scipy.integrate import solve_ivp
from scipy.optimize import brentq
```

106.2 The static model

The true economy is a version of the natural-rate model of Kydland and Prescott [1977]:

$$\begin{aligned} U_n &= u - (\pi_n - \hat{x}_n) + \sigma_1 W_{1n}, \qquad u > 0, \\ \pi_n &= x_n + \sigma_2 W_{2n}, \\ \hat{x}_n &= x_n, \end{aligned} \tag{106.1}$$

where U_n is unemployment, π_n is inflation, x_n is the systematic part of inflation set by the government, $\hat{x}_n$ is the public's (rational) forecast, and $W_n = (W_{1n}, W_{2n})^\top$ is IID standard Gaussian noise.

Since $\pi_n - \hat{x}_n = \sigma_2 W_{2n}$, the true unemployment rate is $U_n = u - \sigma_2 W_{2n} + \sigma_1 W_{1n}$ — it fluctuates around the natural rate u regardless of systematic policy.

The government does not know this.

In the **static model** it fits a non-expectational Phillips curve by regressing unemployment on current inflation and a constant,

$$U_n = a + b\,\pi_n + \eta_n, \tag{106.2}$$

with belief vector $\gamma = (a, b)$ (intercept and slope), and it treats η_n as an exogenous shock.

> **Warning**
>
> *Escaping Nash Inflation* studies this same static model but orders the belief vector the other way round, as $\gamma = (\gamma_1, \gamma_{-1})$ with the *slope* first and regressors $\Phi = (\pi, 1)$, following Cho *et al.* [2002].
>
> Here we put the *intercept* first, with $\Phi = (1, \pi)$, following Sargent and Williams [2005], as *A government learning the Phillips curve* also does.

The two are the same model in different coordinates: $a = \gamma_{-1}$ and $b = \gamma_1$, so the self-confirming belief $(2u, -1)$ of this lecture is the $(-1, u(1+\theta^2))$ of the last one, with $\theta = 1$.

Matrices such as M, V, and P have their rows and columns correspondingly transposed.

A government learning the Phillips curve uses our calibration but other letters, as the Bounded Rationality lectures do (*Notation across the series*): there the beliefs are α and the gain is γ.

Here, following Sargent and Williams [2005], the beliefs are γ, the gain is ε, and α denotes the drifting coefficients that the government thinks generate its data.

Believing (106.2), the government solves the Phelps problem — minimize $\hat{\mathbb{E}} \sum_n \delta^n (U_n^2 + \pi_n^2)$ — whose static best response sets inflation to the constant

$$x(\gamma) = -\frac{a\, b}{1 + b^2}. \tag{106.3}$$

```
class StaticPhillips:
    "The static Sargent-Williams model: government regresses U on (1, π)."

    def __init__(self, u=5.0, σ1=0.3, σ2=0.3):
        self.u, self.σ1, self.σ2 = u, σ1, σ2
        self.σ = σ1                          # govt regression error std = σ1

    def x(self, γ):
        "Government best response (systematic inflation) given beliefs γ."
        a, b = γ
        return -a * b / (1 + b**2)

    def M(self, γ):
        "Second moment matrix E[ΦΦ'] of regressors Φ = (1, π), given γ."
        x = self.x(γ)
        return np.array([[1.0, x], [x, x**2 + self.σ2**2]])

    def g_bar(self, γ):
        "Least squares moment E[Φ(U - Φ'γ)] under the data γ generates."
        u, σ2 = self.u, self.σ2
        x = self.x(γ)
        E_ΦU = np.array([u, x * u - σ2**2])
        return E_ΦU - self.M(γ) @ γ
```

Three belief vectors are worth naming.

- **Belief 1 (Nash):** $b = -1$ with an intercept that makes the government set $x = u$, the time-consistent outcome of Kydland and Prescott [1977].
- **Belief 2 (Ramsey):** $b = 0$, so the government perceives *no* tradeoff and sets $x = 0$.
- **Belief 3 (induction):** in a dynamic version, coefficients on current and lagged inflation summing to zero, which for a patient government also sends inflation toward 0.

106.3 The self-confirming equilibrium

A self-confirming equilibrium is a belief $\bar{\gamma}$ that reproduces itself: the data generated when the government acts on $\bar{\gamma}$ make the population regression coefficients equal $\bar{\gamma}$, i.e. $\bar{g}(\bar{\gamma}) = 0$.

For the static model this is easy to solve by hand.

The slope is $b = \mathrm{cov}(U, \pi)/\mathbb{V}[\pi] = -\sigma_2^2/\sigma_2^2 = -1$, and matching means gives the intercept $a = u + x(\bar{\gamma})$.

Substituting the best response (106.3) with $b = -1$ gives $x = a/2$, so $a = u + a/2$, i.e. $a = 2u$.

```
model = StaticPhillips(u=5.0, σ1=0.3, σ2=0.3)
γ_sce = np.array([2 * model.u, -1.0])

print(f"self-confirming beliefs  γ = {γ_sce}  (intercept 2u, slope -1)")
print(f"self-confirming inflation x = {model.x(γ_sce):.2f}  (= Nash = u)")
print(f"check g_bar(γ_sce) = {model.g_bar(γ_sce)}")
```

```
self-confirming beliefs  γ = [10. -1.]  (intercept 2u, slope -1)
self-confirming inflation x = 5.00  (= Nash = u)
check g_bar(γ_sce) = [0. 0.]
```

The self-confirming equilibrium inflation rate equals the Nash (time-consistent) outcome $u = 5$, even though the government's model is misspecified (*Why the classical equilibrium is Nash* explains why).

The government's non-expectational Phillips curve is observationally equivalent to the truth *along* the equilibrium path, but wrong *off* it — which is exactly what its adaptive behavior repeatedly probes.

106.4 Drifting beliefs and the Kalman filter

We now make the government adaptive.

Following Sargent and Williams [2005], the government believes that its data come from a Phillips curve whose coefficients *drift* as a random walk,

$$U_n = \Phi_n^\top \alpha_n + \eta_n, \qquad \alpha_{n+1} = \alpha_n + \Lambda_{n+1}, \qquad \mathbb{E}\,\eta_n^2 = \sigma^2, \qquad \mathrm{cov}(\Lambda_n) = V, \tag{106.4}$$

with regressors $\Phi_n = (1, \pi_n)^\top$ and IID shocks η_n and Λ_n.

The covariance matrix V is the government's **prior about parameter drift**, the object we set free, and σ^2 is the variance that the government attributes to its regression error η_n.

The government's estimate γ_n is its best forecast of α_n from data through $n-1$, which it computes with the Kalman filter.

This is the linear state-space model of *A First Look at the Kalman Filter*, with hidden state α_n, transition matrix I, state-noise covariance V, a time-varying observation matrix $\Phi_n^\top$, and measurement-noise variance σ^2.

Following Sargent and Williams [2005], we measure the covariance of the estimation error in units of σ^2, writing $\mathrm{cov}(\alpha_n - \gamma_n) = \sigma^2 P_n$.

Then the Kalman filter is

$$\begin{aligned} \gamma_{n+1} &= \gamma_n + \frac{P_n \Phi_n}{1 + \Phi_n^\top P_n \Phi_n}\left(U_n - \Phi_n^\top \gamma_n\right), \\ P_{n+1} &= P_n - \frac{P_n \Phi_n \Phi_n^\top P_n}{1 + \Phi_n^\top P_n \Phi_n} + \sigma^{-2} V. \end{aligned} \tag{106.5}$$

The normalization is what puts a 1 in the denominators and the scaled drift $\sigma^{-2}V$ in the update of P_n.

For large n, Benveniste *et al.* [1990] show that the filter is well approximated by

$$\begin{aligned} \gamma_{n+1} &= \gamma_n + P_n \Phi_n \left(U_n - \Phi_n^\top \gamma_n\right), \\ P_{n+1} &= P_n - P_n M(\gamma_n) P_n + \sigma^{-2} V, \end{aligned} \tag{106.6}$$

in which the second moment matrix $M(\gamma_n)$ replaces $\Phi_n \Phi_n^\top$ in the update of P_n.

Sargent and Williams [2005] base their analysis on (106.6), and report that for the small drift they study it gives simulations nearly indistinguishable from those of (106.5).

We simulate with the exact filter (106.5) throughout, because the approximation can be unstable when the drift is large, as it is in Sims's example below.

For a fixed γ, the matrix P_n settles at the solution of the algebraic Riccati equation

$$-PM(\gamma)P + \sigma^{-2}V = 0, \tag{106.7}$$

the counterpart for this model of the algebraic Riccati equation in *Convergence*.

Following Sargent and Williams [2005], we index the size of the drift by a scalar ε, writing $V = \varepsilon^2 \hat{V}$ for a fixed matrix $\hat{V}$.

Equation (106.7) then makes P proportional to ε/σ, so ε plays the role of the constant gain of *Adaptive Learning and Escape Dynamics*.

Most of our calculations use $\varepsilon = 0.05$, the largest gain in Tables 1 and 2 of Sargent and Williams [2005]; when we compare with constant-gain least squares we use the gain 0.02 of *A government learning the Phillips curve*, and Sims's example carries its own, much larger, drift.

Constant-gain recursive least squares is a special case.

If the government's prior is $V = \varepsilon^2 V^*$, with $V^* \equiv \sigma^2 M(\bar{\gamma})^{-1}$, and $\sigma = \sigma_1$, then (106.7) gives $P = \varepsilon M(\bar{\gamma})^{-1}$, and (106.6) becomes the constant-gain recursive least squares algorithm of *Adaptive Learning and Escape Dynamics*, with gain ε and with the estimated moment matrix replaced by its limit.

The connection is asymptotic, not exact.

In large samples the two algorithms merge, but their transient responses differ: Sargent and Williams [2005] (section 3.4) show that after an escape the Kalman filter returns to the self-confirming equilibrium much faster than recursive least squares does (Exercise 106.10.3).

```
def solve_riccati(V, M, σ):
    "Symmetric positive-definite P solving P M P = σ^{-2} V."
    W = V / σ**2
    Mh = sqrtm(M).real
    Mh_inv = np.linalg.inv(Mh)
    return Mh_inv @ sqrtm(Mh @ W @ Mh).real @ Mh_inv

M_sce = model.M(γ_sce)
V_star = model.σ**2 * np.linalg.inv(M_sce)      # the RLS prior (ε = 1)
P_star = solve_riccati(V_star, M_sce, model.σ)

print("RLS prior gives P = M^{-1}?", np.allclose(P_star, np.linalg.inv(M_sce)))
```

```
RLS prior gives P = M^{-1}? True
```

The next function simulates the economy when the government uses the exact filter (106.5).

```
def kalman_path(model, V, σ, T, seed, γ0=None):
    """
    Simulate T periods in which the government uses the exact Kalman filter
    with prior (V, σ), while the truth uses model.σ1.

    Beliefs start at γ0 (default: the self-confirming equilibrium), with P at
    its Riccati value.  Returns inflation π, unemployment U, systematic
    inflation x, and beliefs γ.
    """
    rng = np.random.default_rng(seed)
    u, σ1, σ2 = model.u, model.σ1, model.σ2
    γ = np.array([2 * u, -1.0]) if γ0 is None else np.array(γ0, dtype=float)
    P = solve_riccati(V, model.M(γ), σ)
    W = V / σ**2
    π, U, x = np.empty(T), np.empty(T), np.empty(T)
    beliefs = np.empty((T, 2))
    for n in range(T):
        beliefs[n] = γ
        x[n] = model.x(γ)
        w1, w2 = rng.standard_normal(2)
        π[n] = x[n] + σ2 * w2
        U[n] = u - σ2 * w2 + σ1 * w1                # truth uses σ1
        Φ = np.array([1.0, π[n]])
        PΦ = P @ Φ
        denom = 1 + Φ @ PΦ
        γ = γ + PΦ / denom * (U[n] - Φ @ γ)
        P = P - np.outer(PΦ, PΦ) / denom + W
    return π, U, x, beliefs
```

106.5 Mean dynamics and E-stability

As in *Adaptive Learning and Escape Dynamics*, the beliefs are organized by mean dynamics, now a *joint* ordinary differential equation in (γ, P), with time measured in periods:

$$\dot{\gamma} = P\,\bar{g}(\gamma), \qquad \dot{P} = \sigma^{-2}V - PM(\gamma)P. \tag{106.8}$$

A rest point of (106.8) has $\bar{g}(\gamma) = 0$ and $P =$ the Riccati solution — a self-confirming equilibrium.

Local stability turns on the Jacobian of $\bar{g}$ at the self-confirming equilibrium.

For the static model this can be computed in closed form,

$$\frac{\partial \bar{g}}{\partial \gamma}(\bar{\gamma}) = -\begin{bmatrix} \frac{1}{2} & u \\ \frac{1}{2}u & u^2 + \sigma_2^2 \end{bmatrix}. \tag{106.9}$$

```
def jacobian(model, γ, h=1e-6):
    "Numerical Jacobian of g_bar at γ."
    J = np.zeros((2, 2))
    for j in range(2):
        gp, gm = γ.copy(), γ.copy()
        gp[j] += h; gm[j] -= h
        J[:, j] = (model.g_bar(gp) - model.g_bar(gm)) / (2 * h)
    return J

J = jacobian(model, γ_sce)
print("∂g/∂γ at SCE =\n", J.round(3))
```

```
∂g/∂γ at SCE =
 [[ -0.5   -5.  ]
 [ -2.5  -25.09]]
```

Under constant-gain recursive least squares the moment-matrix block of the corresponding differential equation decouples, and stability is governed by the eigenvalues of $M^{-1}\,\partial\bar{g}/\partial\gamma$.

Writing $\bar{g}(\gamma) = M(\gamma)\,[T(\gamma) - \gamma]$, where $T(\gamma) = M(\gamma)^{-1}\,\mathbb{E}[\Phi U]$ maps the government's perceived Phillips curve into the population regression that its policy generates, shows that at the self-confirming equilibrium $M^{-1}\,\partial\bar{g}/\partial\gamma = DT - I$.

Negative real parts of these eigenvalues are the **E-stability** condition.

The idea goes back to DeCanio [1979] and Evans [1985], Evans [1989]; Marcet and Sargent [1989] and Woodford [1990] showed that it governs the convergence of least squares learning, and Evans and Honkapohja [2001] systematized the theory (*One recursion, many learners*).

```
eig_rls = np.linalg.eigvals(np.linalg.inv(M_sce) @ J)
print(f"E-stability eigenvalues (RLS): {eig_rls.round(3)}")
print("both negative ⇒ the SCE is E-stable")
```

```
E-stability eigenvalues (RLS): [-0.5 -1. ]
both negative ⇒ the SCE is E-stable
```

Both eigenvalues are negative: they are -1 and $-\frac{1}{2}$.

They are the static model's version of numbers met earlier in the suite.

With $\theta = 1$, as here, $-\frac{1}{2} = -1/(1+\theta^2)$ is the slope $\mathcal{M}$ of the mean dynamics of expected inflation in *Least squares learning converges to Nash*, and *Mean dynamics near the self-confirming equilibrium* finds the eigenvalues -1 and $-1/(1+\theta^2)$ again in the dynamic model of *Adaptive Learning and Escape Dynamics*.

At $\theta = 1$ the second eigenvalue sits exactly on the boundary $\mathcal{M} = -\frac{1}{2}$ that *The Credibility Problem* identifies for $\sqrt{t}$ asymptotic normality of decreasing-gain least squares.

That boundary concerns the rate of convergence; how often beliefs escape is governed instead by the large-deviation rate discussed below.

With a decreasing gain, then, least squares beliefs converge to the Nash self-confirming equilibrium asymptotically [Marcet and Sargent, 1989], although in a finite sample a falling gain also slows the return, so that an early escape can stick (*Least squares learning: a decreasing gain*).

With a constant gain, beliefs hover near the self-confirming equilibrium and escape from it recurrently.

But the reduction to $M^{-1}\,\partial\bar{g}/\partial\gamma$ relied on the special RLS prior.

Under a *general* prior V, the P block of (106.8) does **not** decouple, and local stability is governed instead by the eigenvalues of $\bar{P}\,\partial\bar{g}/\partial\gamma$ — where $\bar{P}$ is the Riccati solution for that prior.

Prior beliefs about parameter drift now matter for whether the self-confirming equilibrium is even stable.

106.6 Learning cycles

Here is the paper's most striking result: some priors make the self-confirming equilibrium *unstable*, and the mean dynamics then cycle.

We illustrate it, as Sargent and Williams [2005] do, by *tightening the government's prior on the slope coefficient*, starting from the RLS prior V^* and shrinking the slope-related entries by a factor $\lambda \in [0, 1]$:

$$V(\lambda) = \begin{bmatrix} V^*_{11} & \sqrt{\lambda}\, V^*_{12} \\ \sqrt{\lambda}\, V^*_{12} & \lambda\, V^*_{22} \end{bmatrix}. \tag{106.10}$$

For each λ we solve the Riccati equation with $\varepsilon = 0.05$ and look at the largest real part among the eigenvalues of $\bar{P}(\lambda)\, \partial\bar{g}/\partial\gamma$: where it is positive, the self-confirming equilibrium is unstable.

```
def V_tighten_slope(λ, V_star):
    V = V_star.copy()
    V[0, 1] = V[1, 0] = np.sqrt(λ) * V_star[0, 1]
    V[1, 1] = λ * V_star[1, 1]
    return V

ε = 0.05                                    # gain (sets the timescale)

def eig_PJ(V, σ=model.σ):
    "Eigenvalues of P̄ ∂g/∂γ at the SCE for the prior (V, σ)."
    return np.linalg.eigvals(solve_riccati(V, M_sce, σ) @ J)

λ_grid = np.linspace(0.01, 0.999, 200)
max_re = np.array([eig_PJ(ε**2 * V_tighten_slope(λ, V_star)).real.max()
                   for λ in λ_grid])

fig, ax = plt.subplots(figsize=(8, 4.5))
ax.plot(λ_grid, max_re)
ax.axhline(0, color='k', lw=0.8)
ax.set_xlabel(r'prior-tightening parameter $\lambda$')
ax.set_ylabel('max real part of eigenvalue')
plt.show()
```

Over an intermediate range of λ the maximum real part becomes *positive*: the self-confirming equilibrium loses stability.

The figure reproduces Fig. 4 of Sargent and Williams [2005].

Let's locate the two points where stability changes, and look at the eigenvalues there and deep inside the unstable range.

```
def max_real(λ):
    return eig_PJ(ε**2 * V_tighten_slope(λ, V_star)).real.max()

sign_changes = np.where(np.diff(np.sign(max_re)) != 0)[0]
for i in sign_changes:
    λ_c = brentq(max_real, λ_grid[i], λ_grid[i + 1])
    eigs = eig_PJ(ε**2 * V_tighten_slope(λ_c, V_star))
    print(f"stability changes at λ = {λ_c:.3f}; eigenvalues there: {eigs.round(4)}")
print(f"eigenvalues at λ = 0.7: {eig_PJ(ε**2 * V_tighten_slope(0.7, V_star)).round(4)}
 ↪")
```

```
stability changes at λ = 0.261; eigenvalues there: [-0.+0.0253j -0.-0.0253j]
stability changes at λ = 0.956; eigenvalues there: [0.+0.035j 0.-0.035j]
eigenvalues at λ = 0.7: [0.0055 0.1897]
```

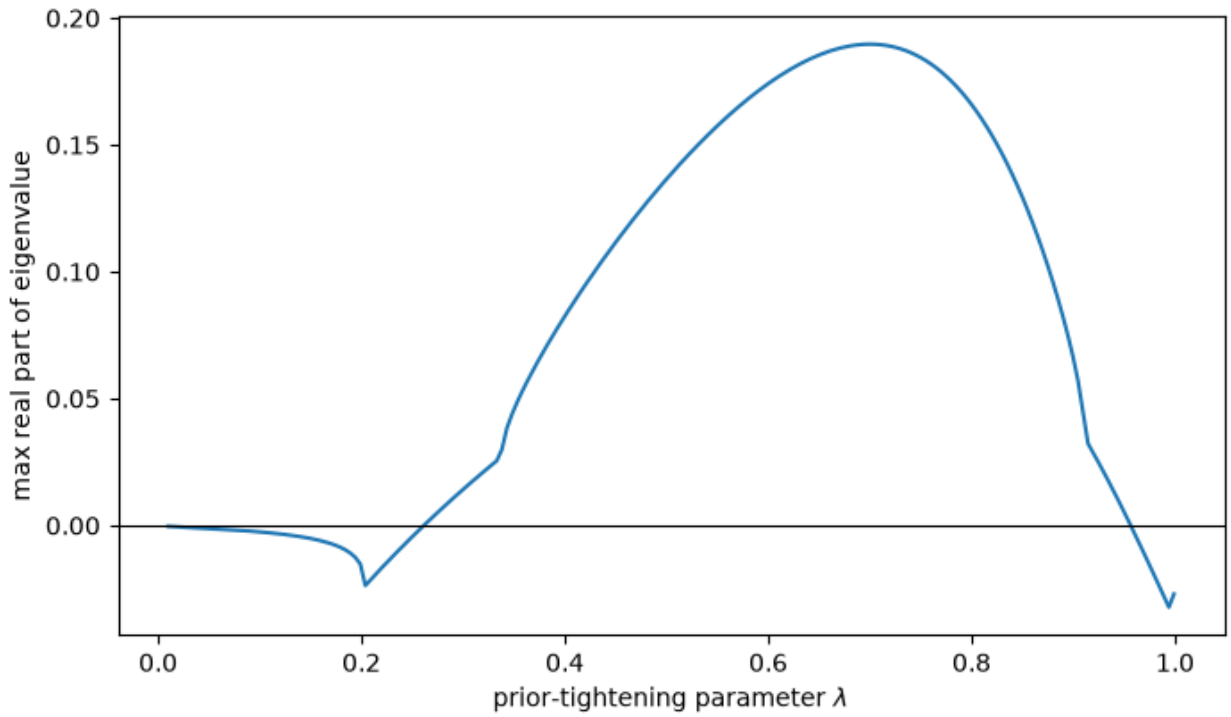

Fig. 106.1: Stability of the self-confirming equilibrium as the slope prior tightens

At each end of the unstable range a complex pair of eigenvalues crosses the imaginary axis.

That is the situation the Hopf bifurcation theorem addresses (see Perko [1996]): a stable limit cycle bifurcates from the self-confirming equilibrium as the real parts cross zero (Theorem 4.1 of Sargent and Williams [2005]).

Bullard [1994] calls such a cycle a *learning equilibrium*: the underlying model has no cycles, and learning creates them.

Deep inside the unstable range, at $\lambda = 0.7$, both eigenvalues are real and positive, so the self-confirming equilibrium is an unstable node.

The Hopf theorem describes cycles near the bifurcation points, so at $\lambda = 0.7$ we find the cycle numerically, as Sargent and Williams [2005] do in their Fig. 5, by integrating the joint mean dynamics (106.8) for (γ, P) from a point near the self-confirming equilibrium.

```
def mean_dynamics(t, z, V, σ):
    "The joint ODE pp_ode for (γ, P), stacked into one vector."
    γ, P = z[:2], z[2:].reshape(2, 2)
    γ_dot = P @ model.g_bar(γ)
    P_dot = V / σ**2 - P @ model.M(γ) @ P
    return np.concatenate([γ_dot, P_dot.ravel()])

λ = 0.7
V = ε**2 * V_tighten_slope(λ, V_star)
P_bar = solve_riccati(V, M_sce, model.σ)

z0 = np.concatenate([γ_sce + np.array([0.3, 0.05]), P_bar.ravel()])
sol = solve_ivp(mean_dynamics, [0, 3000], z0, args=(V, model.σ),
                max_step=1.0, rtol=1e-9, atol=1e-11)
t_path, a_path, b_path = sol.t, sol.y[0], sol.y[1]
x_path = model.x((a_path, b_path))
```

(continues on next page)

(continued from previous page)

```
# period: time between upward crossings of x through u/2, once the cycle has settled
up = t_path[1:][(x_path[:-1] < model.u / 2) & (x_path[1:] >= model.u / 2)]
period = np.diff(up[up > 1000]).mean()
mask = t_path > t_path[-1] - 2 * period        # the last two cycles

print(f"period of the cycle ≈ {period:.0f} periods")
print(f"along the cycle: intercept in [{a_path[mask].min():.2f}, {a_path[mask].max():.
↪2f}], "

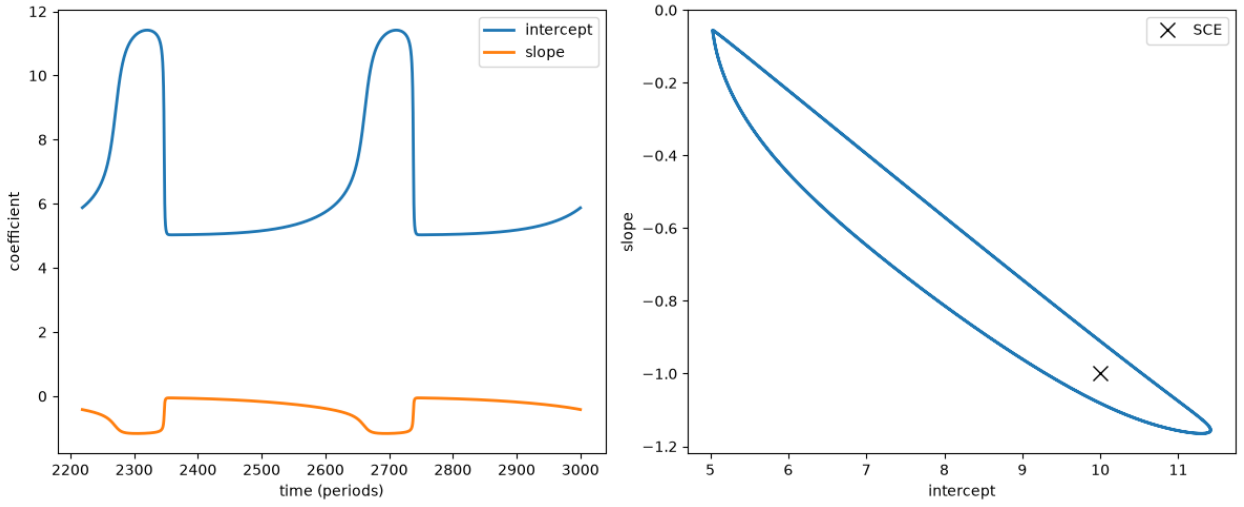

Fig. 106.2: Mean dynamics at $\lambda = 0.7$, the coefficients over two cycles (left) and the limit cycle in belief space (right)

The beliefs settle into a closed orbit around the self-confirming equilibrium, which matches Fig. 5 of Sargent and Williams [2005].

The intercept falls from near $2u$ to near u while the slope climbs from about -1 toward 0, and then both snap back.

Because inflation is a function of the coefficients through the best response (106.3), the cycle in beliefs shows up as a cycle in inflation between the Nash and Ramsey outcomes.

```
fig, ax = plt.subplots(figsize=(9, 4.5))
ax.plot(t_path[mask], x_path[mask])
ax.axhline(model.u, color='k', ls='--', lw=1, label='Nash')
ax.axhline(0, color='C2', ls=':', lw=1, label='Ramsey')
ax.set_xlabel('time (periods)')
ax.set_ylabel('inflation $x$')
ax.legend()
plt.show()
```

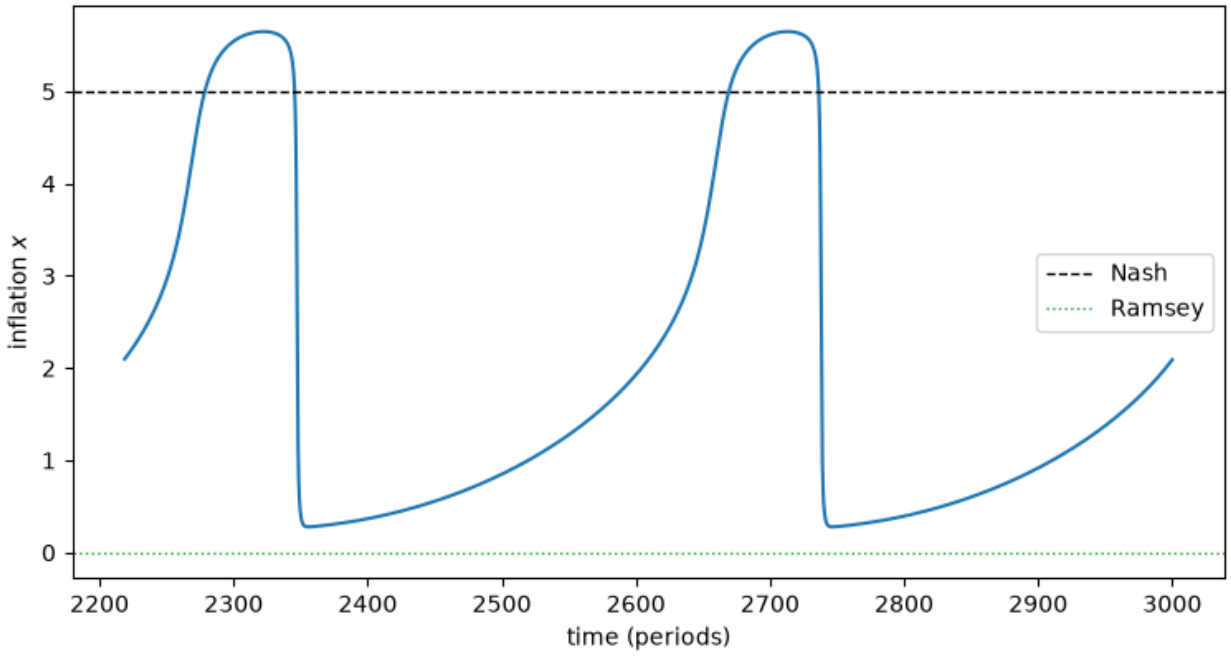

Fig. 106.3: Inflation oscillates between Nash and Ramsey along the learning cycle

This is a different mechanism from the escapes of *Adaptive Learning and Escape Dynamics* and *Escaping Nash Inflation*.

There the self-confirming equilibrium is stable, and a disinflation needs an unusual run of shocks to push beliefs away from it; here the mean dynamics themselves carry beliefs from Nash toward Ramsey and back.

The difference is sharpest as the gain shrinks.

As $\varepsilon \to 0$ the cycle persists, with a period proportional to $1/\varepsilon$, while escapes from a stable self-confirming equilibrium become exponentially rare.

But "rare" is a statement about small gains.

For the baseline prior, Sargent and Williams [2005] compute a large-deviation rate $\bar{S} \approx 3 \times 10^{-4}$ (their Table 1), so the factor $\exp(\bar{S}/\varepsilon)$ that makes escapes rare is close to one at the gains of 0.02 to 0.05 used in this lecture and elsewhere in the suite, and escapes are frequent; *Simulating escapes* shows how escape times grow as the gain shrinks.

At those gains, escapes from a stable self-confirming equilibrium recur on the same time scale as this cycle turns over, and Exercise 106.10.4 shows that a simulated time series can hardly tell the two apart.

106.7 Escape dynamics and the direction of escape

For priors that keep the self-confirming equilibrium stable, disinflations are escapes.

The theory of large deviations (*A primer on recursive algorithms*), in the form developed in Noah Williams's dissertation [Williams, 2001], later published as Williams [2019], characterizes the most likely escape as the solution of a control problem: apply the least-cost perturbation to beliefs that pushes them a fixed distance from $\bar{\gamma}$.

The minimized cost $\bar{S}$ is the rate at which escapes become rare as the gain shrinks: if τ is the time of the first escape, then $\varepsilon \log \mathbb{E}\tau \to \bar{S}$ as $\varepsilon \to 0$.

The *instantaneous* escape direction has a beautifully simple characterization: it is the eigenvector associated with the largest eigenvalue of the belief-innovation covariance $Q(\bar{\gamma}, \bar{P}) = \hat{V}$ — the prior itself.

```
w, vecs = np.linalg.eigh(V_star)            # baseline prior V*
v_escape = vecs[:, np.argmax(w)]
v_escape = v_escape / np.linalg.norm(v_escape)

# scale the escape so the slope moves from -1 up to 0
t_star = 1.0 / v_escape[1]
terminal = y_sce + t_star * v_escape

print(f"escape direction  ≈ {v_escape.round(3)}   (∝ [-u, 1])")
print(f"terminal beliefs  ≈ {terminal.round(2)}   (Belief 2 = [u, 0] = Ramsey)")
```

```
escape direction  ≈ [-0.981  0.195]   (∝ [-u, 1])
terminal beliefs  ≈ [4.98 0.  ]   (Belief 2 = [u, 0] = Ramsey)
```

For the baseline prior the escape direction is nearly proportional to $(-u, 1)$, exactly so in the limit $\sigma \to 0$, and it carries beliefs from Nash $(2u, -1)$ toward $(u, 0)$ — Belief 2, which supports the Ramsey outcome.

So an escape, when it happens, is a movement toward zero inflation.

Different priors bend the *path* and change the *rate* of escape.

Tightening the slope prior can destabilize the equilibrium entirely (the cycles above).

Tightening the intercept prior keeps it stable but makes escapes much *slower*: in Table 2 of Sargent and Williams [2005] it raises $\bar{S}$ from 3.1×10^{-4} to 0.28, and the mean escape time at $\varepsilon = 0.05$ from 23 to 167 periods (Exercise 106.10.1).

Yet in every case that Sargent and Williams [2005] study, the escapes lead to zero inflation, by different routes and supported by different beliefs (Exercise 106.10.2).

106.8 Sims's nonconvergence

We can now resolve the puzzle described in *The Rise and Fall of U.S. Inflation*.

Sims [1988] and Chung [1990] gave their governments Kalman filters on drifting coefficients; Sims's government fit a static Phillips curve like ours, and Chung's a distributed lag.

In their simulations the government escapes from Nash inflation once and then *stays* near the Ramsey outcome, apparently indefinitely.

Sargent [1999] and CWS instead used constant-gain recursive least squares, and their governments escape and are pulled back, again and again, producing the sawtooth of *A government learning the Phillips curve*.

Sargent and Williams [2005] trace the difference to the government's prior: the drift covariance V and the noise variance σ^2 that its filter assumes.

106.8.1 The variance of the regression error

So far, following CWS, the government's σ has equaled the true σ_1.

That is natural: in a self-confirming equilibrium the regression (106.2) and the truth (106.1) coincide, and with $\sigma = \sigma_1$ the government correctly splits the variation it sees in unemployment between its regressors and the shocks.

Sims instead set σ well below σ_1, and he did not let the drift in the coefficients shrink toward zero.

A government that attributes too little variance to its regression error must attribute the variation it sees to something else, and the only thing else available is drift in its own coefficients.

The Riccati equation (106.7) makes this precise: $\bar{P}$ solves $\bar{P}M\bar{P} = \sigma^{-2}V$, so $\bar{P}$ is proportional to $1/\sigma$.

Understating σ by some factor therefore raises the government's gain by the same factor, exactly as raising ε would.

```
Φ_sce = np.array([1.0, model.x(y_sce)])
P_by_σ = {}
for σ_govt in (model.σ1, model.σ1 / 3):
    P_by_σ[σ_govt] = solve_riccati(ε**2 * V_star, M_sce, σ_govt)
    P = P_by_σ[σ_govt]
    gain = (P @ Φ_sce)[0] / (1 + Φ_sce @ P @ Φ_sce)
    print(f"σ = {σ_govt:.2f}: steady-state weight on a forecast error "
          f"(intercept) = {gain:.4f}")

ratio = P_by_σ[model.σ1 / 3] / P_by_σ[model.σ1]
print(f"P(σ1/3) / P(σ1), element by element: {ratio.round(6).ravel()}")
```

```
σ = 0.30: steady-state weight on a forecast error (intercept) = 0.0476
σ = 0.10: steady-state weight on a forecast error (intercept) = 0.1304
P(σ1/3) / P(σ1), element by element: [3. 3. 3. 3.]
```

Cutting σ to a third of σ_1 triples $\bar{P}$ exactly.

The weight that the filter puts on each forecast error rises almost as much: the 1 in the denominator of (106.5) keeps the ratio a little below three at this gain, and the ratio tends to three as ε shrinks.

At small gains, a larger gain changes the speed of learning but not the local balance between the mean dynamics and the noise: Sargent and Williams [2005] (section 5) show that the local strength of the pull toward the self-confirming equilibrium, measured as drift per unit of standard deviation, does not depend on the prior.

What a large gain can change is whether the mean dynamics describe the beliefs at all, because they are a small-gain approximation.

106.8.2 Replicating Sims's example

Sargent and Williams [2005] simulate a specification analogous to one of Sims's benchmark cases, his Chart 5, which in our notation has $u = 6$, $\sigma_1 = 0.5$, $\sigma_2 = 0.4$, $V = 0.01\,I$ and $\sigma = 0.1$, so that σ_1 is five times σ; they treat it as a benchmark with $\varepsilon = 1$.

We start the government at the self-confirming equilibrium $(2u, -1) = (12, -1)$, with P at its Riccati value, and run 10,000 periods, as Sims and Sargent–Williams did.

We compare it with the variation $\sigma = \sigma_1$, holding V fixed.

This variation leaves $\sigma^{-2}V = 0.04\,I$, the same as shrinking the drift by setting $\varepsilon = 0.2$ with $\sigma = 0.1$, so the two give *identical* paths, as Sargent and Williams [2005] note.

We also need a way to count escapes and returns along a path of inflation.

```
def escapes_and_returns(π, lo, hi, k=50):
    """
    Count escapes and returns along a path of inflation that starts near Nash.

    An escape is a fall of the k-period moving average of inflation below lo;
    a return is a later rise back above hi.  Also returns the period by which
    the first escape is complete (None if there is none).
    """
    ma = np.convolve(π, np.ones(k) / k, mode='valid')
    near_nash, n_esc, n_ret, first = True, 0, 0, None
    for n, m in enumerate(ma):
        if near_nash and m < lo:
            near_nash, n_esc = False, n_esc + 1
            if first is None:
                first = n + k - 1
        elif not near_nash and m > hi:
            near_nash, n_ret = True, n_ret + 1
    return n_esc, n_ret, first
```

Now we simulate ten paths of Sims's specification and of the variation, counting an escape when the 50-period average of inflation falls below $u/3 = 2$ and a return when it climbs back above $5u/6 = 5$.

```
sims = StaticPhillips(u=6.0, σ1=0.5, σ2=0.4)
V_sims, σ_sims = 0.01 * np.eye(2), 0.1
T_sims, seeds = 10_000, range(10)
lo, hi = sims.u / 3, 5 * sims.u / 6

runs = {s: kalman_path(sims, V_sims, σ_sims, T_sims, s) for s in seeds}
runs_σ1 = {s: kalman_path(sims, V_sims, sims.σ1, T_sims, s) for s in seeds}

same = all(np.allclose(kalman_path(sims, 0.04 * V_sims, σ_sims, T_sims, s)[0],
                       runs_σ1[s][0]) for s in (0, 1))
print(f"σ = σ1 and ε = 0.2 give identical paths: {same}\n")

print(f"{'':6}{'Sims: σ = 0.1':^42}| {'σ = σ1':^24}")
print(f"{'seed':>4} {'escapes':>8} {'by period':>10} {'returns':>8} "
      f"{'mean π after':>13} | {'escapes':>8} {'mean π':>8}")
first_escape = {}
for s in seeds:
    π = runs[s][0]
    n_esc, n_ret, first = escapes_and_returns(π, lo, hi)
    first_escape[s] = first
    after = π[first:].mean() if first is not None else np.nan
```

(continues on next page)

(continued from previous page)

```
    n_esc1 = escapes_and_returns(runs_σ1[s][0], lo, hi)[0]
    print(f"{s:>4} {n_esc:>8} {str(first):>10} {n_ret:>8} {after:>13.2f} | "
          f"{n_esc1:>8} {runs_σ1[s][0].mean():>8.2f}")
```

```
σ = σ1 and ε = 0.2 give identical paths: True

                    Sims: σ = 0.1                |          σ = σ1
seed  escapes  by period  returns  mean π after |  escapes   mean π
   0        1       4807        0          0.61 |        0     6.14
   1        1       3488        0          0.57 |        0     6.15
   2        1        307        0          0.59 |        0     5.83
   3        1        417        0          0.65 |        0     5.89
   4        1        598        0          0.63 |        0     5.52
   5        1       4509        0          0.60 |        0     6.07
   6        1       1289        0          0.67 |        0     5.94
   7        1       1284        0          0.59 |        0     5.82
   8        1       1133        0          0.59 |        0     6.03
   9        1       1433        0          0.57 |        0     5.61
```

Every one of Sims's paths escapes, at very different dates, and none returns: after its escape each path settles into a noisy regime with mean inflation close to the 0.61 that Sargent and Williams [2005] report.

With $\sigma = \sigma_1$, or equivalently $\varepsilon = 0.2$, no path escapes, and inflation stays near the self-confirming value $u = 6$.

The next figure shows the first 1,000 periods of the path whose escape comes earliest, the analog of Fig. 14 of Sargent and Williams [2005].

```
s_show = min(seeds, key=lambda s: first_escape[s])

fig, ax = plt.subplots(figsize=(9.5, 4.5))
ax.plot(runs[s_show][0][:1000], lw=0.8, label=r"Sims: $\sigma = 0.1$")
ax.plot(runs_σ1[s_show][0][:1000], lw=0.8, ls='--',
        label=r"$\sigma = \sigma_1$ or $\varepsilon = 0.2$")
ax.axhline(sims.u, color='k', ls='--', lw=1)
ax.axhline(0, color='C2', ls=':', lw=1)
ax.set_xlabel('$n$')
ax.set_ylabel('inflation')
ax.legend(frameon=False, loc='lower right')
plt.show()
```

106.8.3 Why the mean dynamics do not reassert themselves

The mean dynamics (106.8) average the data over many periods while holding beliefs, and hence the government's policy $x(\gamma)$, fixed.

That is a good approximation when beliefs move slowly, but not under Sims's prior, which lets beliefs move a lot from one period to the next.

Then the government's own policy injects variation into inflation, and that variation does not move unemployment, because only surprises do.

The regression of U on π then reads the induced variation as evidence of a nearly vertical Phillips curve: with policy variance $\mathbb{V}[x]$, the population slope is $-\sigma_2^2/(\sigma_2^2 + \mathbb{V}[x])$ rather than -1.

A flat perceived curve supports low inflation, so the low-inflation regime sustains itself.

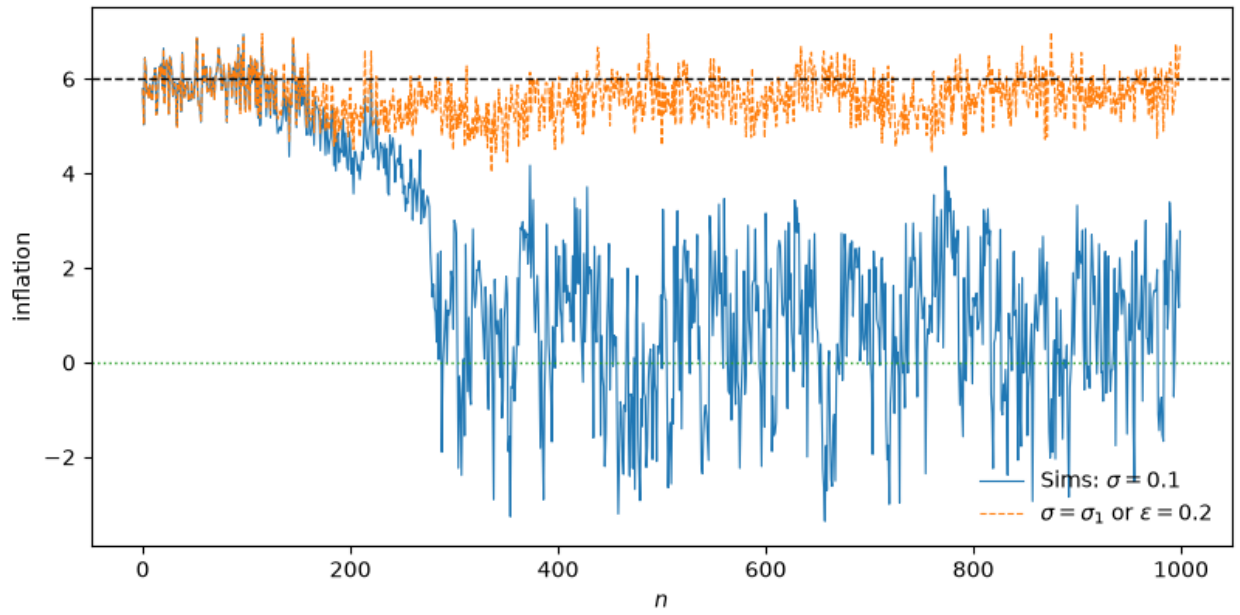

Fig. 106.4: Inflation under Sims's specification and under σ = σ1 (equivalently ε = 0.2), first 1,000 periods

Let's check this on the simulated paths after their escapes.

```
var_x, slope, theory = [], [], []
for s in seeds:
    π, U, x, _ = runs[s]
    n0 = first_escape[s] + 200                    # well after the escape
    var_x.append(x[n0:].var())
    slope.append(np.cov(U[n0:], π[n0:])[0, 1] / π[n0:].var())
    theory.append(-sims.σ2**2 / (sims.σ2**2 + var_x[-1]))

print(f"variance of systematic inflation x after the escape: "
      f"{min(var_x):.2f} to {max(var_x):.2f}")
print(f"sample slope of U on π after the escape:  {min(slope):.3f} to {max(slope):.3f}
↪")
print(f"-σ2²/(σ2² + var x):                        {min(theory):.3f} to {max(theory):.
↪3f}")
```

```
variance of systematic inflation x after the escape: 2.10 to 2.21
sample slope of U on π after the escape:  -0.073 to -0.062
-σ2²/(σ2² + var x):                       -0.071 to -0.068
```

The government's beliefs, and therefore its policy, keep moving after the escape, and the data it generates confirm a Phillips curve whose slope is close to zero, the Ramsey belief.

That is the sense in which Sargent and Williams [2005] say that the results about mean and escape dynamics are "approximations for small parameter drift": with drift as large as Sims's, the mean dynamics fail to reassert themselves.

106.8.4 Constant gains and the sawtooth

Now give the government of the same economy constant-gain recursive least squares instead, with the gain 0.02 of *A government learning the Phillips curve* (the economy of that section has the calibration of the rest of this lecture).

```
def rls_path(model, gain, T, seed):
    "Constant-gain recursive least squares, as in olg_phillips, from the SCE."
    rng = np.random.default_rng(seed)
    u, σ1, σ2 = model.u, model.σ1, model.σ2
    γ = np.array([2 * u, -1.0])
    R = model.M(γ)
    π = np.empty(T)
    for n in range(T):
        w1, w2 = rng.standard_normal(2)
        π[n] = model.x(γ) + σ2 * w2
        U = u - σ2 * w2 + σ1 * w1
        Φ = np.array([1.0, π[n]])
        R = R + gain * (np.outer(Φ, Φ) - R)
        γ = γ + gain * np.linalg.solve(R, Φ * (U - Φ @ γ))
    return π

runs_cg = {s: rls_path(sims, 0.02, T_sims, s) for s in seeds}
counts_cg = [escapes_and_returns(runs_cg[s], lo, hi)[:2] for s in seeds]
print("constant gain 0.02, (escapes, returns) by seed:", counts_cg)
```

```
constant gain 0.02, (escapes, returns) by seed: [(4, 3), (4, 3), (6, 5), (3, 2),␣
↪(2, 1), (6, 5), (3, 2), (3, 2), (5, 4), (3, 2)]
```

Under constant-gain least squares every path escapes and returns, most of them several times.

The count of returns is conservative: many climbs back toward Nash turn into new escapes before the 50-period average reaches 5.

The figure compares 50-period moving averages of inflation under the two learning rules.

```
def moving_average(π, k=50):
    return np.convolve(π, np.ones(k) / k, mode='valid')

fig, axes = plt.subplots(2, 1, figsize=(9.5, 7), sharex=True, sharey=True)
for s in seeds:
    axes[0].plot(moving_average(runs[s][0]), lw=0.6)
for s in (0, 1, 2):
    axes[1].plot(moving_average(runs_cg[s]), lw=0.8, label=f'seed {s}')
titles = [r"Sims's Kalman filter ($\sigma = 0.1$), ten seeds",
          'constant-gain least squares (gain 0.02), three seeds']
for ax, title in zip(axes, titles):
    ax.axhline(sims.u, color='k', ls='--', lw=1)
    ax.axhline(0, color='C2', ls=':', lw=1)
    ax.set_ylabel('inflation, 50-period average')
    ax.set_title(title)
axes[1].legend(frameon=False, fontsize=8, ncol=3, loc='lower right')
axes[1].set_xlabel('$n$')
plt.tight_layout()
plt.show()
```

The same economy produces both of the histories in the literature.

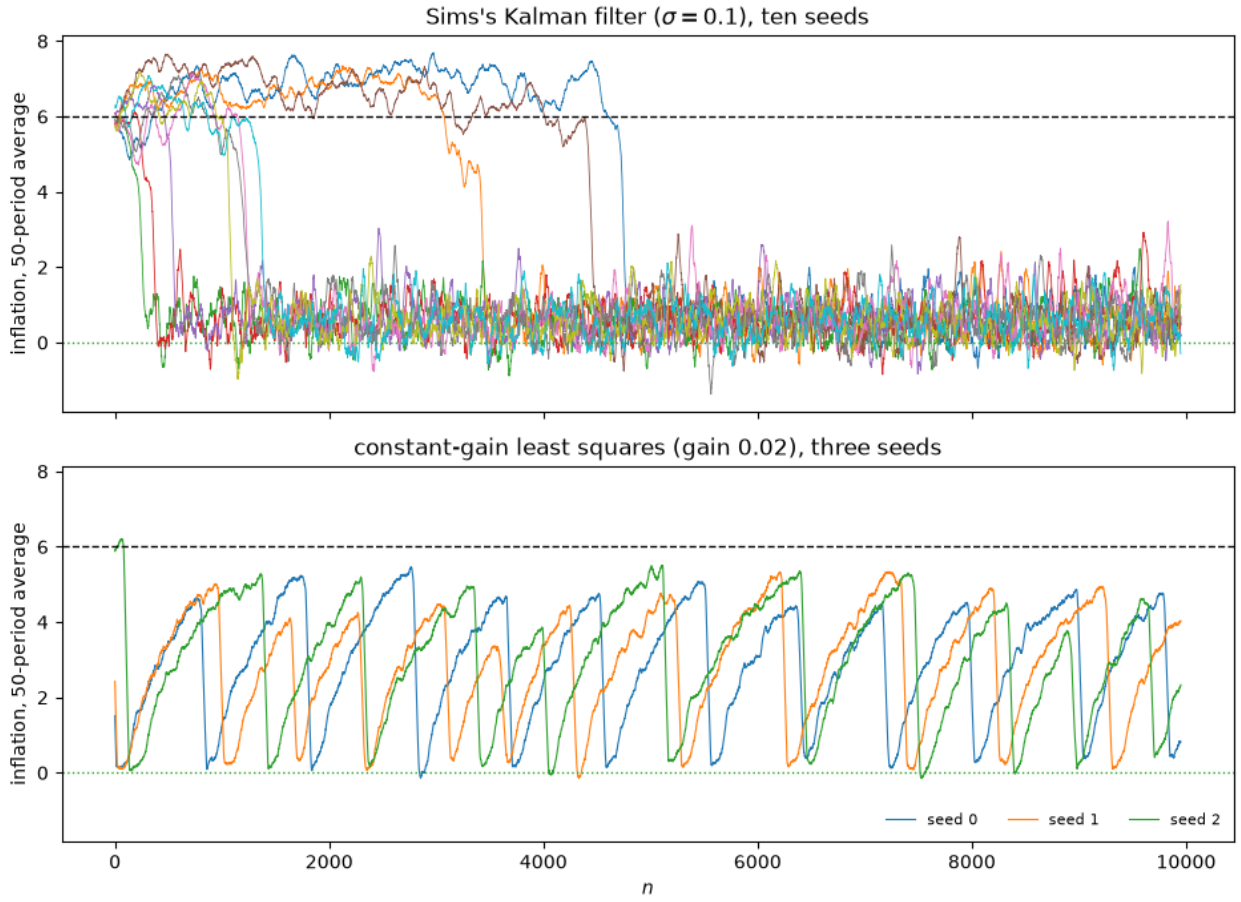

Fig. 106.5: One escape under Sims's Kalman filter, recurrent escapes under constant-gain least squares (50-period moving averages)

With Sims's prior the government escapes once and stays near Ramsey; with constant-gain least squares the mean dynamics pull it back toward Nash after every escape, the sawtooth of Sargent [1999] and CWS.

With Sims's prior and $\sigma = \sigma_1$, the government never escapes in 10,000 periods.

A decreasing gain gives a third route to an escape that sticks, for a different reason: least squares then converges to the self-confirming equilibrium asymptotically, but in a finite sample the falling gain slows the return (*Least squares learning: a decreasing gain*).

As Sargent and Williams [2005] put it, one can read the difference between Sims's results and theirs in two equivalent ways: either Sims allowed too much parameter drift to permit convergence, or he did not let the government attribute enough variation to its regression error.

Here the two readings are exactly equivalent, because the filter (106.5) depends on ε and σ only through ε/σ; Exercise 106.10.6 draws the econometric implication.

106.9 Conclusion

Free parameters are dangerous, as Arthur Goldberger and Robert Lucas warned.

This lecture's government carries free parameters in the covariance matrix V of the drift in its beliefs.

But those parameters buy something.

The empirical sequel Sargent *et al.* [2006] gives the government the Kalman filter of this lecture, estimates V from post-war U.S. data, and so reverse-engineers a sequence of policy makers' evolving subjective models of the Phillips curve that rationalize the actual rise and fall of American inflation — the vindication story of *The Rise and Fall of U.S. Inflation*, made quantitative.

Its authors draw a guarded lesson, though: their estimates "teach us to deemphasize the empirical relevance of both the mean dynamics and the escape dynamics" and to focus instead on the short-term impact of shocks on government beliefs, and their estimated gap between Nash and Ramsey inflation is small, which supports Alan Blinder's skepticism about whether that gap matters much for policy.

Related evidence that the reduced-form coefficients and the shock volatilities both drifted appears in Cogley and Sargent [2005] (*Drifts and Volatilities*), whose model holds the covariance of the coefficient drift constant.

Estimating V is possible because a Kalman filter with a fixed prior has a gain that never vanishes, so the drift parameters stay identified by the whole sample; *The econometricians did return the compliment* tells how econometricians came to exploit this, and Exercise **??** and Exercise 106.10.6 pose stripped-down versions of the estimation problem that Chung [1990] first solved.

106.9.1 Are the estimated beliefs realistic?

That empirical success came with a challenge that is really a challenge about the *prior*.

To fit the data, Sargent *et al.* [2006] estimated a large drift covariance V — a government so open to new data that its beliefs about the monetary transmission mechanism lurch from month to month.

Primiceri [2006], Sims [2007], and, candidly, Sargent [2008] in his presidential address objected that such volatile beliefs are *unrealistic*: the imputed government forecasts unemployment poorly and holds views no real central bank would.

Carboni and Ellison [2009] answer the objection by disciplining the prior with data the Federal Reserve actually produced.

They re-estimate the model subject to the requirement that its beliefs reproduce the unemployment forecasts published in the Fed's *Greenbook* — imposing on the learning model a cross-equation restriction of the kind familiar from rational-expectations econometrics.

Imposing it shrinks the estimated drift variance of the constant term about fiftyfold, from 30.57 to 0.63, and removes the wild belief swings, yet leaves the low-frequency conquest story intact: a *stable* evolution of Federal Reserve beliefs still explains the rise and fall of inflation.

The volatile beliefs, they conclude, "appear to matter only for 'overfitting' high frequency inflation movements", which Sargent [1999] never set out to explain.

The restricted model's perceived tradeoff peaks at about a tenth of its unrestricted size, so the Greenbook evidence supports the account of Sargent [1999] more than the estimates of Sargent *et al.* [2006].

The moral for this lecture is direct: the prior V is not a nuisance parameter to be maximized over freely — it is an economic object, and pinning it down with independent evidence on what policy makers actually believed is what makes the vindication story credible.

The broader message is that *how* an adaptive government learns — the prior it brings to the drift in its own beliefs — is not a technical detail.

It determines whether the economy hovers near Nash with recurrent escapes, cycles between Nash and Ramsey, or escapes to Ramsey and stays there.

The next lecture, *Econometric Policy Evaluation*, takes the adaptive models to data, as chapter 9 of Sargent [1999] did following Chung [1990], by estimating them by maximum likelihood on U.S. data.

Drifts and Volatilities and *Drifts and Volatilities after 2000* then fit a drifting-coefficient, stochastic-volatility VAR to post-war data and ask how much of the Great Inflation was drifting beliefs and how much was simply bad luck, and *The Lost Conquest: Fed Policy in the 2020s* closes the suite by carrying these tools into the present, to rationalize the Federal Reserve's response to the inflation of the 2020s.

106.10 Exercises

Exercise 106.10.1

The learning cycle above tightened the prior on the *slope* coefficient.

Tightening the prior on the *intercept* coefficient instead — using

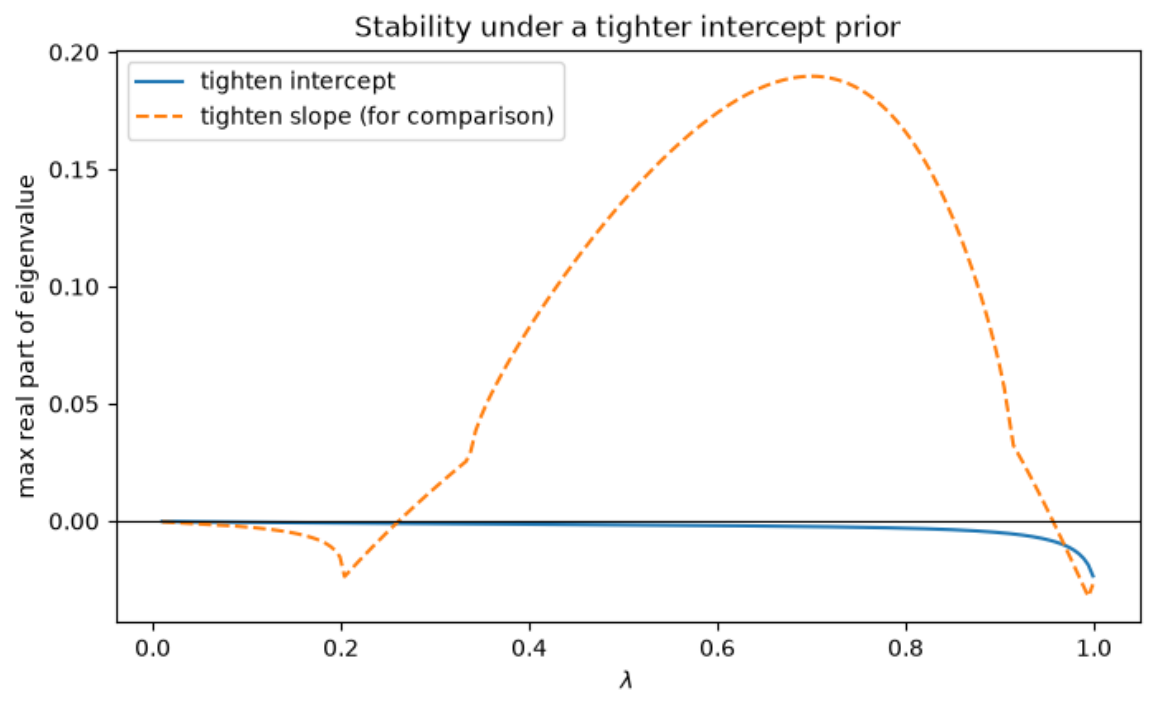
$$V(\lambda) = \begin{bmatrix} \lambda V_{11}^* & \sqrt{\lambda} V_{12}^* \\ \sqrt{\lambda} V_{12}^* & V_{22}^* \end{bmatrix}$$

— does *not* destabilize the self-confirming equilibrium.

1. Verify this by plotting the maximum real part of the eigenvalues of $\bar{P}(\lambda)\, \partial \bar{g}/\partial \gamma$ against λ for this intercept-tightening family, and confirm it stays negative.
2. Sargent and Williams [2005] find that this prior nonetheless changes the *speed* of escapes. With $\varepsilon = 0.05$, simulate 100 paths from the self-confirming equilibrium under the baseline prior and under their intercept-tightened prior with $\lambda = 0.63$. For each path, record the first period in which beliefs are farther from $\bar{\gamma}$ than $\sqrt{26}$, the distance from the self-confirming equilibrium to Belief 2. Are escapes faster or slower under the tighter prior?

Solution

Here is the stability calculation.



```
def V_tighten_intercept(λ, V_star):
    V = V_star.copy()
```

```
    V[0, 0] = λ * V_star[0, 0]
    V[0, 1] = V[1, 0] = np.sqrt(λ) * V_star[0, 1]
    return V

max_re_int = [eig_PJ(ε**2 * V_tighten_intercept(λ, V_star)).real.max()
              for λ in λ_grid]

fig, ax = plt.subplots(figsize=(8, 4.5))
ax.plot(λ_grid, max_re_int, label='tighten intercept')
ax.plot(λ_grid, max_re, ls='--', label='tighten slope (for comparison)')
ax.axhline(0, color='k', lw=0.8)
ax.set_xlabel(r'$\lambda$')
ax.set_ylabel('max real part of eigenvalue')
ax.set_title('Stability under a tighter intercept prior')
ax.legend()
plt.show()

print(f"largest value over the grid: {max(max_re_int):.2e}")
```

```
largest value over the grid: -1.58e-04
```

Tightening the intercept prior keeps the maximum real part negative for all λ: the self-confirming equilibrium stays stable, so there is no learning cycle.

Now the escape times.

The function below stops each path as soon as beliefs leave the ball.

```
def first_exit(model, V, σ, radius, seed, T_max=50_000):
    "First period in which |y - y_sce| > radius under the exact Kalman filter."
    rng = np.random.default_rng(seed)
    u, σ1, σ2 = model.u, model.σ1, model.σ2
    y_bar = np.array([2 * u, -1.0])
    y, P, W = y_bar.copy(), solve_riccati(V, model.M(y_bar), σ), V / σ**2
    for n in range(T_max):
```

```
        w1, w2 = rng.standard_normal(2)
        π = model.x(y) + σ2 * w2
        U = u - σ2 * w2 + σ1 * w1
        Φ = np.array([1.0, π])
        PΦ = P @ Φ
        denom = 1 + Φ @ PΦ
        y = y + PΦ / denom * (U - Φ @ y)
        P = P - np.outer(PΦ, PΦ) / denom + W
        if np.linalg.norm(y - y_bar) > radius:
            return n + 1
    return np.nan

radius = np.sqrt(26)
for name, V_hat in [("baseline V*", V_star),
                    ("tighter intercept, λ = 0.63", V_tighten_intercept(0.63, V_
 ↪star))]:
    times = np.array([first_exit(model, ε**2 * V_hat, model.σ, radius, s)
                      for s in range(100)])
    print(f"{name:28s}: mean escape time {np.nanmean(times):6.1f} periods "
          f"(median {np.nanmedian(times):.0f}, censored {np.isnan(times).sum()})")
```

```
baseline V*                  : mean escape time   23.0 periods (median 20,␣
 ↪censored 0)
tighter intercept, λ = 0.63 : mean escape time  259.5 periods (median 220,␣
 ↪censored 0)
```

Escapes are much *slower* under the tighter intercept prior.

The baseline time is close to the 22.9 periods that Sargent and Williams [2005] report in their Table 2 at this gain; the intercept-tightened time is of the same order as their 167.3 periods, many times the baseline.

A government that is surer that its intercept is not drifting puts less weight on the forecast errors that would carry its beliefs along the escape route, and Sargent and Williams [2005] (section 6.3) show that priors that make $\bar{P}^{-1}$ larger raise the rate $\bar{S}$ that governs how rare escapes are.

So this prior changes the escape dynamics substantially, without overturning the mean dynamics.

Exercise 106.10.2

The instantaneous escape direction is the dominant eigenvector of the prior covariance $\hat{V}$.

1. Compute the escape direction, and the terminal beliefs implied by following it in a straight line until the slope reaches 0, for the baseline prior V^* and for the intercept-tightened prior of Exercise 106.10.1 with $\lambda = 0.63$, the case of Fig. 9 of Sargent and Williams [2005]. Why would the slope-tightened prior $V(0.5)$ be a poor choice for this comparison?
2. With $\varepsilon = 0.05$, simulate five escapes under each prior, stopping each path when the slope first reaches 0, and plot the belief paths in the (intercept, slope) plane together with the two instantaneous directions.
3. Where do the escapes end, and how well does the instantaneous direction predict their route?

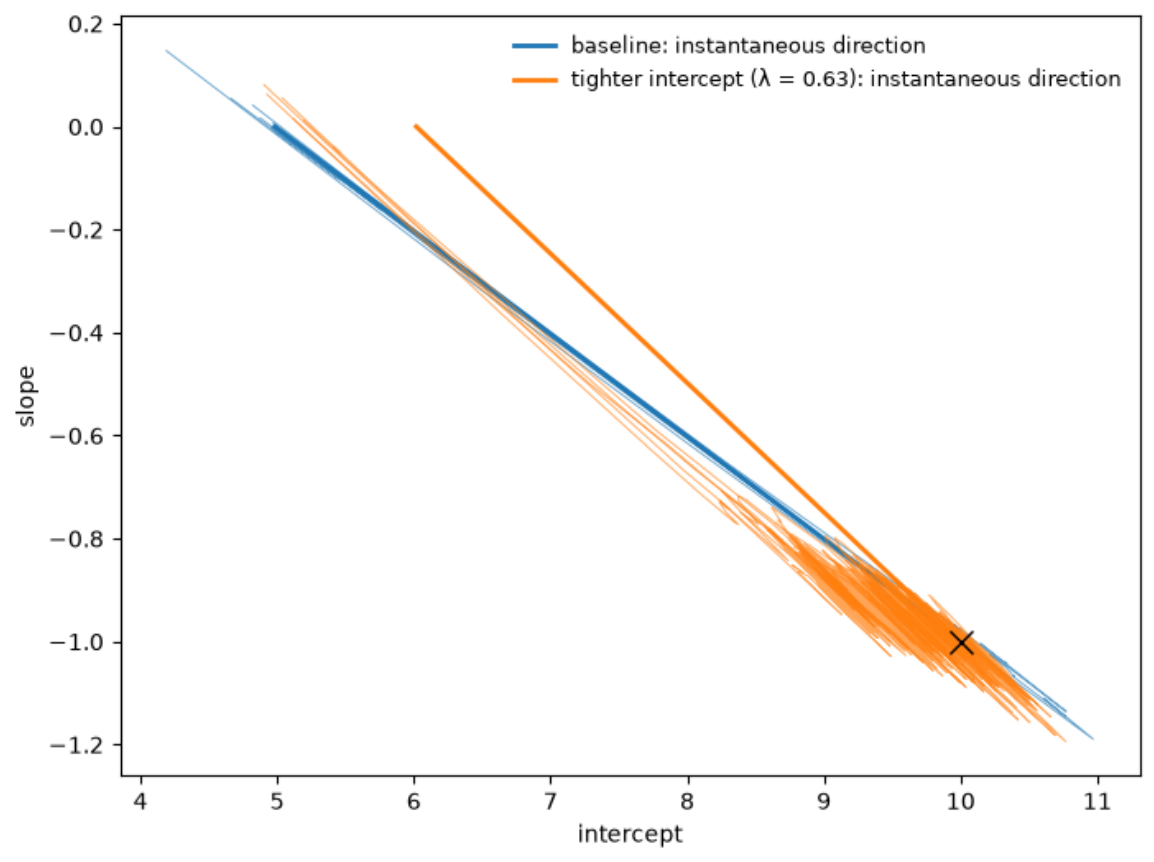
Solution

The slope-tightened prior $V(0.5)$ lies inside the unstable range of Fig. 106.1, so it has no stable self-confirming equilibrium to escape from.

The intercept-tightened prior keeps the equilibrium stable (Exercise 106.10.1).

```
def escape_direction(V):
    "Dominant eigenvector of V, oriented toward a higher slope, and its terminal␣
 ↪point."
    w, vecs = np.linalg.eigh(V)
    v = vecs[:, np.argmax(w)]
    v = v / np.linalg.norm(v)
    if v[1] < 0:
        v = -v
    return v, y_sce + v / v[1]

priors = {"baseline": V_star,
          "tighter intercept (λ = 0.63)": V_tighten_intercept(0.63, V_star)}
for name, V_hat in priors.items():
    v, term = escape_direction(V_hat)
    stable = eig_PJ(ε**2 * V_hat).real.max() < 0
    print(f"{name:30s}: direction {v.round(3)}, straight-line terminal "
          f"{term.round(2)}, SCE stable: {stable}")
```



```
baseline                       : direction [-0.981  0.195], straight-line␣
 ↪terminal [4.98 0.  ], SCE stable: True
tighter intercept (λ = 0.63)  : direction [-0.97   0.244], straight-line␣
 ↪terminal [6.02 0.  ], SCE stable: True
```

The directions differ only by a few degrees, but because the escape covers a long distance, the straight-line terminal intercepts differ by about one unit.

Now the simulated escapes.

```
fig, ax = plt.subplots(figsize=(8, 6))
for (name, V_hat), color in zip(priors.items(), ('C0', 'C1')):
    v, term = escape_direction(V_hat)
    ax.plot([y_sce[0], term[0]], [y_sce[1], term[1]], color=color, lw=2,
            label=f'{name}: instantaneous direction')
    ends = []
    for s in range(5):
        _, _, _, beliefs = kalman_path(model, ε**2 * V_hat, model.σ, 5_000, s)
        n_end = np.argmax(beliefs[:, 1] >= 0)
        ax.plot(beliefs[:n_end + 1, 0], beliefs[:n_end + 1, 1], color=color,
                lw=0.6, alpha=0.7)
        ends.append((n_end, beliefs[n_end, 0]))
    print(f"{name:30s}: (period, intercept) when the slope reaches 0: "
          f"{[(int(n), round(a, 2)) for n, a in ends]}")
ax.plot(*y_sce, 'kx', ms=10)
ax.set_xlabel('intercept')
ax.set_ylabel('slope')
ax.legend(frameon=False, fontsize=9)
plt.show()
```

```
baseline                       : (period, intercept) when the slope reaches 0:␣
 ↪[(10, np.float64(4.87)), (35, np.float64(4.66)), (13, np.float64(4.82)), (33,␣
 ↪np.float64(4.97)), (8, np.float64(4.19))]
tighter intercept (λ = 0.63)  : (period, intercept) when the slope reaches 0:␣
 ↪[(142, np.float64(5.19)), (767, np.float64(4.92)), (193, np.float64(5.04)),␣
 ↪(287, np.float64(5.12)), (267, np.float64(4.9))]
```

Under the baseline prior the simulated escapes run close to the straight line, as in Fig. 7 of Sargent and Williams [2005], and end near Belief 2, $(u, 0)$.

Under the tighter intercept prior the escapes take much longer to start: beliefs first wander around the self-confirming equilibrium, and when they do escape they run along a line close to the baseline's, not along their own instantaneous direction, ending at slope 0 with an intercept close to the baseline's rather than at the straight-line terminal point.

So the instantaneous direction predicts the route well only in the baseline case, where, as $\sigma \to 0$, the mean dynamics themselves keep pushing beliefs along it once an escape has started (section 6.2 of Sargent and Williams [2005]); for other priors the whole dynamic control problem matters.

In both cases the escape ends at a slope of 0, where the government perceives no exploitable tradeoff and (106.3) sets inflation to zero whatever the intercept.

The destination is robust; the route and its timing depend on the shape of the prior.

Exercise 106.10.3

Sargent and Williams [2005] (section 3.4) stress that constant-gain recursive least squares is only *asymptotically* a special case of the Kalman filter with $V = \varepsilon^2 V^*$.

With $\varepsilon = 0.05$ and $V = \varepsilon^2 V^*$, start both algorithms' mean dynamics at the Ramsey belief $\gamma_0 = (u, 0)$, with the Kalman P at its Riccati value for $M(\gamma_0)$ and the RLS moment matrix at $R = M(\gamma_0)$.

The RLS mean dynamics are

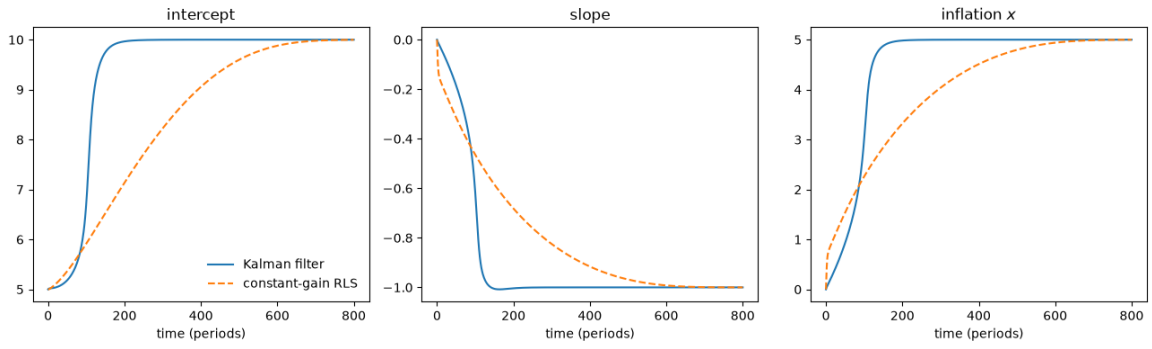
$$\dot{\gamma} = \varepsilon R^{-1} \bar{g}(\gamma), \qquad \dot{R} = \varepsilon \left[M(\gamma) - R \right].$$

Integrate both systems for 800 periods and plot the intercept, the slope, and inflation $x(\gamma)$.

Which algorithm returns to the self-confirming equilibrium faster, and do they end at the same place?

Solution

The Kalman mean dynamics are the function `mean_dynamics` from the lecture.



```
def rls_mean_dynamics(t, z):
    "Mean dynamics of constant-gain RLS for (γ, R), stacked into one vector."
    γ, R = z[:2], z[2:].reshape(2, 2)
    γ_dot = ε * np.linalg.solve(R, model.g_bar(γ))
    R_dot = ε * (model.M(γ) - R)
    return np.concatenate([γ_dot, R_dot.ravel()])

γ0 = np.array([model.u, 0.0])                    # Belief 2 (Ramsey)
M0 = model.M(γ0)
V = ε**2 * V_star
t_eval = np.linspace(0, 800, 801)

kal = solve_ivp(mean_dynamics, [0, 800],
                np.concatenate([γ0, solve_riccati(V, M0, model.σ).ravel()]),
                args=(V, model.σ), t_eval=t_eval, rtol=1e-8, atol=1e-10)
rls = solve_ivp(rls_mean_dynamics, [0, 800], np.concatenate([γ0, M0.ravel()]),
                t_eval=t_eval, rtol=1e-8, atol=1e-10)

fig, axes = plt.subplots(1, 3, figsize=(13, 4))
for out, label, ls in [(kal, 'Kalman filter', '-'), (rls, 'constant-gain RLS', '--
↪')]:
    a, b = out.y[0], out.y[1]
    for ax, series in zip(axes, (a, b, model.x((a, b)))):
        ax.plot(out.t, series, ls=ls, label=label)
for ax, title in zip(axes, ('intercept', 'slope', 'inflation $x$')):
    ax.set_title(title)
    ax.set_xlabel('time (periods)')
axes[0].legend(frameon=False)
plt.tight_layout()
plt.show()

for out, label in [(kal, 'Kalman filter'), (rls, 'constant-gain RLS')]:
    x = model.x((out.y[0], out.y[1]))
    print(f"{label:18s}: x first exceeds 0.8u at period {out.t[np.argmax(x > 0.8 *␣
↪model.u)]:.0f}; "
          f"beliefs at period 800 = {out.y[:2, -1].round(3)}")
```

```
Kalman filter     : x first exceeds 0.8u at period 111; beliefs at period 800 =␣
↪[10. -1.]
constant-gain RLS : x first exceeds 0.8u at period 294; beliefs at period 800 =␣
↪[ 9.998 -1.   ]
```

Both algorithms end at the self-confirming equilibrium $(2u, -1)$, but the Kalman filter gets there much faster, with an abrupt reversal of the slope rather than a gradual one, as in Figs. 1 and 2 of Sargent and Williams [2005].

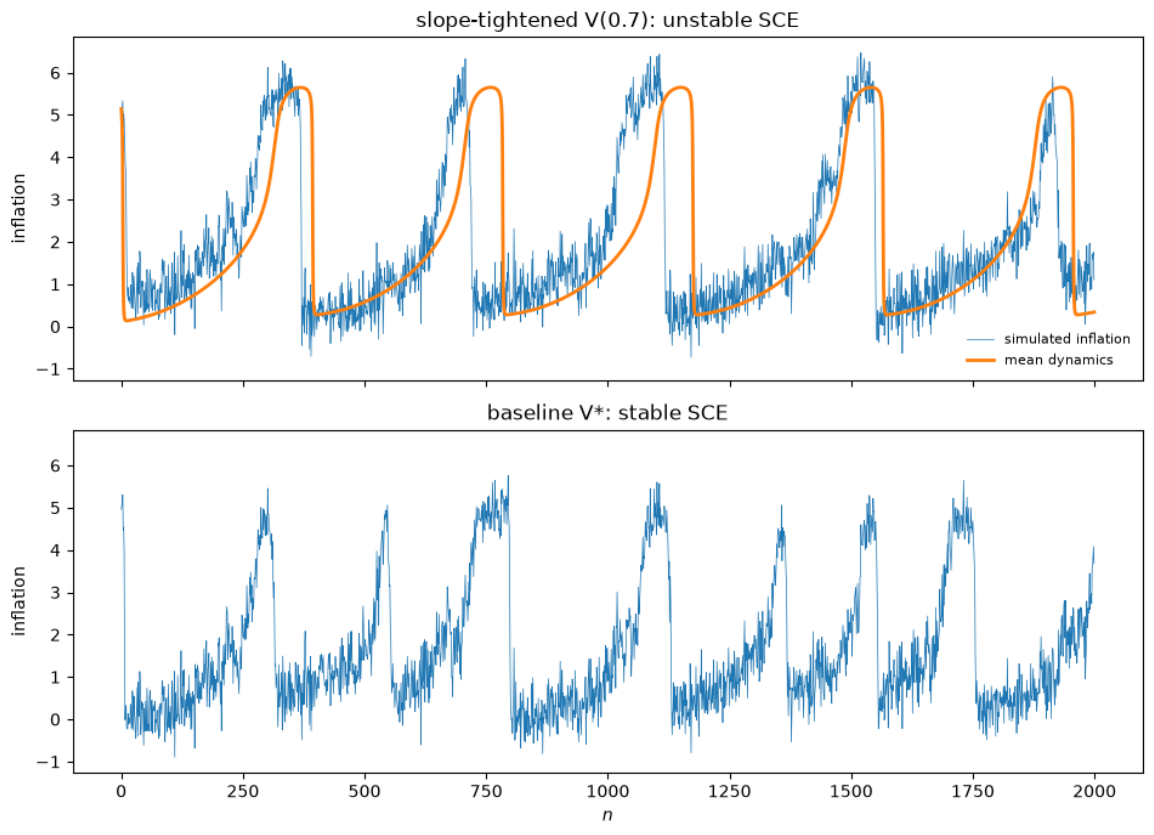
The difference comes from how the gain matrices respond to the changing moments of the data: in the Kalman filter P responds through the term $PM(\gamma)P$, while the RLS moment matrix R only follows $M(\gamma)$ with a lag.

Because the two algorithms share their rest point and its local stability, they agree asymptotically; their transient responses, which matter after every escape, differ.

Exercise 106.10.4

This exercise compares the learning cycle with recurrent escapes, as Sargent and Williams [2005] do in their Fig. 6.

1. With $\varepsilon = 0.05$, simulate 2,000 periods of the exact Kalman filter from the self-confirming equilibrium with the slope-tightened prior $V(0.7)$, and plot inflation together with the mean-dynamics path $x(t)$ computed in the lecture. Repeat the simulation with the baseline prior V^*, under which the self-confirming equilibrium is stable.
2. For $\varepsilon \in \{0.05, 0.02, 0.005\}$ and both priors, count disinflations (the 20-period average of inflation falling below 1, after having been above 4) per 100 units of εn, averaging over three seeds.
3. What distinguishes the learning cycle from recurrent escapes at these gains? What would distinguish them as $\varepsilon \to 0$?



Solution

Here are the two simulations.

```
priors = {"slope-tightened V(0.7): unstable SCE": V_tighten_slope(0.7, V_star),
          "baseline V*: stable SCE": V_star}

fig, axes = plt.subplots(2, 1, figsize=(9.5, 7), sharex=True, sharey=True)
for ax, (name, V_hat) in zip(axes, priors.items()):
    π = kalman_path(model, ε**2 * V_hat, model.σ, 2_000, 0)[0]
    ax.plot(π, lw=0.5, label='simulated inflation')
    ax.set_title(name)
    ax.set_ylabel('inflation')
keep = t_path <= 2_000
```

```
axes[0].plot(t_path[keep], x_path[keep], lw=2, label='mean dynamics')
axes[0].legend(frameon=False, loc='lower right', fontsize=8)
axes[1].set_xlabel('$n$')
plt.tight_layout()
plt.show()
```

Both simulated series show recurrent disinflations.

Under the slope-tightened prior the simulation tracks the deterministic cycle of the mean dynamics closely; under the baseline prior the disinflations are escapes, but they come about as often.

Now the counts.

```
def disinflations_per_100(V_hat, ε_, seeds=range(3)):
    "Disinflations per 100 units of εn under the exact Kalman filter."
    T = int(100 / ε_)
    counts = [escapes_and_returns(kalman_path(model, ε_**2 * V_hat, model.σ, T,␣
 ↪s)[0],
                                  lo=1.0, hi=4.0, k=20)[0] for s in seeds]
    return np.mean(counts)

print(f"{'ε':>6} | {'V(0.7): cycle':>14} | {'V*: escapes':>12}")
for ε_ in (0.05, 0.02, 0.005):
    print(f"{ε_:>6} | {disinflations_per_100(priors['slope-tightened V(0.7):␣
 ↪unstable SCE'], ε_):>14.1f}"
          f" | {disinflations_per_100(V_star, ε_):>12.1f}")
```

```
     ε |  V(0.7): cycle |  V*: escapes
  0.05 |            5.3 |          7.7
  0.02 |            6.0 |          7.0
 0.005 |            6.0 |          6.7
```

At every gain in the table, both priors produce disinflations at a similar rate per unit of εn, so the stable prior's escapes are not rare at these gains.

For the cycle that is expected: its period is proportional to $1/\varepsilon$, about 20 units of εn.

For the stable prior it reflects the small large-deviation rate $\bar{S} \approx 3 \times 10^{-4}$ that Sargent and Williams [2005] compute: the mean time to escape grows like $\exp(\bar{S}/\varepsilon)$ only once ε is small relative to $\bar{S}$, and until then it scales roughly like $1/\varepsilon$, just as the period of the cycle does.

The stable prior's rate per unit of εn does fall as ε shrinks, but slowly.

A simulated time series at these gains therefore cannot easily tell a learning cycle from recurrent escapes.

The distinction is asymptotic: as $\varepsilon \to 0$ the cycle's rate per unit of εn stays put, while the stable prior's escapes eventually become exponentially rare.

Exercise 106.10.5

This exercise varies the replication of Sims's example in *Sims's nonconvergence*.

1. The time series in Fig. 14 of Sargent and Williams [2005] appear to start away from the self-confirming equilibrium, at low inflation. Start Sims's specification and the $\sigma = \sigma_1$ variation at the Ramsey belief $(u, 0)$ instead, with P at its Riccati value, and report mean inflation over the first 1,000 and the last 2,000 of 10,000 periods for five seeds.
2. Starting from the self-confirming equilibrium, scale Sims's drift covariance to $V = \varepsilon^2 \times 0.01\, I$ for $\varepsilon \in \{0.2, 0.3, 0.4, 0.6\}$, keeping $\sigma = 0.1$. For each ε, count escapes and returns over ten seeds of 10,000 periods, as in the lecture. How does the history change as the drift grows?

Solution

First, the paths that start at the Ramsey belief.

```
y_ramsey = np.array([sims.u, 0.0])
for name, σ_govt in [("Sims, σ = 0.1", σ_sims), ("σ = σ1", sims.σ1)]:
    early, late = [], []
    for s in range(5):
        π = kalman_path(sims, V_sims, σ_govt, T_sims, s, y0=y_ramsey)[0]
        early.append(π[:1000].mean())
        late.append(π[-2000:].mean())
    print(f"{name:14s}: mean π, first 1,000 periods {np.round(early, 2)}")
    print(f"{'':14s}  mean π, last 2,000 periods  {np.round(late, 2)}")
```

```
Sims, σ = 0.1 : mean π, first 1,000 periods [0.87 0.62 0.58 0.55 0.51]
                mean π, last 2,000 periods  [0.5  0.65 0.69 0.8  0.62]
σ = σ1        : mean π, first 1,000 periods [4.45 4.77 3.16 2.73 3.08]
                mean π, last 2,000 periods  [5.96 6.09 5.45 5.66 5.74]
```

Started at low inflation, Sims's government never converges to the self-confirming equilibrium: inflation stays low throughout.

With $\sigma = \sigma_1$, inflation climbs toward the self-confirming value $u = 6$ during the first thousand periods and then stays near it, which is what Fig. 14 of Sargent and Williams [2005] shows.

Now the scan over the size of the drift.

```
for ε_ in (0.2, 0.3, 0.4, 0.6):
    counts = [escapes_and_returns(
                  kalman_path(sims, ε_**2 * V_sims, σ_sims, T_sims, s)[0], lo,␣
↪hi)[:2]
              for s in seeds]
    n_escape = sum(c[0] > 0 for c in counts)
    n_return = sum(c[1] > 0 for c in counts)
    print(f"ε = {ε_}: paths that escape {n_escape}/10, paths that return {n_return}
↪/10, "
          f"(escapes, returns) by seed {counts}")
```

```
ε = 0.2: paths that escape 0/10, paths that return 0/10, (escapes, returns) by␣
↪seed [(0, 0), (0, 0), (0, 0), (0, 0), (0, 0), (0, 0), (0, 0), (0, 0), (0, 0),␣
↪(0, 0)]
ε = 0.3: paths that escape 8/10, paths that return 5/10, (escapes, returns) by␣
↪seed [(1, 1), (0, 0), (2, 2), (2, 1), (1, 0), (1, 0), (1, 0), (2, 1), (0, 0),␣
↪(3, 3)]
ε = 0.4: paths that escape 10/10, paths that return 1/10, (escapes, returns) by␣
↪seed [(1, 0), (1, 0), (1, 0), (1, 0), (1, 0), (1, 0), (2, 1), (1, 0), (1, 0),␣
↪(1, 0)]
ε = 0.6: paths that escape 10/10, paths that return 0/10, (escapes, returns) by␣
↪seed [(1, 0), (1, 0), (1, 0), (1, 0), (1, 0), (1, 0), (1, 0), (1, 0), (1, 0),␣
↪(1, 0)]
```

The history changes with the size of the drift.

With the smallest drift no path escapes in 10,000 periods: the mean dynamics hold beliefs near the self-confirming equilibrium.

With somewhat larger drift, paths escape and some return, the beginnings of a sawtooth.

With larger drift still, almost every path escapes once and never returns, as in Sims's own case $\varepsilon = 1$ in the lecture.

The two kinds of history in the literature are two ends of a continuum indexed by the drift that the government entertains, relative to the noise it attributes to its regression.

Exercise 106.10.6

Exercise **??** asked an econometrician to estimate the gain of a constant-gain government from the data that its policy generates.

Here the government runs the exact Kalman filter of this lecture with prior $V = \varepsilon^2 V^*$, $\varepsilon = 0.02$, and $\sigma = \sigma_1$.

Simulate 5,000 periods from the self-confirming equilibrium.

Suppose an econometrician knows everything about the economy and the government except ε and the government's σ.

1. Show that the candidate pairs (ε, σ) and $(c\varepsilon, c\sigma)$ imply exactly the same history of targets x_n for any $c > 0$.
2. Compute the Gaussian log likelihood of inflation, $\ell(\varepsilon, \sigma) = -\sum_n (\pi_n - x_n(\varepsilon, \sigma))^2/(2\sigma_2^2)$ up to a constant, on a grid of (ε, σ), and plot its contours.
3. What do the data identify? Relate your answer to the two equivalent interpretations of Sims's example in *Sims's nonconvergence*.

Solution

The government's beliefs are a deterministic function of the data and of the filter's parameters, so the econometrician can rerun the filter for each candidate pair, as in Exercise **??**.

The function below does this for many candidates at once.

```
def reconstruct_targets(π, U, ε_vals, σ_vals):
    """
    Targets x_n implied by the exact Kalman filter with prior (ε² V*, σ),
    reconstructed from data (π, U), for each candidate pair (ε, σ).
    """
    K = len(ε_vals)
    γ = np.tile(γ_sce, (K, 1))
    P = np.array([solve_riccati(e**2 * V_star, M_sce, s)
                  for e, s in zip(ε_vals, σ_vals)])
    W = np.array([e**2 * V_star / s**2 for e, s in zip(ε_vals, σ_vals)])
    targets = np.empty((len(π), K))
    for n in range(len(π)):
        targets[n] = -γ[:, 0] * γ[:, 1] / (1 + γ[:, 1]**2)
        Φ = np.array([1.0, π[n]])
        PΦ = P @ Φ
        denom = 1 + PΦ @ Φ
        γ = γ + PΦ / denom[:, None] * (U[n] - γ @ Φ)[:, None]
        P = P - PΦ[:, :, None] * PΦ[:, None, :] / denom[:, None, None] + W
    return targets

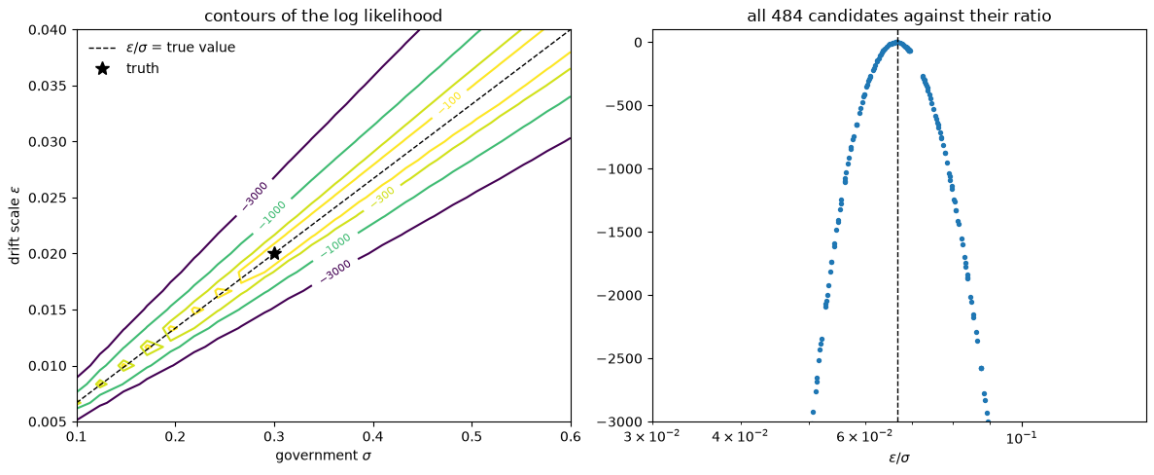
ε_true, σ_true = 0.02, model.σ1
π_data, U_data, x_data, _ = kalman_path(model, ε_true**2 * V_star, σ_true, 5_000,␣
↪1)

check = reconstruct_targets(π_data, U_data, [ε_true, 2 * ε_true, ε_true],
                            [σ_true, 2 * σ_true, σ_true / 2])
print(f"largest error at the true (ε, σ):          {np.max(np.abs(check[:, 0] - x_
↪data)):.1e}")
print(f"largest difference, (2ε, 2σ) vs (ε, σ):    {np.max(np.abs(check[:, 1] -␣
↪check[:, 0])):.1e}")
print(f"largest difference, (ε, σ/2) vs (ε, σ):    {np.max(np.abs(check[:, 2] -␣
↪check[:, 0])):.1e}")
```

```
largest error at the true (ε, σ):          0.0e+00
largest difference, (2ε, 2σ) vs (ε, σ):    0.0e+00
largest difference, (ε, σ/2) vs (ε, σ):    1.5e+00
```

Doubling both ε and σ leaves the targets unchanged, while changing σ alone does not.

The reason is that the filter (106.5) uses V and σ only through $\sigma^{-2}V = (\varepsilon/\sigma)^2 V^*$, and the Riccati value of P_0 depends on them in the same way.



Now the likelihood on a grid.

```
ε_grid = np.linspace(0.005, 0.04, 22)
σ_grid = np.linspace(0.1, 0.6, 22)
EE, SS = np.meshgrid(ε_grid, σ_grid)
targets = reconstruct_targets(π_data, U_data, EE.ravel(), SS.ravel())
loglik = -np.sum((π_data[:, None] - targets)**2, axis=0) / (2 * model.σ2**2)
loglik = (loglik - loglik.max()).reshape(EE.shape)

fig, axes = plt.subplots(1, 2, figsize=(12, 5))
cs = axes[0].contour(SS, EE, loglik, levels=[-3000, -1000, -300, -100])
axes[0].clabel(cs, fontsize=8)
s_line = np.linspace(0.1, 0.6, 2)
axes[0].plot(s_line, (ε_true / σ_true) * s_line, 'k--', lw=1,
             label=r'$\varepsilon / \sigma$ = true value')
axes[0].plot(σ_true, ε_true, 'k*', ms=10, label='truth')
axes[0].set_xlabel(r'government $\sigma$')
axes[0].set_ylabel(r'drift scale $\varepsilon$')
axes[0].set_title('contours of the log likelihood')
axes[0].legend(frameon=False, loc='upper left')

axes[1].scatter((EE / SS).ravel(), loglik.ravel(), s=8)
axes[1].axvline(ε_true / σ_true, color='k', ls='--', lw=1)
axes[1].set_xscale('log')
axes[1].set_xlim(0.03, 0.15)
axes[1].set_ylim(-3000, 100)
axes[1].set_xlabel(r'$\varepsilon / \sigma$')
axes[1].set_title(f'all {loglik.size} candidates against their ratio')
plt.tight_layout()
plt.show()

ratio_hat = (EE.ravel() / SS.ravel())[np.argmax(loglik)]
print(f"true ε/σ = {ε_true / σ_true:.4f}; ratio at the grid maximum = {ratio_hat:.
↪4f}")
```

```
true ε/σ = 0.0667; ratio at the grid maximum = 0.0664
```

The contours of the likelihood are rays through the origin, and plotted against ε/σ the log likelihoods of all the candidates fall on a single curve: the data pin down ε/σ, the government's effective gain, but say nothing about ε and σ separately.

That is the econometric counterpart of the two equivalent interpretations of Sims's example: "too much drift" and "too little error variance" are observationally equivalent descriptions of the same learning rule.

Separating them would require evidence on how *uncertain* the government says it is, for example its predictive variance $\sigma^2(1 + \Phi_n^\top P_n \Phi_n)$, and not only on what it does or forecasts.

What the data do identify, they keep identifying as the sample grows, because the filter's gain never vanishes and so keeps shaping beliefs (*The econometricians did return the compliment*).

107.1 Overview

This lecture follows chapter 9 of Sargent [1999], "Econometric Policy Evaluation".

The preceding lectures built the adaptive governments of the book's chapter 8 and studied them by simulation (*Adaptive Learning and Escape Dynamics*, *Escaping Nash Inflation*, *Priors, Escapes, and Learning Cycles*).

Chapter 9 takes the same models to U.S. data, estimating them by maximum likelihood under both the classical and the Keynesian identification schemes, following Chung [1990].

It is the book's only structural confrontation of the vindication story of *The Rise and Fall of U.S. Inflation* with data.

The question is counterfactual: what would a policy adviser of the 1960s and 1970s have recommended if he had fit a distributed-lag Phillips curve, discounted old data, and fed the estimates into the Phelps problem of *Adaptive Expectations and the Phelps Problem*?

The estimated model answers directly, because in it the fitted value of inflation *is* the government's recommendation.

Once the gain and the discount factor are fixed, the likelihood has no free parameters describing beliefs: we compute the government's beliefs and recommendations from the data, as the government itself would have.

We reproduce the book's main findings:

- both models fit inflation badly, and the classical model fits much worse;
- the misses are systematic, with recommended inflation below actual inflation through the 1970s, which is the sense in which "the pattern of misses from the estimated models favors vindication";
- the Keynesian government's estimated Phillips curve satisfied the induction hypothesis by the mid-1970s, and its plans called for low inflation years before Volcker arrived;
- the classical government recommended low inflation all along, which is why its recommendations "would have been even more timely."

The book does not report its lag lengths or how it converted its data to quarterly frequency, and we say where these choices matter.

Let's start with some imports.

```
import matplotlib.pyplot as plt
import numpy as np
import pandas as pd
from scipy.linalg import solve_discrete_are
from scipy.optimize import minimize
from scipy.signal import lfilter
from scipy.stats import chi2
```

107.2 The model

The model combines the actual Phillips curve of *Self-Confirming Equilibria* with the adaptive government of *Adaptive Learning and Escape Dynamics*; the notation is that of *A note on notation*.

107.2.1 The actual Phillips curve

With U_t unemployment, y_t inflation and x_t the public's expectation of inflation, the economy obeys a natural-rate Phillips curve with a geometric distributed lag in surprise inflation $v_{2t} = y_t - x_t$ and a serially correlated disturbance:

$$U_t = U^* - \frac{\theta}{1-\rho_2 L}\, v_{2t} + \frac{1}{1-\rho_1 L}\, v_{1t}, \tag{107.1}$$

where L is the lag operator, $|\rho_1| < 1$ and $|\rho_2| < 1$.

Multiplying through by $(1-\rho_1 L)(1-\rho_2 L)$ gives the form that the book numbers (48):

$$U_t = U^*(1-\rho_1)(1-\rho_2) + (\rho_1+\rho_2)U_{t-1} - \rho_1\rho_2 U_{t-2} + (1-\rho_2 L)v_{1t} - \theta(1-\rho_1 L)v_{2t}. \tag{107.2}$$

The shock vector $v_t = (v_{1t}, v_{2t})^\top$ is Gaussian white noise with an unrestricted covariance matrix V_v.

Chapters 7 and 8 of the book set $\rho_1 = \rho_2 = 0$ and made V_v diagonal to make theoretical points; chapter 9 frees both.

107.2.2 The government

Let $X_{t-1} = \begin{bmatrix} U_{t-1} & \cdots & U_{t-m_U} & y_{t-1} & \cdots & y_{t-m_y} & 1 \end{bmatrix}^\top$ collect information dated $t-1$ and earlier.

As in *Adaptive Expectations and the Phelps Problem*, the government fits one of two reduced-form Phillips curves, which differ only in their direction of fit:

$$\text{classical:} \quad U_t = \gamma^\top X_{C,t} + \varepsilon_{C,t}, \qquad \text{Keynesian:} \quad y_t = \beta^\top X_{K,t} + \varepsilon_{K,t}, \tag{107.3}$$

where $X_{C,t} = \begin{bmatrix} y_t & X_{t-1}^\top \end{bmatrix}^\top$ and $X_{K,t} = \begin{bmatrix} U_t & X_{t-1}^\top \end{bmatrix}^\top$.

It re-estimates its curve every period by constant-gain recursive least squares, which for the classical scheme is

$$\begin{aligned} \gamma_t &= \gamma_{t-1} + g\, R_{XC,t}^{-1} X_{C,t} \left(U_t - \gamma_{t-1}^\top X_{C,t} \right), \\ R_{XC,t} &= R_{XC,t-1} + g \left(X_{C,t} X_{C,t}^\top - R_{XC,t-1} \right), \end{aligned} \tag{107.4}$$

with a constant gain $g = 1 - \lambda$; the Keynesian scheme updates β_t and $R_{XK,t}$ in the same way.

A Keynesian government converts its estimate into the classical form by inverting the Phillips curve: if β_1 is the coefficient on U_t and β_{-1} collects the rest, then $\gamma(\beta) = \begin{bmatrix} \beta_1^{-1} & -\beta_{-1}^\top / \beta_1 \end{bmatrix}^\top$.

Each period the government acts as if its current estimate will govern the Phillips curve forever and sets inflation by solving the Phelps problem, minimizing $\mathbb{E} \sum_t \delta^t (U_t^2 + y_t^2)$ subject to its estimated curve, which yields the rule

$$y_t = h(\gamma_{t-1}) X_{t-1} + v_{2t}, \tag{107.5}$$

where γ_{t-1} is the classical estimate or $\gamma(\beta_{t-1})$, and v_{2t} is a control error.

Following Sims [1988] and Chung [1990], the public knows the rule, so $x_t = h(\gamma_{t-1}) X_{t-1}$, and the control error v_{2t} is also the inflation surprise in (107.1).

107.3 The likelihood function

To simulate the model, we would draw shocks $\{v_t\}$ and compute histories of (y_t, U_t) and of the government's beliefs.

To estimate it, we reverse the procedure: starting from initial beliefs, we use the data $\{y_t, U_t\}$ to solve for the shocks that would have produced them,

$$\begin{aligned} v_{2t} &= y_t - h(\gamma_{t-1}) X_{t-1}, \\ v_{1t} - \theta v_{2t} &= U_t - (\rho_1 + \rho_2) U_{t-1} + \rho_1 \rho_2 U_{t-2} + \rho_2 v_{1,t-1} - \rho_1 \theta v_{2,t-1} - U^* (1-\rho_1)(1-\rho_2), \end{aligned} \tag{107.6}$$

while updating γ_t (or β_t) by (107.4); these are the book's equations (105).

Given the past, the map from v_t to (U_t, y_t) is triangular with unit diagonal, so its Jacobian is one and the Gaussian log likelihood of a sample of length T is

$$\log L = -T \log 2\pi - \frac{T}{2} \log \det V_v - \frac{1}{2} \sum_{t=1}^{T} v_t^\top V_v^{-1} v_t. \tag{107.7}$$

As the book suggests, we concentrate out V_v: its maximizer is $\hat{V}_v = T^{-1} \sum_t v_t v_t^\top$, and then $\log L = -T \log 2\pi - \frac{T}{2} \log \det \hat{V}_v - T$.

> **Note**
>
> The book's appendix to chapter 9 writes the log of a sum of densities where it means a sum of log densities, and gives the constant as $-\frac{T}{2}\log 2\pi$, which is right for a scalar observation; a bivariate density has $-T\log 2\pi$.
>
> Neither misprint affects the estimates, but the second shifts the level of $\log L$.

The book estimates $(\theta, U^*, \rho_1, \rho_2, V_v)$, and it fixes the discount factor at $\delta = .999$ and the forgetting factor at $\lambda = .985$, so the gain is $g = .015$.

Notice what is *not* on the list: nothing describes beliefs.

With λ, δ and the initial beliefs fixed, the government's beliefs γ_t, its recommendations $h(\gamma_{t-1})X_{t-1}$ and therefore its misses v_{2t} are computed from the data alone, whatever the values of the parameters being estimated.

This has two consequences.

1. Because $\det \hat{V}_v$ equals the mean square of v_{2t} times the mean square of the part of v_{1t} not explained by v_{2t}, the parameters $(\theta, U^*, \rho_1, \rho_2)$ are estimated from the unemployment equation, taking the government's misses as given.
2. The comparison between the two identification schemes is mostly a comparison of the size of their misses, that is, of how far the recommendations were from what actually happened.

This is a cross-equation restriction of the kind familiar from rational expectations econometrics: the government's rule is pinned down by its econometrics and the Phelps problem, not left free.

107.4 Data

Chapter 9 uses the measures of chapter 1: the consumer price index (all items) and the unemployment rate of white men aged 20 and over, the series plotted in *The Rise and Fall of U.S. Inflation*.

Although chapter 1 plots monthly data, chapter 9's estimates appear to be quarterly:

- the sample period is dated in quarters (it is printed as "1995I–1997I", evidently a misprint for 1955I–1997I, since the figures begin in 1955);
- Figure 9.2b refers to "the first quarter of 1960";
- quarterly data reproduce the book's estimates and figures closely, while monthly data do not, for a reason we explain *below*.

We therefore convert the monthly series to quarterly by taking the last month of each quarter, and measure inflation as the annualized percentage change in the CPI.

Because we sample one month per quarter, we use the seasonally adjusted index rather than the unadjusted one plotted in *The Rise and Fall of U.S. Inflation*.

```
def read_fred(series_id):
    "Read a monthly series from FRED."
    url = f'https://fred.stlouisfed.org/graph/fredgraph.csv?id={series_id}'
    s = pd.read_csv(url, index_col=0, parse_dates=True)[series_id]
    return pd.to_numeric(s, errors='coerce')

cpi_monthly = read_fred('CPIAUCSL')      # CPI, all items, seasonally adjusted
u_monthly = read_fred('LNS14000028')     # unemployment rate, white men 20+
```

(continues on next page)

(continued from previous page)

```
def make_data(how='last', end='1997-03'):
    "Inflation (annualized percent) and unemployment at quarterly or monthly␣
 ↪frequency."
    if how == 'monthly':
        cpi, u, scale = cpi_monthly, u_monthly, 1200
    elif how == 'last':                          # last month of each quarter
        cpi, u, scale = (cpi_monthly.resample('QS').last(),
                         u_monthly.resample('QS').last(), 400)
    else:                                        # quarterly averages
        cpi, u, scale = (cpi_monthly.resample('QS').mean(),
                         u_monthly.resample('QS').mean(), 400)
    y = scale * np.log(cpi).diff()
    data = pd.concat([y.rename('y'), u.rename('U')], axis=1).dropna()
    return data.loc[:end]

data = make_data()
print(f"{data.index[0]:%Y-%m} to {data.index[-1]:%Y-%m}: {len(data)} quarters")
```

```
1954-01 to 1997-01: 173 quarters
```

The unemployment series begins in 1954, and the government's regression needs a few years of data before its estimates mean anything.

So we treat 1954–1957 as a training sample for the government's beliefs and evaluate the likelihood from 1958Q1 through 1997Q1.

The book does not report its lag lengths m_U and m_y; the simulations of its chapter 8 used two lags of each.

We use one lag of unemployment and two of inflation, which among the lag lengths we tried puts our estimates closest to the book's; the robustness table *below* shows what changes with two lags of each.

107.5 Beliefs and recommendations

The Phelps problem is the discounted LQ problem of *Adaptive Learning and Escape Dynamics*, generalized to any number of lags.

Write the believed Phillips curve as $U_t = \gamma_0 y_t + c^\top s_t$ with state $s_t = X_{t-1}$, so that the per-period loss is $s_t^\top c c^\top s_t + (\gamma_0^2 + 1) y_t^2 + 2\gamma_0 y_t c^\top s_t$.

We use the same solver as *Adaptive Learning and Escape Dynamics*: in the discounted problem only A and B are multiplied by $\sqrt{\delta}$, and the cross term N is passed to the Riccati solver unscaled.

```
def lq_matrices(y, mU, my):
    """
    Believed law of motion s_{t+1} = A s_t + B y_t for the state
    s_t = [U_{t-1},...,U_{t-mU}, y_{t-1},...,y_{t-my}, 1]
    when the believed Phillips curve is U_t = y[0] y_t + y[1:] @ s_t.
    """
    y0, c = y[0], y[1:]
    n = mU + my + 1
    A, B = np.zeros((n, n)), np.zeros((n, 1))
    if mU > 0:
        A[0, :], B[0, 0] = c, y0                 # U_t
        for j in range(1, mU):
            A[j, j - 1] = 1.0
```

(continues on next page)

(continued from previous page)

```
    if my > 0:
        B[mU, 0] = 1.0                              # y_t
        for j in range(mU + 1, mU + my):
            A[j, j - 1] = 1.0
    A[-1, -1] = 1.0                                 # constant
    return A, B

def phelps_h(γ, δ, mU, my):
    "Phelps rule y_t = h @ s_t for the believed Phillips curve γ."
    γ0, c = γ[0], γ[1:]
    A, B = lq_matrices(γ, mU, my)
    R = np.outer(c, c)
    Q = np.array([[γ0**2 + 1.0]])
    N = (γ0 * c).reshape(1, -1)
    Ad, Bd = np.sqrt(δ) * A, np.sqrt(δ) * B
    P = solve_discrete_are(Ad, Bd, R, Q, s=N.T)
    F = np.linalg.solve(Q + Bd.T @ P @ Bd, Bd.T @ P @ Ad + N)
    return -F.ravel()

def γ_of_β(β):
    "Invert a Keynesian Phillips curve into classical form."
    return np.concatenate([[1 / β[0]], -β[1:] / β[0]])
```

With a diffuse initial condition, $R_{XC,-1} = 0$, the recursion (107.4) delivers *discounted least squares*: γ_t minimizes $\sum_{s \le t} \lambda^{t-s}(U_s - \gamma^\top X_{C,s})^2$, so an observation k quarters old gets weight λ^k.

The function below computes the beliefs this way from the first quarter of data, and rebuilds, quarter by quarter, the recommendation $h(\gamma_{t-1})X_{t-1}$ that the government would have made.

```
def government(data, scheme, λ=0.985, δ=0.999, mU=1, my=2, n_init=8):
    """
    Beliefs and recommendations of a government that fits the classical ('C')
    or Keynesian ('K') Phillips curve by discounted least squares and solves
    the Phelps problem, reconstructed from data on (y, U).
    """

```

107.6 Estimates

The function `loglik` evaluates (107.7) with V_v concentrated out.

It uses data from two quarters before the likelihood sample to supply U_{t-1} and U_{t-2}, and, as the book does, it sets the pre-sample shocks to zero.

```
def residuals(params, U, v2):
    "Solve the actual Phillips curve for v_1 given the misses v_2."
    θ, U_star, ρ1, ρ2 = params
    U0, U1, U2 = U[2:], U[1:-1], U[:-2]
    v2 = v2[2:]
    v2_lag = np.r_[0.0, v2[:-1]]
    rhs = (θ * (v2 - ρ1 * v2_lag) + U0 - (ρ1 + ρ2) * U1 + ρ1 * ρ2 * U2
           - U_star * (1 - ρ1) * (1 - ρ2))
    v1 = lfilter([1.0], [1.0, -ρ2], rhs)           # v1_t = ρ2 v1_{t-1} + rhs_t
    return v1, v2

def loglik(params, U, v2):
    "Gaussian log likelihood with V_v concentrated out."
    v = np.vstack(residuals(params, U, v2))
    T = v.shape[1]
    V = v @ v.T / T
    return -T * np.log(2 * np.pi) - T / 2 * np.linalg.slogdet(V)[1] - T, V

	ρ2	0.667	0.720	0.071	0.745
	log L	-333.000	-457.271	NaN	NaN

The book's estimates of θ and ρ_1 lie within a fraction of a standard error of ours under both schemes; its values of U^* and ρ_2 are within about one and a half of our standard errors.

The impact effect θ of an inflation surprise is small, between a tenth and a fifth of a percentage point of unemployment per percentage point of annualized quarterly inflation.

The Phillips-curve disturbance is persistent (ρ_1 above .9), and the effect of a surprise decays faster (ρ_2 near .7).

Two parameters are weakly determined: the estimate of ρ_2 moves noticeably if the likelihood sample starts two quarters later, after the 1958 recession,

```
for s, label in [('C', 'classical'), ('K', 'Keynesian')]:
    p = estimate(gov[s], start='1958-07')['params']
    print(f"{label:10s} from 1958Q3: θ = {p[0]:.3f}, U* = {p[1]:.2f}, "
          f"ρ1 = {p[2]:.3f}, ρ2 = {p[3]:.3f}")
```

```
classical  from 1958Q3: θ = 0.114, U* = 0.34, ρ1 = 0.924, ρ2 = 0.519
Keynesian  from 1958Q3: θ = 0.138, U* = 2.60, ρ1 = 0.938, ρ2 = 0.612
```

and the natural rate U^* has a large standard error.

The Keynesian scheme has a much higher likelihood.

Our gap between the two schemes is smaller than the book's; the levels of $\log L$ are not comparable, because of the misprinted constant and different data vintages, but the sign of the gap is the same.

The residuals show where the gap comes from, and why U^* is hard to pin down:

```
for s, label in [('C', 'classical'), ('K', 'Keynesian')]:
    v1, v2 = residuals(est[s]['params'], est[s]['U'], est[s]['v2'])
    rms = lambda v: np.sqrt(np.mean(v**2))
    print(f"{label:10s}: misses v2: root mean square {rms(v2):.2f}, mean {v2.mean():.
 ↪2f};  "
          f"v1: root mean square {rms(v1):.2f}, mean {v1.mean():.2f};  "
          f"corr(v1, v2) = {np.corrcoef(v1, v2)[0, 1]:.2f}")
print(f"average unemployment over the sample: {est['C']['U'][2:].mean():.2f}")
```

```
classical : misses v2: root mean square 6.82, mean 6.08;  v1: root mean square 0.
 ↪69, mean 0.52;  corr(v1, v2) = 0.58
Keynesian : misses v2: root mean square 3.11, mean 1.55;  v1: root mean square 0.
 ↪51, mean 0.19;  corr(v1, v2) = 0.68
average unemployment over the sample: 4.44
```

The classical government's misses are more than twice as large, in root mean square, as the Keynesian government's.

Both sets of misses have a positive mean, because the recommendations lay below actual inflation for long stretches.

Because v_1 is correlated with v_2, it can have a positive mean too, and a low U^* combined with a positive mean of v_1 fits nearly as well as a higher U^*; that is presumably why both the book and we find values of U^* below the average unemployment rate.

107.7 Recommendations and misses

The fitted value of inflation in this model is not a forecast made by an outside econometrician: it is the inflation rate that the government's own procedure recommended, given the data it had seen.

The next two figures reproduce the book's Figures 9.1 and 9.2a: each shows the recommendation against actual inflation, and the sum of the coefficients on inflation in the government's estimated Phillips curve.

The induction hypothesis (*Testing the natural-rate hypothesis*) holds when that sum is 0 in the classical regression and 1 in the Keynesian regression.

```
def plot_government(g, ref, title, sum_label, start='1958'):
    f = g['frame'].loc[start:]
    fig, axes = plt.subplots(2, 1, figsize=(9, 7), sharex=True)
    axes[0].plot(f.index, f['y'], 'C0--', lw=1, label='actual')
    axes[0].plot(f.index, f['yhat'], 'C1', lw=1.8, label='recommended')
    axes[0].axhline(0, color='k', lw=0.5)
    axes[0].set_ylabel('inflation (percent)')
    axes[0].legend(frameon=False)
    axes[1].plot(f.index, f['sum_y'], 'C2', lw=1.5)
    axes[1].axhline(ref, color='k', ls=':', lw=1, label='induction hypothesis')
    axes[1].set_ylabel(sum_label)
```

(continues on next page)

(continued from previous page)

```

    axes[0].set_title(title)
    plt.tight_layout()
    plt.show()
```

First the classical government.

```
plot_government(gov['C'], 0, 'Classical identification',
                'sum on current and lagged $y$')
```

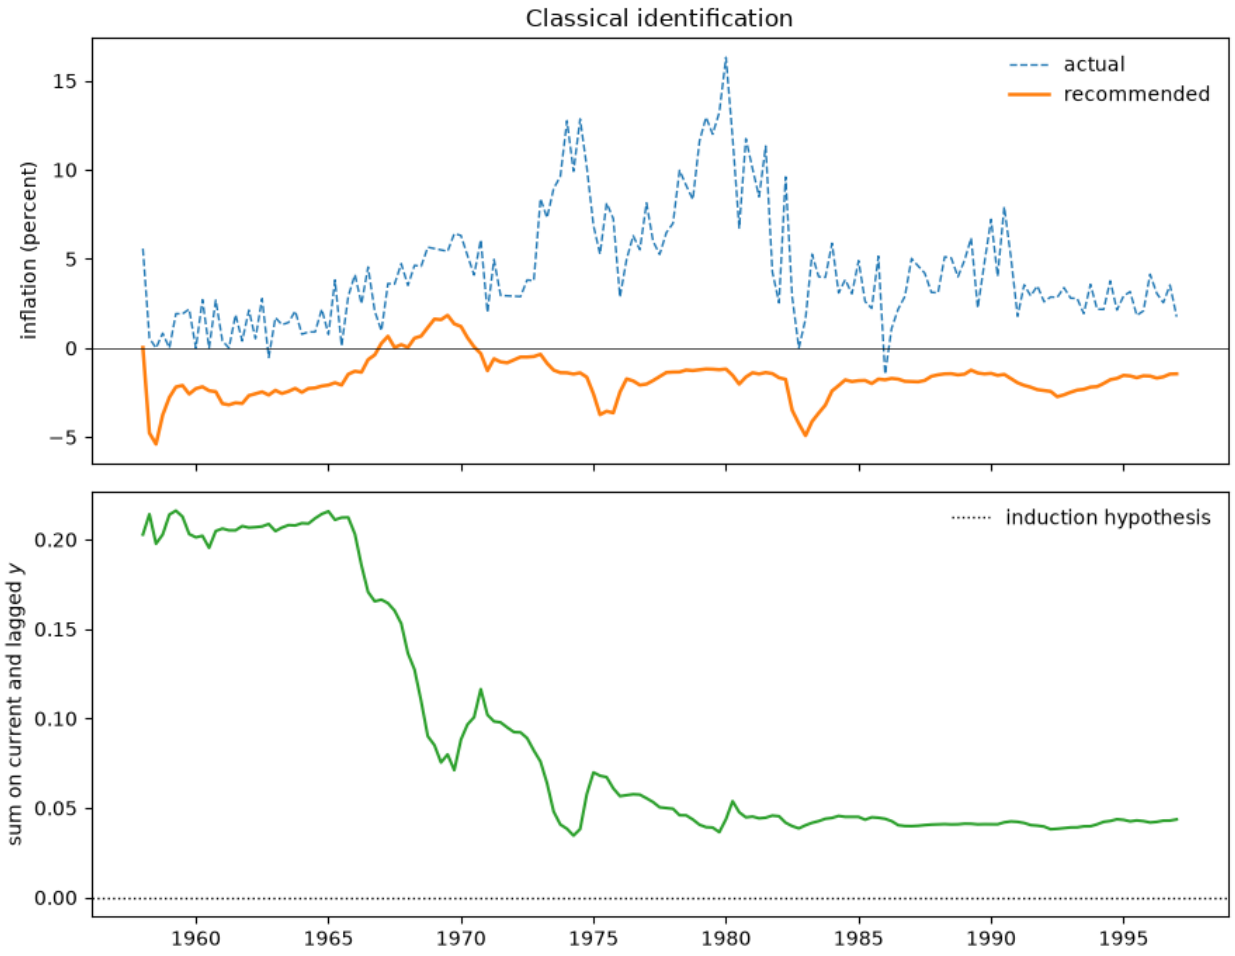

Fig. 107.1: Classical government: recommended and actual inflation, and the sum of coefficients on current and lagged inflation (book Figure 9.1)

The classical government recommends inflation below zero almost throughout, rising above it only briefly around 1970.

As the book says, “the classical model fails even to match the acceleration in inflation leading up to 1970.”

Its regression of unemployment on current and lagged inflation finds coefficients on inflation whose sum is small, and close to zero from the early 1970s on.

Such a government sees almost no exploitable tradeoff, so the Phelps problem tells it to aim for low inflation.

```
plot_government(gov['K'], 1, 'Keynesian identification', 'sum on lagged $y$')
```

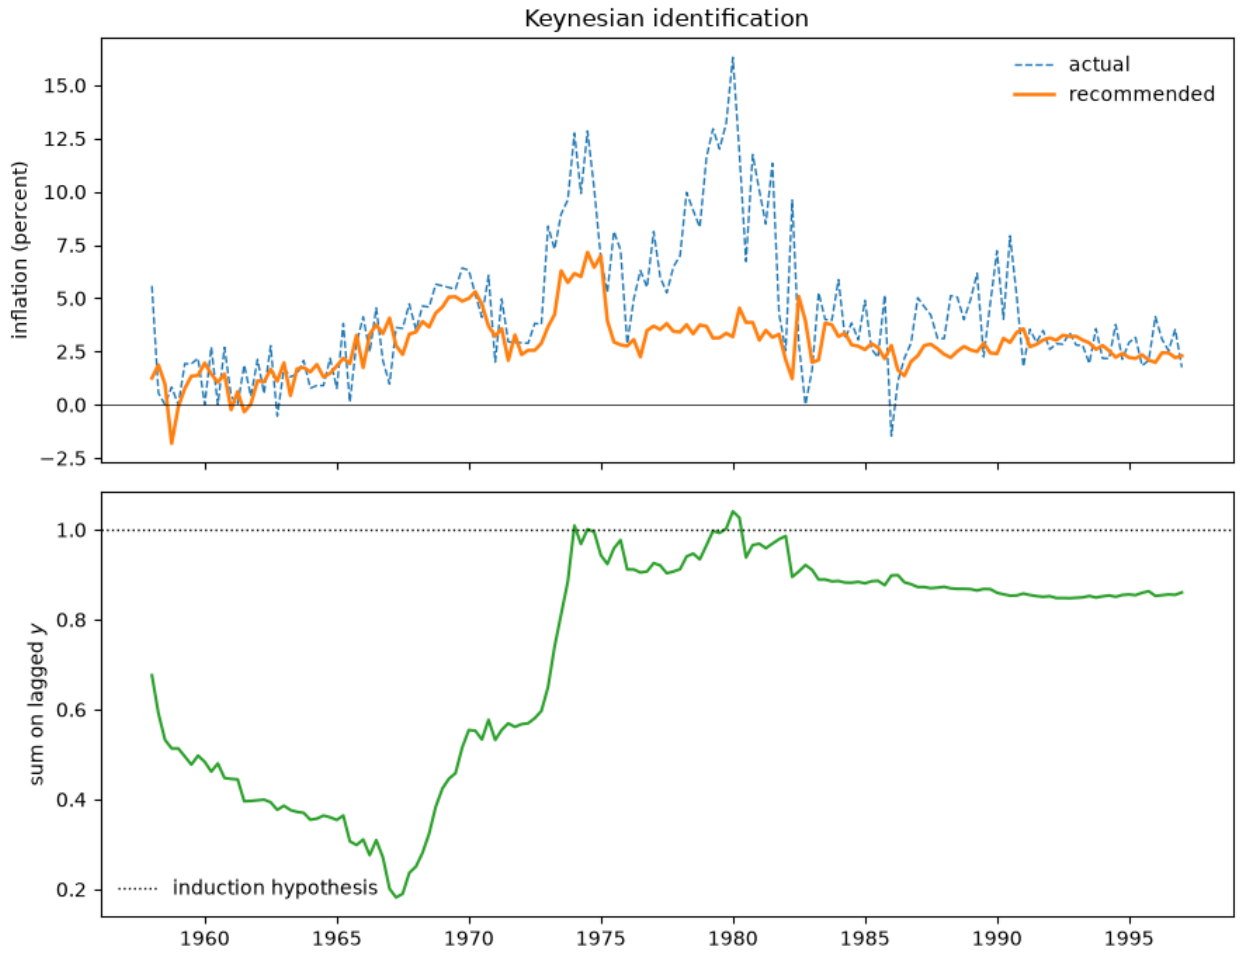

Fig. 107.2: Keynesian government: recommended and actual inflation, and the sum of coefficients on lagged inflation (book Figure 9.2a)

The Keynesian recommendations reflect the inflation pattern better, partly matching the acceleration of the late 1960s.

From the early 1970s, however, they lie well below actual inflation, and they stay below it for most of the next two decades.

The lower panel shows why.

The sum of the weights on lagged inflation climbs from well below one in the 1960s to about one by the mid-1970s and stays near it.

By then the Keynesian government had learned the Solow–Tobin version of the natural-rate hypothesis, and the Phelps problem told it to bring inflation down.

107.7.1 The induction hypothesis emerges

The book's Figure 9.2b shows how the data gradually removed the government's doubt.

We approximate the government's uncertainty about β_t by $\hat{\sigma}_t^2 \left(\sum_{s \le t} \lambda^{t-s} X_{K,s} X_{K,s}^\top\right)^{-1}$, with $\hat{\sigma}_t^2$ the discounted residual variance.

This is the covariance matrix that a Kalman filter implementing constant-gain least squares would attach to its estimate.

The figure plots the 95 and 99 percent confidence ellipses for the sum of the weights on lagged inflation and the constant in the first quarter of 1960, 1965, …, 1985.

```
def ellipse(center, cov, level, n=200):
    "Points on a confidence ellipse for a bivariate normal estimate."
    w, Q = np.linalg.eigh(cov)
    a = np.linspace(0, 2 * np.pi, n)
    circle = np.vstack([np.cos(a), np.sin(a)])
    return center[:, None] + Q @ (np.sqrt(chi2.ppf(level, 2) * w)[:, None] * circle)

g = gov['K']
k = g['coef'].shape[1]
D = np.zeros((2, k))
D[0, 1 + g['mU']:1 + g['mU'] + g['my']] = 1.0      # sum of weights on lagged y
D[1, -1] = 1.0                                      # constant

fig, axes = plt.subplots(2, 3, figsize=(10, 6.5), sharex=True, sharey=True)
for ax, year in zip(axes.ravel(), range(1960, 1990, 5)):
    t = g['frame'].index.get_loc(pd.Timestamp(f'{year}-01-01'))
    center = D @ g['coef'][t]
    cov = g['σ2'][t] * D @ np.linalg.inv(g['S'][t]) @ D.T
    for level, ls in [(0.95, '-'), (0.99, '--')]:
        e = ellipse(center, cov, level)
        ax.plot(e[0], e[1], 'C0', ls=ls, lw=1)
    ax.plot(*center, 'C0o', ms=3)
    ax.axvline(1, color='k', ls=':', lw=1)
    ax.set_title(f'{year}Q1')
for ax in axes[1]:
    ax.set_xlabel('sum on lagged $y$')
for ax in axes[:, 0]:
    ax.set_ylabel('constant')
plt.tight_layout()
plt.show()
```

The pattern resembles the book's figure and the confidence ellipses from the simulations of its chapter 8.

In the 1960s the ellipses lie away from the induction hypothesis (the dotted line) but are large enough to leave room for doubt.

During the 1970s the centers move onto the induction hypothesis and stay there, and the ellipses become smaller than those of the early 1960s, though not as small as the book's.

In the book's words, the point estimates move, "causing the centers of the ellipsoids to shift and doubt to dwindle."

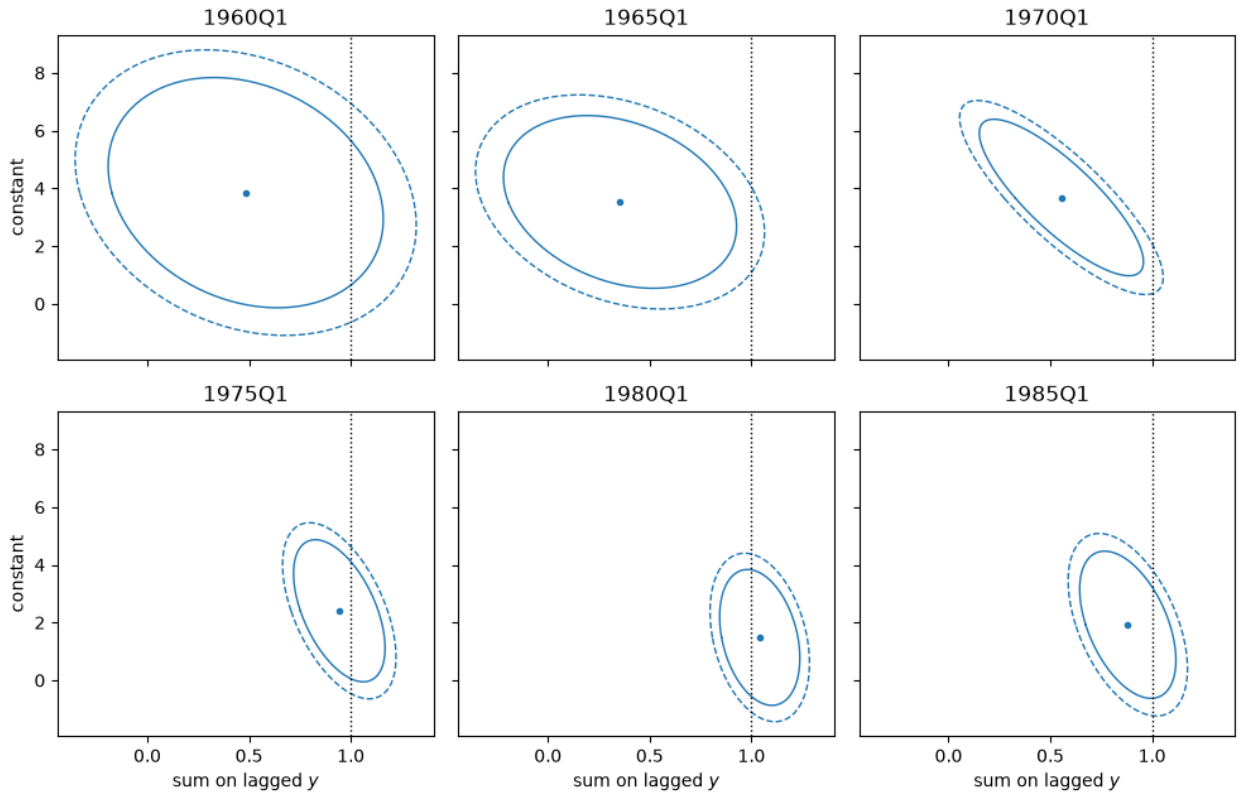

Fig. 107.3: Keynesian government: 95% and 99% confidence ellipses for the sum of weights on lagged inflation and the constant (book Figure 9.2b)

107.8 Misses favor vindication

Judged by period-by-period fit, the adaptive models are disappointing: there is a long string of under-predictions of inflation during the 1970s, even for the Keynesian model.

Sargent reads the misses differently:

> But such misses do not necessarily fail to vindicate econometric policy evaluation. To the contrary, the pattern of misses from the estimated models favors vindication. Remembering that the fitted value from the adaptive model is the government's recommendation as time passes extracts vindication from the econometric shortcomings.

The misses say that the recommendations were systematically *lower* than the inflation that actually occurred: the government's procedure was telling it to disinflate while actual policy did not.

The one-step recommendation $h(\gamma_{t-1})X_{t-1}$ mixes two things: where the government wanted inflation to go, and how fast it planned to get there from the inflation it inherited.

To separate them, we compute the steady state of the government's plan, the long-run inflation rate toward which the Phelps rule would steer the economy if the current beliefs were correct.

```
def planned_long_run(γ, δ, mU, my):
    "Steady-state inflation of the government's plan under its own beliefs."
    h = phelps_h(γ, δ, mU, my)
    A, B = lq_matrices(γ, mU, my)
    M = A + B @ h[None, :]                          # believed closed loop
    n = M.shape[0] - 1                              # last state is the constant
    s_bar = np.linalg.solve(np.eye(n) - M[:n, :n], M[:n, -1])
    return h @ np.r_[s_bar, 1.0]

def long_run_path(g):
    path = np.full(len(g['frame']), np.nan)
    for t in range(1, len(path)):
        β = g['coef'][t - 1]
        if not np.isnan(β).any():
            γ = β if g['scheme'] == 'C' else γ_of_β(β)
            path[t] = planned_long_run(γ, g['δ'], g['mU'], g['my'])
    return pd.Series(path, index=g['frame'].index)

for s in 'CK':
    gov[s]['frame']['long_run'] = long_run_path(gov[s])
```

The next figure puts the Keynesian government's plan next to its one-step recommendation, the classical recommendation, and actual inflation.

```
fK, fC = gov['K']['frame'].loc['1958':], gov['C']['frame'].loc['1958':]
fig, ax = plt.subplots(figsize=(9, 4.8))
ax.plot(fK.index, fK['y'], 'C0--', lw=1, label='actual inflation')
ax.plot(fK.index, fK['yhat'], 'C1', lw=1.5, label='Keynesian recommendation')
ax.plot(fK.index, fK['long_run'], 'C3', lw=2, label='Keynesian planned long-run␣
↪inflation')
ax.plot(fC.index, fC['yhat'], 'C2', lw=1, alpha=0.8, label='classical recommendation')
ax.axvline(pd.Timestamp('1979-08-01'), color='k', ls=':', lw=1)
ax.text(pd.Timestamp('1980-06-01'), -4, 'Volcker', fontsize=9)
ax.axhline(0, color='k', lw=0.5)
ax.set_ylabel('percent')
ax.legend(frameon=False, fontsize=9, loc='upper left')
plt.show()
```

Keynesian long-run plan (median)     2.71
```

From 1973 through 1990 the recommendations were mostly below actual inflation:

```
for s, label in [('C', 'classical'), ('K', 'Keynesian')]:
    m = gov[s]['frame']['miss'].loc['1973':'1990']
    print(f"{label:10s}: mean miss 1973-1990 = {m.mean():5.2f}, "
          f"share of quarters with recommendation below actual = {(m > 0).mean():.0%}
↪")
```

```
classical : mean miss 1973-1990 =  8.26, share of quarters with recommendation␣
↪below actual = 100%
Keynesian : mean miss 1973-1990 =  3.04, share of quarters with recommendation␣
↪below actual = 86%
```

The computation bears out the book's interpretation:

> The econometric estimates tell us that unreconstructed Keynesian Phillips curve fitters would have detected the adverse shift in the empirical Phillips curve and through the induction hypothesis combined with the Phelps problem would have recommended lowering the inflation rate. Those quantitative policy evaluators would not have concurred with the loosely argued recommendations current in the late 1970's that long lags in expectations made it too costly to disinflate. Our results say that recommendations under classical identification would have been even more timely.

Through the 1960s the Keynesian government aimed at a long-run inflation rate of two to three percent.

Once its estimated sum of weights on lagged inflation approached one, its target fell to about one percent or less, and it stayed there through the early 1980s, while actual inflation ran far higher.

Its one-step recommendations in the late 1970s, around four percent, called for cutting inflation well below the rates it inherited.

After the Volcker disinflation, the sum of weights drifted down a little and the planned long-run rate returned to two to three percent, close to actual inflation.

The classical government's recommendations were close to zero even during the acceleration of the late 1960s, and below zero after it: that is the sense in which they "would have been even more timely."

Chapter 1 of the book draws the moral: "The econometric estimates present the mystery of why the stabilization was postponed."

107.8.1 How robust are the misses?

Because the book does not report its lag lengths or its conversion to quarterly data, the table varies the lags, the quarterly sampling, and the frequency.

The monthly columns use $\lambda^{1/3}$ and $\delta^{1/3}$, which keep the same memory and the same discounting in calendar time.

```
specs = [('end of quarter', 'last', 1, 2), ('end of quarter', 'last', 2, 2),
         ('quarterly average', 'avg', 1, 2), ('quarterly average', 'avg', 2, 2),
         ('monthly', 'monthly', 1, 2), ('monthly', 'monthly', 2, 2)]
rows = []
for label, how, mU, my in specs:
    d = make_data(how)
    λ, δ = (0.985**(1/3), 0.999**(1/3)) if how == 'monthly' else (0.985, 0.999)
    g = {s: government(d, s, λ=λ, δ=δ, mU=mU, my=my) for s in 'CK'}
    e = {s: estimate(g[s]) for s in 'CK'}
    fk = g['K']['frame']
    fk['long_run'] = long_run_path(g['K'])
    β_U = pd.Series(g['K']['coef'][:, 0], index=fk.index)
    m = fk['miss'].loc['1973':'1990']
```

(continues on next page)

(continued from previous page)

```
    rows.append([label, f'({mU}, {my})',
                 e['K']['loglik'] - e['C']['loglik'],
                 e['K']['params'][0],
                 g['C']['frame']['yhat'].loc['1973':'1979'].mean(),
                 β_U.loc['1973':'1979'].mean(),
                 fk['yhat'].loc['1973':'1979'].mean(),
                 (m > 0).mean(),
                 fk['sum_y'].loc['1975':'1984'].mean(),
                 fk['long_run'].loc['1973':'1984'].median()])
robust = pd.DataFrame(rows, columns=[
    'data', '(m_U, m_y)', 'log L: K minus C', 'K estimate of θ',
    'C recommendation 1973-79', 'K coefficient on U_t, 1973-79',
    'K recommendation 1973-79', 'K share of misses > 0, 1973-90',
    'K sum on lagged y, 1975-84', 'K long-run plan 1973-84'])
robust.set_index(['data', '(m_U, m_y)']).round(2).T
```

K sum on lagged y, 1975-84	0.97	0.80	0.80
K long-run plan 1973-84	0.71	5.39	5.40

Some findings hold in every column: the Keynesian scheme fits better, and the classical government recommends inflation below zero in the 1970s.

With quarterly data, whatever the lags or the sampling, the Keynesian government's sum of weights on lagged inflation is close to one after 1975, and its long-run plan calls for inflation of about one percent or less in 1973–1984.

The *one-step* Keynesian recommendations are more fragile, and so are the estimates of θ.

The reason is the coefficient β_1 on current unemployment in the Keynesian regression, which the government inverts to get its short-run tradeoff $1/\beta_1$.

With one lag of unemployment it is clearly negative in 1973–1979; with two lags it is about half as large with end-of-quarter sampling and about zero with quarterly averages.

Inverting the curve then divides by a number near zero, so the believed unemployment dynamics become erratic and the government's short-run response to the inflation it inherits swings with them; that is why the one-step misses shrink in those columns.

Monthly data fail for a more basic reason.

Two lags of monthly inflation span only two months, and their coefficients sum to well short of one, so the monthly

Keynesian government never activates the induction hypothesis and its long-run plan rises with inflation instead of falling.

A distributed lag long enough to capture the induction hypothesis needs to span quarters, not months.

107.8.2 A positive, not a normative, conclusion

Sargent does not turn these estimates into an endorsement.

The simulations of *Adaptive Learning and Escape Dynamics* show that the mean dynamics eventually pull an adaptive government back toward the self-confirming equilibrium, so a long spell of good advice is no guarantee of lasting good policy.

Chapter 10 of the book closes:

> In the end, though our simulations and econometric evidence bolster the vindication of econometric policy evaluation story, we hope that this is the wrong story. We hope instead that policy makers somehow have learned a correct rational expectations version of the natural rate hypothesis and to commit themselves to low inflation.

107.9 What came later

Chapter 9 fixed the gain.

Exercise **??** poses Chung's problem of estimating the gain itself on simulated data from the Bounded Rationality suite, where the gain is called γ and the beliefs α; Exercise 107.10.1 below takes up the same question on the data of this lecture.

The econometricians did return the compliment explains why a gain that does not vanish makes such learning parameters estimable.

Sargent *et al.* [2006] are the modern counterpart of this chapter.

Their government runs a Kalman filter (*A First Look at the Kalman Filter*) on drifting Phillips-curve coefficients, the Sims–Chung specification, and, as in chapter 9, the systematic part of inflation solves the Phelps problem at the government's current estimates.

Unlike chapter 9, they estimated the drift covariance that sets the government's gain, jointly with the parameters of the true model, using a Bayesian Markov chain Monte Carlo algorithm.

Priors, Escapes, and Learning Cycles discusses their estimates and Carboni and Ellison [2009]'s refinement, which disciplines the government's beliefs with the Federal Reserve's Greenbook forecasts.

The Lost Conquest: Fed Policy in the 2020s asks Chung's question about the Federal Reserve of the 2020s.

Here the government's beliefs left no free parameters in the likelihood.

The next lecture, *Drifts and Volatilities*, takes the opposite tack: it fits a reduced-form vector autoregression whose coefficients drift and whose shocks have stochastic volatility.

It asks whether the drifting beliefs that the vindication story puts at the center of post-war inflation leave the footprints in the data that the story predicts.

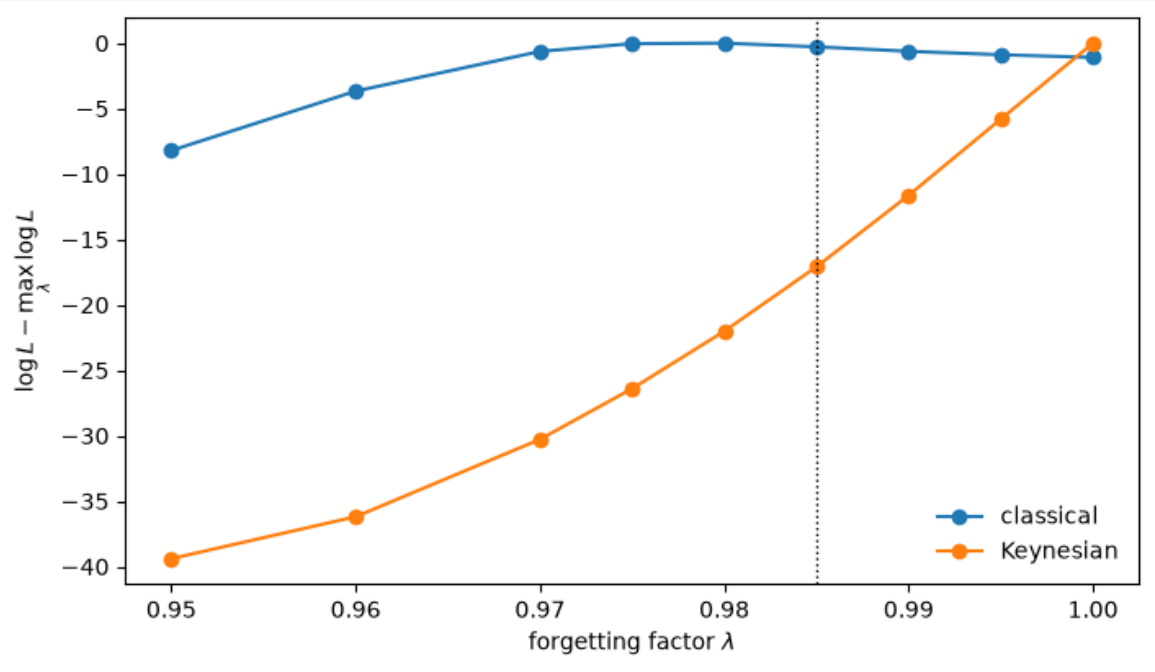
107.10 Exercises

Exercise 107.10.1

The book fixed $\lambda = .985$.

Compute the profile likelihood of the gain: for λ on a grid from .95 to 1, rebuild the government's beliefs and recommendations, re-estimate $(\theta, U^*, \rho_1, \rho_2)$, and plot the maximized log L against λ for both identification schemes.

Note that $\lambda = 1$ is least squares, with a gain that falls like $1/t$.



Which values of λ do the data favor, and how does the answer bear on the book's "mystery of why the stabilization was postponed"?

Solution

```
λ_grid = [0.95, 0.96, 0.97, 0.975, 0.98, 0.985, 0.99, 0.995, 1.0]
profile = {s: [] for s in 'CK'}
mean_K = []
for λ in λ_grid:
    for s in 'CK':
        g = government(data, s, λ=λ)
        profile[s].append(estimate(g)['loglik'])
        if s == 'K':
            mean_K.append(g['frame']['yhat'].loc['1973':'1979'].mean())

fig, ax = plt.subplots(figsize=(8, 4.5))
for s, label in [('C', 'classical'), ('K', 'Keynesian')]:
    ax.plot(λ_grid, np.array(profile[s]) - max(profile[s]), 'o-', label=label)
ax.axvline(0.985, color='k', ls=':', lw=1)
ax.set_xlabel(r'forgetting factor $\lambda$')
ax.set_ylabel(r'$\log L - \max_\lambda \log L$')
ax.legend(frameon=False)
plt.show()

print(" λ      log L (C)  log L (K)  K recommendation 1973-79")
for λ, lc, lk, m in zip(λ_grid, profile['C'], profile['K'], mean_K):
    print(f"{λ:5.3f}  {lc:9.1f}  {lk:9.1f}  {m:8.2f}")
```

λ	log L (C)	log L (K)	K recommendation 1973–79
0.950	−595.5	−479.6	3.12
0.960	−591.0	−476.4	3.22
0.970	−588.0	−470.5	3.49
0.975	−587.4	−466.6	3.68
0.980	−587.3	−462.2	3.90
0.985	−587.6	−457.3	4.14
0.990	−588.0	−451.8	4.39
0.995	−588.2	−446.0	4.64
1.000	−588.4	−440.2	4.86

The classical likelihood is nearly flat for λ above .97, because the classical government recommends low inflation whatever its memory.

The Keynesian likelihood rises steadily as λ approaches one: the data prefer the government that discounts the past least.

The printed averages show why.

A government with a longer memory gives more weight to the 1950s and 1960s, when its regression showed a long-run tradeoff, so it activates the induction hypothesis later and recommends higher inflation in the 1970s, closer to the inflation that actually occurred.

Because the likelihood can reward a gain only by bringing the recommendations closer to actual inflation, it favors the slowest learner.

That is another way to state the book's mystery: actual policy behaved as if it learned the natural-rate hypothesis later than the book's constant-gain government did.

In the simulated economy of Exercise **??** the government really does follow its recommendations, and the likelihood recovers the true gain; here a preference for slow learning partly measures how far actual policy lagged behind the procedure.

Exercise 107.10.2

Sims [1988] gave his government a *static* Phillips curve, $U_t = \gamma_0 y_t + \gamma_c + \varepsilon_t$, with no lags.

Estimate the static model ($m_U = m_y = 0$) under both identification schemes, and compare it with the distributed-lag model of the lecture.

For each of the four models, report the maximized log L, the average recommendation in 1973–1979, and the correlation between recommended and actual inflation.

Does the static classical model fail, and is it the lags or the direction of fit that matters more?

Solution

```
rows = []
for mU, my, lag_label in [(0, 0, 'static'), (1, 2, 'distributed lag')]:
    for s, label in [('C', 'classical'), ('K', 'Keynesian')]:
        g = government(data, s, mU=mU, my=my)
        f = g['frame'].loc['1958':]
        rows.append([lag_label, label, estimate(g)['loglik'],
                     f['yhat'].loc['1973':'1979'].mean(),
                     f[['y', 'yhat']].corr().iloc[0, 1]])
pd.DataFrame(rows, columns=['lags', 'scheme', 'log L', 'recommendation 1973-79',
                            'corr(recommended, actual)']
             ).set_index(['lags', 'scheme']).round(2)
```

```
                              log L  recommendation 1973-79  \
lags             scheme
static           classical -537.58                    0.23
                 Keynesian -473.11                    4.05
distributed lag  classical -587.61                   -1.72
                 Keynesian -457.27                    4.14

                           corr(recommended, actual)
lags             scheme
static           classical                     -0.24
                 Keynesian                      0.07
distributed lag  classical                      0.31
                 Keynesian                      0.58
```

The static classical model does fail: it recommends inflation near zero in the 1970s, and its recommendations are negatively correlated with actual inflation.

But adding lags does not rescue the classical scheme: the distributed-lag classical government recommends even lower inflation, and its likelihood is lower than the static one's.

The direction of fit matters more than the lags, and both Keynesian models fit far better than either classical model.

In a regression of unemployment on inflation, noise in quarterly inflation attenuates the coefficient on inflation, so a classical government sees only a weak tradeoff; inverting a regression of inflation on unemployment yields a steep one.

For the Keynesian scheme the lags matter too: the distributed-lag model has the higher likelihood, and its recommendations track actual inflation far more closely.

Only a distributed lag lets the government discover the induction hypothesis; a static Keynesian government has no lagged inflation in its model, so it cannot learn the natural-rate hypothesis in the Solow–Tobin form.

The book takes the two identification schemes, and their names, from King and Watson [1994], and it notes that the better fit of the Keynesian direction is what led the U.S. Phillips-curve literature to adopt it.

Exercise 107.10.3

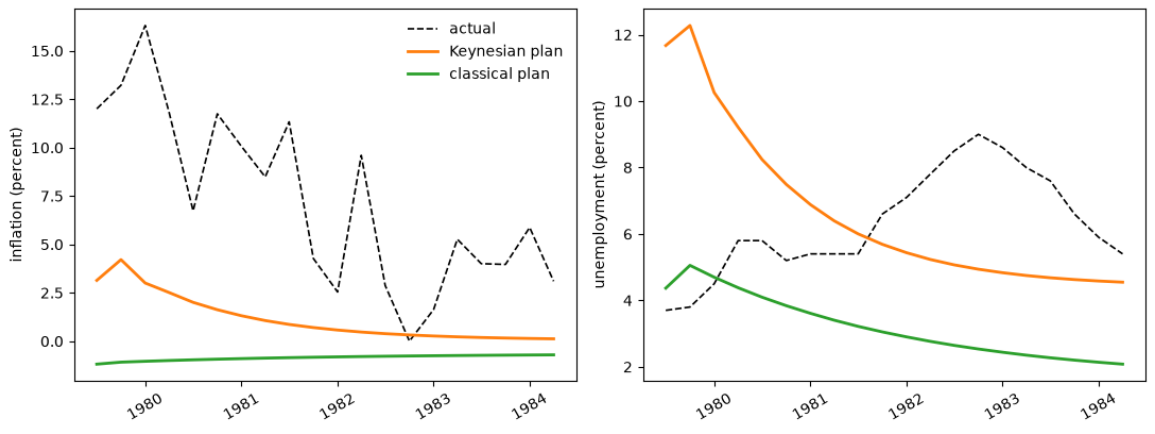
Take the Keynesian government's beliefs at the end of 1979Q2, just before Paul Volcker became chairman of the Federal Reserve.

Compute the paths of inflation and unemployment that it *planned* for the next twenty quarters: the paths implied by its Phelps rule and its own estimated Phillips curve, with all future shocks set to zero, starting from the state in 1979Q3.

Do the same for the classical government, and plot both plans against what actually happened.

How does the Keynesian plan compare with the actual disinflation, and how large a rise in unemployment did each government expect to pay for it?

Solution



```
def planned_paths(g, date, H=20):
    "Inflation and unemployment the government planned from `date` on."
    t = g['frame'].index.get_loc(pd.Timestamp(date))
    β = g['coef'][t - 1]
    γ = β if g['scheme'] == 'C' else γ_of_β(β)
    h = phelps_h(γ, g['δ'], g['mU'], g['my'])
    A, B = lq_matrices(γ, g['mU'], g['my'])
    s = g['states'][t].copy()
    y_plan, U_plan = [], []
    for _ in range(H):
        y = h @ s
        y_plan.append(y)
        U_plan.append(γ[0] * y + γ[1:] @ s)
        s = A @ s + B[:, 0] * y
    index = g['frame'].index[t:t + H]
    return pd.DataFrame({'y': y_plan, 'U': U_plan}, index=index[:H])

date = '1979-07-01'
plans = {s: planned_paths(gov[s], date) for s in 'CK'}
actual = data.loc[date:].iloc[:20]

fig, axes = plt.subplots(1, 2, figsize=(11, 4.2))
for ax, var, ylabel in [(axes[0], 'y', 'inflation'), (axes[1], 'U', 'unemployment
↪')]:
    ax.plot(actual.index, actual[var], 'k--', lw=1.2, label='actual')
    ax.plot(plans['K'].index, plans['K'][var], 'C1', lw=2, label='Keynesian plan')
    ax.plot(plans['C'].index, plans['C'][var], 'C2', lw=2, label='classical plan')
    ax.set_ylabel(f'{ylabel} (percent)')
    ax.tick_params(axis='x', rotation=30)
axes[0].legend(frameon=False)
plt.tight_layout()
plt.show()

print(f"1979Q2: inflation {data.loc['1979-04-01', 'y']:.1f}, "
      f"unemployment {data.loc['1979-04-01', 'U']:.1f}")
paths = {'Keynesian plan': plans['K'], 'classical plan': plans['C'], 'actual':␣
```

```
 ↪actual}
print(f"{'':16s} {'y, 1st qtr':>10s} {'y, 4th qtr':>10s} {'y, 20th qtr':>11s} {
 ↪'peak U':>7s}")
for label, p in paths.items():
    print(f"{label:16s} {p['y'].iloc[0]:10.1f} {p['y'].iloc[3]:10.1f} "
          f"{p['y'].iloc[-1]:11.1f} {p['U'].max():7.1f}")
```

```
1979Q2: inflation 12.9, unemployment 3.4
                 y, 1st qtr y, 4th qtr y, 20th qtr  peak U
Keynesian plan          3.1        2.5         0.1    12.3
classical plan         -1.2       -1.0        -0.7     5.1
actual                 12.0       11.8         3.1     9.0
```

On the eve of Volcker's appointment the Keynesian government planned to cut inflation at once, from double digits to a few percent, and then to lower it slowly toward zero.

It expected the cut to be costly: unemployment in its plan jumps to well above its 1979 level and then declines slowly.

This is the pattern of the Phelps problem in chapter 5 of the book (*Adaptive Expectations and the Phelps Problem*), where the government "engineers a major recession and immediately brings inflation down more than half way toward its eventual limiting value."

The classical government planned a mild deflation and expected it to cost little, because its estimated curve showed hardly any short-run effect of inflation on unemployment.

Actual policy moved more slowly than either plan: inflation stayed high for more than a year and reached its 1980s level only in 1982–1983, while the unemployment rate of white men rose to its peak at the end of 1982.

Both governments' econometrics said disinflate now, and the Keynesian government recommended it even though it expected disinflation to be costly.

Neither would have accepted the argument, current in the late 1970s, that long lags in expectations made disinflation too costly to attempt.

108.1 Overview

The lectures in this section have told a story about how a government's *model* of the Phillips curve, and the *policy* it induces, can drift over time.

In *Adaptive Learning and Escape Dynamics* and *Escaping Nash Inflation* a government that refits an approximating Phillips curve by constant-gain least squares escapes recurrently from a bad *self-confirming equilibrium* and is then drawn back toward it.

Priors, Escapes, and Learning Cycles shows how the government's prior about drifting coefficients shapes those dynamics, and *Econometric Policy Evaluation* confronts the adaptive models with postwar U.S. data by maximum likelihood.

That confrontation was *structural*: it estimated a particular model of a learning government.

This lecture steps back to a *reduced-form* question that every one of those models has to answer.

It studies Cogley and Sargent [2005], which asks a deceptively simple question:

> When we look at postwar U.S. time series on inflation, unemployment, and interest rates, do we see evidence that the dynamics have *drifted*?

Tim Cogley and Thomas Sargent began this work as an empirical companion to the *Conquest* book [Sargent, 1999] and to Cho *et al.* [2002], whose recurrent escapes generate nonlinearities that an econometrician would see as drifting coefficients.

It answers searching comments by Sims [2001] and Stock [2001] on an earlier paper [Cogley and Sargent, 2001], and it confronts evidence from Sims [1999] and Bernanke and Mihov [1998] that the coefficients of vector autoregressions had *not* changed.

That evidence bears on a question that organizes this whole section:

Was the Great Inflation of the 1970s and its conquest in the 1980s a story of bad policy, or of bad luck?

To let the data speak to that question we need a statistical model flexible enough to accommodate *both* answers.

That model is a *Bayesian vector autoregression whose coefficients drift as random walks and whose shock variances evolve as stochastic volatilities*.

It is the very specification that Sims [1988] and Chung [1990] handed their model governments: a Kalman filter on regression coefficients that are believed to drift as random walks (*The econometricians did return the compliment*).

There the government ran the filter to learn the Phillips curve; here the econometrician runs it to learn about the government.

Fitting the model requires a Markov chain Monte Carlo algorithm that combines the *Kalman filter*, the forward-filter/backward-sample smoother of Carter and Kohn [1994], and the stochastic-volatility sampler of Jacquier *et al.* [1994].

Companion-form vector autoregressions are treated in *Linear State Space Models* and *Vector Autoregressions for Subsets of Variables*, and the Kalman filter in *A First Look at the Kalman Filter*.

No other QuantEcon lecture covers the Kalman *smoother*, so this lecture introduces it inside the sampler, and Exercise **??** shows why it matters here.

We fit the model to Cogley and Sargent's sample, which ends in 2000; *Drifts and Volatilities after 2000* re-estimates it with another quarter-century of data.

Let's start with some imports and the URL for the data.

```
import time

import matplotlib.pyplot as plt
import numpy as np
import pandas as pd
from IPython.display import display
from scipy import linalg
from scipy.special import expit
from threadpoolctl import threadpool_limits

# The matrices in this lecture are small, so extra BLAS threads only add overhead.
threadpool_limits(1)

data_url = 'https://github.com/QuantEcon/data-lectures/raw/main/lectures/NEWQDATA.csv'
```

108.2 Bad policy or bad luck?

Two respectable views compete to explain the American Great Inflation.

The **bad policy** view is the one dramatized throughout this section and in the *Conquest* book [Sargent, 1999].

Something about Arthur Burns's *model* of the economy, his *patience*, or his inability to *commit* to a better rule led the Federal Reserve to administer monetary policy in a way that produced the greatest peacetime inflation in U.S. history, while an improved model, more patience, or greater discipline led Paul Volcker to conquer it [DeLong, 1997, Taylor, 1997].

The two stories that open *The Rise and Fall of U.S. Inflation*, triumph and vindication, are both versions of this view: they disagree about how the Fed's model improved, not about whether policy changed.

On this view, what changed between the 1970s and the 1980s was the *systematic part* of policy, namely the way the Fed's interest-rate setting responded to inflation and unemployment.

The **bad luck** view rejects both stories.

What distinguished the Burns and Volcker eras was not their models or policies, but the *shocks* that hit the economy.

On this view the *coefficients* of a reduced-form description of the economy were essentially constant, and what changed was the *size* of the disturbances, namely the *volatility*.

Classical tests supported the second view.

Sims [1999] and Bernanke and Mihov [1998] could not reject the hypothesis that VAR coefficients were time invariant, while finding that innovation variances had shifted.

Sims and Zha [2006] reached a similar verdict by a different route.

Comparing Markov-switching models by their posterior fit, they found that the best fit lets only the variances of the disturbances switch.

When the systematic coefficients were also allowed to switch, the best fit changed only the monetary policy rule, and the estimated policy regimes differed too little to account for the rise and fall of inflation [Sargent, 2008].

Markov switching and the random-walk volatilities used below describe changing volatility differently.

A hidden Markov chain permits *jumps*, but without an absorbing state it switches forever among the same few configurations, and with one it permits a permanent shift only once.

A random-walk volatility must adjust continuously, but it permits *recurrent, permanent* shifts, such as a Great Inflation followed by a Great Moderation.

Primiceri [2005] fit a time-varying VAR close to the one below, with drifting coefficients and stochastic volatility and a prior that puts more weight on slow drift.

He found that systematic monetary policy had changed, but that the changes had small effects on the rest of the economy, which puts him nearer the bad-luck side [Sargent, 2008].

How can we discriminate?

A constant-coefficient, constant-volatility VAR can generate unusually large realized shocks, but it cannot represent systematic changes in their variance over time.

A model with drifting coefficients but constant volatility can also mistake changing volatility for coefficient drift, which is what Stock [2001] suspected of the 2001 paper.

So Cogley and Sargent build a model that has room for *both* channels at once, and they let a Bayesian posterior sort out how much of each the data call for.

108.3 A VAR with drifting coefficients and stochastic volatility

Let the variables be ordered as nominal interest, transformed unemployment, and inflation,

$$y_t = \begin{bmatrix} i_t & u_t & \pi_t \end{bmatrix}^\top .$$

Here u_t is not the raw unemployment rate but its logit, a transformation we define in the data section below.

The measurement equation is a VAR with two lags and date-specific coefficients,

$$y_t = X_t^\top \theta_t + \varepsilon_t, \qquad X_t^\top = I_3 \otimes \begin{bmatrix} 1 & y_{t-1}^\top & y_{t-2}^\top \end{bmatrix}. \tag{108.1}$$

Each equation has an intercept and six lag coefficients, so θ_t contains $3(1 + 2 \times 3) = 21$ elements.

A two-lag VAR can be rewritten as a one-lag system by stacking y_t and y_{t-1} into a single vector; the matrix that multiplies this stacked vector is the **companion matrix**, and the rewritten system is the VAR in **companion form** (*Linear State Space Models*, *Vector Autoregressions for Subsets of Variables*).

The following function builds the companion matrix from the stacked coefficients.

```
n_variables = 3
n_lags = 2
n_regressors = 1 + n_variables * n_lags
n_coefficients = n_variables * n_regressors

def companion_matrix(θ):
    """Return the intercept and companion matrix for one coefficient vector."""
    rows = np.asarray(θ, dtype=float).reshape(n_variables, n_regressors)
    intercept = np.r_[rows[:, 0], np.zeros(n_variables)]
    companion = np.zeros((n_variables * n_lags, n_variables * n_lags))
    companion[:n_variables] = rows[:, 1:]
    companion[n_variables:, :n_variables] = np.eye(n_variables)
    return intercept, companion
```

The coefficient vector follows a driftless random walk,

$$\theta_t = \theta_{t-1} + v_t, \qquad v_t \sim N(0, Q). \tag{108.2}$$

The drift covariance Q is a close relative of the drift covariance V in *Priors, Escapes, and Learning Cycles*.

There V is the *government's* prior about how fast the Phillips curve drifts, and it sets the gain of the government's Kalman filter; here Q is a parameter of the *econometrician's* model, to be estimated.

For a given drift covariance the Kalman gain does not die out, so the filter behaves like the constant-gain least squares of *Adaptive Learning and Escape Dynamics*, a stochastic-approximation algorithm of the kind studied in *One recursion, many learners*.

Exercise **??** asks how well such a gain can be estimated from data, and Exercise **??** computes the gain that this model's estimates imply.

When Sargent *et al.* [2006] estimated V by requiring a learning government's policy to fit U.S. inflation, they needed a large V, a government that "discounts past data heavily" [Sargent, 2008]; Carboni and Ellison [2009] shrank it by asking the government's beliefs to match the Fed staff's Greenbook forecasts.

The companion system is stable when every companion-matrix eigenvalue lies strictly inside the unit circle.

For an $AR(1)$, this is $|\rho| < 1$; equivalently, the zero of $1 - \rho z$ lies outside the unit circle.

Cogley and Sargent rule out explosive paths with the truncated prior

$$p(\theta^T, Q) \propto I(\theta^T) f(\theta^T \mid Q) f(Q), \tag{108.3}$$

where $I(\theta^T) = 1$ if the companion matrix is stable at every date and $I(\theta^T) = 0$ otherwise.

Their reason is economic.

A Fed that chooses its rule purposefully, with a loss function that penalizes the variance of inflation, would never choose a rule that leaves a unit root in inflation, because that would deliver an infinite loss.

The roots of the VAR are not determined by the Phillips curve alone; they also depend on the policy rule.

Under an arbitrary rule they can lie inside, on, or outside the unit circle, but under optimal or nearly optimal rules they are stable: when a shock moves inflation away from its target, a badly chosen rule may let it drift, while a well-chosen rule pulls it back.

The Phelps problem of *Adaptive Expectations and the Phelps Problem* is an example: the optimal rule steers inflation to a rest point even when the Phillips curve itself has the Solow–Tobin unit-sum form.

The restriction also tilts the marginal prior for Q toward values that are less likely to generate explosive coefficient paths.

The code below tests a whole trajectory for stability.

```
def companion_roots(θ_path):
    """Return the companion roots at every date of a (21, T) path."""
    rows = np.asarray(θ_path, dtype=float).reshape(n_variables, n_regressors, -1)
    companions = np.zeros((rows.shape[2], 6, 6))
    companions[:, :n_variables] = rows[:, 1:].transpose(2, 0, 1)
    companions[:, n_variables:, :n_variables] = np.eye(n_variables)
    return np.linalg.eigvals(companions)

def is_stable(θ_path):
    """Test whether every companion root lies strictly inside the unit circle."""
    return bool(np.max(np.abs(companion_roots(θ_path))) < 1)
```

The reduced-form innovation covariance changes over time according to

$$\varepsilon_t = R_t^{1/2}\xi_t, \qquad \xi_t \sim N(0, I_3), \qquad R_t = B^{-1}H_tB^{-1\prime}, \tag{108.4}$$

where

$$B = \begin{bmatrix} 1 & 0 & 0 \\ \beta_{21} & 1 & 0 \\ \beta_{31} & \beta_{32} & 1 \end{bmatrix}, \qquad H_t = \operatorname{diag}(h_{1t}, h_{2t}, h_{3t}).$$

The diagonal elements h_{it} let the size of each orthogonalized shock wax and wane over time.

The matrix B orthogonalizes ε_t, but it is not an identification scheme.

The next two functions construct B and R_t.

```
def b_matrix(β):
    """Construct B from β_21, β_31, and β_32."""
    matrix = np.eye(n_variables)
    matrix[1, 0], matrix[2, 0], matrix[2, 1] = β
    return matrix

def innovation_covariance(h, β):
    """Construct R_t = B^{-1} H_t B^{-1}' from one vector of variances."""
    inverse = np.linalg.inv(b_matrix(β))
    return inverse @ np.diag(h) @ inverse.T
```

Each diagonal volatility is a geometric random walk,

$$\log h_{it} = \log h_{i,t-1} + \sigma_i \eta_{it}, \qquad \eta_{it} \sim N(0,1). \tag{108.5}$$

The standardized measurement innovations, coefficient innovations, and volatility innovations are mutually independent.

Setting $Q = 0$ produces constant coefficients with drifting volatility, while holding H_t fixed produces drifting coefficients with constant volatility.

The posterior contains the full paths θ^T and H^T together with Q, $\beta = (\beta_{21}, \beta_{31}, \beta_{32})$, and $\sigma = (\sigma_1, \sigma_2, \sigma_3)$.

108.4 The data

We use Cogley and Sargent [2005]'s quarterly U.S. dataset, which ends in 2000Q4.

Inflation is the log difference of the seasonally adjusted CPI for all urban consumers, point sampled in the third month of each quarter.

Unemployment is the quarterly average of the seasonally adjusted civilian unemployment rate and enters the VAR as $0.01 \log[u/(1-u)]$, a logit transformation that maps a bounded rate into an unconstrained variable.

The nominal interest rate starts from the three-month Treasury-bill rate i, in annual percent and averaged over daily observations in the first month of each quarter, and enters as $i/(400 - i)$, the quarterly return on a bill bought at a discount of $i/400$ of its face value.

The data start in 1948Q2 because the first inflation observation is already differenced, so two VAR lags make 1948Q4 the first usable regression date.

Observations through 1958Q4 calibrate the prior, and 1959Q1–2000Q4 form the estimation sample.

```

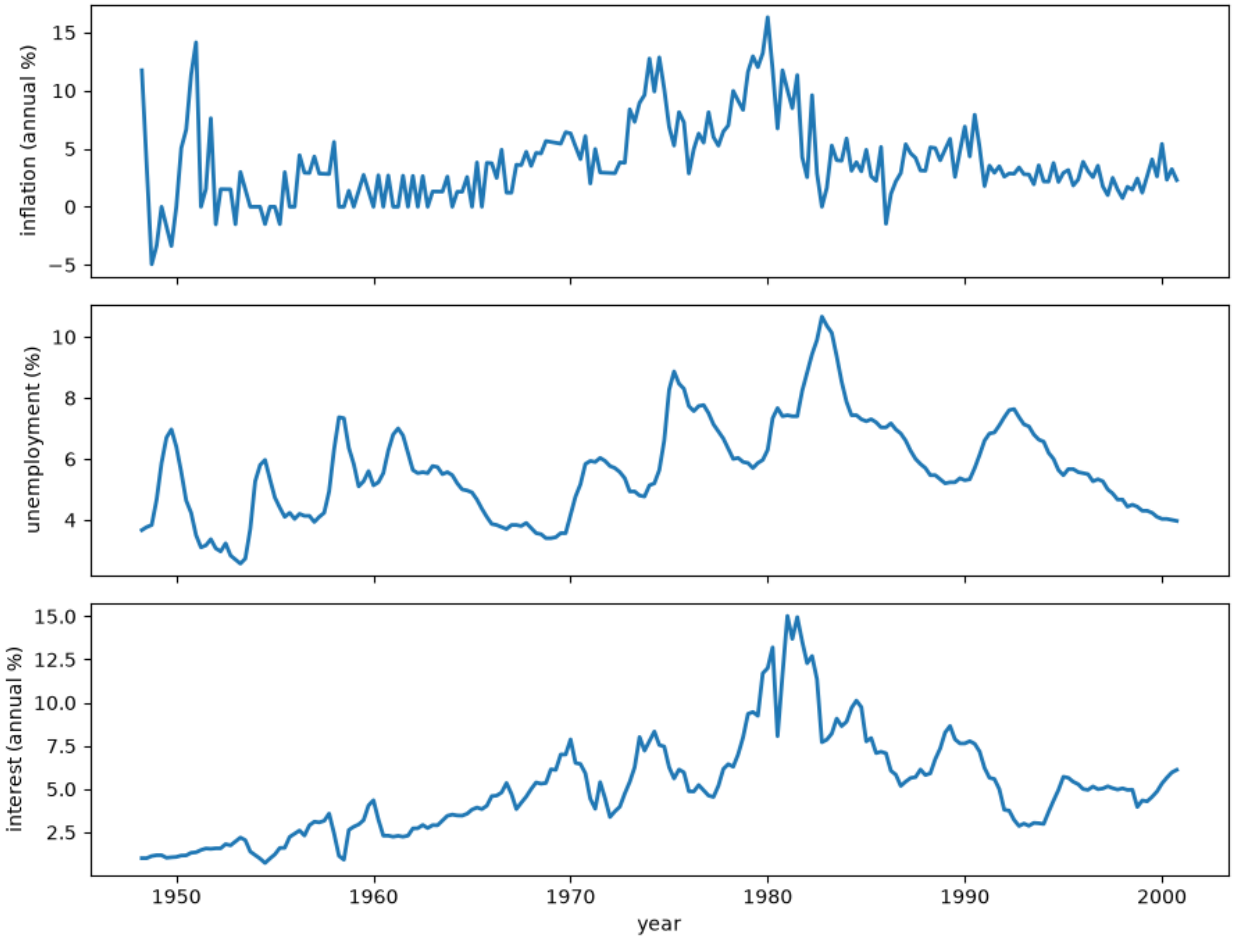

Fig. 108.1: Observed π_t, u_t, and i_t, 1948Q2–2000Q4

Inflation and nominal interest rates rise together through the 1970s and peak around 1980, unemployment peaks only after disinflation begins, and all three series are calmer in the 1990s.

These observations locate the episode but cannot tell whether changed systematic dynamics or unusually large shocks produced it, which is the distinction the model is built to examine.

108.5 Priors

The priors are independent across parameters and deliberately weak so that, in Cogley and Sargent's phrase, "the data are free to speak."

They are calibrated from a time-invariant VAR fitted to the training sample.

The initial coefficient prior is a stable, truncated Gaussian,

$$p(\theta_0) \propto I(\theta_0) N(\bar{\theta}, \bar{P}),$$

where $\bar{\theta}$ and $\bar{P}$ are the point estimate and asymptotic covariance of a constant-coefficient seemingly unrelated regression fitted to 1948–1958.

Because all three equations have identical regressors, the SUR estimates equal equation-by-equation OLS estimates.

The coefficient-drift covariance has the inverse-Wishart prior

$$Q \sim IW_{21}\left(T_0, T_0 \bar{Q}\right), \qquad T_0 = 22, \qquad \bar{Q} = \gamma^2 \bar{P}, \qquad \gamma^2 = 3.5 \times 10^{-4}, \tag{108.6}$$

where the first argument is the degrees of freedom and the second the scale matrix.

Here γ^2 is Cogley and Sargent's prior scale, not a learning gain; in the Bounded Rationality lectures γ denotes the gain (*Notation across the series*).

Because T_0 is only one greater than the dimension of θ_t, the prior is proper but has no finite mean.

The matrix $\bar{Q}$ is therefore a conservative scale calibration that implies little drift, not the expectation of Q, and the weakness of the prior lets the data move far away from it.

The remaining priors are

$$\begin{aligned} \log h_{i0} &\sim N(\log \bar{R}_{ii}, 10), \\ \beta &\sim N(0, 10000\, I_3), \\ \sigma_i^2 &\sim IG\left(\frac{1}{2}, \frac{0.01^2}{2}\right), \end{aligned}$$

where $\bar{R}$ is the residual covariance from the training-sample regression.

The next function gathers these hyperparameters.

```
def calibrate_prior(model_data, γ_squared=3.5e-4):
    """Calibrate every prior from a constant-coefficient training-sample VAR."""
    y, x = model_data['prior_y'], model_data['prior_x']
    xx_inverse = np.linalg.inv(x.T @ x)
    coefficients = xx_inverse @ x.T @ y          # SUR = equation-by-equation OLS
    residuals = y - x @ coefficients
    r_bar = np.cov(residuals, rowvar=False, ddof=1)
    p_bar = np.kron(r_bar, xx_inverse)
    T0 = n_coefficients + 1
    return {
        'θ_mean': coefficients.T.reshape(-1),
        'θ_covariance': p_bar,
        'q_center': γ_squared * p_bar,           # Q bar
        'q_scale': T0 * γ_squared * p_bar,       # T0 Q bar
        'q_degrees_freedom': T0,
        'log_h_mean': np.log(np.diag(r_bar)),
        'log_h_variance': 10.0,
        'β_variance': 10_000.0,
```

(continues on next page)

(continued from previous page)

```
        'σ_degrees_freedom': 1.0,
        'σ_scale': 0.01**2,
        'γ_squared': γ_squared,
    }

prior = calibrate_prior(data)
trace_q_bar = np.trace(prior['q_center'])
assert is_stable(prior['θ_mean'])

pd.Series({
    'T0': prior['q_degrees_freedom'],
    'γ squared': prior['γ_squared'],
    'tr(Q bar)': trace_q_bar,
}, name='value').to_frame()
```

```
                value
T0          22.000000
γ squared    0.000350
tr(Q bar)    0.003004
```

The training-sample estimate $\bar{\theta}$ is itself stable, so the chain can start there.

108.6 Simulating the posterior

We simulate the posterior by cycling through the five blocks that Cogley and Sargent [2005] use; one pass through all five is a *sweep*.

1. **The coefficient path** $\theta_0, \ldots, \theta_T$, given Q and the covariances R^T: a Kalman filter runs forward, and the Carter–Kohn backward pass then draws θ_T and each θ_t conditional on the draw of θ_{t+1}. This is the Kalman *smoother* run as a sampler.
2. **The drift covariance** Q, given the path: an inverse-Wishart draw whose scale adds the T outer products $v_t v_t^\top$ of the increments to $T_0 \bar{Q}$.
3. **The volatility scales** σ_i^2, given the volatility paths: inverse-gamma draws.
4. **The covariance parameters** β, given the VAR residuals and H^T: two Gaussian regressions.
5. **The volatility paths** H^T: the single-site Metropolis step of Jacquier *et al.* [1994], one date at a time.

Any fixed order of valid conditional updates leaves the posterior invariant.

The order needs care only in samplers that represent the volatility likelihood with mixture indicators, as in Kim *et al.* [1998]; Del Negro and Primiceri [2015] show that Primiceri [2005] drew those indicators in the wrong place in the cycle.

The Jacquier–Polson–Rossi step has no such indicators.

108.6.1 Imposing stability

The restricted posterior assigns zero density to paths that are explosive at any date, including θ_0.

Cogley and Sargent simulate the *unrestricted* posterior and keep only the sweeps whose coefficient path is stable.

That is valid because the restricted posterior is the unrestricted posterior conditioned on stability, but if a is the share of unrestricted sweeps that are stable, it takes about $1/a$ complete sweeps to produce one that is kept.

We impose stability inside block 1 instead, by redrawing the backward pass until it delivers a stable path.

An accepted draw comes from the Gaussian Carter–Kohn distribution conditioned on stability, which is exactly the restricted full conditional, so the step is an exact Gibbs update.

Because the forward filter does not change between redraws, each redraw costs only a backward pass.

In rare sweeps the conditioning values make a stable draw very unlikely; if 1,000 passes all fail, the step keeps the current path.

The probability of that event depends only on the other blocks, not on the current path, so the step is a mixture of an exact draw and staying put, and it still leaves the restricted conditional invariant.

The two schemes are linked by an identity.

Collect the other blocks in $\Omega = (Q, H^T, \beta, \sigma)$ and let $p(\Omega)$ be the probability that one unrestricted Carter–Kohn draw is stable.

The restricted posterior of Ω is the unrestricted posterior $\pi_U(\Omega)$ reweighted by $p(\Omega)$, and the number of backward passes in a sweep is geometric with mean $1/p(\Omega)$, so at stationarity the mean number of passes per sweep is

$$\int \frac{1}{p(\Omega)} \frac{p(\Omega)\,\pi_U(\Omega)}{a}\, d\Omega = \frac{1}{a}.$$

Our sampler therefore pays in cheap backward passes what the discard scheme pays in complete sweeps, and the average number of passes estimates $1/a$, where a is Cogley and Sargent's share of stable sweeps.

Because rare sweeps need very many passes, the average is noisy, and the cap at 1,000 passes biases it down, so the implied a is an upper bound.

Another exact option is the elliptical slice sampler of Murray *et al.* [2010], which moves along an ellipse through the current path and a fresh Carter–Kohn draw and shrinks toward the current stable path.

Its new path stays close to the current one, whereas a redraw is independent of it, but in our experiments the slow mixing of both samplers came mainly from the dependence between Q and the coefficient path, which neither step addresses.

Appendix: the sampler in detail writes out the recursions.

The code is long, so it is collapsed; expand the cells to read it.

The first cell implements block 1.

The second cell implements blocks 2–5.

The last cell composes the five blocks, after a warm-up that lets the volatilities settle with the coefficients held at $\bar{\theta}$.

Passing `fixed_q` holds Q at that value instead of drawing it; a matrix of zeros nests the constant-coefficient model.

Cogley and Sargent ran 100,000 sweeps, discarded the first half, and kept every tenth of the rest.

We run 40,000 sweeps, discard the first 4,000, and keep every 20th of the rest for the posterior summaries, while recording $\mathrm{tr}(Q)$ and the number of backward passes at every sweep.

```
burn = 4_000
posterior = run_sampler(
    data['y'], data['x'], prior,
    n_sweeps=40_000, burn=burn, thin=20, seed=42,
)
passes = posterior['passes'][burn:]

pd.Series({
    'run time (minutes)': posterior['minutes'],
    'retained draws': len(posterior['β']),
    'mean backward passes per sweep': passes.mean(),
    'share of sweeps stable at the first pass': np.mean(passes == 1),
    'implied share a of stable unrestricted sweeps': 1 / passes.mean(),
    'sweeps that kept the current path': np.sum(passes > 1_000),
}, name='value').to_frame().round(3)
```

```
                                                value
run time (minutes)                             15.372
retained draws                               1800.000
mean backward passes per sweep                  4.686
share of sweeps stable at the first pass        0.458
implied share a of stable unrestricted sweeps   0.213
sweeps that kept the current path               4.000
```

The implied share a is well below one half, so the discard scheme would throw away most of its sweeps, each of which costs a forward filter and four other blocks, while our sampler pays for each failure with a backward pass alone.

Successive sweeps remain strongly correlated, especially in the direction of Q, so *Monte Carlo error* measures the Monte Carlo error in the numbers quoted below.

108.7 What the data say

We summarize the posterior by its mean coefficient path $\mathbb{E}(\theta_t \mid T)$ and mean covariance path $\mathbb{E}(R_t \mid T)$, and then interpret them in the context of the question we asked.

108.7.1 The rate and structure of drift

The trace of Q measures the total rate of coefficient drift, with $\mathrm{tr}(Q) = 0$ corresponding to constant coefficients.

The histogram shows $\mathrm{tr}(Q)$ at every sweep after the burn-in, together with the prior scale $\mathrm{tr}(\bar{Q})$.

```
trace_q = posterior['trace_q'][burn:]
fig, ax = plt.subplots()
ax.hist(trace_q, bins=50, histtype='step', lw=2)
ax.axvline(trace_q_bar, color='C1', lw=2, label=r'prior $\mathrm{tr}(\bar Q)$')
ax.set_xlabel(r'$\mathrm{tr}(Q)$')
ax.set_ylabel('sweeps')
ax.legend()
plt.show()
```

The next table compares summaries of Q with the numbers that Cogley and Sargent report (their Table 1 and p. 272).

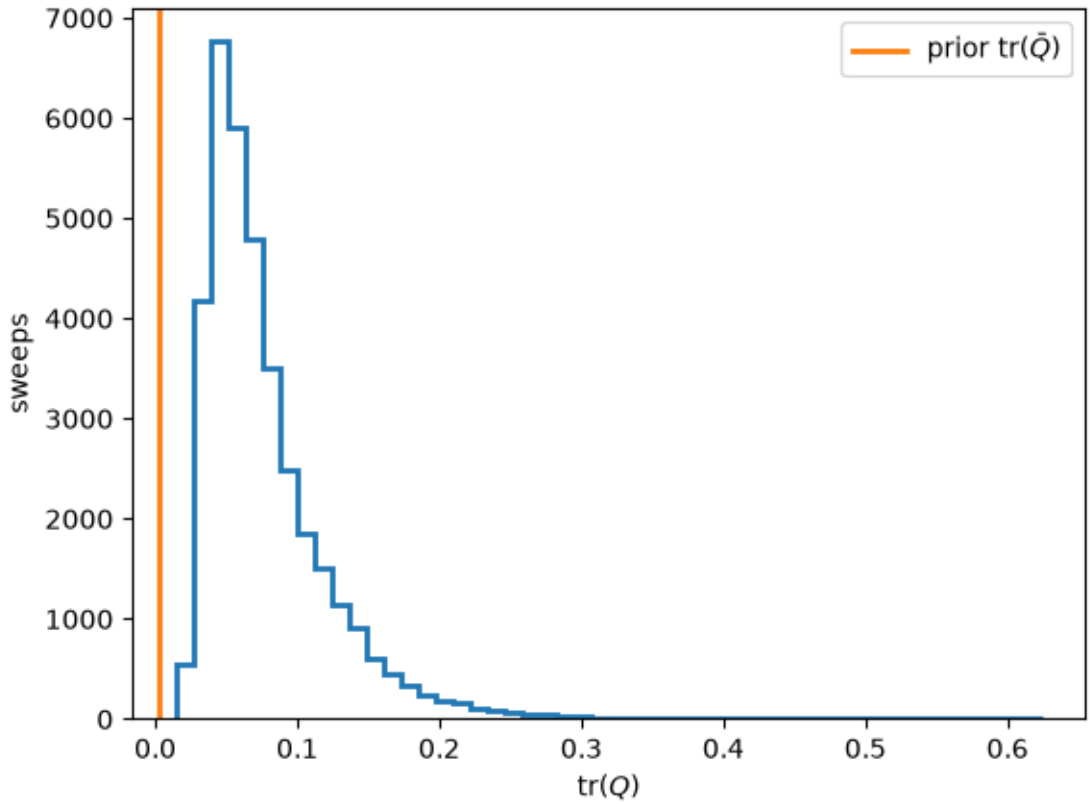

Fig. 108.2: Posterior tr(Q) and prior tr($\bar{Q}$)

```
q_mean = posterior['Q'].mean(axis=0)
q_eigenvalues = np.linalg.eigvalsh(q_mean)[::-1]
retained_trace_q = np.trace(posterior['Q'], axis1=1, axis2=2)

pd.DataFrame({
    'this lecture': [
        trace_q.mean(),
        q_eigenvalues[0],
        retained_trace_q.min() / trace_q_bar,
    ],
    'Cogley and Sargent': [0.047, 0.023, 3.0],
}, index=[
    'posterior mean of tr(Q)',
    'largest eigenvalue of posterior-mean Q',
    'smallest retained tr(Q) / tr(Q bar)',
]).round(3)
```

```
                                    this lecture  Cogley and Sargent
posterior mean of tr(Q)                    0.077               0.047
largest eigenvalue of posterior-mean Q     0.034               0.023
smallest retained tr(Q) / tr(Q bar)        6.145               3.000
```

The whole posterior lies far to the right of the conservative prior scale, so within this model the data call for much more coefficient drift than the prior anticipated.

The posterior mean of $\mathrm{tr}(Q)$ and the largest eigenvalue are larger than Cogley and Sargent's.

The posterior of $\mathrm{tr}(Q)$ has a long right tail that the chain explores slowly, so its mean carries noticeable Monte Carlo error (*Monte Carlo error*), but it was above Cogley and Sargent's value in every run we made with other seeds as well.

This is not a formal test of $Q = 0$, because the continuous prior assigns no mass to $Q = 0$; Cogley and Sargent avoid Bayes factors because their prior on Q is so diffuse.

Variation attributed to θ_t is variation in the *systematic* part of the reduced form; the VAR does not by itself say whether policy or private behavior caused it.

Cogley and Sargent estimated every ordering of the three variables, and their posterior means show that the ordering changes magnitudes but does not remove drift:

Ordering	Stable $\mathrm{tr}(Q)$	Stable $\max(\lambda)$	Unrestricted $\mathrm{tr}(Q)$	Unrestricted $\max(\lambda)$
(i, π, u)	0.055	0.025	0.056	0.027
(i, u, π)	0.047	0.023	0.059	0.031
(π, i, u)	0.064	0.031	0.082	0.044
(π, u, i)	0.062	0.031	0.088	0.051
(u, i, π)	0.057	0.026	0.051	0.028
(u, π, i)	0.055	0.024	0.072	0.035

Here $\max(\lambda)$ is the largest eigenvalue of the posterior mean of Q.

The ordering matters because the first two variables share sources of stochastic volatility with the others, while the third has its own; following the paper, we use (i, u, π), the ordering with the least drift.

For that ordering, removing the stability restriction raises the posterior mean drift rate, so the restriction does not manufacture the drift.

Diagonalizing the posterior mean of Q shows that the drift is low dimensional.

```
q_shares = np.cumsum(q_eigenvalues) / q_eigenvalues.sum()
pd.DataFrame({
    'eigenvalue': q_eigenvalues[:3],
    'cumulative share': q_shares[:3],
    'Cogley and Sargent': [0.485, 0.832, 0.945],
}, index=pd.Index([1, 2, 3], name='principal component')).round(3)
```

principal component	eigenvalue	cumulative share	Cogley and Sargent
1	0.034	0.448	0.485
2	0.029	0.824	0.832
3	0.009	0.936	0.945

As Cogley and Sargent found, only a few linear combinations of the 21 coefficients drift: the first principal component accounts for more than two-fifths of total drift and the first three for the large majority.

The posterior mean coefficient paths show where the drift lives.

```
θ_mean = posterior['θ'].mean(axis=0)
dates = data['dates']
coefficient_labels = ('constant', r'$i_{t-1}$', r'$u_{t-1}$', r'$\pi_{t-1}$',
                      r'$i_{t-2}$', r'$u_{t-2}$', r'$\pi_{t-2}$')
equation_labels = ('interest', 'unemployment', 'inflation')

fig, axes = plt.subplots(1, 3, figsize=(10, 4), sharex=True)
for equation, ax in enumerate(axes):
    rows = slice(7 * equation, 7 * equation + 7)
    lines = ax.plot(dates, θ_mean[rows].T, lw=2)
    ax.axhline(0, color='0.65', lw=1)
    ax.set_xlabel('year')
    ax.set_title(f'{equation_labels[equation]} equation')
fig.legend(lines, coefficient_labels, loc='lower center', ncol=4)
plt.tight_layout(rect=(0, 0.17, 1, 1))
plt.show()
```

Fig. 108.3: Posterior mean VAR coefficients $E(\theta_t \mid T)$

The interest and unemployment equations are comparatively stable, whereas coefficients of the inflation equation, especially the one on lagged interest, move strongly through the 1970s and turn around near 1980.

Individual lag coefficients should not be given structural interpretations, because paired lags can offset one another; the dynamic summaries below are more informative.

108.7.2 The evolution of volatility

We first ask how the *size* of the shocks changed.

The posterior mean $\mathbb{E}(R_t \mid T)$ averages $B^{-1}H_tB^{-1\prime}$ over the retained draws.

```
def mean_innovation_covariance(h_draws, β_draws):
    """E(R_t | T): the average of B^{-1} H_t B^{-1}' over retained draws."""
    b_inverse = np.linalg.inv(np.stack([b_matrix(β) for β in β_draws]))
    total = np.einsum('dij,dtj,dkj->tik', b_inverse, h_draws, b_inverse,
                      optimize=True)
    return total / len(β_draws)

r_mean = mean_innovation_covariance(posterior['h'], posterior['β'])
```

The next plot shows the innovation standard deviations, in basis points at quarterly rates, and the innovation correlations.

```
variances = ((0, 'Nominal interest'), (2, 'Inflation'), (1, 'Unemployment'))
correlations = ((0, 1, 'Interest--unemployment'),
                (0, 2, 'Interest--inflation'),
                (2, 1, 'Inflation--unemployment'))
fig, axes = plt.subplots(3, 2, figsize=(9, 8), sharex=True)
for row, (index, label) in enumerate(variances):
    axes[row, 0].plot(dates, 1e4 * np.sqrt(r_mean[:, index, index]), lw=2)
    axes[row, 0].set_title(label)
for row, (left, right, label) in enumerate(correlations):
    scale = np.sqrt(r_mean[:, left, left] * r_mean[:, right, right])
    axes[row, 1].plot(dates, r_mean[:, left, right] / scale, lw=2)
    axes[row, 1].set_title(label)
axes[1, 0].set_ylabel(r'standard deviation $\times 10^4$')
axes[1, 1].set_ylabel('correlation')
axes[-1, 0].set_xlabel('year')
axes[-1, 1].set_xlabel('year')
plt.tight_layout()
plt.show()
```

The interest-rate and inflation innovation standard deviations spike around 1980 and fall back within a few years, while unemployment innovation volatility trends down over the whole sample, punctuated by countercyclical bumps.

All three innovation correlations are largest in magnitude around the Volcker disinflation, so both the size and the composition of reduced-form shocks changed.

These movements give the changing-shocks, or bad-luck, explanation an important role, although the interest-rate innovation is not itself a structural monetary-policy shock.

Indeed, its positive correlation with inflation innovations and negative correlation with unemployment innovations look more like a policy *reaction* than like policy shocks, which conventional wisdom says should move inflation and unemployment the other way.

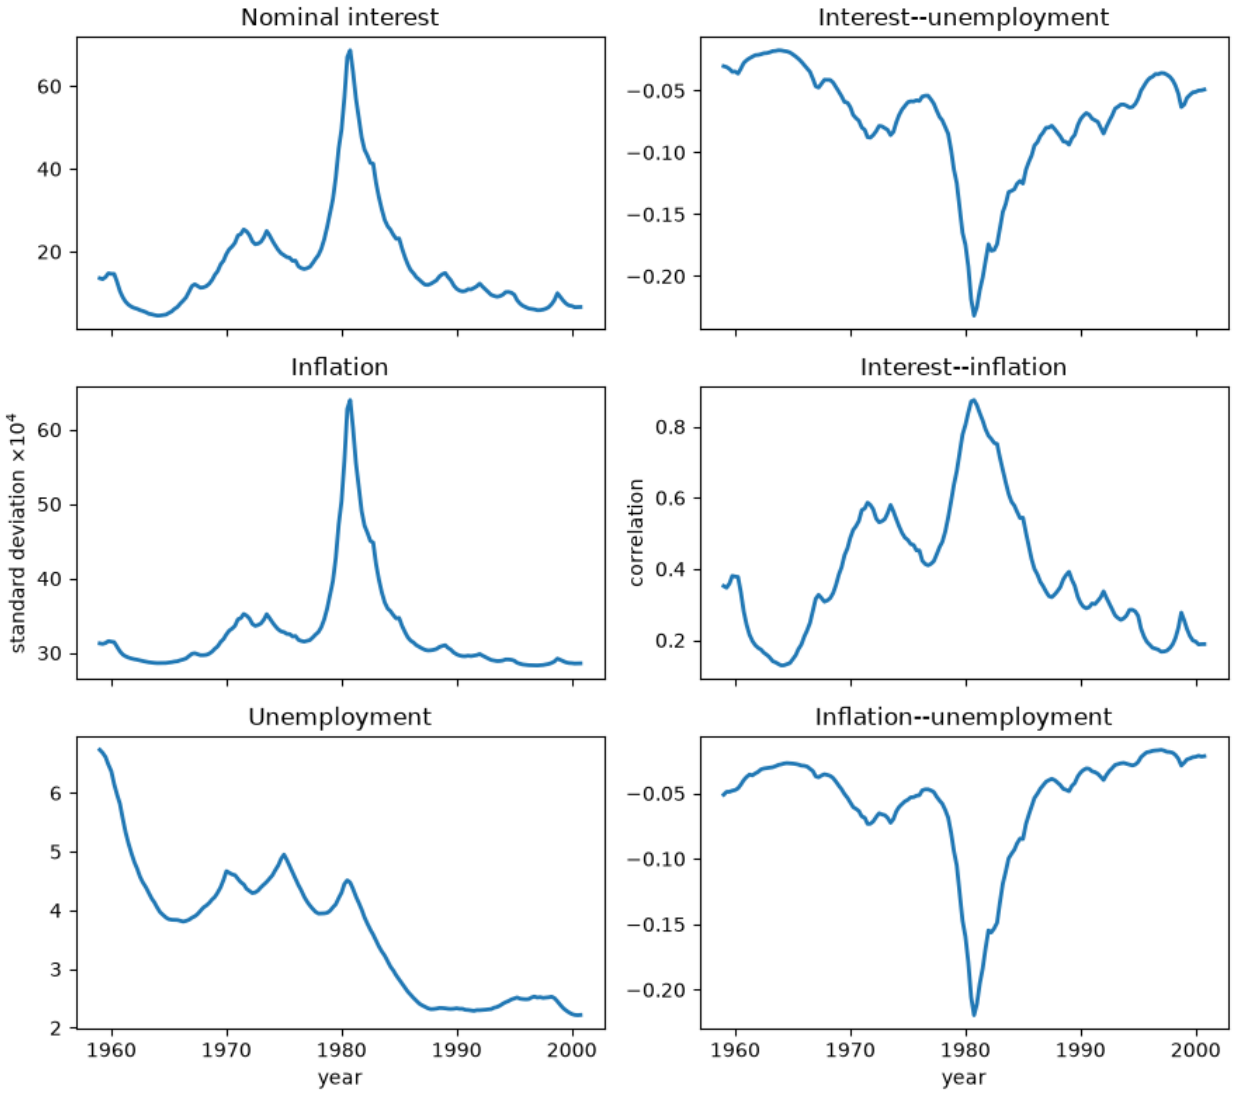

Fig. 108.4: Standard deviations and correlations implied by $E(R_t \mid T)$

Following Whittle [1953], the log determinant of $\mathbb{E}(R_t \mid T)$ summarizes the total one-step uncertainty entering the system at each date.

```
years = np.floor(dates + 1e-8).astype(int)
logdet_r = np.linalg.slogdet(r_mean)[1]

fig, ax = plt.subplots()
ax.plot(dates, logdet_r, lw=2)
ax.set_xlabel('year')
ax.set_ylabel(r'$\log |E(R_t\mid T)|$')
plt.show()
```

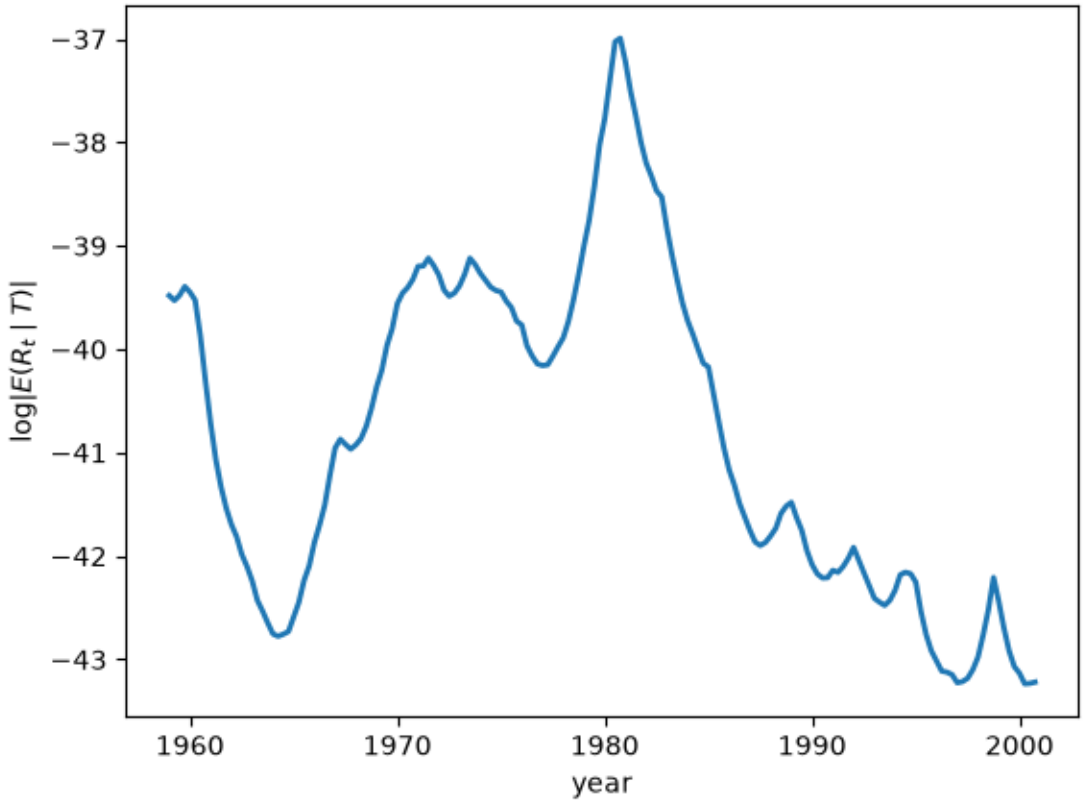

Fig. 108.5: Generalized innovation variance $\log|E(R_t \mid T)|$

The table below gives the numbers behind the figure.

```
def period_mean(values, first, last):
    """Average a quarterly series over the years first, ..., last."""
    return values[(years >= first) & (years <= last)].mean()

pd.Series({
    'mean, 1960--1964': period_mean(logdet_r, 1960, 1964),
    'peak': logdet_r.max(),
    'date of peak': dates[np.argmax(logdet_r)],
    'mean, 1990--2000': period_mean(logdet_r, 1990, 2000),
}, name='log |E(R_t | T)|').to_frame().round(2)
```

```
                    log |E(R_t | T)|
mean, 1960--1964             -41.61
peak                         -36.99
date of peak                1980.75
mean, 1990--2000             -42.59
```

Total innovation variance rises in two steps, from the mid-1960s to the early 1970s and again in the late 1970s, to a peak at the end of 1980, and most of the subsequent decline comes in the first half of the 1980s.

Its 1990s average is at or below its early-1960s average, so the Great Moderation documented by Kim and Nelson [1999] and McConnell and Perez-Quiros [2000] looks like a return to the stability of the early 1960s.

Cogley and Sargent read this as a *return* to stability, and they note how short-lived the earlier calm proved to be.

This is the clearest aggregate evidence for changing luck, but it cannot explain the coefficient-based changes in inflation dynamics examined next.

108.7.3 Core inflation and the natural rate

To study the systematic dynamics, write the VAR at date t in companion form as

$$z_t = \mu_{t|T} + A_{t|T} z_{t-1} + \begin{bmatrix} \varepsilon_t \\ 0 \end{bmatrix},$$

where $z_t = (y_t^\top, y_{t-1}^\top)^\top$ and $\mu_{t|T}$ and $A_{t|T}$ are built from $\mathbb{E}(\theta_t \mid T)$.

At date t, the local mean m_t is the point to which the companion system would converge if its coefficients stayed at their date-t values and future innovations were zero:

$$m_t = (I - A_{t|T})^{-1} \mu_{t|T}, \qquad \bar{\pi}_t = 4 s_\pi m_t, \qquad \bar{u}_t = \frac{\exp(100 s_u m_t)}{1 + \exp(100 s_u m_t)}. \tag{108.7}$$

Here s_π and s_u select inflation and unemployment from m_t, the factor four annualizes inflation, and the inverse logit returns unemployment to a rate.

Core inflation $\bar{\pi}_t$ is the long-horizon inflation forecast implied by freezing the date-t coefficients, and the natural rate $\bar{u}_t$ is the corresponding long-run unemployment anchor.

They are steady states of frozen local systems, not unconditional means of the drifting process.

Freezing the current coefficients and projecting forward is the *anticipated-utility* device [Kreps, 1998] of the learning governments of *Adaptive Learning and Escape Dynamics*, *Escaping Nash Inflation*, and *The Lost Conquest: Fed Policy in the 2020s*, which act as if their current beliefs will never be revised.

```
def local_means(θ_path):
    """Core inflation (annual rate) and the natural unemployment rate."""

(continued from previous page)

```
    'correlation of core and natural rate': np.corrcoef(core_inflation, natural_
↪rate)[0, 1],
}, name='estimate').to_frame().round(2)
```

	estimate
core inflation, 1960--1964 mean	1.53
core inflation, peak	11.82
year of the core peak	1978.00
core inflation, 1985--2000 mean	3.09
natural rate, 1960	5.38
natural rate, peak	8.38
year of the natural-rate peak	1979.00
natural rate, 2000	3.64
correlation of core and natural rate	0.84

Core inflation climbs from about 1.5 percent in the early 1960s to a peak in the late 1970s and then falls to about 3 percent, the pattern Cogley and Sargent report (about 1.5, 8, and 2.5 to 3.5 percent), although our peak is higher.

The natural rate rises from about 5 percent to a peak in the late 1970s and falls below 4 percent by 2000.

Because both lines are determined by the fitted coefficients rather than by realized shocks, their persistent shifts point to a changing systematic component.

The two anchors are highly correlated, more so than the 0.748 that Cogley and Sargent report: the model's long-run inflation and unemployment rates rose and fell together, which is not the same as current inflation and unemployment moving together.

Because $(I - A_t)^{-1}$ amplifies small coefficient changes when the largest root is close to one, long-run means are intrinsically more sensitive than short-horizon forecasts.

108.7.4 Inflation persistence

We now ask whether the *systematic* dynamics drifted on top of the moving volatilities.

The main summary is inflation persistence, measured by the normalized spectrum of inflation at frequency zero.

The spectral density of inflation at date t is

$$f_{\pi\pi}(\omega, t) = \frac{1}{2\pi} s_\pi (I - A_{t|T} e^{-i\omega})^{-1} \mathcal{R}_t (I - A_{t|T}^\top e^{i\omega})^{-1} s_\pi^\top, \tag{108.8}$$

where $\mathcal{R}_t$ embeds $\mathbb{E}(R_t \mid T)$ in the companion system.

Low-frequency power depends on both the autoregressive coefficients and the innovation covariance, so Cogley and Sargent normalize by the variance of inflation at date t,

$$g_{\pi\pi}(\omega, t) = \frac{f_{\pi\pi}(\omega, t)}{\int_{-\pi}^{\pi} f_{\pi\pi}(\omega, t) d\omega}, \tag{108.9}$$

which measures autocorrelation rather than autocovariance.

They interpret $g_{\pi\pi}(0, t)$ as a measure of inflation persistence.

Statistics at frequency zero are long-run statistics: *Two Illustrations of the Quantity Theory of Money* computes long-run slopes as ratios of spectral densities at frequency zero, and Exercise **??** computes such a slope of inflation on unemployment from this model.

The normalization removes a common scale factor from R_t, but it can still depend on the relative variances and covariances in R_t.

The next function evaluates both spectra at frequencies measured in cycles per quarter.

```
def inflation_spectrum(θ, covariance, frequencies):
    """Inflation power f(ω) and normalized power g(ω) at one date."""
    _, companion = companion_matrix(θ)
    innovation = np.zeros((6, 6))
    innovation[:3, :3] = covariance
    variance = linalg.solve_discrete_lyapunov(companion, innovation)[2, 2]
    power = np.empty(len(frequencies))
    for j, frequency in enumerate(frequencies):
        transfer = np.linalg.inv(
            np.eye(6) - companion * np.exp(-2j * np.pi * frequency))
        power[j] = np.real(transfer @ innovation @ transfer.conj().T)[2, 2]
    return power / (2 * np.pi), power / (2 * np.pi * variance)

def persistence_path(θ_path, r_path):
    """g_ππ(0, t) at every date."""
    return np.array([inflation_spectrum(θ, r, [0.0])[1][0]
                     for θ, r in zip(θ_path.T, r_path)])

inflation_persistence = persistence_path(θ_mean, r_mean)
white_noise = 1 / (2 * np.pi)
```

For white noise the spectrum is flat, so $g_{\pi\pi}(0) = 1/(2\pi) \approx 0.16$; that is the benchmark against which to read the path.

```
fig, ax = plt.subplots()
ax.plot(dates[annual], inflation_persistence[annual], 'o-', lw=2, markersize=3)
ax.axhline(white_noise, color='0.45', ls='--', lw=1,
           label=r'white noise, $1/(2\pi)$')
ax.set_xlabel('year')
ax.set_ylabel(r'$g_{\pi\pi}(0,t)$')
ax.legend()
plt.show()
```

The table below gives the numbers behind the figure.

```
pd.Series({
    '1960--1964 mean': period_mean(inflation_persistence, 1960, 1964),
    '1970--1979 mean': period_mean(inflation_persistence, 1970, 1979),
    'peak': inflation_persistence[annual].max(),
    'year of the peak': years[annual][np.argmax(inflation_persistence[annual])],
    '1985--2000 mean': period_mean(inflation_persistence, 1985, 2000),
}, name='g(0, t)').to_frame().round(3)
```

```
                    g(0, t)
1960--1964 mean       0.180
1970--1979 mean       3.839
peak                  6.886
year of the peak   1979.000
1985--2000 mean       0.350
```

Persistence is close to the white-noise value in the early 1960s, sweeps upward in the late 1960s, stays high through the 1970s with a peak in 1979, and falls sharply after 1980, back toward the white-noise value for much of the 1980s and 1990s.

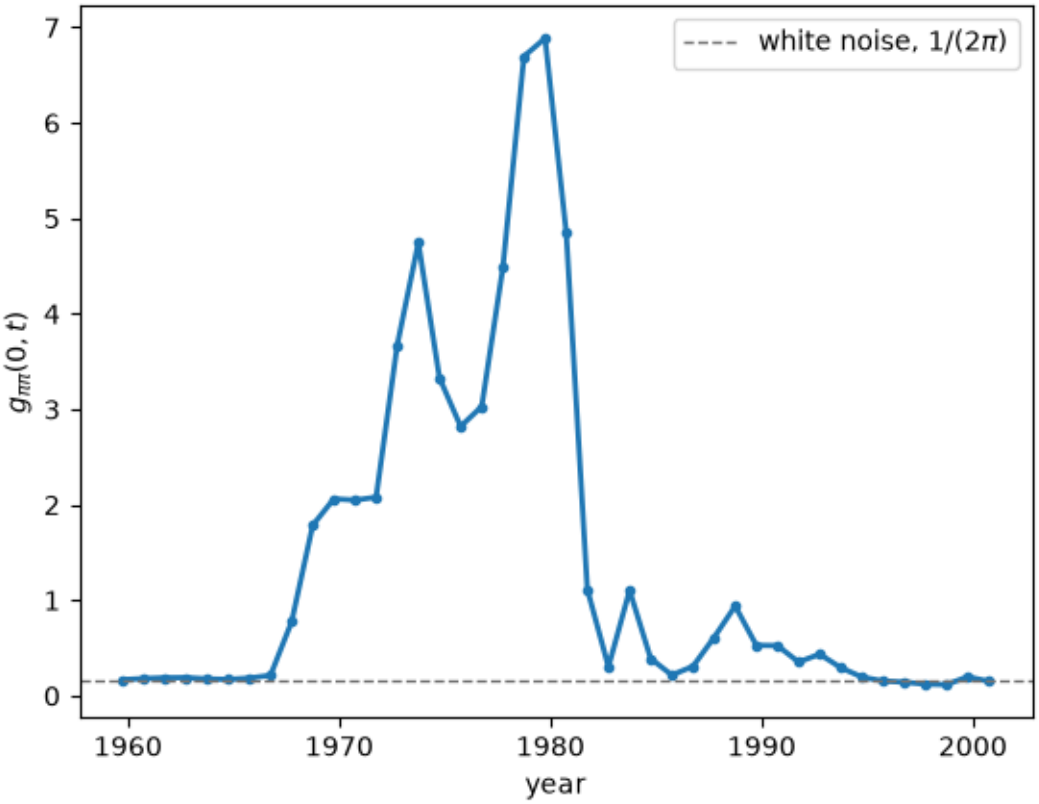

Fig. 108.7: Normalized zero-frequency spectrum $g_{\pi\pi}(0,t)$

The post-1980 fall cannot be explained by a proportional rescaling of all innovations, although the normalized statistic can still depend on the composition of R_t.

For comparison, an $AR(1)$ with coefficient ρ has $g(0) = (1+\rho)/[2\pi(1-\rho)]$, so values between 2 and 10 correspond to ρ between about 0.85 and 0.97; Exercise 108.11.1 converts the whole path into such an "equivalent $AR(1)$" coefficient.

The zero-frequency path omits the rest of the frequency distribution, which the next heatmap shows.

```
spectrum_frequencies = np.linspace(0, 0.5, 41)
normalized_spectrum = np.column_stack([
    inflation_spectrum(θ_mean[:, t], r_mean[t], spectrum_frequencies)[1]
    for t in range(len(dates))
])

fig, ax = plt.subplots(figsize=(8, 4))
image = ax.pcolormesh(dates, spectrum_frequencies,
                      np.log10(normalized_spectrum), shading='auto')
ax.set_xlabel('year')
ax.set_ylabel('cycles per quarter')
fig.colorbar(image, ax=ax, label=r'$\log_{10} g_{\pi\pi}(\omega,t)$')
plt.show()
```

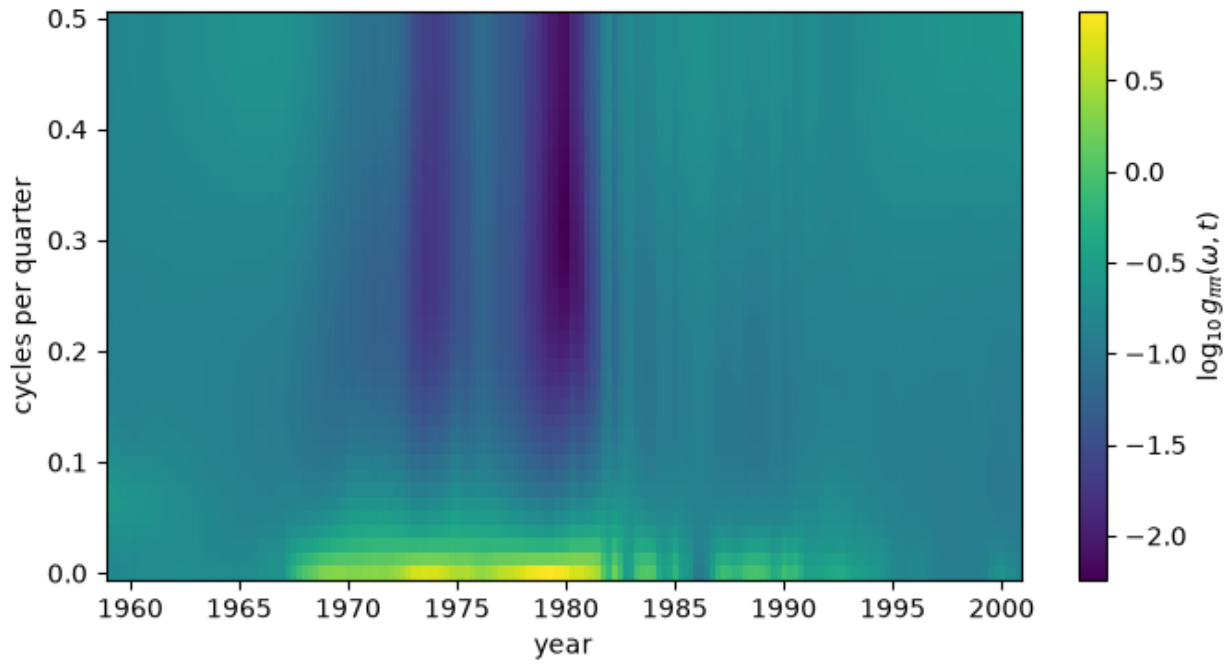

Fig. 108.8: Normalized inflation spectrum $g_{\pi\pi}(\omega, t)$

A ridge of low-frequency power runs from the late 1960s to the early 1980s and then recedes.

Because the ridge survives normalization, the Great Inflation was not only a period of large shocks: inflation shocks were also propagated more persistently.

Point estimates do not reveal how strongly the data locate these paths, so we compute the annual features from every retained draw.

```
def posterior_feature_draws(draws, indices):
    """Core inflation, the natural rate, and g(0) at selected dates, by draw."""
    n_draws = len(draws['β'])
    core = np.empty((len(indices), n_draws))
    natural = np.empty_like(core)
    persistence = np.empty_like(core)
    for d in range(n_draws):
        θ_d = draws['θ'][d][:, indices]
        core[:, d], natural[:, d] = local_means(θ_d)
        for row, t in enumerate(indices):
            covariance = innovation_covariance(draws['h'][d][t], draws['β'][d])
            persistence[row, d] = inflation_spectrum(
                θ_d[:, row], covariance, [0.0])[1][0]
    return {'core': 100 * core, 'natural': 100 * natural,
            'persistence': persistence}

feature_draws = posterior_feature_draws(posterior, annual)
```

The figure plots, for each feature, the posterior median and a 90 percent band across draws.

```
feature_specs = (('core', 'core inflation (%)'),
                 ('natural', 'natural rate (%)'),
                 ('persistence', r'$g_{\pi\pi}(0,t)$'))
fig, axes = plt.subplots(3, 1, figsize=(9, 8), sharex=True)
for ax, (key, ylabel) in zip(axes, feature_specs):
    lower, median, upper = np.quantile(feature_draws[key], (0.05, 0.5, 0.95),
                                       axis=1)
    line, = ax.plot(dates[annual], median, lw=2)
    ax.fill_between(dates[annual], lower, upper, color=line.get_color(),
                    alpha=0.2)
    ax.set_ylabel(ylabel)
axes[-1].set_xlabel('year')
plt.tight_layout()
plt.show()
```

The bands are pointwise, not bands for whole paths.

The bands are wide and skewed to the right in the 1970s, so the rise and the post-1980 fall are clearer than their magnitudes.

As Cogley and Sargent note, uncertainty about core inflation grows with persistence, because core inflation is a long-horizon forecast.

The next plot compares the timing of core inflation and persistence, as in Cogley and Sargent's Figure 11.

```
fig, ax = plt.subplots()
ax.plot(dates[annual], 100 * core_inflation[annual], 'o-', lw=2,
        markersize=3, label='core inflation (%)')
ax.plot(dates[annual], inflation_persistence[annual], 'x-', lw=2,
        markersize=4, label=r'$g_{\pi\pi}(0,t)$')
ax.set_xlabel('year')
ax.legend()
plt.show()

core_persistence_correlation = np.corrcoef(
    core_inflation, inflation_persistence)[0, 1]
```

(continues on next page)

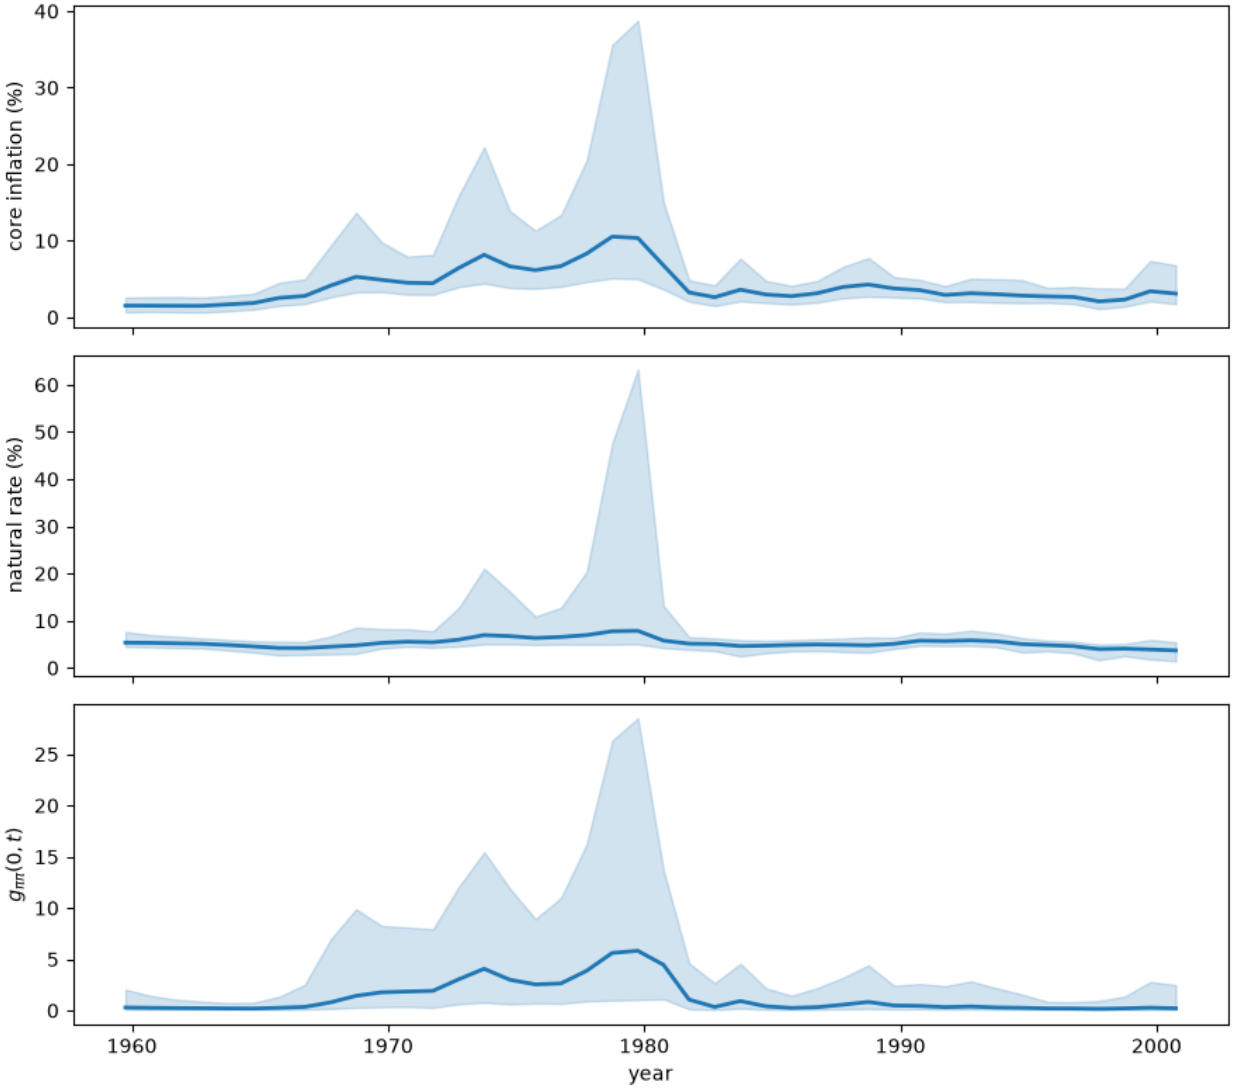

Fig. 108.9: Posterior medians and pointwise 90 percent intervals for $\bar{\pi}_t$, $\bar{u}_t$, and $g_{\pi\pi}(0,t)$

(continued from previous page)

```
print(f'correlation of core inflation and persistence: '
      f'{core_persistence_correlation:.3f}')
```

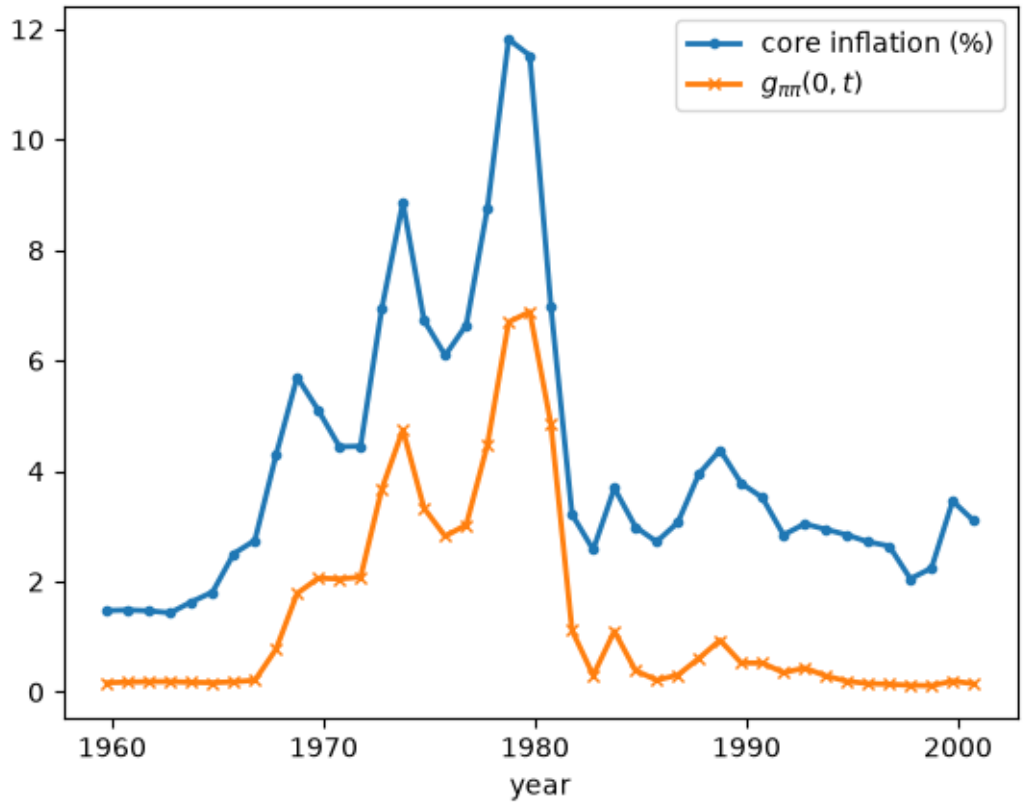

Fig. 108.10: Core inflation $\bar{\pi}_t$ and persistence $g_{\pi\pi}(0,t)$

```
correlation of core inflation and persistence: 0.965
```

Core inflation and persistence rise together through the late 1960s and 1970s and fall together during the Volcker disinflation.

The printed quarterly correlation is high and close to the 0.92 that Cogley and Sargent report.

It summarizes common timing rather than a causal relation: both measures are nonlinear functions of the same fitted coefficients.

Bad policy or bad luck? A verdict explains why this positive correlation troubled the escape-route models of *Escaping Nash Inflation*.

108.7.5 Monetary policy activism

Cogley and Sargent summarize systematic policy with the forward-looking Taylor rule of Clarida *et al.* [2000], with interest-rate smoothing,

$$i_t = \psi_0 + \psi_1 \mathbb{E}_t \bar{\pi}_{t,t+h_\pi} + \psi_2 \mathbb{E}_t \bar{u}_{t,t+h_u} + \psi_3 i_{t-1} + e_t, \tag{108.10}$$

where $\bar{\pi}_{t,t+h_\pi}$ and $\bar{u}_{t,t+h_u}$ are average inflation and unemployment over the next h_π and h_u quarters.

They define the activism coefficient $\mathcal{A}_t = \psi_1/(1-\psi_3)$ and call policy active when $\mathcal{A}_t \geq 1$, so that the nominal rate rises more than one-for-one with expected inflation in the long run.

The long-run response $\psi_1(1+\psi_3+\psi_3^2+\cdots)$ exists only when $|\psi_3| < 1$.

At each date, population two-stage least squares projections implied by the local VAR deliver the coefficients.

The first stage projects the Fed's forecasts on lagged information, namely the VAR's forecasts made at $t-1$, because the Fed does not see current-quarter inflation and unemployment when it sets the rate.

The second stage projects i_t on those fitted forecasts and i_{t-1}.

The benchmark horizons are $h_\pi = 4$ quarters and $h_u = 2$ quarters, reflecting Federal Reserve folk wisdom about policy lags.

```
def policy_rule_coefficients(θ, covariance, h_pi=4, h_u=2):
    """Population 2SLS coefficients (ψ_1, ψ_2, ψ_3) implied by a local VAR."""
    _, companion = companion_matrix(θ)
    innovation = np.zeros((6, 6))
    innovation[:3, :3] = covariance
    stationary = linalg.solve_discrete_lyapunov(companion, innovation)
    power, π_load, u_load = np.eye(6), np.zeros(6), np.zeros(6)
    for horizon in range(1, max(h_pi, h_u) + 1):
        power = power @ companion
        if horizon <= h_pi:
            π_load += power[2] / h_pi
        if horizon <= h_u:
            u_load += power[1] / h_u
    loadings = np.vstack((π_load, u_load, np.eye(6)[0]))
    return np.linalg.solve(loadings @ stationary @ loadings.T,
                           loadings @ stationary @ companion.T[:, 0])

rules = np.array([policy_rule_coefficients(θ_mean[:, t], r_mean[t])
                  for t in range(len(dates))])
ψ1, ψ3 = rules[:, 0], rules[:, 2]
activism = np.where(np.abs(ψ3) < 1, ψ1 / (1 - ψ3), np.nan)
print(f'share of dates with |ψ_3| < 1: {np.mean(np.abs(ψ3) < 1):.3f}')
```

```
share of dates with |ψ_3| < 1: 1.000
```

The figure plots $\mathcal{A}_t$ at the posterior mean, as in Cogley and Sargent's Figure 12, leaving blank any date with $|\psi_3| \geq 1$.

```
fig, ax = plt.subplots()
ax.plot(dates, activism, lw=2)
ax.axhline(1, color='0.45', lw=1)
ax.set_xlabel('year')
ax.set_ylabel(r'$\mathcal{A}_t$')
plt.show()
```

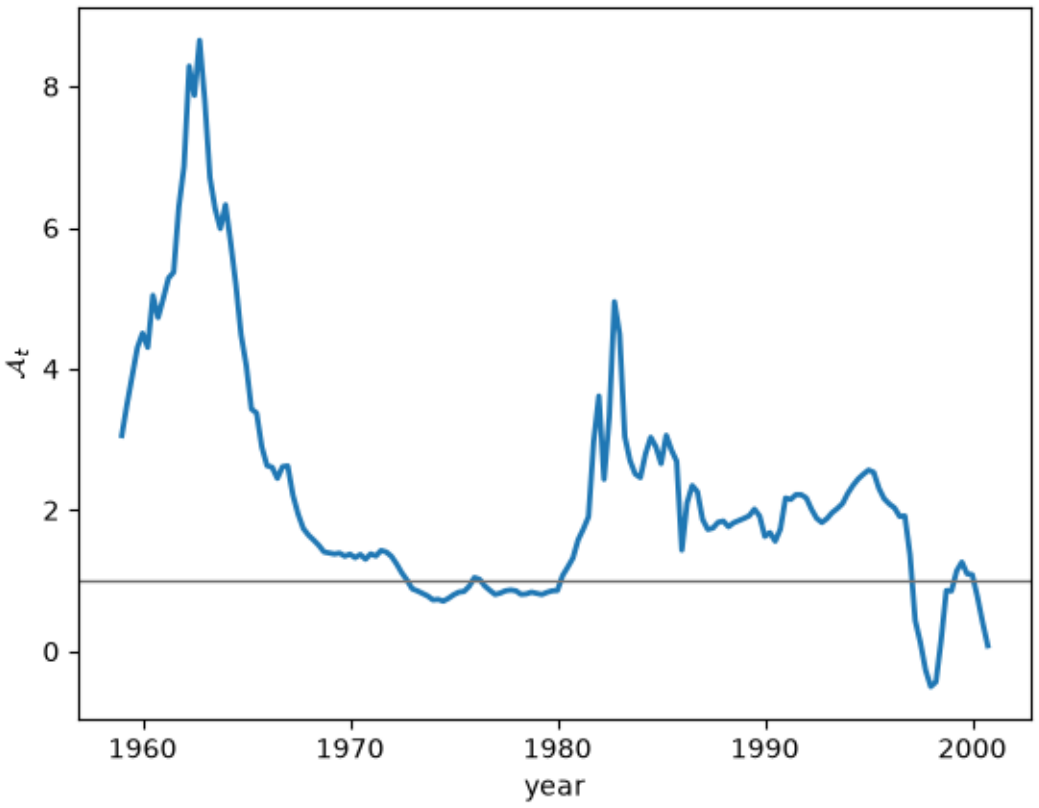

Fig. 108.11: Activism coefficient $\mathcal{A}_t = \psi_{1t}/(1 - \psi_{3t})$ at the posterior mean

Judged by point estimates, policy was active in the early 1960s, was mostly passive from the early 1970s until 1980, and turned active at the start of the Volcker disinflation, staying active through the mid-1990s.

Estimates at the very end of the sample are erratic, for a reason explained next.

The rule's coefficients are weakly identified when inflation is close to white noise, because lagged variables are then poor instruments for future inflation, so a path built from posterior-mean inputs understates the uncertainty.

We therefore compute $\mathcal{A}_t$ from every retained draw in 1975, 1985, and 1995 and compare the posterior probabilities with Cogley and Sargent's.

```
selected_years = (1975, 1985, 1995)
selected_dates = [np.flatnonzero(years == year)[-1] for year in selected_years]
n_draws = len(posterior['β'])
activism_draws = {year: np.empty(n_draws) for year in selected_years}
inside = {year: np.empty(n_draws, dtype=bool) for year in selected_years}
for d in range(n_draws):
    for year, t in zip(selected_years, selected_dates):
        covariance = innovation_covariance(posterior['h'][d][t],
                                           posterior['β'][d])
        ψ = policy_rule_coefficients(posterior['θ'][d][:, t], covariance)
        activism_draws[year][d] = ψ[0] / (1 - ψ[2])
        inside[year][d] = abs(ψ[2]) < 1

activism_events = (
    activism_draws[1975] > 1,
    activism_draws[1985] > 1,
    activism_draws[1995] > 1,
    activism_draws[1985] > activism_draws[1975],
    activism_draws[1995] > activism_draws[1975],
)
pd.DataFrame({
    'this lecture': [event.mean() for event in activism_events],
    'Cogley and Sargent': [0.208, 0.919, 0.941, 0.923, 0.943],
}, index=['P(A_1975 > 1)', 'P(A_1985 > 1)', 'P(A_1995 > 1)',
          'P(A_1985 > A_1975)', 'P(A_1995 > A_1975)']).round(3)
```

	this lecture	Cogley and Sargent
P(A_1975 > 1)	0.285	0.208
P(A_1985 > 1)	0.736	0.919
P(A_1995 > 1)	0.693	0.941
P(A_1985 > A_1975)	0.744	0.923
P(A_1995 > A_1975)	0.699	0.943

Like Cogley and Sargent, these probabilities use every draw; the share of draws with $|\psi_3| < 1$, for which $\mathcal{A}_t$ has its long-run interpretation, is

```
pd.Series({year: inside[year].mean() for year in selected_years},
          name='share of draws with |ψ_3| < 1').to_frame().round(3)
```

	share of draws with |ψ_3| < 1
1975	1.000
1985	0.961
1995	0.973

The posterior favors passive policy in 1975 and active policy in 1985 and 1995, and it says that activism probably rose.

But our probabilities of active policy in 1985 and 1995, and of a rise since 1975, are noticeably lower than Cogley and Sargent's, in every run we made.

That is consistent with the larger drift covariance in our posterior, which locates the coefficients at any date less precisely.

108.7.6 The disinflation and the calm

Escaping Nash Inflation ends by asking whether the calm of the mid-1980s and the disinflation arrived together, because a model in which calm makes escapes easier would predict that they should.

The fitted model separates the two: core inflation measures the disinflation, and the generalized innovation variance measures the calm.

The table dates the peak of each and the quarter in which each had covered half the distance from its peak to its post-1985 average.

```
def peak_and_halfway(series, first_after=1985):
    """Date of the peak, and of the first later date halfway to the later mean."""
    peak = np.argmax(series)
    later_mean = series[years >= first_after].mean()
    halfway = 0.5 * (series[peak] + later_mean)
    after = peak + np.flatnonzero(series[peak:] <= halfway)[0]
    return dates[peak], dates[after]

pd.DataFrame(
    [peak_and_halfway(core_inflation), peak_and_halfway(logdet_r)],
    index=['core inflation', 'log |E(R_t | T)|'],
    columns=['peak', 'halfway down'],
).round(2)
```

	peak	halfway down
core inflation	1979.25	1980.25
log |E(R_t | T)|	1980.75	1984.00

Core inflation fell first: it was halfway down a year after its peak, while total innovation variance peaked later and covered half of its decline only around 1984.

The disinflation preceded most of the calm, so the timing gives no support to the idea that a calm made the escape to low inflation possible, although a reduced-form VAR cannot settle questions of causation.

108.8 Why classical tests missed the drift

How can a model with this much drift coexist with the classical tests that failed to reject time invariance?

Cogley and Sargent's answer, in their section 3.7, is that those tests have little power against drift of the kind their posterior describes.

They first applied Bernanke and Mihov's test, the sup-LM test of Andrews [1993] for a single break at an unknown date, to their data, and like Bernanke and Mihov they could not reject.

A failure to reject is evidence against drift only if the test would probably have rejected had drift been present.

To measure that probability, they drew (θ^T, H^T, B) from their posterior, simulated an artificial sample from each draw, applied the test, and counted rejections at the 5 percent level in 10,000 replications.

They did the same for the test of Nyblom [1989] and Hansen [1992], which is designed for parameters that drift as random walks, and for the sup-Wald version of Andrews's test.

Rejection frequency under the posterior	Nominal interest	Unemployment	Inflation	VAR
Andrews sup-LM (Table 4)	0.136	0.172	0.112	0.252
Nyblom–Hansen (Table 5)	0.076	0.170	0.086	0.234
Andrews sup-Wald (Table 6)	0.173	0.269	0.711	0.296

On the actual data the sup-LM and Nyblom–Hansen tests fail to reject for every equation and for the VAR as a whole.

Yet even when θ drifts as the posterior says it does, these tests fail to reject about three times as often as they reject, or more.

The one case with better-than-even power is the sup-Wald test for the inflation equation, and on the actual data that test rejects time invariance at the 1 percent level; it also rejects for the VAR as a whole at 5 percent.

Tests aimed at the parameters of the Clarida *et al.* [2000] policy rule, or at the first principal component of θ_t, also turn out to have low power.

So the failures to reject by Bernanke and Mihov [1998] and Sims [1999] are what one should expect even if the coefficients drifted as much as they do here.

Low power is not surprising.

The drifting-coefficient model nests time invariance at $Q = 0$: for Q near zero power is close to size, for very large Q the tests reject almost surely, and in between lies a range of economically meaningful drift that the tests usually miss.

Relatedly, Stock and Watson [1998] show that when the drift variance is small its maximum likelihood estimate is often exactly zero, so a classical estimate of "no drift" is weak evidence as well.

Cogley and Sargent close with a deeper reason, clearest in continuous time [Anderson *et al.*, 2003].

The volatility of a diffusion can be recovered from its quadratic variation over an arbitrarily short stretch of a path, but its drift can be learned only slowly, over long spans of data.

Movements in the *systematic* part of a time series are therefore much harder to detect than movements in its *volatility*, which is exactly the asymmetry between the two halves of the bad-luck evidence: strong evidence of changing variances and weak evidence against changing coefficients.

Exercise 108.11.3 computes the power of the Nyblom–Hansen test in a simple autoregression with a drifting coefficient.

108.9 Bad policy or bad luck? A verdict

The Bayesian VAR delivers a nuanced answer to the question that opened this lecture.

- *Volatilities drifted:* the size of the shocks changed enormously, with a spike around 1980 and a return to calm in the mid-1980s, so the bad-luck story captures something real.
- *Coefficients drifted too:* core inflation and inflation persistence rose through the 1970s and fell in the 1980s, and the estimated policy rule moved from passive to active; Exercise 108.11.2 shows that freezing the coefficients cannot reproduce the post-1980 fall in persistence.
- *Classical tests are not counterevidence:* they have little power against drift of this kind.

The reduced-form VAR cannot by itself prove that changes in Federal Reserve beliefs caused the coefficient drift, because private behavior and other omitted mechanisms can also change reduced-form dynamics.

There is one more twist, and it loops us back to the theory of this section.

The escape-route models of *Adaptive Learning and Escape Dynamics* and *Escaping Nash Inflation* make a sharp prediction about persistence.

At the high-inflation self-confirming equilibrium the government's inflation target barely moves, so inflation is nearly serially uncorrelated; in the static model it is white noise.

Measured persistence rises only *along the transition* from high to low inflation, when beliefs, and with them mean inflation, shift rapidly within any window of data.

These models therefore predict that persistence should peak during a disinflation and be low when inflation is high, an inverse relation between the level and the persistence of inflation in the words of Cogley and Sargent [2005] (footnote 28).

The data show the opposite: persistence was highest when core inflation was highest, and both fell together after 1980.

Exercise 108.11.4 checks the prediction in the model of *Escaping Nash Inflation*.

The positive correlation helped motivate a different mechanism, a policymaker who is *reluctant to disinflate*.

In Cogley and Sargent [2005], a Fed that averages over competing Phillips-curve models wants to reduce inflation in the 1970s but moves very slowly, because a model that warns of large unemployment costs still carries weight, and that gradualism makes deviations from target persistent precisely when inflation is highest.

In Primiceri [2006], policymakers who underestimated the natural rate and the persistence of inflation and overestimated the cost of disinflation are likewise slow to act in the 1970s and then change course.

The friendly debate with Sims, Zha, Bernanke, and Mihov thus did more than adjudicate a historical question: it sharpened the models of learning and drift that run through this section.

Cogley and Sargent's sample ends in 2000.

Drifts and Volatilities after 2000 re-estimates the model with data through the financial crisis, the zero lower bound, the pandemic, and the 2021–2022 inflation surge, and *The Lost Conquest: Fed Policy in the 2020s* then returns to a learning Fed to interpret the 2020s.

108.10 Appendix: the sampler in detail

108.10.1 The coefficient block

Conditional on Q and R^T, the measurement equation (108.1) and the random walk (108.2) form a linear Gaussian state-space model, and the forward recursion is the Kalman filter of *A First Look at the Kalman Filter*, started from $\theta_{0|0} = \bar{\theta}$ and $P_{0|0} = \bar{P}$:

$$
\begin{aligned}
P_{t|t-1} &= P_{t-1|t-1} + Q, \\
K_t &= P_{t|t-1} X_t \left(X_t^\top P_{t|t-1} X_t + R_t \right)^{-1}, \\
\theta_{t|t} &= \theta_{t-1|t-1} + K_t \left(y_t - X_t^\top \theta_{t-1|t-1} \right), \\
P_{t|t} &= P_{t|t-1} - K_t X_t^\top P_{t|t-1}.
\end{aligned}
$$

The backward pass draws $\theta_T \sim N(\theta_{T|T}, P_{T|T})$ and then, for $t = T-1, \dots, 0$,

$$
\theta_t \mid \theta_{t+1} \sim N\left(\theta_{t|t} + J_t(\theta_{t+1} - \theta_{t|t}),\; P_{t|t} - J_t P_{t+1|t} J_t^\top \right), \qquad J_t = P_{t|t} P_{t+1|t}^{-1}.
$$

Setting the random draws to zero turns the backward pass into the Rauch–Tung–Striebel smoother, which delivers $\mathbb{E}(\theta_t \mid T)$ given Q and R^T.

The gains J_t and the Cholesky factors of the conditional covariances depend only on Q and R^T, so `backward_factors` computes them once per sweep and each redraw reuses them.

Drawing θ_0 supplies all T increments to the update of Q.

Because the stability test runs after every backward pass, the sampler uses `stable_path`, which applies the Schur–Cohn criterion to the characteristic polynomials of all the companion matrices at once instead of computing their eigenvalues: the roots lie inside the unit circle exactly when a recursion of "reflection coefficients" stays inside $(-1, 1)$, and the test gives the same answer as `is_stable` several times faster.

When $Q = 0$, $P_{t+1|t} = P_{t|t}$, so $J_t = I$ and the conditional covariance is zero: the backward pass returns a constant path, which is how the sampler nests the constant-coefficient model.

The redraw step is rejection sampling.

Given Ω, the backward passes are independent draws from the Gaussian $N(\hat{z}, C)$ of the whole path, and the first draw that lands in the stable set $\mathcal{S}$ has density

$$\frac{N(z; \hat{z}, C)\, \mathbb{1}_{\mathcal{S}}(z)}{\mathbb{P}\{z \in \mathcal{S} \mid \Omega\}},$$

which is the restricted full conditional; the normalizing probability is $p(\Omega)$ in the identity of *Simulating the posterior*, and it never has to be computed.

108.10.2 The volatility block

Given its neighbors and the orthogonalized residual ε^*_{it}, the i-th component of $B\varepsilon_t$, the conditional density of h_{it} is proportional to

$$h_{it}^{-1/2} \exp\left(-\frac{(\varepsilon^*_{it})^2}{2h_{it}}\right) \times \frac{1}{h_{it}} \exp\left(-\frac{\left(\log h_{it} - \frac{1}{2}(\log h_{i,t-1} + \log h_{i,t+1})\right)^2}{\sigma_i^2}\right).$$

The proposal draws $\log h_{it}$ from the normal factor, with mean $\frac{1}{2}(\log h_{i,t-1} + \log h_{i,t+1})$ and variance $\sigma_i^2/2$, so the Metropolis acceptance ratio involves only the likelihood factor.

The last date has a single neighbor, and $\log h_{i0}$ has a conjugate normal conditional.

108.10.3 Monte Carlo error

Successive sweeps are correlated, so the chain's draws carry less information than their number suggests.

The trace of $\mathrm{tr}(Q)$ over all sweeps, including the burn-in, shows how slowly the chain moves in the direction of Q.

The reason is the dependence between Q and the coefficient path: given the path, its T increments pin Q down tightly, and given Q, the roughness of the next path is pinned down too, so the two can move only gradually together.

```
fig, ax = plt.subplots(figsize=(9, 3.5))
ax.plot(posterior['trace_q'], lw=0.5)
ax.axvline(burn, color='0.45', ls='--', lw=1, label='end of burn-in')
ax.set_xlabel('sweep')
ax.set_ylabel(r'$\mathrm{tr}(Q)$')
ax.legend()
plt.show()
```

The integrated autocorrelation time τ measures how many sweeps are worth one independent draw; we estimate it with Sokal's adaptive window.

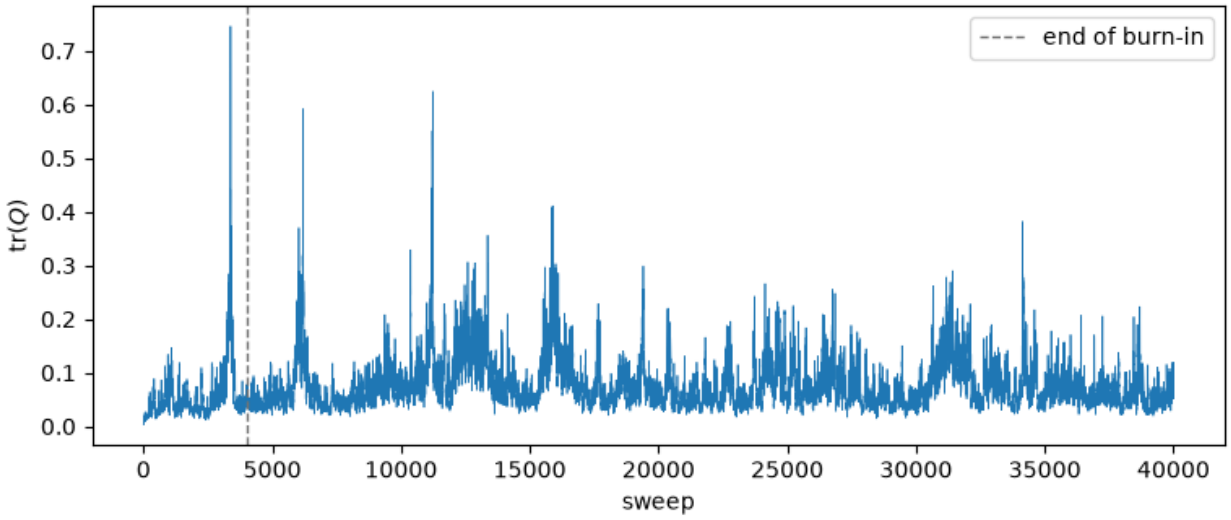

Fig. 108.12: tr(Q) at every sweep

```
def integrated_autocorrelation_time(x, c=5):
    """Sokal's adaptive-window estimate of the integrated autocorrelation time."""
    x = np.asarray(x) - np.mean(x)
    n = len(x)
    spectrum = np.fft.rfft(x, 2 * n)
    acf = np.fft.irfft(spectrum * np.conj(spectrum))[:n]
    τ = 2 * np.cumsum(acf / acf[0]) - 1
    window = np.flatnonzero(np.arange(n) >= c * τ)
    return τ[window[0]] if window.size else τ[-1]   # chain too short for the window

τ_trace_q = integrated_autocorrelation_time(trace_q)
pd.Series({
    'sweeps after burn-in': len(trace_q),
    'autocorrelation time of tr(Q)': τ_trace_q,
    'effective sample size of tr(Q)': len(trace_q) / τ_trace_q,
}, name='value').to_frame().round(1)
```

```
                                value
sweeps after burn-in          36000.0
autocorrelation time of tr(Q)   416.0
effective sample size of tr(Q)   86.5
```

For the other headline numbers we use batch means: split the retained draws into ten consecutive batches, recompute each statistic on every batch, and estimate the Monte Carlo standard error of the full-run value by the standard deviation across batches divided by $\sqrt{10}$.

```
def headline_statistics(s):
    """Statistics quoted in the lecture, from the retained draws in slice s."""
    θ_s = posterior['θ'][s].mean(axis=0)
    r_s = mean_innovation_covariance(posterior['h'][s], posterior['β'][s])
    core, natural = local_means(θ_s)
    persistence = persistence_path(θ_s, r_s)
    eigenvalues = np.linalg.eigvalsh(posterior['Q'][s].mean(axis=0))[::-1]
```

(continues on next page)

(continued from previous page)

```

P(A_1995 > A_1975)	0.943

These standard errors are rough, because each batch spans only a few autocorrelation times of $\text{tr}(Q)$.

Runs with other seeds differ from this one by more than the standard errors suggest for $\text{tr}(Q)$, the peak of core inflation, and the activism probabilities.

The statements in the text are those that held in all of our runs: the structure of drift, the timing of the rise and fall of

core inflation and persistence, their high correlation, and the shift from passive to active policy, but not exact magnitudes.

108.11 Exercises

Exercise 108.11.1

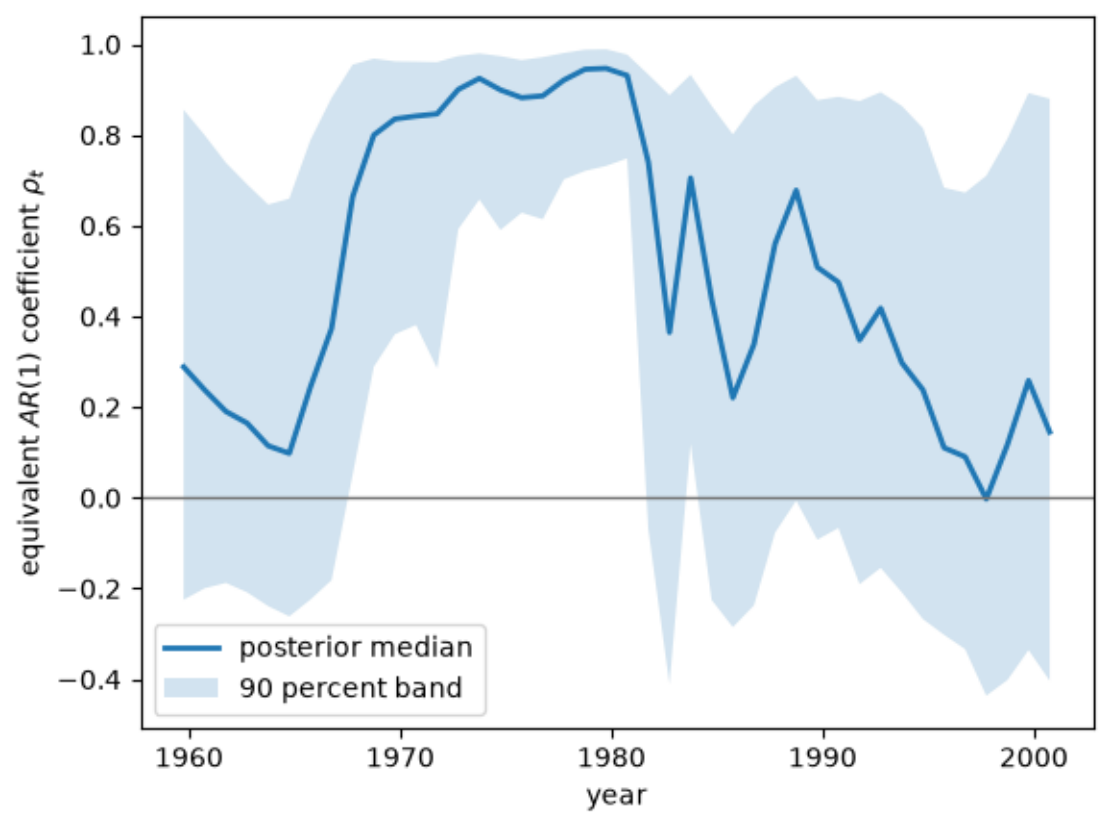
Consider a stationary $AR(1)$, $\pi_t = \rho \pi_{t-1} + w_t$ with $|\rho| < 1$.

1. Use (108.8), with the companion matrix replaced by the scalar ρ, to show that $g(0) = (1+\rho)/[2\pi(1-\rho)]$, and invert the formula to express ρ as a function of $g(0)$.
2. Apply the inversion draw by draw to the persistence draws in `feature_draws['persistence']`, and plot the posterior median and pointwise 90 percent band of the resulting "equivalent $AR(1)$" coefficient ρ_t.
3. Which ρ corresponds to white noise, and which to $g(0) = 1$? How did the equivalent ρ_t change between the early 1960s, the 1970s, and the 1990s?

Solution

For the $AR(1)$, $f(0) = \sigma_w^2/[2\pi(1-\rho)^2]$ and the variance is $\sigma_w^2/(1-\rho^2)$, so

$$g(0) = \frac{1-\rho^2}{2\pi(1-\rho)^2} = \frac{1+\rho}{2\pi(1-\rho)}, \qquad \rho = \frac{2\pi g(0) - 1}{2\pi g(0) + 1}.$$



White noise, $g(0) = 1/(2\pi)$, gives $\rho = 0$, and $g(0) = 1$ gives $\rho = (2\pi - 1)/(2\pi + 1) \approx 0.73$.

The inversion is increasing in $g(0)$, so it maps posterior quantiles of $g_{\pi\pi}(0, t)$ into posterior quantiles of ρ_t.

```
def equivalent_ar1(g):
    """AR(1) coefficient with the same normalized power at frequency zero."""
    return (2 * np.pi * g - 1) / (2 * np.pi * g + 1)

ρ_draws = equivalent_ar1(feature_draws['persistence'])
lower, median, upper = np.quantile(ρ_draws, (0.05, 0.5, 0.95), axis=1)

fig, ax = plt.subplots()
ax.plot(dates[annual], median, lw=2, label='posterior median')
ax.fill_between(dates[annual], lower, upper, alpha=0.2, label='90 percent band')
ax.axhline(0, color='0.45', lw=1)
ax.set_xlabel('year')
ax.set_ylabel(r'equivalent $AR(1)$ coefficient $\rho_t$')
ax.legend()
plt.show()
```

The table below gives the numbers behind the figure.

```
pd.Series({
    period: np.median(ρ_draws[(years[annual] >= first) & (years[annual] <= last)])
    for period, (first, last) in {'1960--1964': (1960, 1964),
                                  '1970--1979': (1970, 1979),
                                  '1990--2000': (1990, 2000)}.items()
}, name='median equivalent ρ').to_frame().round(2)
```

```
           median equivalent ρ
1960--1964                0.16
1970--1979                0.91
1990--2000                0.22
```

The equivalent coefficient is small in the early 1960s, about 0.9 in the 1970s, and below one half in the 1990s, although the band in the 1970s is wide.

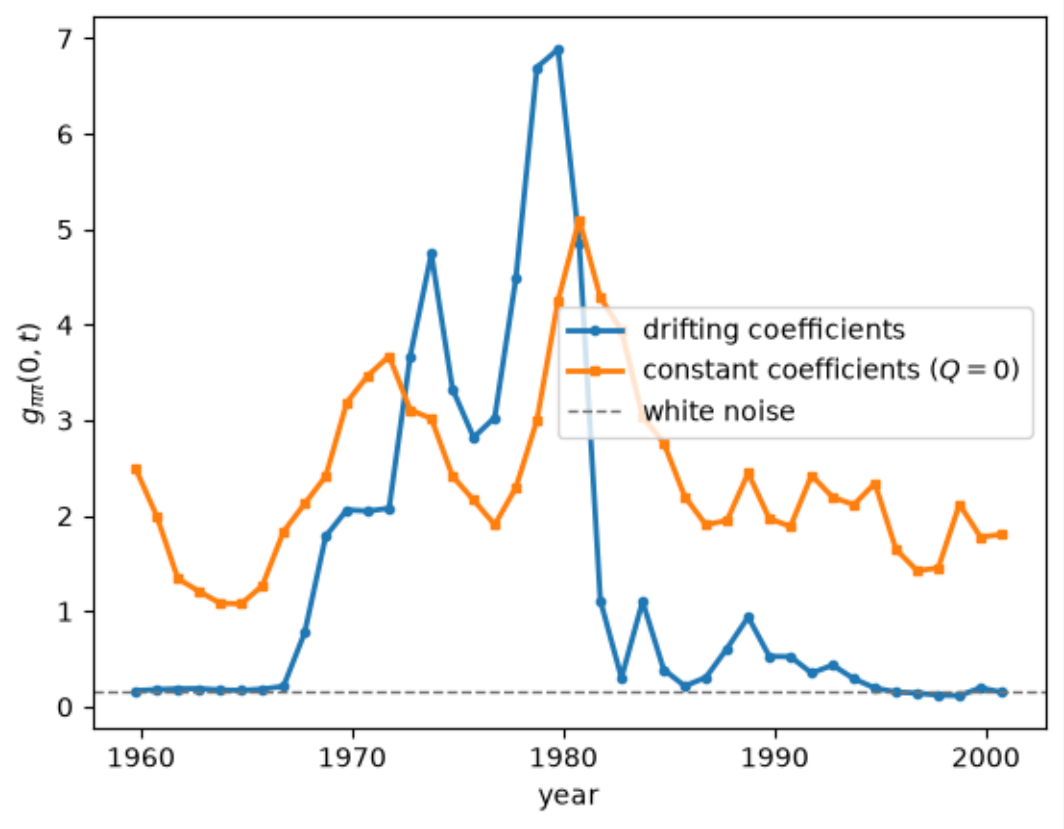
Exercise 108.11.2

A formal contrast between drifting and constant coefficients requires refitting the model with $Q = 0$, the special case in which the VAR coefficients are constant and only the stochastic volatilities H_t move.

The sampler supports this: passing `fixed_q=np.zeros((n_coefficients, n_coefficients))` to `run_sampler` holds Q at zero.

Fit the constant-coefficient model to the same sample and plot its $g_{\pi\pi}(0, t)$ against the drifting-coefficient path of Fig. 108.7.

Can drifting volatility alone account for the rise and fall of measured persistence?



Solution

With $Q = 0$ the coefficient path is constant (*Appendix: the sampler in detail*), so $A_{t|T}$ no longer moves and $g_{\pi\pi}(0, t)$ can vary only through the composition of R_t.

The constant-coefficient chain mixes much faster, so a shorter run suffices.

```
constant_posterior = run_sampler(
    data['y'], data['x'], prior,
    n_sweeps=4_000, burn=1_000, thin=10, seed=42,
    fixed_q=np.zeros((n_coefficients, n_coefficients)),
)
constant_θ = constant_posterior['θ'].mean(axis=0)
constant_r = mean_innovation_covariance(constant_posterior['h'],
                                        constant_posterior['β'])
constant_persistence = persistence_path(constant_θ, constant_r)

fig, ax = plt.subplots()
ax.plot(dates[annual], inflation_persistence[annual], 'o-', lw=2,
        markersize=3, label='drifting coefficients')
ax.plot(dates[annual], constant_persistence[annual], 's-', lw=2,
        markersize=3, label=r'constant coefficients ($Q=0$)')
ax.axhline(white_noise, color='0.45', ls='--', lw=1, label='white noise')
ax.set_xlabel('year')
ax.set_ylabel(r'$g_{\pi\pi}(0,t)$')
ax.legend(loc='center right')
plt.show()
```

The table below gives the numbers behind the figure.

```
after_1981 = years[annual] >= 1982
pd.DataFrame({
    label: {
        '1960--1964 mean': period_mean(path, 1960, 1964),
        '1970--1979 mean': period_mean(path, 1970, 1979),
        'peak': path[annual].max(),
        'year of the peak': years[annual][np.argmax(path[annual])],
        '1990--2000 mean': period_mean(path, 1990, 2000),

share of 1982--2000 years below one                  0.00
```

With constant coefficients, measured persistence still moves, because the composition of R_t changes even after its scale is normalized out, and the constant-coefficient path peaks around 1980, when inflation innovations are large relative to the others.

But it misses both ends of the story.

It puts persistence in the early 1960s far above the white-noise value, and after 1980 it stays above one, with 1990s persistence not far below its 1970s level, while the drifting-coefficient path is below one in most or all of those years.

Drifting volatility alone accounts for some of the movement in measured persistence but neither its low level in the early 1960s nor its post-1980 collapse, which is why both channels are needed to answer the bad-policy-or-bad-luck question.

Exercise 108.11.3

For a regression $z_t = x_t^\top b + u_t$ estimated by least squares with residuals $\hat{u}_t$, the statistic of Nyblom [1989] and Hansen [1992] for constancy of all coefficients is

$$L = \frac{1}{T^2} \sum_{t=1}^{T} S_t^\top V^{-1} S_t, \qquad S_t = \sum_{s \le t} x_s \hat{u}_s, \qquad V = \frac{1}{T} \sum_{s=1}^{T} x_s x_s^\top \hat{u}_s^2.$$

Apply it to the $AR(1)$ with intercept $y_t = 0.5 + \rho_t y_{t-1} + w_t$, $w_t \sim N(0,1)$, with $T = 168$ and $\rho_0 = 0.6$, using 2,000 replications per case.

1. Simulate the 5 percent critical value when ρ_t is constant, and compare it with Hansen's asymptotic value of 0.749 for two coefficients.
2. Compute the rejection frequency when ρ_t is a random walk, kept inside $[-0.97, 0.97]$, with innovation variance $q \in \{10^{-4}, 4 \times 10^{-4}, 10^{-3}, 4 \times 10^{-3}\}$.
3. Compute the rejection frequency when ρ is constant but the standard deviation of w_t triples halfway through the sample.

Relate your results to the power that Cogley and Sargent report in *Why classical tests missed the drift*.

Solution

We simulate all replications at once.

```
def simulate_ar1_panel(n, T, q, rng, volatility_break=False):
    """n replications of y_t = 0.5 + ρ_t y_{t-1} + s_t w_t."""

random-walk ρ, q = 0.0004                                     0.259
random-walk ρ, q = 0.001                                      0.410
random-walk ρ, q = 0.004                                      0.820
constant ρ, shock sd triples                                  0.000

                              rejection frequency
random-walk ρ, q = 0.0001                   0.100
random-walk ρ, q = 0.0004                   0.210
random-walk ρ, q = 0.001                    0.292
random-walk ρ, q = 0.004                    0.428
constant ρ, shock sd triples                0.032
```

The simulated critical value is close to Hansen's asymptotic value.

Power rises with q but stays below one half even when the standard deviation of the change in ρ over the sample is about 0.8, and drift that moves ρ by a few tenths over the sample is detected only a fifth to a third of the time, the same order as the 0.08 to 0.23 that Cogley and Sargent find for their posterior.

A tripling of the shock standard deviation with constant ρ is rejected no more often than the test's 5 percent size, so the test does not mistake volatility for drift; it is simply weak against drift.

Exercise 108.11.4

Do escape-route models predict the positive correlation between mean inflation and persistence that we found in *Inflation persistence*?

Simulate the static model of *Escaping Nash Inflation*, with $\theta = 1$, $u = 5$, and $\sigma_1 = \sigma_2 = 0.3$, under constant-gain least squares with gain $\varepsilon = 0.02$ for 40,000 periods, starting at the self-confirming equilibrium.

In rolling windows of 40 periods, fit an $AR(1)$ to inflation, compute its $g(0) = (1 + \hat{\rho})/[2\pi(1 - \hat{\rho})]$, and record mean inflation.

1. Compare the median $g(0)$ in windows that sit at Nash (mean inflation above 4 in both halves), near Ramsey (below 1 in both halves), and that span a fall (above 3.5 in the first half and below 1.5 in the second).
2. Compute the correlation between rolling mean inflation and rolling $g(0)$, and compare it with the correlation between core inflation and persistence in the data.

Solution

The simulation repeats `simulate_path` from *Escaping Nash Inflation*, with beliefs $\gamma = (\gamma_1, \gamma_{-1})$ about the slope and intercept of the perceived Phillips curve $U = \gamma_1 \pi + \gamma_{-1}$.

```
def simulate_escapes(ε, n_periods, θ=1.0, u=5.0, σ1=0.3, σ2=0.3, seed=0):
    """Inflation in the static CWS model under constant-gain least squares."""
    rng = np.random.default_rng(seed)
    γ = np.array([-θ, u * (1 + θ**2)])                    # SCE beliefs
    x = -γ[1] * γ[0] / (1 + γ[0]**2)
    R = np.array([[x**2 + σ2**2, x], [x, 1.0]])
    π = np.empty(n_periods)
    for n in range(n_periods):
        x = -γ[1] * γ[0] / (1 + γ[0]**2)                   # Phelps choice
        w1, w2 = rng.standard_normal(2)
        π[n] = x + σ2 * w2
        U = u - θ * σ2 * w2 + σ1 * w1
        Φ = np.array([π[n], 1.0])
        R = R + ε * (np.outer(Φ, Φ) - R)
        γ = γ + ε * np.linalg.solve(R, Φ * (U - Φ @ γ))
    return π

π_sim = simulate_escapes(0.02, 40_000, seed=2)
windows = np.lib.stride_tricks.sliding_window_view(π_sim, 40)[::2]
centered = windows - windows.mean(axis=1, keepdims=True)
ρ_hat = np.clip(np.sum(centered[:, 1:] * centered[:, :-1], axis=1)
                / np.sum(centered[:, :-1]**2, axis=1), -0.99, 0.99)
g0 = (1 + ρ_hat) / (2 * np.pi * (1 - ρ_hat))
first, second = windows[:, :20].mean(axis=1), windows[:, 20:].mean(axis=1)

groups = {
    'at Nash': (first > 4) & (second > 4),
    'near Ramsey': (first < 1) & (second < 1),
    'spanning a fall': (first > 3.5) & (second < 1.5),
}
display(pd.DataFrame({
    'windows': {label: mask.sum() for label, mask in groups.items()},
    'median g(0)': {label: np.median(g0[mask]) for label, mask in groups.items()},
}).round(2))
print(f'correlation of rolling mean inflation and rolling g(0): '
      f'{np.corrcoef(windows.mean(axis=1), g0)[0, 1]:.3f}')
print(f'correlation of core inflation and persistence in the data: '
      f'{core_persistence_correlation:.3f}')
```

```
                 windows  median g(0)
at Nash             1849         0.16
near Ramsey         3125         0.17
spanning a fall      135         9.73
```

```
correlation of rolling mean inflation and rolling g(0): 0.033
correlation of core inflation and persistence in the data: 0.965
```

Measured persistence is close to the white-noise value $1/(2\pi)$ both at Nash and near Ramsey, and it is high only in windows that span a fall, where the shifting mean inside the window looks like persistence.

Over the whole simulation, rolling mean inflation and rolling persistence are nearly uncorrelated, far from the strong positive correlation in the data.

The escape-route model ties persistence to *changes* in inflation, not to its *level*: high inflation at the self-confirming equilibrium comes with white-noise inflation, and persistence peaks while inflation falls, the inverse relation that Cogley and Sargent [2005] describe.

109.1 Overview

Drifts and Volatilities fit the Bayesian vector autoregression of Cogley and Sargent [2005], with drifting coefficients and stochastic volatilities, to quarterly U.S. data on interest, unemployment, and inflation for 1959–2000.

It found that both the volatilities and the coefficients drifted: shocks were large around 1980, and core inflation and inflation persistence rose through the 1970s and fell together after 1980.

Cogley and Sargent's sample ends in 2000, so it misses the financial crisis, the long stretch at the zero lower bound, the pandemic, and the 2021–2022 inflation surge.

This lecture re-estimates the same model, with the same priors and the same 1948–1958 training sample, on data extended through the latest complete quarter, and asks two questions.

1. Do the new observations change what the model says about 1959–2000?
2. Did the recent inflation surge bring back 1970s-style persistence?

The code repeats that of *Drifts and Volatilities*, where each piece is explained; it is collapsed below so that this lecture runs on its own.

We begin with imports and the addresses of the data.

```
import time

import matplotlib.pyplot as plt
import numpy as np
import pandas as pd
from scipy import linalg
from scipy.special import expit
from threadpoolctl import threadpool_limits

# The matrices in this lecture are small, so extra BLAS threads only add overhead.
threadpool_limits(1)

archive_url = 'https://github.com/QuantEcon/data-lectures/raw/main/lectures/NEWQDATA.
 ↪csv'
fred_url = ('https://fred.stlouisfed.org/graph/fredgraph.csv?'
            'id=CPIAUCSL%2CUNRATE%2CTB3MS')
```

109.2 The model and the sampler

The model is the one in *A VAR with drifting coefficients and stochastic volatility*: a VAR(2) in the nominal interest rate, the logit of unemployment, and inflation, $y_t = X_t^\top \theta_t + \varepsilon_t$, whose coefficients follow a random walk $\theta_t = \theta_{t-1} + v_t$ with $v_t \sim N(0, Q)$, restricted to stable paths, and whose innovation covariance $R_t = B^{-1} H_t B^{-1\prime}$ has random-walk log volatilities.

The first cell builds the model, the data, and the priors.

The second cell is the sampler of *Simulating the posterior*: a Carter–Kohn draw of the coefficient path, redrawn until it is stable, followed by the updates of Q, the volatility scales σ, the covariance parameters β, and the volatility paths.

The third cell computes the summaries of *What the data say*: the posterior mean of R_t, core inflation and the natural rate, and the normalized inflation spectrum $g_{\pi\pi}(\omega, t)$.

109.3 The extended sample

We keep Cogley and Sargent's archived data through 2000Q4 and append newer observations from FRED: seasonally adjusted CPI, seasonally adjusted unemployment, and the three-month Treasury-bill rate.

The transformations and within-quarter timing are unchanged: CPI comes from the third month of each quarter, unemployment is a three-month average, and the interest rate comes from the first month.

Keeping the archive for 1948–2000 means that revisions to old data are not mistaken for information in the new quarters; the first appended inflation rate uses revised CPI levels for both 2000Q4 and 2001Q1.

As the BLS notes, the October 2025 unemployment rate was never collected, because of the federal government shutdown, so 2025Q4 lacks one of its three months.

Rather than end the sample at 2025Q3 forever, we fill isolated missing months by linear interpolation between their neighbors, and we print the months filled.

The sample then ends at the last quarter for which all three series are complete, found automatically.

```
archive = pd.read_csv(archive_url)
fred = pd.read_csv(fred_url, parse_dates=['observation_date'],
                   index_col='observation_date')
```

(continues on next page)

(continued from previous page)

```
unrate = fred['UNRATE'].dropna()
unrate = unrate.reindex(pd.date_range(unrate.index[0], unrate.index[-1],
                                      freq='MS'))
filled_months = list(unrate.index[unrate.isna()].strftime('%Y-%m'))
unrate = unrate.interpolate(limit=1, limit_area='inside')

def by_quarter(series, months):
    """Observations from the given months of each quarter, indexed by quarter."""
    picked = series[series.index.month.isin(months)].dropna()
    picked.index = picked.index.to_period('Q')
    return picked

month_counts = unrate.groupby(unrate.index.to_period('Q')).count()
table = pd.concat({
    'interest': by_quarter(fred['TB3MS'], (1, 4, 7, 10)),
    'cpi': by_quarter(fred['CPIAUCSL'], (3, 6, 9, 12)),
    'unemployment': unrate.groupby(unrate.index.to_period('Q')).mean()[
        month_counts == 3],
}, axis=1)
table['y3'] = table['interest'] / (400 - table['interest'])
table['ur'] = table['unemployment'] / 100
table['dp'] = np.log(table['cpi']).diff()
table['date'] = table.index.year + (table.index.quarter - 1) / 4

extension = table.loc['2001Q1':, ['date', 'y3', 'ur', 'dp']]
incomplete = extension.index[extension.isna().any(axis=1)]
if len(incomplete):
    extension = extension.loc[:incomplete[0] - 1]
spliced = pd.concat((archive, extension.reset_index(drop=True)),
                    ignore_index=True)
assert np.allclose(np.diff(spliced['date']), 0.25)
sample_end = extension.index[-1]

print('months filled by interpolation:', filled_months)
print('last quarter of the sample:', sample_end)
```

```
months filled by interpolation: ['2025-10']
last quarter of the sample: 2026Q3
```

The next figure shows the data, with a dashed line at the end of Cogley and Sargent's sample.

```
shown = spliced[spliced['date'] >= 1959]
fig, axes = plt.subplots(3, 1, figsize=(9, 7), sharex=True)
axes[0].plot(shown['date'], 400 * shown['dp'], lw=2)
axes[0].set_ylabel('inflation (annual %)')
axes[1].plot(shown['date'], 100 * shown['ur'], lw=2)
axes[1].set_ylabel('unemployment (%)')
axes[2].plot(shown['date'], 400 * shown['y3'] / (1 + shown['y3']), lw=2)
axes[2].set_ylabel('interest (annual %)')
axes[2].set_xlabel('year')
for ax in axes:
    ax.axvline(2000.75, color='0.6', ls='--', lw=1)
plt.tight_layout()
plt.show()
```

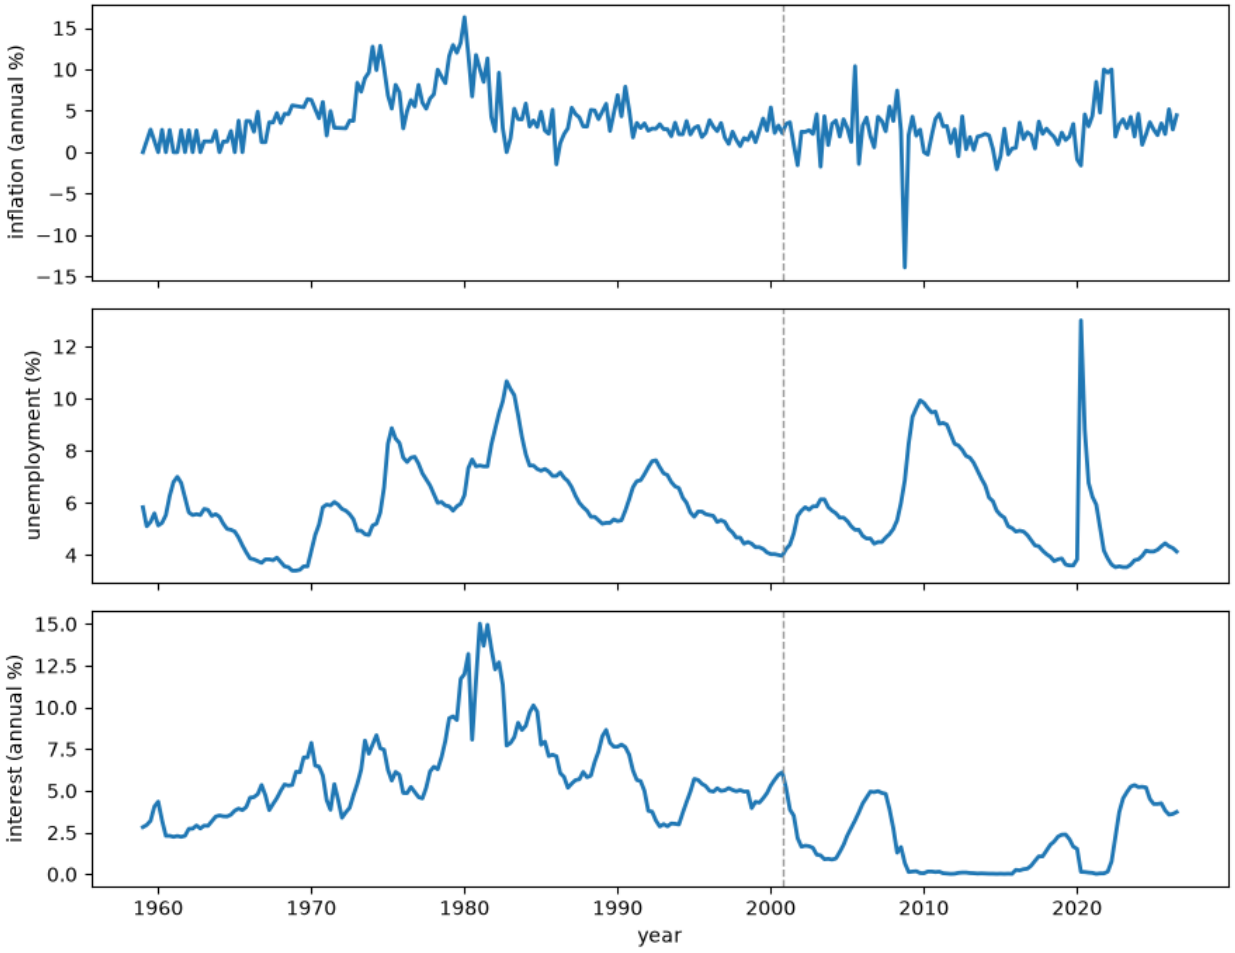

Fig. 109.1: Observed π_t, u_t, and i_t in the extended sample

The extension adds the financial-crisis recession, a pandemic spike in quarterly unemployment, a short inflation surge in 2021–2022, and two long stretches of near-zero interest rates.

Because inflation is annualized from quarterly changes, isolated movements look large, but the recent surge is much shorter than the sustained rise of the 1970s.

109.4 Fitting the extended sample

The sample is now much longer, and stable coefficient paths are much harder to draw over it, so a sweep costs several times more than in *Drifts and Volatilities*.

To bound the cost, a sweep tries at most 50 backward passes before keeping the current path, which still leaves the posterior invariant (the table reports how often that happens), and we run 10,000 sweeps, discard the first 1,000, and keep every 5th of the rest.

```
data = prepare_data(spliced)
prior = calibrate_prior(data)
burn = 1_000
posterior = run_sampler(data['y'], data['x'], prior,
                        n_sweeps=10_000, burn=burn, thin=5, seed=42)

dates = data['dates']
years = np.floor(dates + 1e-8).astype(int)
annual = np.array([np.flatnonzero(years == year)[-1]
                   for year in np.unique(years)])
trace_q = posterior['trace_q'][burn:]
τ = integrated_autocorrelation_time(trace_q)
passes = posterior['passes'][burn:]

pd.Series({
    'run time (minutes)': posterior['minutes'],
    'quarters in the estimation sample': len(dates),
    'retained draws': len(posterior['β']),
    'mean backward passes per sweep': passes.mean(),
    'sweeps that kept the current path': np.sum(passes > 50),
    'autocorrelation time of tr(Q)': τ,
    'effective sample size of tr(Q)': len(trace_q) / τ,
}, name='value').to_frame().round(3)
```

```
                                    value
run time (minutes)                 12.235
quarters in the estimation sample  271.000
retained draws                    1800.000
mean backward passes per sweep      18.675
sweeps that kept the current path 1834.000
autocorrelation time of tr(Q)      992.580
effective sample size of tr(Q)       9.067
```

As in *Drifts and Volatilities*, the chain moves slowly in the direction of Q, and with fewer sweeps the effective sample size of $\mathrm{tr}(Q)$ is even smaller, so magnitudes that depend on Q carry large Monte Carlo error; the text relies only on features that held in runs with other seeds.

109.5 Did coefficient drift continue?

The histogram shows $\text{tr}(Q)$ at every sweep after the burn-in.

```
fig, ax = plt.subplots()
ax.hist(trace_q, bins=50, histtype='step', lw=2)
ax.axvline(np.trace(prior['q_center']), color='C1', lw=2,
           label=r'prior $\mathrm{tr}(\bar Q)$')
ax.set_xlabel(r'$\mathrm{tr}(Q)$')
ax.set_ylabel('sweeps')
ax.legend()
plt.show()
```

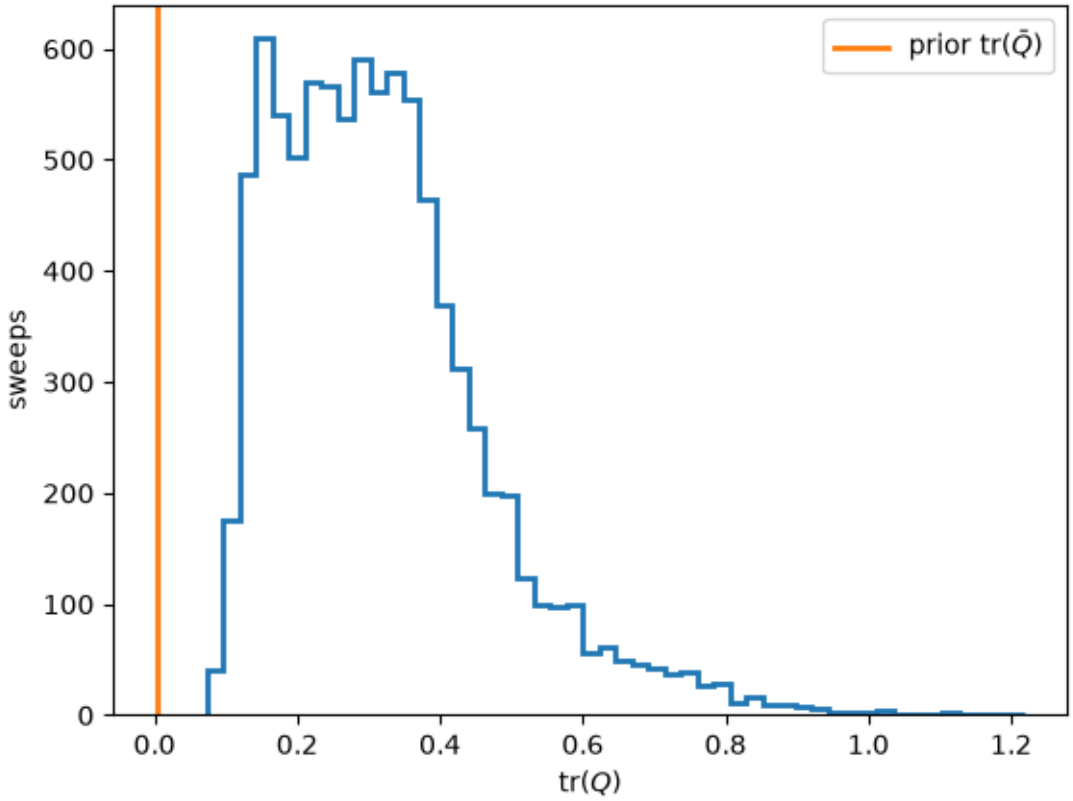

Fig. 109.2: Posterior $\text{tr}(Q)$ in the extended sample and prior $\text{tr}(\bar{Q})$

The table below gives the numbers behind the figure.

```
q_eigenvalues = np.linalg.eigvalsh(posterior['Q'].mean(axis=0))[::-1]
pd.Series({
    'posterior mean of tr(Q)': trace_q.mean(),
    'smallest tr(Q) / tr(Q bar)': trace_q.min() / np.trace(prior['q_center']),
    'share of the first principal component': q_eigenvalues[0] / q_eigenvalues.sum(),
    'share of the first three': q_eigenvalues[:3].sum() / q_eigenvalues.sum(),
}, name='value').to_frame().round(3)
```

```
                                          value
posterior mean of tr(Q)                   0.318
smallest tr(Q) / tr(Q bar)               24.456
share of the first principal component    0.639
share of the first three                  0.976
```

The drift rate is several times larger than in the 1959–2000 fit of *Drifts and Volatilities*, and the drift is concentrated in even fewer directions.

The chain explores this posterior very slowly: in runs with other seeds the posterior mean of $\mathrm{tr}(Q)$ differed by a factor of more than two, although it was always several times the 1959–2000 value.

One likely contributor is the pandemic: in 2020Q2 the logit of unemployment jumped by dozens of innovation standard deviations, far more than a random-walk volatility can absorb within a quarter, so part of the jump is attributed to the coefficients.

Because Q is a single drift covariance for the whole sample, this histogram cannot by itself say whether drift slowed or sped up after 2000; for that we look at what the coefficients imply.

109.6 Volatility after the Great Moderation

The innovation standard deviations and correlations come from the posterior mean $\mathbb{E}(R_t \mid T)$, as in *Drifts and Volatilities*.

```
r_mean = mean_innovation_covariance(posterior['h'], posterior['β'])
sd = 1e4 * np.sqrt(np.diagonal(r_mean, axis1=1, axis2=2))

def correlation(left, right):
    return r_mean[:, left, right] / np.sqrt(r_mean[:, left, left]
                                            * r_mean[:, right, right])

fig, axes = plt.subplots(3, 2, figsize=(9, 8), sharex=True)
for row, (index, label) in enumerate(((0, 'Nominal interest'),
                                      (2, 'Inflation'), (1, 'Unemployment'))):
    axes[row, 0].plot(dates, sd[:, index], lw=2)
    axes[row, 0].set_title(label)
for row, (left, right, label) in enumerate(((0, 1, 'Interest--unemployment'),
                                            (0, 2, 'Interest--inflation'),
                                            (2, 1, 'Inflation--unemployment'))):
    axes[row, 1].plot(dates, correlation(left, right), lw=2)
    axes[row, 1].set_title(label)
for ax in axes.flat:
    ax.axvline(2000.75, color='0.6', ls='--', lw=1)
axes[1, 0].set_ylabel(r'standard deviation $\times 10^4$')
axes[1, 1].set_ylabel('correlation')
axes[-1, 0].set_xlabel('year')
axes[-1, 1].set_xlabel('year')
plt.tight_layout()
plt.show()
```

The table below gives the numbers behind the figure.

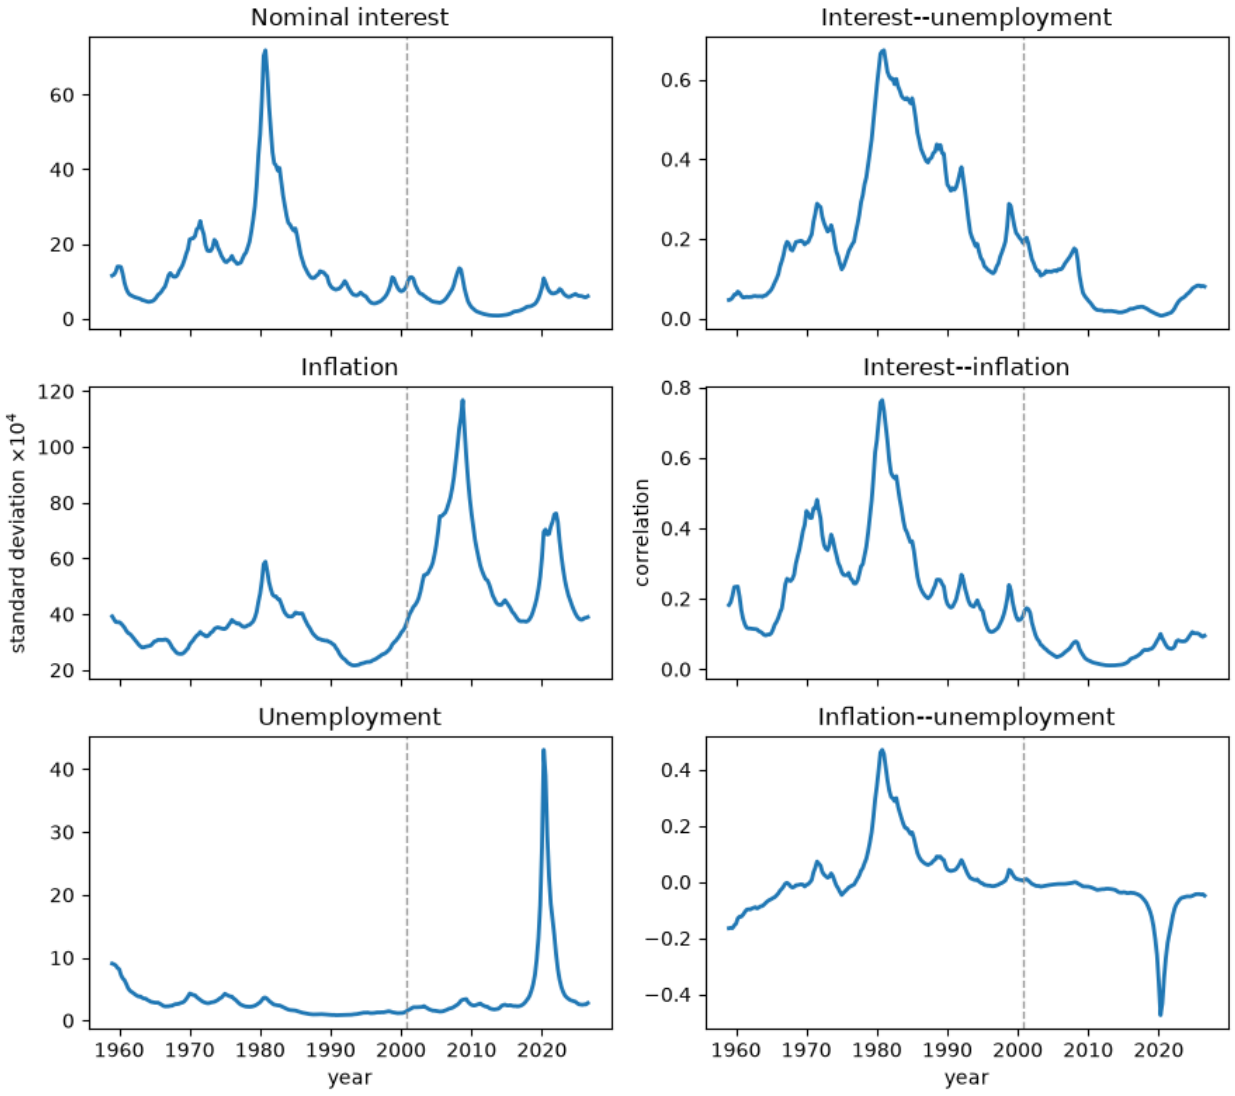

Fig. 109.3: Standard deviations and correlations implied by $E(R_t \mid T)$, extended sample

```
pd.DataFrame({
    'peak date': [dates[np.argmax(sd[:, i])] for i in range(3)],
    'standard deviation at the end': sd[-1],
}, index=['interest', 'unemployment', 'inflation']).round(2)
```

	peak date	standard deviation at the end
interest	1980.75	6.02
unemployment	2020.25	2.77
inflation	2008.75	38.97

The Volcker years still dominate interest-rate innovations, the financial crisis produces the largest inflation innovations, and the pandemic produces by far the largest unemployment innovations, together with a sharp swing in the inflation–unemployment correlation.

Recent episodes thus changed the size and composition of reduced-form shocks dramatically, which is direct evidence for a bad-luck component, although reduced-form innovations are not structural shocks.

The generalized innovation variance $\log|\mathbb{E}(R_t \mid T)|$ summarizes the total one-step uncertainty.

```
logdet_r = np.linalg.slogdet(r_mean)[1]
fig, ax = plt.subplots()
ax.plot(dates, logdet_r, lw=2)
ax.axvline(2000.75, color='0.6', ls='--', lw=1)
ax.set_xlabel('year')
ax.set_ylabel(r'$\log |E(R_t\mid T)|$')
plt.show()
```

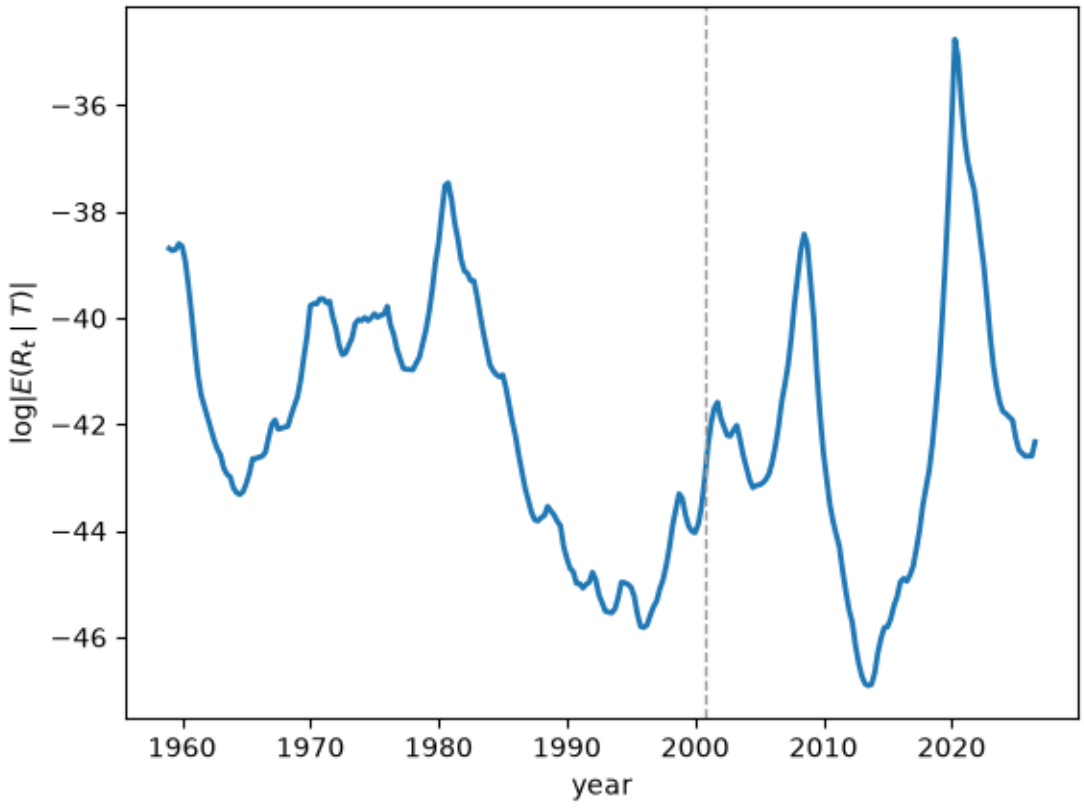

Fig. 109.4: Generalized innovation variance $\log|E(R_t \mid T)|$, extended sample

The table below gives the numbers behind the figure.

```
def period_mean(values, first, last):
    """Average a quarterly series over the years first, ..., last."""
    return values[(years >= first) & (years <= last)].mean()

display_periods = {'1980--1982': (1980, 1982), '1990--2000': (1990, 2000),
                   '2010--2015': (2010, 2015), '2020--2021': (2020, 2021)}

def extreme(values, first, last, statistic):
    return statistic(values[(years >= first) & (years <= last)])

pd.DataFrame({
    'interest innovation sd (basis points)': [
        period_mean(sd[:, 0], *p) for p in display_periods.values()],
    'interest-inflation correlation': [
        period_mean(correlation(0, 2), *p) for p in display_periods.values()],
    'log |E(R_t | T)|, max or min': [
        extreme(logdet_r, 1980, 1982, np.max), extreme(logdet_r, 1990, 2000, np.min),
        extreme(logdet_r, 2010, 2015, np.min), extreme(logdet_r, 2020, 2021, np.max)],
}, index=display_periods.keys()).round(3)
```

```
           interest innovation sd (basis points)  \
1980--1982                                 52.647
1990--2000                                  7.133
2010--2015                                  1.333
2020--2021                                  8.145

           interest-inflation correlation  log |E(R_t | T)|, max or min
1980--1982                           0.645                       -37.459
1990--2000                           0.172                       -45.819
2010--2015                           0.015                       -46.911
2020--2021                           0.075                       -34.759
```

Joint innovation variance rises in the financial crisis, falls to a trough in the early 2010s deeper than its 1990s low, and jumps in 2020 above even its 1981 peak before falling back.

The trough is not a second Great Moderation.

At the zero lower bound the Treasury-bill rate barely moved, so its innovations nearly vanished and lost their correlation with inflation innovations, as the table shows, and the log determinant collapses with them.

For the same reason a short-rate measure of policy activism carries little information after 2008, and we do not compute one here.

109.7 Core inflation, the natural rate, and persistence

We compute core inflation, the natural rate, and $g_{\pi\pi}(0, t)$ from every retained draw, as in *Inflation persistence*.

```
feature_draws = posterior_feature_draws(posterior, annual)

```

Adding a quarter-century of data changes the estimated history of 1959–2000 a great deal.

With the larger drift rate, many draws put a root of the late-1970s VAR close to the unit circle, so the medians of core inflation and of the natural rate around 1979 are higher than in *Drifts and Volatilities*, in some runs far higher, their bands are enormous, and persistence stays above one until 1980 or later.

How large these numbers are depends on how far the chain has wandered into the tail of Q, and they differed a lot across runs with other seeds; what survives in all runs is the shape: core inflation and persistence rise through the 1970s and collapse in the early 1980s.

After 2000 the picture is calm and robust.

Core inflation stays below about 4 percent, and persistence stays close to the white-noise value, apart from a brief rise around 2020–2021 that is far smaller than in the 1970s and soon reverses.

A burst of large inflation innovations kept measured inflation high for several quarters in 2021–2022 without the strong propagation that the model finds in the 1970s.

The normalized spectrum over all frequencies shows the same thing.

```
θ_mean = posterior['θ'].mean(axis=0)
frequencies = np.linspace(0, 0.5, 41)
normalized = np.column_stack([
    inflation_spectrum(θ_mean[:, t], r_mean[t], frequencies)[1]
    for t in range(len(dates))
])
fig, ax = plt.subplots(figsize=(8, 4))
image = ax.pcolormesh(dates, frequencies, np.log10(normalized), shading='auto')
ax.axvline(2000.75, color='0.9', ls='--', lw=1)
ax.set_xlabel('year')
ax.set_ylabel('cycles per quarter')
fig.colorbar(image, ax=ax, label=r'$\log_{10} g_{\pi\pi}(\omega,t)$')
plt.show()
```

The normalized spectrum has a low-frequency ridge from the late 1960s to the early 1980s and, after 2000, only a brief one around 2020: the recent inflation surge shows up mainly as large shocks, not as lasting stronger propagation.

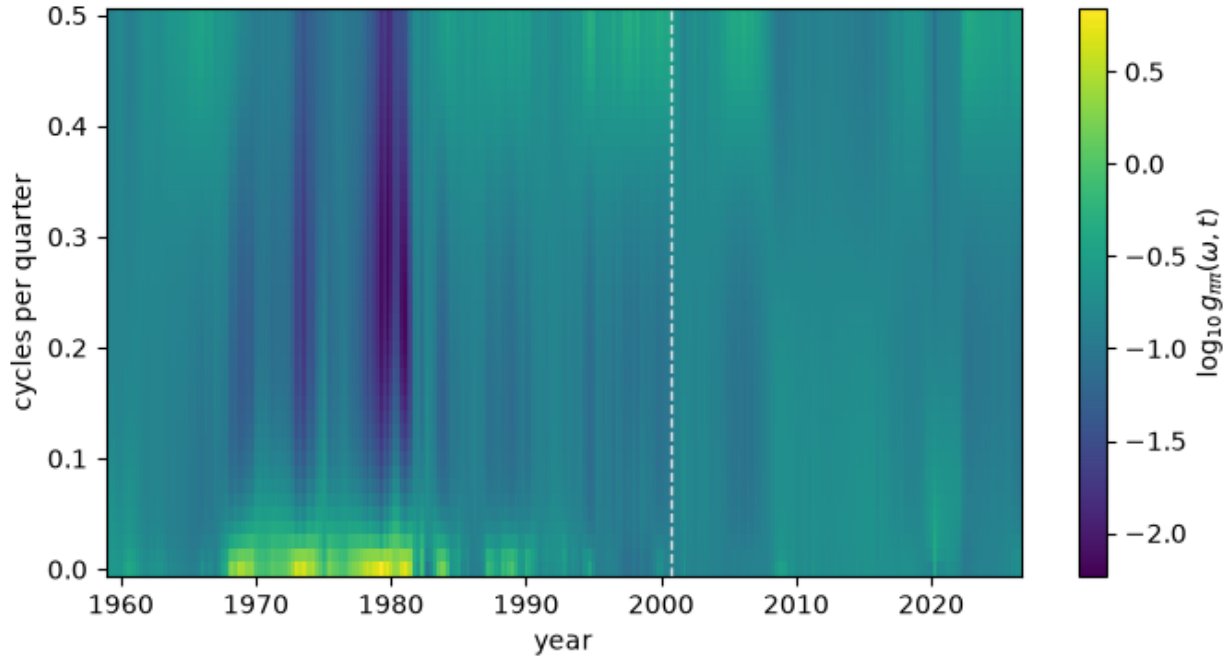

Fig. 109.6: Normalized inflation spectrum $g_{\pi\pi}(\omega, t)$, extended sample

109.7.1 Two measures of persistence

The Lost Conquest: Fed Policy in the 2020s gives the Fed a learning model in which perceived persistence is the coefficient on lagged inflation in a regression of *year-over-year* inflation on its own lag, sampled quarterly.

Year-over-year rates overlap: consecutive values share three of their four quarters.

Even if quarterly inflation were white noise, year-over-year inflation sampled quarterly would have a first-order autocorrelation of $3/4$, so a persistence measure based on it is pushed toward one and falls later and less than a measure based on quarterly rates.

The next cell compares least-squares $AR(1)$ coefficients of the two inflation rates in our data, period by period; Exercise **??** reruns that lecture's learning Fed on quarterly inflation.

```
cpi_inflation = pd.Series(400 * spliced['dp'].to_numpy(), index=spliced['date'])
year_over_year = cpi_inflation.rolling(4).mean()

def ar1_coefficient(series, first, last):
    """Least-squares AR(1) slope over the years first, ..., last."""
    z = series[(series.index >= first) & (series.index < last + 1)].dropna()
    X = np.column_stack((np.ones(len(z) - 1), z.to_numpy()[:-1]))
    return np.linalg.lstsq(X, z.to_numpy()[1:], rcond=None)[0][1]

periods = ((1960, 1969), (1970, 1979), (1985, 1999), (2000, 2019), (2020, 2100))
pd.DataFrame({
    'quarterly inflation': [ar1_coefficient(cpi_inflation, *p) for p in periods],
    'year-over-year inflation': [ar1_coefficient(year_over_year, *p)
                                 for p in periods],
}, index=['1960s', '1970s', '1985--1999', '2000--2019', '2020 onward']).round(2)
```

```
             quarterly inflation  year-over-year inflation
1960s                       0.43                      1.02
1970s                       0.80                      1.01
1985--1999                  0.37                      0.89
2000--2019                 -0.05                      0.68
2020 onward                 0.43                      0.87
```

The $AR(1)$ coefficient of year-over-year inflation is near one in the 1960s and 1970s, and it stays high after 1985 and even in 2000–2019, when the coefficient for quarterly inflation is about zero.

The overlap both inflates the year-over-year measure and blunts its decline, which is why the perceived persistence in *The Lost Conquest: Fed Policy in the 2020s* falls later and less than the quarterly measures here and in *Drifts and Volatilities*.

109.8 What the additional observations change

The extra quarter-century strengthens the bad-luck evidence for the recent period.

- It adds large volatility episodes, the financial crisis in inflation and the pandemic in unemployment, and a zero-lower-bound period in which the short rate says little about policy.
- The recent inflation surge did not bring back 1970s-style propagation: persistence after 2000 stays near the white-noise value, and core inflation stays low.
- The drift rate, and with it the estimated history of the 1970s, becomes much harder to pin down: the posterior puts weight on far faster drift than the 1959–2000 fit, and a chain short enough for a lecture cannot explore that tail reliably, so magnitudes that depend on Q should not be taken at face value.

The shape of the earlier drift documented in *Drifts and Volatilities* survives: persistence and core inflation still rise in the 1970s and fall in the early 1980s.

The next and last lecture, *The Lost Conquest: Fed Policy in the 2020s*, returns to a learning Fed: it asks whether drifting beliefs about persistence and the slope of the Phillips curve, of the kind that *Adaptive Learning and Escape Dynamics* and *Priors, Escapes, and Learning Cycles* model, help explain the Fed's slow response to the inflation of 2021–2022, and so whether the conquest of American inflation was lost.

109.9 Exercises

Exercise 109.9.1

Sims [2001] pointed out that *filtered* estimates of drifting coefficients wander even when the true coefficients are constant, which is why Cogley and Sargent [2005] report *smoothed* estimates.

Simulate $y_t = \rho_t y_{t-1} + w_t$, $w_t \sim N(0,1)$, for $T = 168$ quarters in two cases: (a) $\rho_t = 0.5$ for all t, and (b) ρ_t a random walk that starts at 0.5 with innovation variance 4×10^{-4}.

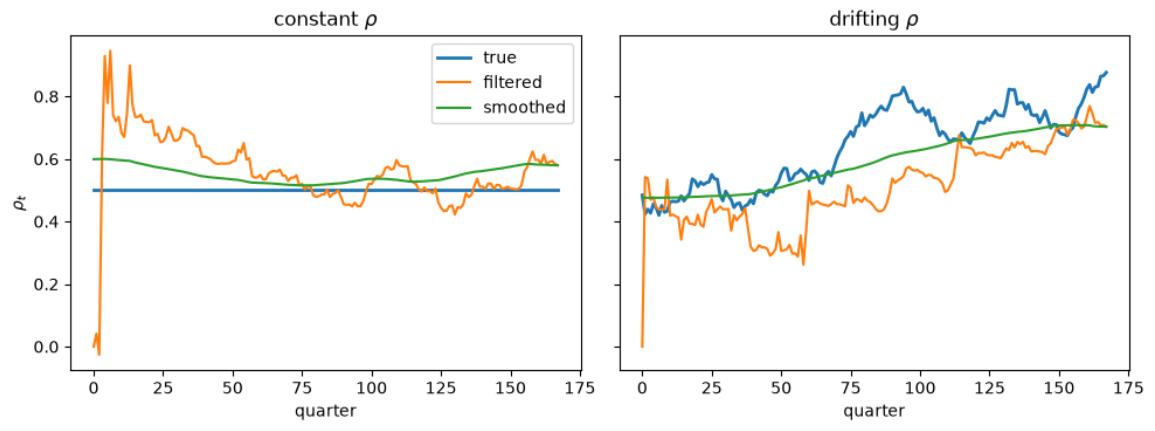
In each case run the scalar Kalman filter of *A First Look at the Kalman Filter* that treats ρ_t as a random walk with innovation variance $q = 4 \times 10^{-4}$, starting from mean 0 and variance 1, and then the smoother of *Appendix: the sampler in detail*.

Compare the standard deviations over time of the true, filtered, and smoothed paths, ignoring the first 20 quarters.

What does the smoothed path look like if the filter assumes $q = 0$?

At the last date of a sample the smoothed and filtered estimates coincide.

What does that imply for the estimates in this lecture that bear on the 2020s?



Solution

Here is one solution.

```
def tvp_ar1(T, ρ0, q, rng):
    """Simulate y_t = ρ_t y_{t-1} + w_t with ρ_t a random walk."""
    ρ = ρ0 + np.r_[0, np.cumsum(np.sqrt(q) * rng.standard_normal(T))]
    y = np.zeros(T + 1)
    for t in range(1, T + 1):
        y[t] = ρ[t] * y[t - 1] + rng.standard_normal()
    return y, ρ

def filter_and_smooth(y, q, mean0=0.0, var0=1.0):
    """Scalar Kalman filter and Rauch-Tung-Striebel smoother for ρ_t."""
    T = len(y) - 1
    m, P, P_pred = np.empty(T + 1), np.empty(T + 1), np.empty(T + 1)
    m[0], P[0] = mean0, var0
    for t in range(1, T + 1):
        P_pred[t] = P[t - 1] + q
        K = P_pred[t] * y[t - 1] / (y[t - 1]**2 * P_pred[t] + 1)
        m[t] = m[t - 1] + K * (y[t] - y[t - 1] * m[t - 1])
        P[t] = P_pred[t] - K * y[t - 1] * P_pred[t]
    s = m.copy()
    for t in range(T - 1, -1, -1):
        s[t] = m[t] + P[t] / P_pred[t + 1] * (s[t + 1] - m[t])
    return m, s

rng = np.random.default_rng(3)
fig, axes = plt.subplots(1, 2, figsize=(10, 3.8), sharey=True)
rows = {}
for ax, (q_true, title) in zip(axes, ((0.0, r'constant $\rho$'),
                                      (4e-4, r'drifting $\rho$'))):
    y, ρ = tvp_ar1(168, 0.5, q_true, rng)
    filtered, smoothed = filter_and_smooth(y, q=4e-4)
    _, flat = filter_and_smooth(y, q=0.0)
    for path, label in ((ρ, 'true'), (filtered, 'filtered'),
                        (smoothed, 'smoothed')):
        ax.plot(path[1:], lw=2 if label == 'true' else 1.5, label=label)
    ax.set_title(title)
    ax.set_xlabel('quarter')
    rows[title] = {'true': ρ[20:].std(), 'filtered': filtered[20:].std(),
                   'smoothed': smoothed[20:].std(),
                   'smoothed, q = 0': flat[20:].std()}
axes[0].set_ylabel(r'$\rho_t$')
axes[0].legend()
plt.tight_layout()
plt.show()
```

The table below gives the numbers behind the figure.

```
pd.DataFrame(rows).T.round(3)
```

	true	filtered	smoothed	smoothed, q = 0
constant ρ	0.000	0.070	0.022	0.0
drifting ρ	0.117	0.127	0.081	0.0

When ρ is constant, the filtered estimate wanders, with a standard deviation over time several times that of the smoothed estimate, which is nearly flat; that is Sims's point.

When ρ drifts, the filtered path adds transient noise to the drift, while the smoothed path is smoother than the truth.

With $q = 0$ the smoother returns an exactly flat path, as in Cogley and Sargent's footnote 16: the backward pass has $J_t = 1$ and no noise, so every date receives the end-of-sample estimate.

Near the end of a sample the smoother has few later observations to draw on, so its estimates behave more like filtered ones, and at the last date they are the filtered estimate.

The estimates for the 2020s in this lecture therefore carry some of the transient wandering that Sims warned about, and they will be revised as new quarters arrive, which is one more reason to read the endpoint bands in *Core inflation, the natural rate, and persistence* with care.

Exercise 109.9.2

A Kalman filter on coefficients that drift as random walks behaves like constant-gain least squares, and this exercise asks how large the implied gain is.

1. For the local-level model $y_t = \mu_t + w_t$, $\mu_t = \mu_{t-1} + v_t$, with $\mathbb{V}[w_t] = 1$ and $\mathbb{V}[v_t] = q$, show that the steady-state predicted variance is $p = (q + \sqrt{q^2 + 4q})/2$ and the steady-state Kalman gain is $K = p/(1+p) \approx \sqrt{q}$ for small q. Check this numerically by iterating the Riccati equation for $q \in \{10^{-4}, 10^{-3}, 10^{-2}\}$.
2. Run the Kalman filter of *Appendix: the sampler in detail* for the 21 coefficients with Q and R_t fixed at their posterior means. At each date compute w_t, the weight that the updated fitted value of inflation puts on the newest inflation forecast error, which is the $(3, 3)$ element of $X_t^\top K_t$.
3. Under constant-gain least squares, that weight is the gain times $x_t^\top R^{-1} x_t$, where R is the regressors' second-moment matrix, and $x_t^\top R^{-1} x_t$ averages k, the number of regressors. Convert w_t into an equivalent gain $w_t/7$ and compare its average by decade with the gains used in this section: 0.025 in *Adaptive Learning and Escape Dynamics*, 0.02 in *A government learning the Phillips curve*, and 0.03 in *The Lost Conquest: Fed Policy in the 2020s*.

Solution

In steady state the predicted variance satisfies $p = p - p^2/(p+1) + q$, so $p^2 - qp - q = 0$ and $p = (q + \sqrt{q^2 + 4q})/2 \approx \sqrt{q}$, which gives $K = p/(1+p) \approx \sqrt{q}$.

```
for q in (1e-4, 1e-3, 1e-2):
    p = 1.0
    for _ in range(10_000):
        p = p - p**2 / (p + 1) + q
    formula = (q + np.sqrt(q**2 + 4 * q)) / 2
    print(f'q = {q:g}: iterated gain {p / (1 + p):.4f}, '
          f'formula {formula / (1 + formula):.4f}, sqrt(q) {np.sqrt(q):.4f}')
```

```
q = 0.0001: iterated gain 0.0100, formula 0.0100, sqrt(q) 0.0100
q = 0.001: iterated gain 0.0311, formula 0.0311, sqrt(q) 0.0316
q = 0.01: iterated gain 0.0951, formula 0.0951, sqrt(q) 0.1000
```

For the VAR we run the forward recursion with the posterior means of Q and R_t and record the weight on the newest inflation surprise.

```
q_bar = posterior['Q'].mean(axis=0)
X = design_matrices(data['x'])
P = prior['θ_covariance'].copy()
weight = np.empty(len(dates))
for t in range(len(dates)):
    predicted = P + q_bar
    px = predicted @ X[t].T
    gain = np.linalg.solve(X[t] @ px + r_mean[t], px.T).T
    weight[t] = (X[t] @ gain)[2, 2]
    P = predicted - gain @ px.T

decades = {f'{d}s': (d, d + 9) for d in (1960, 1970, 1980, 1990, 2000, 2010)}
decades['2020 onward'] = (2020, 2100)
pd.DataFrame({
    'weight on newest surprise': [period_mean(weight, *p) for p in decades.
↪values()],
    'equivalent gain per regressor': [period_mean(weight, *p) / 7
                                      for p in decades.values()],
}, index=decades.keys()).round(3)
```

	weight on newest surprise	equivalent gain per regressor
1960s	0.383	0.055
1970s	0.538	0.077
1980s	0.660	0.094
1990s	0.477	0.068
2000s	0.208	0.030
2010s	0.191	0.027
2020 onward	0.312	0.045

The steady-state gain is close to $\sqrt{q}$, as the formula says.

For the VAR, the weight on the newest inflation surprise is largest before 2000, when the equivalent gain per regressor is roughly two to five times the 0.025 of *Adaptive Learning and Escape Dynamics*; after 2000 it falls to between about one and two times that value, close to the gains of 0.02 to 0.03 used in this section.

These gains inherit the uncertainty about Q noted above, because the gain grows with the drift covariance.

Exercise 109.9.3

Two Illustrations of the Quantity Theory of Money interprets a long-run slope as a ratio of spectral densities at frequency zero, $h(0) = S_{yz}(0)/S_z(0)$.

Compute the analogous low-frequency slope of inflation on unemployment implied by the local VAR at each date,

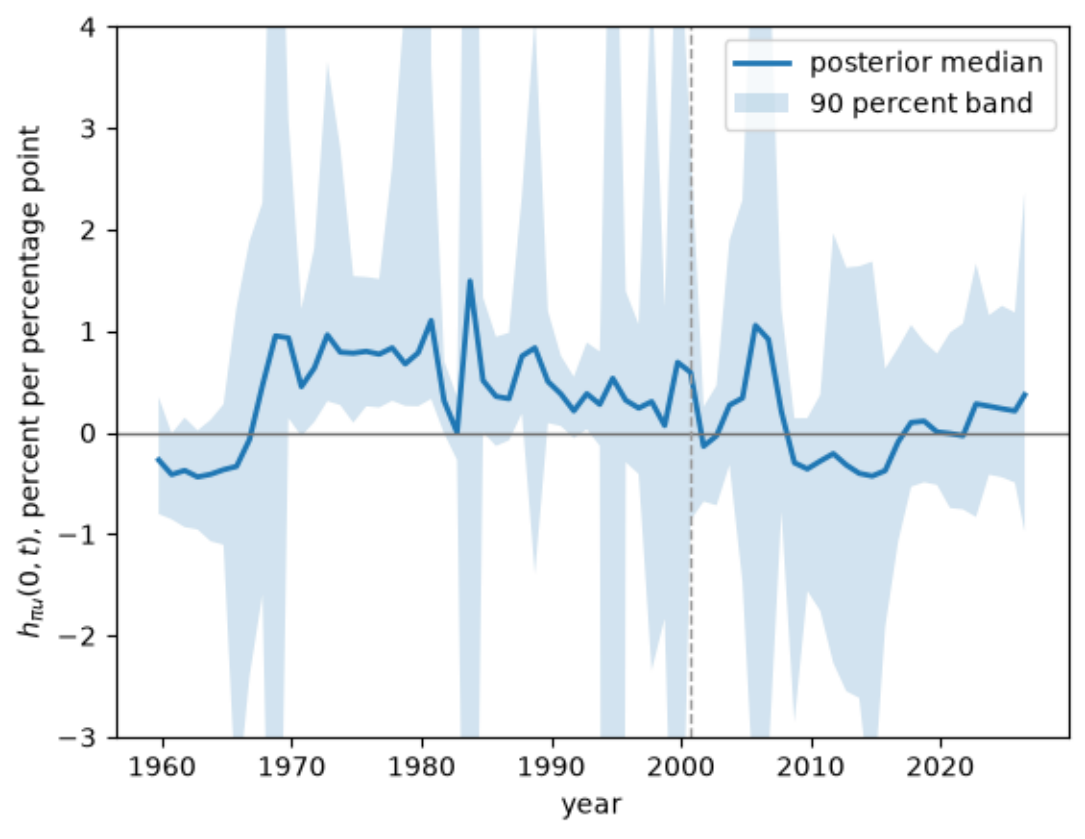
$$h_{\pi u}(0,t) = \frac{\operatorname{Re} f_{\pi u}(0,t)}{f_{uu}(0,t)},$$

draw by draw, and convert it into percentage points of annual inflation per percentage point of the unemployment rate, using the natural rate $\bar{u}_t$ to undo the logit transformation.

Plot the posterior median and a 90 percent band.

When was the low-frequency slope negative, as a long-run Phillips tradeoff would require?

Solution



At frequency zero the companion system gives $2\pi f(0,t) = (I - A_t)^{-1}\mathcal{R}_t(I - A_t)^{-\top}$.

Inflation is a quarterly log change, so it is multiplied by 400; the logit satisfies $du_t = 10^{-4}\, dU/[\bar{u}_t(1-\bar{u}_t)]$ when dU is measured in percentage points.

```
def low_frequency_slope(θ, covariance):
    """Low-frequency slope of annual inflation on the unemployment rate (pp/pp)."""
    intercept, companion = companion_matrix(θ)
    inverse = np.linalg.inv(np.eye(6) - companion)
    innovation = np.zeros((6, 6))
    innovation[:3, :3] = covariance
    S = inverse @ innovation @ inverse.T
    logit_u = 100 * (inverse @ intercept)[1]
    density = expit(logit_u) * expit(-logit_u)      # u(1 - u) at the natural rate
    if density == 0:                                # natural rate at 0 or 100%
        return np.nan
    return 400 * S[2, 1] / S[1, 1] * 1e-4 / density

slopes = np.array([
    [low_frequency_slope(posterior['θ'][d][:, t],
                         innovation_covariance(posterior['h'][d][t],
                                               posterior['β'][d]))
     for t in annual]
    for d in range(len(posterior['β']))
])
lower, median, upper = np.nanquantile(slopes, (0.05, 0.5, 0.95), axis=0)

fig, ax = plt.subplots()
ax.plot(dates[annual], median, lw=2, label='posterior median')
ax.fill_between(dates[annual], lower, upper, alpha=0.2, label='90 percent band')
ax.axhline(0, color='0.45', lw=1)
ax.axvline(2000.75, color='0.6', ls='--', lw=1)
ax.set_xlabel('year')
ax.set_ylabel(r'$h_{\pi u}(0,t)$, percent per percentage point')
ax.set_ylim(-3, 4)      # a few draws near the unit-root boundary explode
ax.legend()
plt.show()
```

The table below gives the numbers behind the figure.

```
pd.DataFrame({'5%': lower, 'median': median, '95%': upper},
             index=annual_years).loc[[1962, 1970, 1975, 1980, 1985, 1990, 2000,
                                      2010, 2020, annual_years[-1]]].round(2)
```

```
         5%  median   95%
1962 -0.95   -0.44  0.02
1970 -0.03    0.45  1.22
1975  0.26    0.80  1.53
1980  0.33    1.10  3.62
1985 -0.13    0.36  0.94
1990  0.06    0.38  0.76
2000 -0.86    0.59  2.85
2010 -1.76   -0.28  0.37
2020 -0.74   -0.01  0.99
2026 -0.97    0.37  2.36
```

The low-frequency slope is positive in the 1970s, with bands that exclude zero in the second half of the decade: at low frequencies, inflation and unemployment rose together, the opposite of an exploitable long-run tradeoff.

It is negative in the early 1960s, and close to zero and imprecise after 2000.

The vertical axis is cut off because in a few years some draws lie near the unit-root boundary, where the slope explodes.

These are reduced-form statistics: as Sargent [1971] and Lucas [1972] argued, a low-frequency slope is not by itself a structural tradeoff that policy could exploit.

THE LOST CONQUEST: FED POLICY IN THE 2020S

110.1 Overview

The previous lecture, *Drifts and Volatilities after 2000*, carried the drifting-coefficients evidence of Cogley and Sargent [2005] past 2000: it asked how the reduced-form dynamics of inflation, and the volatilities of the shocks hitting them, moved in the decades after the *Conquest* was written.

This final lecture of the suite takes the policy maker's point of view instead.

It follows Sargent and Williams [2025], who impute drifting beliefs to the Federal Reserve and ask what policy those beliefs recommended during the inflation of the 2020s.

Their artificial Fed is built from tools that earlier lectures developed:

- a *Phelps control problem*;
- the *anticipated-utility* assumption of Kreps [1998], met in *Adaptive Learning and Escape Dynamics*;
- a *drifting-coefficients* model estimated by *constant-gain recursive least squares*, the constant-gain special case of the Kalman filter of *Priors, Escapes, and Learning Cycles*.

The puzzle is a live one.

After the COVID-19 pandemic, U.S. inflation surged to its highest rate since the early 1980s, the episode at the end of the post-1999 data in *The Rise and Fall of U.S. Inflation*.

That lecture plots CPI inflation; here, following the paper, we use the price index for personal consumption expenditures (PCE), the Fed's preferred measure.

Yet for more than a year the Federal Reserve did not respond.

It first raised its policy rate in March 2022 and began to tighten in earnest only in the second quarter of 2022, with inflation already at its peak.

Why was the Fed so slow?

Sargent and Williams [2025] build an *artificial Fed* that, each quarter,

- re-estimates a drifting-coefficients Phillips curve by constant-gain recursive least squares, and
- solves a linear-quadratic Phelps problem, treating its latest estimates as if they would hold forever, to set its interest-rate instrument.

Control engineers call this *model predictive control*.

It is the *estimate-then-optimize* loop that drove the learning government of *Adaptive Learning and Escape Dynamics*, but now the instrument is the policy rate and the beliefs concern the *persistence* of inflation and the *slope* of the Phillips curve.

Three elements shape the artificial Fed's decisions:

1. **Declining inflation persistence.** The Fed had learned that inflation shocks fade faster than they used to, so the surge looked *transitory*.
2. **A flatter Phillips curve.** The Fed had learned that inflation responds weakly to slack, so disinflation looked *costly*.
3. **Real-time mismeasurement of the output gap.** In real time the Fed perceived more slack than the revised data now show.

We reproduce all three from public data.

The main finding, which is also the paper's, fits in one sentence:

> drifting beliefs make the response *muted*; real-time mismeasurement makes it *late*.

With today's revised data, the artificial Fed responds to the 2021 surge mildly, but *earlier* than the actual Fed did.

Only with the output gap that the Fed saw in real time does its response arrive at about the time the Fed's did.

The last part of the lecture is our own extension.

It asks where the benign beliefs came from: can aggressive past policy make inflation *look* transitory and the Phillips curve *look* flat?

We compute the self-confirming fixed point of that loop and find that, unlike the government of *Escaping Nash Inflation*, this Fed has no escape route.

Note

Readers arriving from the Bounded Rationality suite will find γ in its usual role as the learning gain.

There the beliefs are called α (*Notation across the series*, *A government learning the Phillips curve*); here they are θ_t.

Let's import what we need:

```
import time
import matplotlib.pyplot as plt
import numpy as np
import pandas as pd
from scipy.linalg import solve_discrete_are
from scipy.optimize import brentq
```

110.2 The three elements

The first two elements are among the most documented facts in modern macroeconomics.

Declining persistence. From the 1970s into the 1980s inflation was highly persistent: a shock raised inflation for years.

Cogley and Sargent [2001] and Cogley and Sargent [2005] documented the decline in inflation persistence during the Volcker–Greenspan conquest.

Drifts and Volatilities reproduces their evidence (*Inflation persistence*), and *Drifts and Volatilities after 2000* carries it past 2000 (*Core inflation, the natural rate, and persistence*).

Stock and Watson [2007] found that the permanent component of inflation shrank in the 1980s and 1990s.

Benati and Surico [2008] and Carlstrom *et al.* [2009] linked the decline in persistence to more aggressive monetary policy, a link we take up in *From policy to measured beliefs*.

Pivetta and Reis [2007] cautioned that part of the apparent decline may reflect smaller shocks rather than a structural break; that is the distinction between drifting coefficients and drifting volatilities that *Drifts and Volatilities* draws.

Former Fed Chair Janet Yellen summarized the evidence in 2019: "the slope of the Phillips curve … has diminished very significantly since the 1960s … And second, inflation has become much less persistent, because the impact of lagged inflation on current inflation has declined considerably."

A flatter Phillips curve. Since the 1990s, estimates of the Phillips curve's slope have trended toward zero; the "missing disinflation" after the Great Recession is the leading example.

Policy makers knew what this implied.

Bernanke [2022] (p. 220) writes: "A flat Phillips curve means that inflation is a less reliable indicator of economic overheating. Should inflation get too high, the costs, in terms of unemployment, of bringing inflation back down to target could be higher than in the past."

Notice that a flat Phillips curve points policy in opposite directions here and in the *Conquest*.

In the Lucas-style models of Sargent [1999], a flatter curve means that surprise inflation does less to real activity, so the Phelps problem recommends *lower* inflation.

The induction hypothesis of *Adaptive Expectations and the Phelps Problem* (*Testing the natural-rate hypothesis*), under which inflation has no long-run real effect, is the limiting case, and it is how the *Conquest*'s adaptive government brings inflation down.

In the statistical model of the 2020s, the Fed controls inflation by moving the output gap.

There a flatter curve means a higher sacrifice ratio (*The sacrifice ratio*): each point of disinflation costs more output, so the Phelps problem counsels patience (Sargent and Williams [2025], footnote 5).

Real-time uncertainty. The third element, emphasized by Orphanides [2001], is that the output gap is badly mismeasured in *real time*, especially at business-cycle turning points.

Through 2020–2023 the real-time gap was persistently *below* the later revised measure, so the Fed perceived more slack than there was.

We measure this in *Real-time data and the delay*.

110.3 The Fed's drifting-coefficients beliefs

We give the artificial Fed a backward-looking Phillips curve with drifting coefficients,

$$\pi_t = \alpha_{0,t} + \rho_t \, \pi_{t-1} + \kappa_t \, x_t + \varepsilon_t^{\pi}, \tag{110.1}$$

where π_t is four-quarter PCE inflation, x_t is the CBO output gap, ρ_t is the *perceived persistence*, and κ_t is the *perceived slope*.

ρ_t plays the role that the sum of the coefficients on lagged inflation plays in the *Conquest*'s Phelps problems (*Testing the natural-rate hypothesis*; Sargent and Williams [2025], footnote 11).

The Fed updates $\theta_t = (\alpha_{0,t}, \rho_t, \kappa_t)^\top$ by constant-gain recursive least squares,

$$\theta_t = \theta_{t-1} + \gamma \, M_t^{-1} X_t \left(\pi_t - X_t^\top \theta_{t-1}\right), \qquad M_t = M_{t-1} + \gamma \left(X_t X_t^\top - M_{t-1}\right), \tag{110.2}$$

with regressors $X_t = (1, \pi_{t-1}, x_t)^\top$ and moment matrix M_t.

The estimate θ_t uses data through quarter t, and it is what the Fed brings to its decision in quarter t.

The moment matrix is updated before the coefficients, the timing of Evans and Honkapohja [2001].

The paper's display writes the lagged matrix M_{t-1} in the coefficient update.

The two timings differ by terms of order γ^2 unless the regressors move far outside their past range.

In 2022 they did, and the timing then changes the recommendations noticeably, so it is worth saying which one the code uses.

The gain $\gamma = 0.03$ is the paper's choice for quarterly data; it discounts past observations so that the estimates can track drift.

Constant-gain least squares is the special case of the Kalman filter of *Priors, Escapes, and Learning Cycles* (see also *A First Look at the Kalman Filter*) that Sargent and Williams [2005] obtain with a particular prior about how the coefficients drift.

Which gain best rationalizes the Fed's decisions is a version of Chung's problem, which we pose in Exercise 110.10.4.

We read the PCE price index, real GDP, CBO potential output, and the federal funds rate directly from FRED.

If FRED lacks an isolated month, as happened for some series around the federal government shutdown of October 2025, the code fills it by linear interpolation and says so.

```
FRED = 'https://fred.stlouisfed.org/graph/fredgraph.csv?id='

def fred(series_id):
    "Read one series directly from FRED."
    s = pd.read_csv(FRED + series_id, index_col=0, parse_dates=True).iloc[:, 0]
    s.index.name = None
    return pd.to_numeric(s, errors='coerce')      # FRED marks gaps with '.'

def quarterly_mean(monthly):
    "Quarterly averages of a monthly series, filling isolated missing months."
    monthly = monthly.asfreq('MS')
    missing = monthly.index[monthly.isna()]
    if len(missing) > 0:
        print(f"{monthly.name}: interpolating",
              [f"{d:%Y-%m}" for d in missing])
    filled = monthly.interpolate(limit=1, limit_area='inside')
    q = filled.resample('QS')
    return q.mean()[q.count() == 3]                # complete quarters only
```

(continues on next page)

(continued from previous page)

```
def qtr(date):
    "Label a date by its quarter, e.g. 2022Q2."
    return f"{date.year}Q{date.quarter}"

pce = quarterly_mean(fred('PCEPI'))
fedfunds = quarterly_mean(fred('FEDFUNDS'))
gdp, potential = fred('GDPC1'), fred('GDPPOT')      # real GDP, CBO potential

inflation = 100 * (pce / pce.shift(4) - 1)           # four-quarter PCE inflation
gap = 100 * (gdp / potential - 1)                    # output gap, percent

data = pd.concat([inflation.rename('pi'), gap.rename('x'),
                  fedfunds.rename('i')], axis=1, sort=True).dropna().loc['1960':]
print(f"sample: {qtr(data.index[0])} to {qtr(data.index[-1])}, "
      f"{len(data)} quarters")

peak = data['pi']['2020':].idxmax()
higher = data['pi'][:peak].iloc[:-1]
last_higher = higher[higher > data['pi'][peak]].index[-1]
print(f"PCE inflation peaked at {data['pi'][peak]:.2f}% in {qtr(peak)}, "
      f"the highest since {qtr(last_higher)}")
```

```
sample: 1960Q1 to 2026Q3, 267 quarters
PCE inflation peaked at 6.88% in 2022Q2, the highest since 1981Q4
```

Following the paper, we freeze beliefs during 2020 and 2021, setting the gain to zero, because the pandemic observations were extreme outliers that would otherwise whipsaw the estimates; updating resumes in 2022.

The freeze is not innocuous.

The 2020 quarters are the true outliers, but it is the freeze of 2021 that drives the results below.

If the Fed had learned from the 2021 data, its perceived Phillips curve would have steepened and its recommended rate would have jumped to several percent by the end of 2021 (Exercise 110.10.3).

Setting the gain to zero in 2021 is itself the judgment that the 2021 surge was transitory.

We start the recursion at $\theta = (0.5, 0.9, 0.05)$ rather than at the paper's 1949–1959 presample regression; the belief paths after the mid-1980s hardly depend on this choice.

We compute the beliefs once and reuse them below.

```
def estimate_beliefs(data, γ=0.03, freeze=(2020, 2021)):
    "Constant-gain RLS for the drifting Phillips curve: paths of α₀, ρ, κ."
    π, x = data['pi'].values, data['x'].values
    θ = np.array([0.5, 0.9, 0.05])            # [intercept, persistence, slope]
    M = np.diag([1.0, 10.0, 5.0])             # moment matrix
    rows = []
    for t in range(1, len(data)):
        γ_t = 0.0 if data.index[t].year in freeze else γ
        X = np.array([1.0, π[t - 1], x[t]])
        M = M + γ_t * (np.outer(X, X) - M)                    # M_t first,
        θ = θ + γ_t * np.linalg.solve(M, X * (π[t] - X @ θ))  # then θ_t
        rows.append(θ)
    return pd.DataFrame(rows, index=data.index[1:],
                        columns=['alpha0', 'rho', 'kappa'])
```

(continues on next page)

(continued from previous page)

```
beliefs = estimate_beliefs(data)
```

Here are the perceived persistence and slope.

```
fig, axes = plt.subplots(2, 1, figsize=(10, 6), sharex=True)
axes[0].plot(beliefs['rho'])
axes[0].axhline(1, color='k', lw=0.5, ls=':')
axes[0].set_ylabel(r'persistence $\rho_t$')

axes[1].plot(beliefs['kappa'], color='C1')
axes[1].axhline(0, color='k', lw=0.5, ls=':')
axes[1].set_ylabel(r'slope $\kappa_t$')
axes[1].set_xlabel('year')

plt.tight_layout()
plt.show()

ρ, κ = beliefs['rho'], beliefs['kappa']
after85 = ρ['1985':]
print(f"ρ_t over 1985-2001: mean {ρ['1985':'2001'].mean():.3f}, "
      f"range {ρ['1985':'2001'].min():.3f} to {ρ['1985':'2001'].max():.3f}")
print(f"first quarter after 1985 with ρ_t < 0.96: "

      f"{κ['2009':'2009'].max():.3f} (2009 peak), "
      f"{κ['2019-10-01']:.3f} (2019Q4)")
print(f"2019Q4: ρ = {ρ['2019-10-01']:.3f};   2022Q2: ρ = {ρ['2022-04-01']:.3f}")
```

```
ρ_t over 1985-2001: mean 0.989, range 0.976 to 1.010
first quarter after 1985 with ρ_t < 0.96: 2006Q3
trough of ρ_t: 0.814 in 2011Q1
κ_t: 0.131 (1980-84 average), 0.198 (2009 peak), 0.039 (2019Q4)
2019Q4: ρ = 0.858;   2022Q2: ρ = 0.981
```

Perceived **persistence** ρ_t jumps in the mid-1970s and then stays close to one for a quarter of a century, through 2001.

It drifts down only slowly in the 2000s and falls steeply after the 2008 recession, to a trough in 2011.

Sargent and Williams [2025] describe a decline after the mid-1980s "with an especially precipitous fall following the 2008 recession"; in this replication the decline is mainly that post-2008 fall.

When updating resumes in 2022, ρ_t jumps back toward one, just as the Fed abandoned the "transitory" characterization and began to tighten.

Perceived **slope** κ_t declines from its early-1980s level, spikes during the 2008–2009 recession, when the economy briefly experienced deflation, and is lower still by 2019: the Phillips curve flattens.

A word on the scale of ρ_t.

Because π_t is a four-quarter rate, consecutive observations share three quarters of data.

Even if quarterly inflation were serially uncorrelated, a regression of π_t on π_{t-1} would give a coefficient near 0.75 (Exercise 110.10.5).

Against that floor, the 2019 value of ρ_t means *less persistent*, not *transitory*:

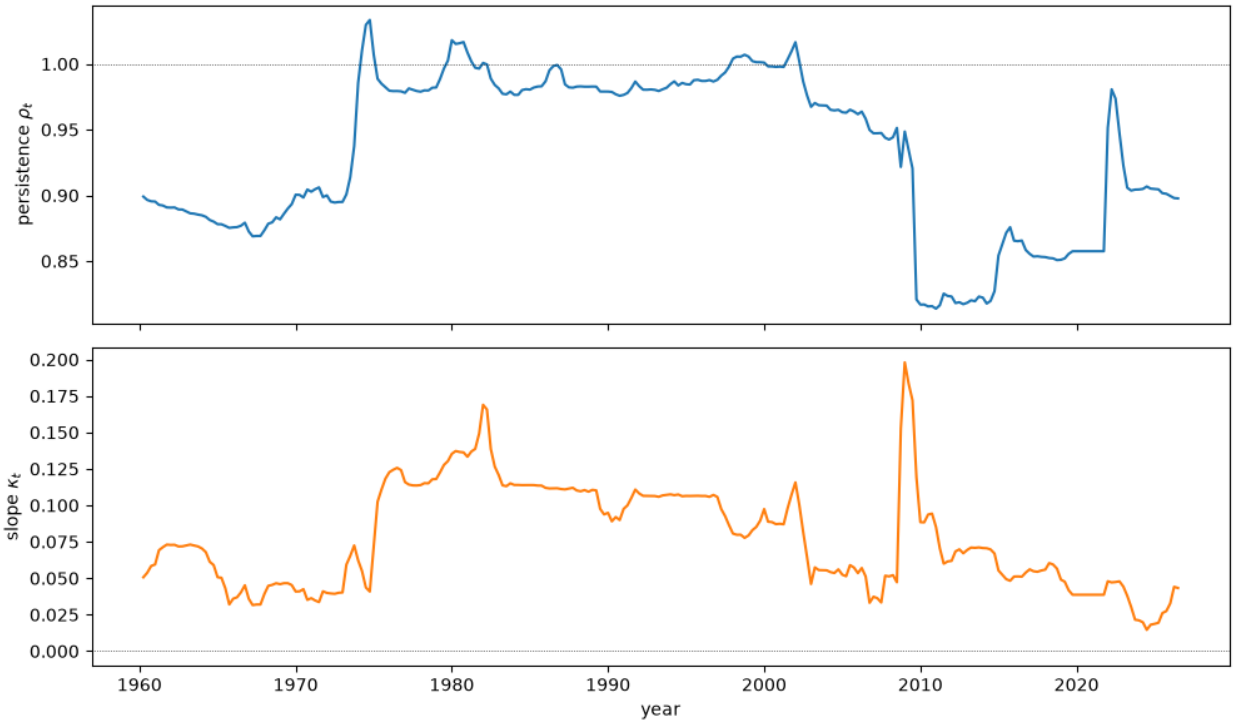

Fig. 110.1: The Fed's perceived inflation persistence and Phillips curve slope

```
ρ_2019 = ρ['2019-10-01']
print(f"half-life of an inflation shock at ρ = {ρ_2019:.3f}: "
      f"{np.log(0.5) / np.log(ρ_2019):.1f} quarters")
```

```
half-life of an inflation shock at ρ = 0.858: 4.5 quarters
```

With quarterly annualized inflation, which has no overlap, the same algorithm finds persistence falling earlier and much further.

That measure is closer in spirit to the one in *Drifts and Volatilities*; Exercise 110.10.5 reconciles the two.

Still, by 2019 the Fed's model said that inflation was less persistent than it used to be and only weakly linked to slack.

Fed into a Phelps problem, these beliefs counsel patience.

110.4 The Fed's Phelps problem

Each quarter the Fed sets its policy rate by solving a linear-quadratic Phelps problem, treating its *current* estimates as if they will hold forever.

That is the anticipated-utility assumption of Kreps [1998] that we met in *Adaptive Learning and Escape Dynamics*.

The belief Phillips curve (110.1) is paired with an IS curve

$$x_t = b_0 + b_1 x_{t-1} + g\,(i_{t-1} - \pi_{t-1}) + \varepsilon_t^x,$$

whose coefficients are estimated once, by OLS over the whole sample.

Together they give linear dynamics for the state $s_t = (1, \pi_t, x_t, i_{t-1})^\top$,

$$s_{t+1} = A_t s_t + B_t\, i_t + C\varepsilon_{t+1},$$

whose matrices depend on the time-t beliefs.

The Fed minimizes

$$\mathbb{E}_t \sum_{j=t}^{\infty} \beta^{j-t}\Big[(\pi_j - \pi^*)^2 + \lambda_x\, x_j^2 + \eta\,(i_j - i_{j-1})^2\Big], \tag{110.3}$$

where $\pi^* = 2$ is the target and the last term penalizes abrupt rate changes.

We use the paper's parameter values: $\beta = 0.95$, $\lambda_x = 0.2$, and $\eta = 0.5$.

The paper says these values were "loosely tuned to provide a reasonable match to the observed policy outcomes."

Writing the period loss as $s^\top Q s + 2 s^\top N i + R\, i^2$ with $R = \eta$ turns this into a discounted linear-quadratic regulator with a cross term (*LQ Control: Foundations*).

The matrix P_t of the expected discounted loss $s^\top P_t s$ (plus a constant) solves the discounted Riccati equation

$$P = Q + \beta A^\top P A - (\beta A^\top P B + N)(R + \beta B^\top P B)^{-1}(\beta B^\top P A + N^\top), \tag{110.4}$$

and the decision rule is $i_t = -F_t s_t$ with $F_t = (R + \beta B^\top P_t B)^{-1}(\beta B^\top P_t A + N^\top)$.

Written out, the rule is a *smoothed Taylor rule*,

$$i_t = \phi_{0,t} + \phi_{\pi,t}\,\pi_t + \phi_{x,t}\,x_t + \phi_{i,t}\,i_{t-1},$$

whose coefficients move as beliefs move.

`scipy.linalg.solve_discrete_are` solves the undiscounted version of (110.4).

Passing $\sqrt{\beta}A$ and $\sqrt{\beta}B$ absorbs the discount factor.

The cross term then enters unscaled, as `s=N`, because $\beta A^\top P B + N = (\sqrt{\beta}A)^\top P(\sqrt{\beta}B) + N$.

Following the paper (Sargent and Williams [2025], section 3.3), we impose the zero lower bound only ex post, $i_t^{\text{opt}} = \max\{-F_t s_t, 0\}$.

The Fed's Phelps problem does not anticipate that the bound might bind.

```
# IS curve, estimated once by OLS over the full sample
π_d, x_d, i_d = data['pi'].values, data['x'].values, data['i'].values
n = len(data)
Z_is = np.column_stack([np.ones(n - 1), x_d[:-1], i_d[:-1] - π_d[:-1]])
b0, b1, g = np.linalg.lstsq(Z_is, x_d[1:], rcond=None)[0]
print(f"IS curve: b0 = {b0:.3f}, b1 = {b1:.3f}, g = {g:.4f}; "
      f"long-run effect of the real rate g/(1-b1) = {g / (1 - b1):.2f}")

    return pd.Series(np.maximum((rules.values * s).sum(axis=1), 0.0),
                     index=rules.index)

rules = phelps_rules(beliefs)
optimal = recommended_rate(data, rules)
```

```
IS curve: b0 = 0.013, b1 = 0.907, g = -0.0220; long-run effect of the real rate g/
↪(1-b1) = -0.24
```

The estimated interest sensitivity g is small.

Policy endogeneity, which we meet again in *From policy to measured beliefs*, is one reason a regression can understate how much interest rates matter: a Fed that leans against expected booms weakens the correlation between the real rate and subsequent output.

```
fig, ax = plt.subplots(figsize=(10, 4.5))
window = slice('1991', None)
ax.plot(optimal[window], 'C0', label="Phelps problem's recommended rate")
ax.plot(data['i'][window], 'C3', lw=1, label='actual federal funds rate')
ax.set_xlabel('year')
ax.set_ylabel('percent')
ax.legend()
plt.show()

def fit(rate, start='1991'):
    "Correlation and root mean squared error against the actual funds rate."
    r = rate[start:]
    actual = data['i'][r.index]
    return np.corrcoef(r, actual)[0, 1], np.sqrt(((r - actual)**2).mean())

no_change = data['i'].shift(1).dropna()               # i_t = i_{t-1}
for name, rate in [('Phelps rule', optimal), ('no-change rule', no_change)]:
    c, rmse = fit(rate)
    print(f"{name:>15}: correlation {c:.3f}, RMSE {rmse:.2f} "
          f"(1991-{data.index[-1].year})")
```

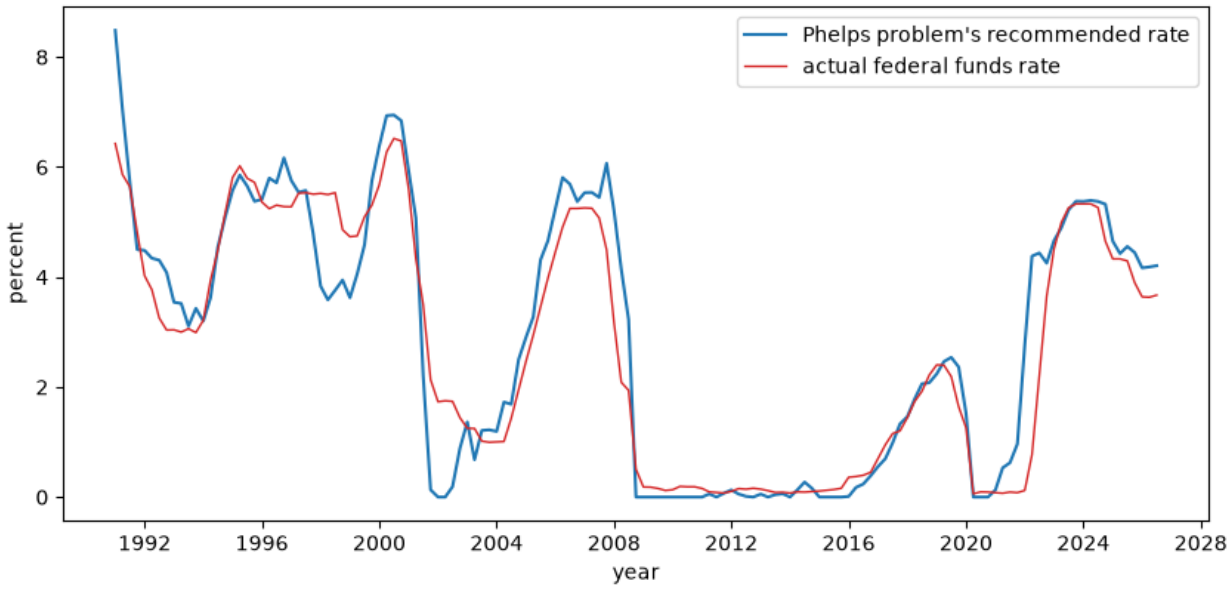

Fig. 110.2: The belief-driven Phelps rule against the actual federal funds rate

```
    Phelps rule: correlation 0.944, RMSE 0.79 (1991–2026)
no-change rule: correlation 0.979, RMSE 0.45 (1991–2026)
```

The subjectively optimal rate tracks the level and turning points of actual policy over three decades: the mid-1990s tightening, the 2001 easing, the zero-bound era after 2008, and the normalization that began in 2015.

It misses some episodes, falling well below the actual rate in 1998 and again in 2002.

The correlation needs a benchmark.

Because the recommendation conditions on the actual lagged rate i_{t-1}, a naive rule that simply sets $i_t = i_{t-1}$ does *better* on both measures, as the output shows.

The paper makes the same point about one-step-ahead fit.

What the Phelps rule offers is not a better forecast of the funds rate but an interpretation of it, in terms of beliefs and a loss function.

Now look at 2021.

Beliefs are frozen, but the state is not: as inflation and the output gap rise, the rule recommends a rising rate.

```
print(pd.DataFrame({'Phelps rule': optimal, 'actual': data['i']})
        .loc['2021':'2022'].rename(index=qtr).round(2).T.to_string())
```

```
             2021Q1  2021Q2  2021Q3  2021Q4  2022Q1  2022Q2  2022Q3  2022Q4
Phelps rule    0.13    0.53    0.62    0.96    2.76    4.38    4.44    4.25
actual         0.08    0.07    0.09    0.08    0.12    0.77    2.19    3.65
```

With today's revised data, the artificial Fed starts raising its rate in 2021 and is well ahead of the actual Fed in early 2022.

So with current-vintage data the drifting-beliefs model *leads* the Fed rather than mirroring it, as the paper also finds when it uses revised data (Sargent and Williams [2025], section 3.5).

Drifting beliefs make the recommended response mild, but they do not make it late.

We return to the delay in *Real-time data and the delay*.

110.4.1 How the rule drifted

The paper's Figure 8 shows the mechanism directly: the coefficients of the Phelps rule, and the long-run response of the policy rate to inflation, $\phi_{\pi,t}/(1-\phi_{i,t})$.

We compute them with today's data; the paper's figure uses real-time data.

A long-run response above one is the Taylor principle.

```
long_run = rules['ψ_π'] / (1 - rules['ψ_i'])

fig, axes = plt.subplots(3, 1, figsize=(10, 8), sharex=True)
axes[0].plot(rules['ψ_π'], label=r'$\phi_{\pi,t}$')
axes[0].plot(rules['ψ_x'], label=r'$\phi_{x,t}$')
axes[0].legend()
axes[0].set_ylabel('response')
axes[1].plot(rules['ψ_i'], color='C2')
axes[1].set_ylabel(r'smoothing $\phi_{i,t}$')
axes[2].plot(long_run, color='C3')
axes[2].axhline(1, color='k', lw=0.5, ls=':')
axes[2].set_ylabel(r'$\phi_{\pi,t}/(1-\phi_{i,t})$')
axes[2].set_xlabel('year')
plt.tight_layout()
plt.show()

for date in ['2000-01-01', '2019-10-01']:
    print(f"long-run inflation response in {qtr(pd.Timestamp(date))}: "
          f"{long_run[date]:.2f}")
peak_lr = long_run['2021':'2023'].idxmax()
print(f"peak in 2021-2023: {long_run[peak_lr]:.2f} in {qtr(peak_lr)}")
```

```
long-run inflation response in 2000Q1: 6.65
long-run inflation response in 2019Q4: 1.30
peak in 2021-2023: 6.05 in 2022Q2
```

As persistence and slope drifted down, the rule's long-run response to inflation fell from well above one in 2000 to just above one by 2019, while interest-rate smoothing rose.

The 2019 rule barely satisfied the Taylor principle.

When updating resumed in 2022 and ρ_t jumped, the long-run response jumped with it, before falling back as inflation receded.

Part of the 2022 tightening in Fig. 110.2 therefore comes from a change in the rule itself, not only from the rise in inflation and the gap.

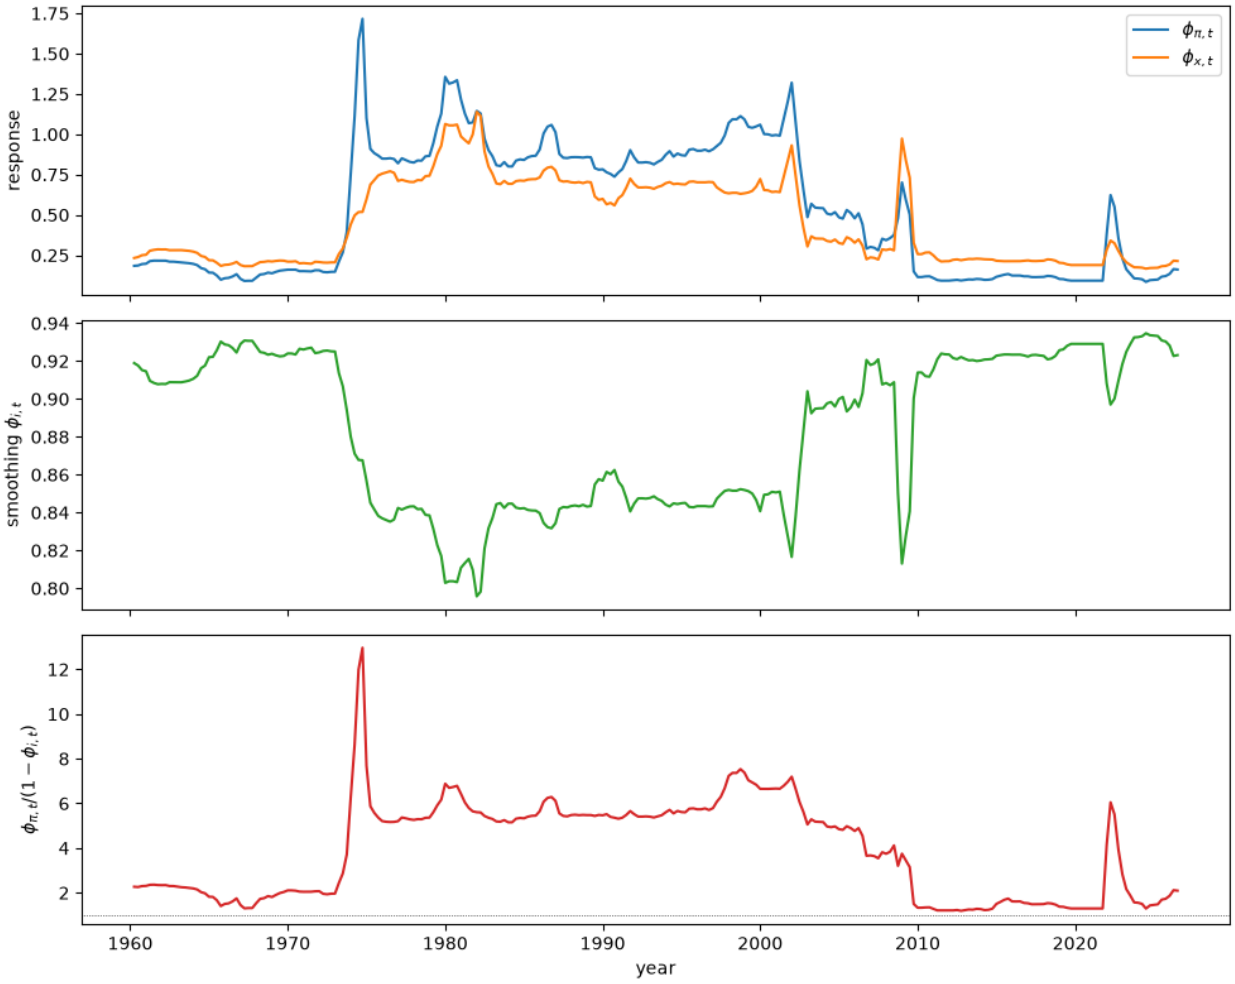

Fig. 110.3: Coefficients of the Phelps rule and its long-run response to inflation

110.5 Why the Fed was slow: a counterfactual

To isolate the role of the drifting beliefs, we recompute the Phelps recommendations holding beliefs fixed at their values in the first quarter of 2000.

```
θ_2000 = beliefs.loc['2000-01-01'].values
print(f"beliefs in 2000Q1: α₀ = {θ_2000[0]:.3f}, ρ = {θ_2000[1]:.3f}, "
      f"κ = {θ_2000[2]:.3f}")
```

```
beliefs in 2000Q1: α₀ = -0.025, ρ = 1.001, κ = 0.097
```

In 2000 the Fed's model had a unit root: $\rho \approx 1$, so inflation shocks were perceived as permanent.

Its perceived slope was more than twice the 2019 value.

```
rules_2000 = pd.DataFrame(np.tile(phelps_rule(θ_2000), (len(beliefs), 1)),
                          index=beliefs.index, columns=rules.columns)
counterfactual = recommended_rate(data, rules_2000)

fig, ax = plt.subplots(figsize=(10, 4.5))
w = slice('2015', None)
ax.plot(optimal[w], 'C0', label='baseline (drifting beliefs)')
ax.plot(counterfactual[w], 'C1--', label='counterfactual (beliefs frozen at 2000)')
ax.plot(data['i'][w], 'C3', lw=1, alpha=0.7, label='actual funds rate')
ax.set_xlabel('year')
ax.set_ylabel('percent')
ax.legend()
plt.show()

print(f"counterfactual rate in 2021Q4: {counterfactual['2021-10-01']:.2f}%  "
      f"(actual {data['i']['2021-10-01']:.2f}%)")
```

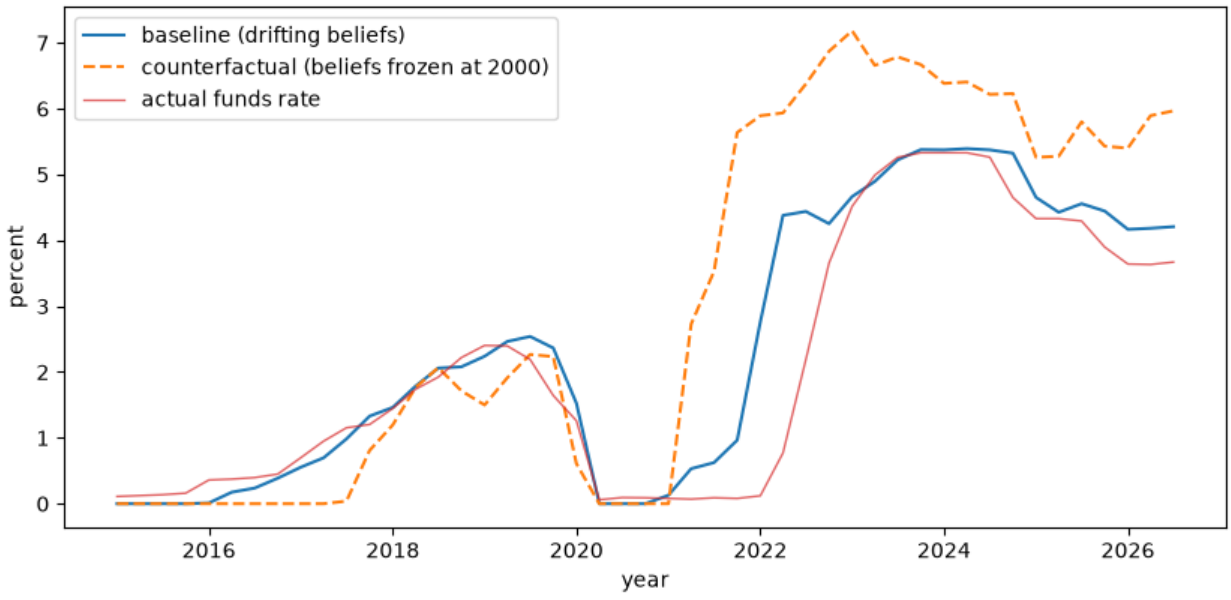

Fig. 110.4: Counterfactual: a Fed that had not updated its beliefs since 2000

```
counterfactual rate in 2021Q4: 5.64%  (actual 0.08%)
```

A Fed with year-2000 beliefs would have tightened immediately and sharply in 2021, driving the funds rate above 5% by the end of 2021, before the actual Fed had moved at all.

The objectives are the same in both paths; only the beliefs differ.

Perceiving inflation as less persistent and the Phillips curve as flatter, the Fed's own Phelps problem told it to respond mildly.

This is the 2020s counterpart of Cogley and Sargent [2005]'s account of the 1970s.

There a Bayesian Fed ran a race among three Phelps problems, and the costly disinflation predicted by the worst-case Samuelson–Solow model made it gradual, even after the data favored a natural-rate model.

110.6 Real-time data and the delay

The paper's conclusion turns on the third element.

In its words, "Only by incorporating real-time uncertainty about the economy, which tends to be elevated during business cycle turning points, do we rationalize the observed delay in the policy response" (Sargent and Williams [2025], section 3.5).

We now rebuild the output gap that the Fed saw in real time.

ALFRED, the St. Louis Fed's archive of past data vintages, keeps every vintage of real GDP (`GDPC1`) and of CBO potential output (`GDPPOT`).

For each quarter since 2019, we compute the gap from the two series as they stood 45 days after the quarter ended, by which time the advance GDP estimate is normally out.

Two kinds of quarters need care.

- Some GDP releases were delayed by the federal government shutdown of late 2025. For any quarter missing from its 45-day vintage, we use the first later vintage that contains it.
- In September 2023 the Bureau of Economic Analysis re-expressed real GDP in 2017 dollars, while CBO's potential output stayed in 2012 dollars until early 2024. A gap computed from such a vintage compares series in different units. We detect this by the ratio of the two series before 2019 and skip vintages in which they are not on the same base.

ALFRED serves up to twelve series per request, so the code asks for six vintages of both series at a time, and the whole history takes only a few requests.

```
ALFRED = 'https://alfred.stlouisfed.org/graph/alfredgraph.csv'

def alfred_vintages(series, dates, per_request=6, tries=3):
    "Vintages of several series at several dates, a few requests in all."
    frames = []
    for j in range(0, len(dates), per_request):
        vd = [f"{d:%Y-%m-%d}" for d in dates[j:j + per_request]]
        url = (f"{ALFRED}?id={','.join(s for s in series for _ in vd)}"
               f"&vintage_date={','.join(vd * len(series))}")
        for attempt in range(tries):
            try:
                frames.append(pd.read_csv(url, index_col=0, parse_dates=True))
                break
            except Exception as err:
```

```

With the gap that the Fed saw in real time, the recommended rate stays below half a percent through 2021.

It starts to rise at the turn of 2022, about when the Fed lifted off.

It runs ahead of the actual rate in the first half of 2022 and falls behind it from the third quarter on, as the Fed tightened in large steps.

That is the paper's "slightly lagging" pattern.

With today's data, by contrast, the rule lifts off about a year before the Fed did.

Putting the pieces together:

- the counterfactual shows that **drifting beliefs make the response muted**: with its 2000 beliefs the Fed would have tightened fast and far;
- this comparison shows that **real-time mismeasurement makes it late**: with drifting beliefs but accurate data, the Fed would have started tightening in 2021.

Both are needed to rationalize what the Fed did.

110.7 How beliefs shape the Phelps rule

Why do lower perceived persistence and a flatter perceived slope make the rule less aggressive?

Sargent and Williams [2025] answer analytically, in their Appendix A, for a stripped-down version of the Phelps problem.

The Fed believes that

$$\begin{aligned} \pi_{t+1} &= \rho\,\pi_t + \kappa\,x_{t+1} + \varepsilon^{\pi}_{t+1}, \\ x_{t+1} &= b_1 x_t + g\,(i_t - \pi_t) + \varepsilon^{x}_{t+1}, \end{aligned} \tag{110.5}$$

with $|b_1| < 1$, $\kappa > 0$, and $g < 0$.

These are the paper's equations (6) and (7), whose a_1 and k are our ρ and κ.

The Fed minimizes $\mathbb{E}\sum_t \beta^t(\pi_t^2 + \lambda_x x_t^2)$, with no smoothing penalty, no intercepts, and a zero target.

Taking the real rate $r_t = i_t - \pi_t$ as the control gives a regulator with state (π_t, x_t) whose Riccati equation has a closed-form solution.

The optimal rule is $i_t = \phi_\pi(\rho,\kappa)\,\pi_t + \phi_x x_t$ with

$$\phi_\pi(\rho,\kappa) = 1 - \frac{\rho}{g\kappa}\,\frac{Z}{Z+\lambda_x}, \qquad \phi_x = -\frac{b_1}{g},$$

where

$$Z = \frac{-\Delta + \sqrt{\Delta^2 + 4\lambda_x\kappa^2}}{2}, \qquad \Delta = \lambda_x(1-\beta\rho^2) - \kappa^2.$$

The paper proves two comparative statics.

Proposition 110.7.1 (Lower perceived persistence ⇒ less aggressive policy)

For any $\beta \in (0,1)$, $\lambda_x > 0$, $\kappa > 0$, and $g < 0$, the inflation coefficient $\phi_\pi(\rho,\kappa)$ is strictly increasing in $\rho \geq 0$.

Proposition 110.7.2 (Flatter perceived slope ⇒ less aggressive policy)

$\partial\phi_\pi/\partial\kappa > 0$ whenever a sufficient condition (the paper's inequality (11)) holds; it holds for small and moderate κ.

Let's verify both numerically, and check the closed form against `solve_discrete_are` along the way.

For the IS beliefs we use illustrative values, $b_1 = 0.9$ and $g = -0.5$.

b_1 is close to the estimate above, but g is much larger in absolute value, so that ϕ_π is of a familiar size.

Since $\phi_\pi - 1$ is proportional to $1/g$, the value of g does not affect the signs of the comparative statics.

```
def ψ_π(ρ, κ, b1=0.9, g=-0.5, λ_x=0.2, β=0.95):
    "Closed-form inflation coefficient of the simplified Phelps rule."
    Δ = λ_x * (1 - β * ρ**2) - κ**2
    Z = (-Δ + np.sqrt(Δ**2 + 4 * λ_x * κ**2)) / 2
    return 1 - (ρ / (g * κ)) * Z / (Z + λ_x)

def ψ_π_riccati(ρ, κ, b1=0.9, g=-0.5, λ_x=0.2, β=0.95, η_r=1e-9):
    "The same coefficient from solve_discrete_are, with control cost η_r r²."
    A = np.array([[ρ, κ * b1], [0, b1]])
    B = np.array([[κ * g], [g]])
    Q, R = np.diag([1, λ_x]), np.array([[η_r]])
    P = solve_discrete_are(np.sqrt(β) * A, np.sqrt(β) * B, Q, R)
    F = np.linalg.solve(R + β * B.T @ P @ B, β * B.T @ P @ A)
    return 1 - F[0, 0]

grid = [(ρ_, κ_) for ρ_ in np.linspace(0.05, 0.99, 12)
        for κ_ in np.linspace(0.01, 1.0, 12)]
gap_cf = max(abs(ψ_π(*p) - ψ_π_riccati(*p)) / ψ_π(*p) for p in grid)
print(f"largest relative difference, closed form vs Riccati: {gap_cf:.1e}")
```

```
largest relative difference, closed form vs Riccati: 1.5e-08
```

The closed form checks out.

Now the two comparative statics.

```
ρ_grid = np.linspace(0, 0.999, 200)
κ_grid = np.linspace(0.005, 1.0, 400)

fig, axes = plt.subplots(1, 2, figsize=(11, 4))
for κ_ in [0.04, 0.1, 0.3]:
    axes[0].plot(ρ_grid, ψ_π(ρ_grid, κ_), label=rf'$\kappa = {κ_}$')
axes[0].set_xlabel(r'perceived persistence $\rho$')
axes[0].set_ylabel(r'$\phi_\pi$')
axes[0].legend()

for ρ_ in [0.5, 0.86, 0.99]:
    axes[1].plot(κ_grid, ψ_π(ρ_, κ_grid), label=rf'$\rho = {ρ_}$')
axes[1].set_xlabel(r'perceived slope $\kappa$')
axes[1].legend()
plt.tight_layout()
plt.show()

increasing = all(np.all(np.diff(ψ_π(ρ_grid, κ_)) > 0)
                 for κ_ in [0.01, 0.04, 0.1, 0.3, 1.0, 3.0])
print("ϕ_π increasing in ρ for every κ tried:", increasing)
for ρ_ in [0.5, 0.86, 0.99]:
    κ_peak = κ_grid[np.argmax(ψ_π(ρ_, κ_grid))]
    print(f"ρ = {ρ_}: ϕ_π increases in κ up to κ = {κ_peak:.3f}, then falls")
print(f"largest κ_t estimated in 2010-2019: {κ['2010':'2019'].max():.3f}")
```

```
ϕ_π increasing in ρ for every κ tried: True
ρ = 0.5: ϕ_π increases in κ up to κ = 0.392, then falls
ρ = 0.86: ϕ_π increases in κ up to κ = 0.244, then falls
ρ = 0.99: ϕ_π increases in κ up to κ = 0.117, then falls
largest κ_t estimated in 2010-2019: 0.094
```

Persistence matters everywhere.

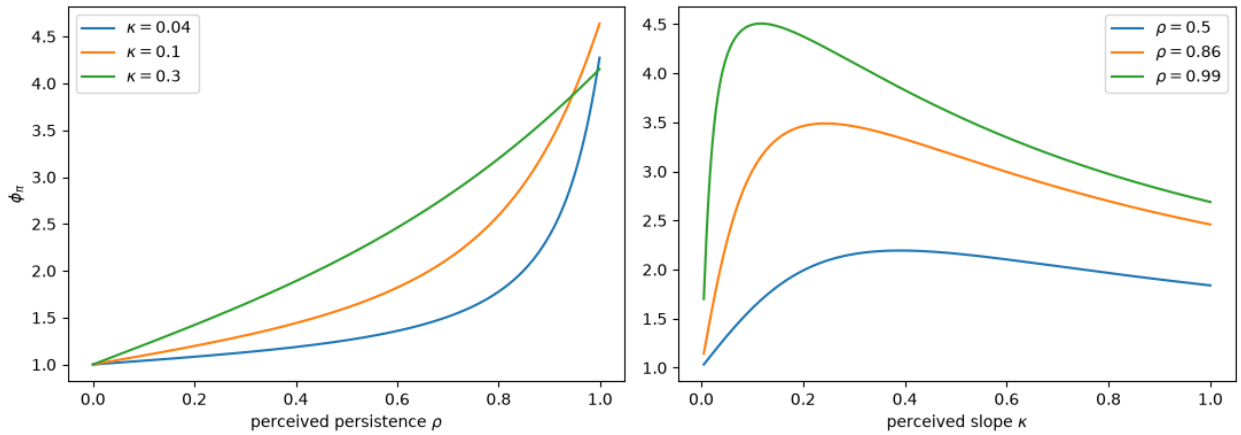

Fig. 110.7: The inflation coefficient of the simplified Phelps rule

The higher ρ, the more today's inflation predicts future inflation, and the harder the Fed leans against it.

The slope matters too: a flatter curve makes each point of disinflation cost more output, so the Fed responds less.

That holds for small slopes, including all those the Fed estimated in the 2010s.

For large slopes the effect reverses, and the peak moves to smaller κ as ρ rises (Exercise 110.10.2).

So *Proposition 110.7.2* should be read as a statement about small slopes.

Together, the two propositions explain the drift of the rule in Fig. 110.3: as ρ_t and κ_t fell, so did the rule's response to inflation.

110.8 From policy to measured beliefs

So far we have taken the Fed's beliefs from the data.

Where did they come from?

In the extended abstract of their project, Sargent and Williams [2025] suggest that "the perceptions of the low persistence of inflation and a flat Phillips curve were based on the past Fed policy, which had reacted strongly to shocks and stabilized inflation."

They frame the outcome as a self-confirming equilibrium in which the Fed is caught in a lack-of-experimentation trap.

This section is the lecture's own extension of that idea; the January 2026 version of the paper does not contain it.

We put a small New Keynesian model on the table as *nature's* model.

We compute what the Fed's regression would measure under different policies, and then close the loop with the Phelps rule of the previous section.

In the terms of Koopmans [1947], the Fed's drifting-coefficients model is a descriptive "Kepler stage" model.

Nature's model, by contrast, is a "Newton stage" model whose parameters are invariant to the Fed's rule.

110.8.1 Nature's model

Suppose that nature runs

$$\begin{aligned} \pi_t &= \beta_f \, \mathbb{E}_t \pi_{t+1} + \omega_b \, \pi_{t-1} + \kappa \, x_t + u_t, \\ x_t &= \mathbb{E}_t x_{t+1} - \sigma \left(i_t - \mathbb{E}_t \pi_{t+1} - r_t \right), \\ i_t &= \phi \, \pi_t, \end{aligned} \qquad \beta_f = \frac{\beta_n}{1 + \beta_n \omega}, \quad \omega_b = \frac{\omega}{1 + \beta_n \omega}, \tag{110.6}$$

where u_t is a cost-push shock and r_t a natural-rate (demand) shock.

The two shocks are IID and mutually uncorrelated, with standard deviations σ_u and σ_r.

The first equation is the hybrid Phillips curve that arises when firms that cannot reset their prices index them to lagged inflation at rate $\omega \in [0, 1]$.

Its weights on expected and lagged inflation sum to $(\beta_n + \omega)/(1 + \beta_n \omega) \leq 1$.

With this normalization the Taylor principle $\phi > 1$ delivers a determinate equilibrium, which the code below checks by counting roots (*Stability in Linear Rational Expectations Models*; [Blanchard and Kahn, 1980]).

Nature's discount factor $\beta_n = 0.99$ is distinct from the Fed's $\beta = 0.95$.

We set $\omega = 1$, a structural slope $\kappa = 0.1$, and $\sigma = 1$.

In the minimum-state-variable equilibrium, $\mathbb{E}_t \pi_{t+1} = \lambda \, \pi_t$, and

$$\pi_t = \lambda \, \pi_{t-1} + a \, u_t + b \, r_t, \qquad x_t = \psi \, \pi_{t-1} + c \, u_t + d \, r_t.$$

Here λ is the stable root of the cubic

$$\beta_f \lambda^3 - (1 + \beta_f + \kappa\sigma)\lambda^2 + (1 + \omega_b + \kappa\sigma\phi)\lambda - \omega_b = 0,$$

$\psi = -\sigma\lambda(\phi - \lambda)/(1 - \lambda)$, and the impact coefficients (a, b, c, d) are computed in the code.

λ is the coefficient of a univariate AR(1): it is what an econometrician who regressed inflation on its own lag would call persistence.

110.8.2 What the Fed measures

The Fed's regression (110.1) also contains x_t.

Since $x_t = \psi \, \pi_{t-1} + v_t$, with $v_t = c \, u_t + d \, r_t$ uncorrelated with π_{t-1}, its population coefficients are

$$\hat{\kappa} = \frac{\operatorname{cov}(\pi_t, v_t)}{\mathbb{V}[v_t]}, \qquad \hat{\rho} = \lambda - \hat{\kappa} \, \psi.$$

So the Fed's measured persistence $\hat{\rho}$ is *not* λ.

When only demand shocks hit ($\sigma_u = 0$), we can substitute $\mathbb{E}_t \pi_{t+1} = \lambda \pi_t$ into the Phillips curve.

That gives the exact relation $\pi_t = [\omega_b \, \pi_{t-1} + \kappa \, x_t]/(1 - \beta_f \lambda)$, so

$$\hat{\rho} = \frac{\omega_b}{1 - \beta_f \, \lambda(\phi)}, \qquad \hat{\kappa} = \frac{\kappa}{1 - \beta_f \, \lambda(\phi)}.$$

The Fed recovers the structural lag weight and slope, each divided by $1 - \beta_f \lambda(\phi)$, a factor that depends on policy.

That is the Lucas critique in one line.

A more aggressive rule lowers λ, and with it both $\hat{\rho}$ and $\hat{\kappa}$: aggressive policy makes inflation look less persistent and the Phillips curve look flatter.

The persistence result is in the spirit of Benati and Surico [2008] and Carlstrom *et al.* [2009]; the slope result in this form is Bullard [2018]'s.

Cost-push shocks push $\hat{\kappa}$ down further and can make it negative.

That is the identification problem stressed by McLeay and Tenreyro [2019]: when the Fed offsets cost-push shocks, high inflation coincides with a low output gap.

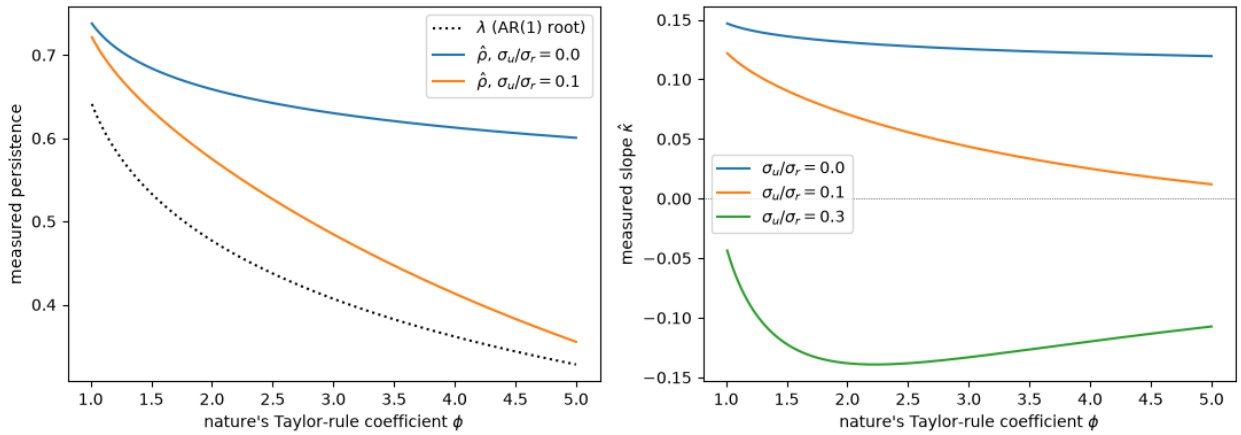

Fig. 110.8: What the Fed's regression measures under different policy rules

The measured persistence $\hat{\rho}$ lies well above the AR(1) root λ, and all three fall as policy grows more aggressive.

With demand shocks only, $\hat{\kappa}$ also falls with ϕ but stays above the structural slope $\kappa = 0.1$, as the formula says.

Even modest cost-push shocks pull it down sharply, and below zero.

The model is a stylized quarterly one, so its numbers are not meant to match the Fed's estimates from four-quarter inflation.

110.8.3 The self-confirming fixed point

Now compose the two maps.

A history of policy ϕ produces measured beliefs $(\hat{\rho}(\phi), \hat{\kappa}(\phi))$.

Fed into the Phelps problem, those beliefs recommend the inflation coefficient

$$T(\phi) = \phi_\pi(\hat{\rho}(\phi), \hat{\kappa}(\phi)).$$

A fixed point $\phi^* = T(\phi^*)$ is a self-confirming equilibrium in the sense of *Self-Confirming Equilibria*.

At ϕ^*, the Fed's rule solves its Phelps problem given its beliefs, and its beliefs satisfy the least-squares orthogonality conditions in the data that its rule generates.

We make two simplifications.

Nature's rule uses only the inflation coefficient that the Phelps problem recommends.

We also hold the Fed's IS beliefs at the illustrative values of the previous section, so the loop runs only through the Phillips curve.

Since $\hat{\rho}$ and $\hat{\kappa}$ fall as ϕ rises, and ϕ_π rises with both (for small κ), T is *decreasing*: the loop is a negative feedback.

```
def T(ψ, **nature):
    "Inflation coefficient recommended by beliefs measured under the rule ψ."
    _, ρ_hat, κ_hat = fed_regression(ψ, **nature)
    return ψ_π(ρ_hat, κ_hat)

def fixed_point(**nature):
    "ψ* = T(ψ*) and the slope T'(ψ*)."
```

(continues on next page)

(continued from previous page)

```
    φ_star = brentq(lambda φ: T(φ, **nature) - φ, 1.01, 5.0)
    h = 1e-5
    slope = (T(φ_star + h, **nature) - T(φ_star - h, **nature)) / (2 * h)
    return φ_star, slope

fig, ax = plt.subplots(figsize=(7, 4.5))
for σ_u in [0.0, 0.1]:
    ax.plot(φ_grid, [T(φ, σ_u=σ_u) for φ in φ_grid],
            label=rf'$T(\phi)$, $\sigma_u/\sigma_r = {σ_u}$')
ax.plot(φ_grid, φ_grid, 'k:', lw=1, label='45° line')
ax.set_xlabel(r'past policy $\phi$')
ax.set_ylabel(r'recommended $\phi_\pi$')
ax.legend()
plt.show()

cases = {'baseline': {}, 'σ_u/σ_r = 0.1': {'σ_u': 0.1},
         'ω = 0.5': {'ω': 0.5}, 'κ = 0.05': {'κ': 0.05}}
for name, nature in cases.items():
    φ_star, slope = fixed_point(**nature)
    _, ρ_hat, κ_hat = fed_regression(φ_star, **nature)
    print(f"{name:>15}: φ* = {φ_star:.3f}, T'(φ*) = {slope:.3f}, "
          f"beliefs (ρ̂, κ̂) = ({ρ_hat:.3f}, {κ_hat:.3f})")
```

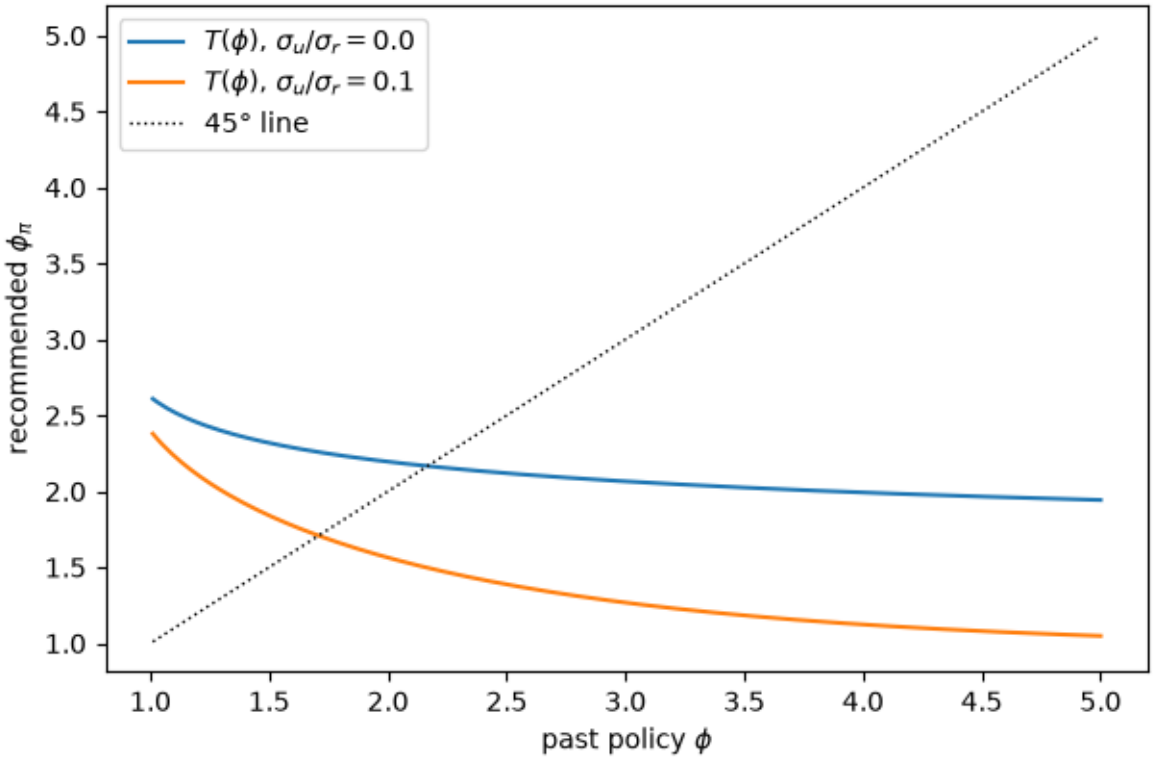

Fig. 110.9: The map from past policy to the policy the Phelps problem recommends

```
      baseline: φ* = 2.166, T'(φ*) = -0.161, beliefs (ρ̂, κ̂) = (0.653, 0.130)
  σ_u/σ_r = 0.1: φ* = 1.708, T'(φ*) = -0.568, beliefs (ρ̂, κ̂) = (0.607, 0.082)
       ω = 0.5: φ* = 1.612, T'(φ*) = -0.076, beliefs (ρ̂, κ̂) = (0.434, 0.130)
```

(continues on next page)

(continued from previous page)

```
κ = 0.05: ψ* = 1.871, T'(ψ*) = -0.199, beliefs (ρ̂, κ̂) = (0.707, 0.070)
```

T crosses the 45-degree line once, so the self-confirming equilibrium is unique.

Is it stable under learning?

A Fed that learns with a small gain follows mean dynamics like $d\phi/d\tau = T(\phi) - \phi$, the ordinary differential equation of *One recursion, many learners*.

The rest point is E-stable if $T'(\phi^*) < 1$.

In belief space the same condition appears.

The map $(\rho, \kappa) \mapsto (\hat{\rho}, \hat{\kappa})(\phi_\pi(\rho, \kappa))$ has a rank-one Jacobian whose nonzero eigenvalue is $T'(\phi^*)$.

So the E-stability eigenvalues are -1 and $T'(\phi^*) - 1$, the kind of calculation that *Self-Confirming Equilibria* carries out for the *Conquest*'s model (*Uniqueness and E-stability*).

Because $T' < 0$, the condition holds with room to spare in every case above.

Because $|T'| < 1$ as well, even the gain-one "cobweb" iteration $\phi_{k+1} = T(\phi_k)$ converges.

It describes a Fed that re-optimizes only after its beliefs have fully adjusted to each policy regime:

```
for name in ['baseline', 'σ_u/σ_r = 0.1']:
    ψ_k, path = 3.0, [3.0]                    # start from an aggressive history
    for _ in range(8):
        ψ_k = T(ψ_k, **cases[name])
        path.append(ψ_k)
    print(f"{name:>15}:", np.round(path, 2))
```

```
       baseline: [3.   2.07 2.18 2.16 2.17 2.17 2.17 2.17 2.17]
 σ_u/σ_r = 0.1: [3.   1.27 2.04 1.55 1.81 1.65 1.74 1.69 1.72]
```

An aggressive history is followed by a timid rule, then by a partial correction, in damped oscillations around ϕ^*.

That is a faint echo of "conquest lost and regained", but it dies out.

110.8.4 A trap without an escape route

The fixed point has the structure of the *Conquest*'s self-confirming equilibria.

The anticipated-utility Fed never experiments, by construction (*Adaptive Learning and Escape Dynamics*).

At ϕ^* its beliefs are right on the equilibrium path and wrong off it: under a less aggressive rule, measured persistence and slope would rise.

This is the lack-of-experimentation trap of *Escaping Nash Inflation* (*The experimentation trap*), and it is the sense of the extended abstract's framing.

The difference lies in the dynamics.

In the model of Cho *et al.* [2002], the escape route is self-reinforcing.

A run of shocks that steepens the perceived Phillips curve makes the government cut inflation, and that generates data that steepen the curve further.

Here the feedback runs the other way.

A run of shocks that raises measured persistence makes the Fed more aggressive, and more aggressive policy *lowers* measured persistence.

A constant-gain learner would wander around ϕ^*, but the mean dynamics pull it back from either side: there is no escape route.

Two facts also limit how much this loop can explain about the data.

First, in Fig. 110.1 the fall in ρ_t came after 2008, when the zero lower bound kept policy from being aggressive at all.

Second, the jump in ρ_t in 2022, alongside the inflation peak, is in line with the positive correlation between the level and the persistence of inflation that *Drifts and Volatilities* documents.

Escape-route models predict an *inverse* correlation; Cogley and Sargent [2005] (footnote 28) note that gradualism of the kind described above can produce the positive one.

So the 2020s were not a replay of the *Conquest*'s recurrent escapes.

What carries over is the *Conquest*'s diagnosis.

The Fed treated a reduced form whose coefficients depend on policy as if it were structural, ignoring the Lucas critique in just the way the vindication story of *The Rise and Fall of U.S. Inflation* describes (Sargent and Williams [2025], footnote 6).

But the misspecification now concerns the slope and persistence of the Phillips curve, not the natural-rate hypothesis.

Note

Sargent and Williams [2025] also acknowledge a very different reading in which the accommodation of the 2020s was fiscal in origin, as in the fiscal-theory accounts they cite.

That would be another rationalization of the same policy path.

110.9 Was the conquest lost?

The Rise and Fall of U.S. Inflation ended by asking what the data since 1999 say about its two stories.

Would a credible low-inflation equilibrium keep re-anchoring after each shock, as the triumph of natural-rate theory suggests?

Or could surprises still set a monetary authority's beliefs drifting, as the vindication of econometric policy evaluation suggests?

Following Sargent and Williams [2025], this lecture's answer is that the conquest was lost for a while.

The reason was not a change in the Fed's objectives.

- The artificial Fed's loss function never changes.
- Its beliefs drifted during a long period of low and stable inflation, so that by 2019 its Phelps problem prescribed a long-run response to inflation only a little above one; that made its response to the surge *muted*.
- Real-time measures of slack, which overstated how much room the economy had, made it *late*.
- Once the 2022 data arrived, perceived persistence jumped back toward one, the rule's response to inflation jumped with it, and the conquest was regained.

In the language of *The Rise and Fall of U.S. Inflation*, the episode looks like the vindication story's adaptive policy maker, misled by a reduced form whose coefficients depend on policy.

But it is not a replay of that story's recurrent escapes.

The policy-to-beliefs loop we built has no escape route; drifting beliefs explain why the response was muted, and mismeasured data explain why it was late.

Nor does anything here contradict the triumph story's reading, recorded in *The Rise and Fall of U.S. Inflation*, that long-run inflation expectations stayed anchored: the artificial Fed's beliefs concern the reduced-form dynamics of inflation, not the public's expectations.

The lesson the episode adds to the *Conquest* is the one the extended abstract draws: the lessons of past successful policy can fade during long tranquil periods, and then have to be learned again.

110.10 Exercises

Exercise 110.10.1

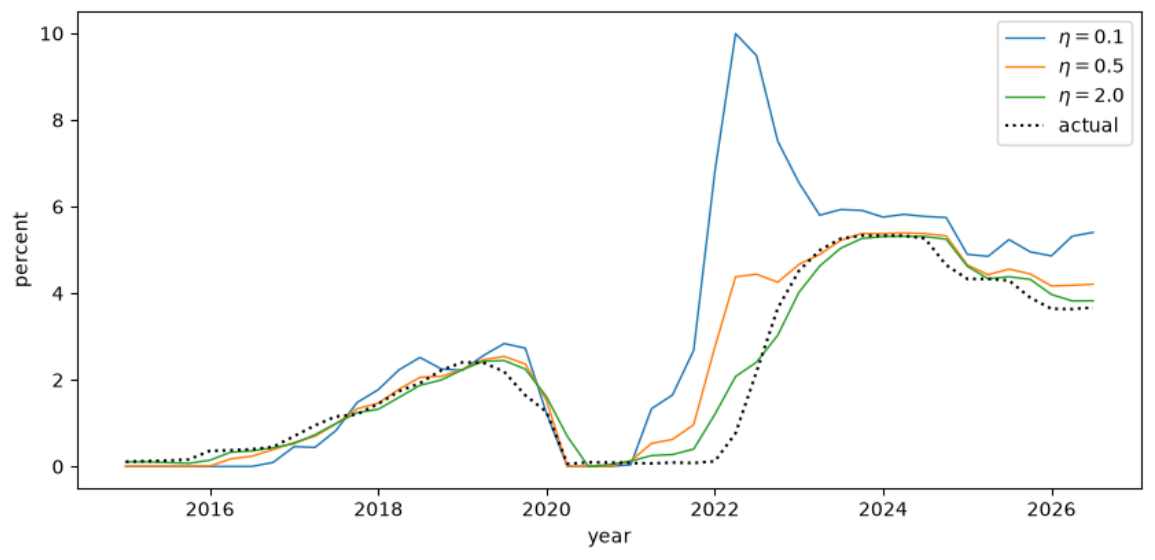
The interest-smoothing weight η in the loss (110.3) is, in the paper's words, "one of the most important parameters."

The paper says that a larger η fits the observed rate better but makes the rule harder to interpret as systematic stabilization policy.

Make that tradeoff quantitative.

For $\eta \in \{0.1, 0.5, 2.0\}$:

1. compute the recommended rates and their root mean squared error (RMSE) against the actual funds rate from 1991 on, and compare with the no-change rule $i_t = i_{t-1}$;
2. compute the 2019Q4 rule and its long-run response to inflation, $\phi_\pi/(1-\phi_i)$;
3. plot the recommendations against the actual rate from 2015 on.



Which η would you choose, and why?

Solution

The beliefs do not depend on η, so we reuse them.

```
fig, ax = plt.subplots(figsize=(10, 4.5))
w = slice('2015', None)
print(f"{'η':>5} {'RMSE':>6} {'φ_π':>7} {'φ_i':>7} {'long run':>9}")
for η_val in [0.1, 0.5, 2.0]:
    rules_η = phelps_rules(beliefs, η=η_val)
    rate = recommended_rate(data, rules_η)
    f = rules_η.loc['2019-10-01']
    print(f"{η_val:>5} {fit(rate)[1]:>6.2f} {f.ψ_π:>7.3f} {f.ψ_i:>7.3f} "
          f"{f.ψ_π / (1 - f.ψ_i):>9.2f}")
    ax.plot(rate[w], lw=1, label=rf'$\eta = {η_val}$')
print(f"no-change rule RMSE: {fit(no_change)[1]:.2f}")
ax.plot(data['i'][w], 'k:', lw=1.5, label='actual')
ax.set_xlabel('year')
ax.set_ylabel('percent')
ax.legend()
plt.show()
```

```
    η   RMSE     φ_π     φ_i  long run
  0.1   1.76   0.297   0.862      2.15
  0.5   0.79   0.092   0.929      1.30
  2.0   0.47   0.030   0.966      0.88
no-change rule RMSE: 0.45
```

A small η produces a volatile rate that jumps sharply with inflation and the gap, and fits badly.

Raising η improves the fit a lot, but at $\eta = 2$ the RMSE is close to that of the no-change rule.

Meanwhile the 2019 rule's long-run response to inflation falls below one, so the rule no longer satisfies the Taylor principle.

A large η buys fit by turning the Phelps rule into a no-change rule.

That is the concrete meaning of the paper's "interpretability."

$\eta = 0.5$ keeps a long-run response above one while fitting far better than $\eta = 0.1$.

Exercise 110.10.2

This exercise explores the simplified Phelps problem (110.5).

1. Show that $P_{12} = 0$ and $P_{22} = \lambda_x$ solve its Riccati equation. (Hint: the second column of A is a multiple of B.) Then derive the quadratic equation for P_{11}, and confirm both results with `solve_discrete_are`.
2. For $\rho \in \{0.5, 0.9\}$, plot ϕ_π against $\kappa \in (0, 3]$ and find the slope at which ϕ_π peaks. Explain why ϕ_π eventually falls as κ grows.
3. Add a penalty $\eta_r r_t^2$ on the real rate to the loss. Does the reversal survive for $\eta_r \in \{0.01, 0.1\}$?

Solution

Part 1. With r_t as the control,

$$A = \begin{bmatrix} \rho & \kappa b_1 \\ 0 & b_1 \end{bmatrix}, \qquad B = g \begin{bmatrix} \kappa \\ 1 \end{bmatrix},$$

so the second column of A equals $(b_1/g)B$.

With no control cost, the Riccati equation is

$$P = Q + \beta A^\top (P - PB(B^\top PB)^{-1} B^\top P) A.$$

The matrix in parentheses annihilates B, so the second row and column of $A^\top(\cdot)A$ vanish.

Hence P agrees with $Q = \mathrm{diag}(1, \lambda_x)$ in its second row and column: $P_{12} = 0$ and $P_{22} = \lambda_x$.

Economically, the Fed can offset the predictable part of next quarter's gap completely, so the current gap carries no cost into the future.

Using $B^\top P B = g^2(\kappa^2 P_{11} + \lambda_x)$ and $(PB)_1 = g\kappa P_{11}$, the $(1,1)$ element gives

$$P_{11} = 1 + \beta\rho^2 \frac{\lambda_x P_{11}}{\kappa^2 P_{11} + \lambda_x}, \quad \text{i.e.} \quad \kappa^2 P_{11}^2 + (\lambda_x(1 - \beta\rho^2) - \kappa^2)P_{11} - \lambda_x = 0,$$

whose positive root is the paper's equation (8); $Z = \kappa^2 P_{11}$.

```
def riccati_P(ρ, κ, b1=0.9, g=-0.5, λ_x=0.2, β=0.95, η_r=1e-9):
    A = np.array([[ρ, κ * b1], [0, b1]])

          f"monotone in κ: {np.all(np.diff(curve) > 0)}")
ax.set_xlabel(r'perceived slope $\kappa$')
ax.set_ylabel(r'$\phi_\pi$')
ax.legend()
plt.show()
```

```
ρ = 0.5, η_r = 0: peak at κ = 0.390
ρ = 0.9, η_r = 0: peak at κ = 0.215
ρ = 0.9, η_r = 0.01: peak at κ = 0.230, monotone in κ: False
ρ = 0.9, η_r = 0.1: peak at κ = 0.290, monotone in κ: False
```

ϕ_π is hump-shaped in κ.

When the curve is very flat, moving inflation through the gap is expensive, so the Fed does little: $Z/(Z+\lambda_x)$ is small.

When the curve is steep, a small change in the gap moves inflation a lot, so a small rate response suffices: $\phi_\pi \approx 1 + \rho/(|g|\kappa)$ falls toward one.

The peak lies in between, at a smaller κ when ρ is larger.

The paper's footnote 19 suggests that a small control cost makes $\partial\phi_\pi/\partial\kappa > 0$ for all κ.

Numerically the hump survives a penalty on the real rate, so *Proposition 110.7.2* is best read as a statement about small slopes.

The slopes the Fed estimated in the 2010s lie inside that region.

Exercise 110.10.3

The baseline sets the gain to zero in both 2020 and 2021.

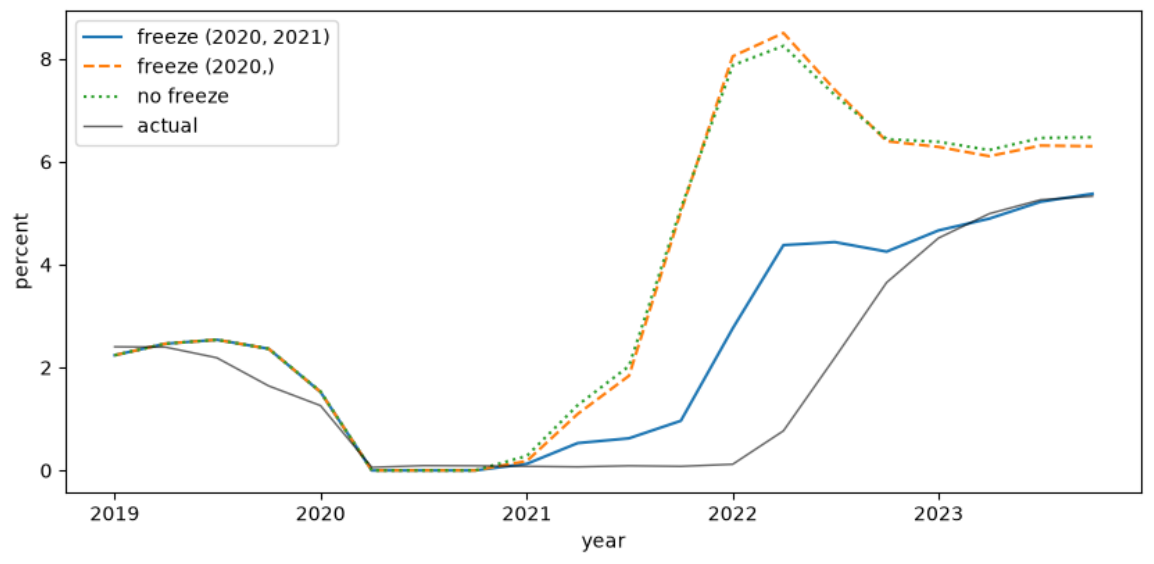
Recompute the beliefs and the recommended rates (a) freezing only 2020 and (b) with no freeze at all.

Report ρ_t, κ_t, and the recommended rate for 2021–2022.

Which part of the freeze drives the result, and what does setting the gain to zero in 2021 assume?

Solution

We loop over the three treatments of the pandemic quarters.



```
fig, ax = plt.subplots(figsize=(10, 4.5))
w = slice('2019', '2023')
for freeze, style in [((2020, 2021), '-'), ((2020,), '--'), ((), ':')]:
```

```
    b = estimate_beliefs(data, freeze=freeze)
    rate = recommended_rate(data, phelps_rules(b))
    label = f"freeze {freeze}" if freeze else 'no freeze'
    print(f"\n{label}")
    print(pd.DataFrame({'ρ': b['rho'], 'κ': b['kappa'], 'rate': rate})
            .loc['2021':'2022'].rename(index=qtr).round(3).T.to_string())
    ax.plot(rate[w], style, label=label)
ax.plot(data['i'][w], 'k', lw=1, alpha=0.6, label='actual')
ax.set_xlabel('year')
ax.set_ylabel('percent')
ax.legend()
plt.show()
```

```
freeze (2020, 2021)

no freeze
      2021Q1  2021Q2  2021Q3  2021Q4  2022Q1  2022Q2  2022Q3  2022Q4
ρ      0.823   0.831   0.869   0.933   0.980   0.985   0.965   0.931
κ      0.078   0.102   0.107   0.121   0.121   0.120   0.122   0.125
rate   0.283   1.268   2.028   5.090   7.875   8.251   7.297   6.438
```

Freezing only 2020 gives almost the same answer as no freeze at all: the extreme 2020 quarters are not what matter.

What matters is 2021.

A Fed that learned from 2021 would have seen inflation rise with a positive gap, so its perceived slope κ_t would have steepened sharply and its perceived persistence would have risen.

Its recommended rate would have reached several percent by the end of 2021.

So the baseline's zero gain in 2021 builds in the judgment that the 2021 data were uninformative about inflation dynamics, which is the "transitory" view itself.

The freeze is a modeling choice that helps the model rationalize a slow Fed, not a neutral treatment of outliers.

Exercise 110.10.4

Chung [1990] treated the gain of a government's learning algorithm as a free parameter to be estimated (Exercise **??**).

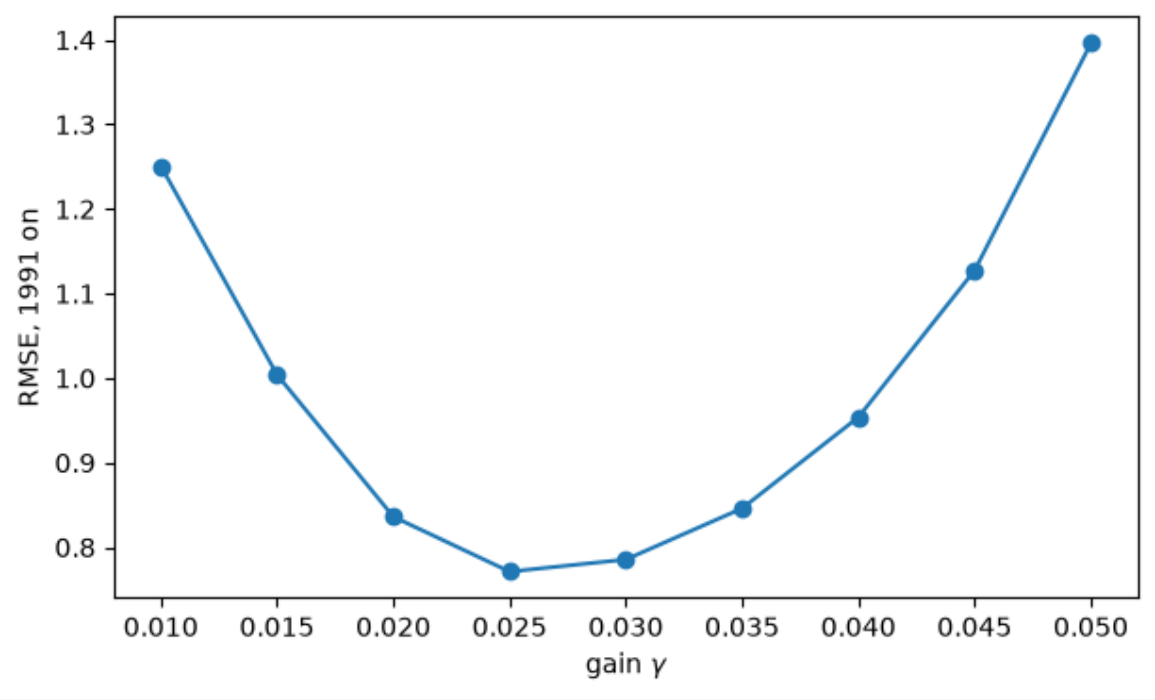
Econometric Policy Evaluation takes up his problem on 1960–1995 data.

Pose Chung's problem for the artificial Fed.

For gains γ between 0.01 and 0.05, recompute the beliefs and recommendations and the RMSE against the actual rate from 1991 on.

Which gain fits best?

What happens to beliefs and recommendations in 2022 at $\gamma = 0.05$?



Solution

We keep track of the largest perceived persistence and the largest recommendation in 2022–2023 for each gain.

```
gains = np.arange(0.01, 0.0501, 0.005)
rmse, extremes = [], {}
for γ_val in gains:
    b = estimate_beliefs(data, γ=γ_val)
    rate = recommended_rate(data, phelps_rules(b))
    rmse.append(fit(rate)[1])
    extremes[round(γ_val, 3)] = (b['rho']['2022':'2023'].max(),
                                 rate['2022':'2023'].max())

fig, ax = plt.subplots(figsize=(7, 4))
ax.plot(gains, rmse, marker='o')
ax.set_xlabel(r'gain $\gamma$')
ax.set_ylabel('RMSE, 1991 on')
plt.show()

print(f"best gain on the grid: {gains[np.argmin(rmse)]:.3f}")
for γ_val in [0.03, 0.05]:
    ρ_max, rate_max = extremes[γ_val]
    print(f"γ = {γ_val}: max ρ_t in 2022-23 = {ρ_max:.3f}, "
          f"max recommended rate = {rate_max:.1f}%")
```

```
best gain on the grid: 0.025
γ = 0.03: max ρ_t in 2022-23 = 0.981, max recommended rate = 5.4%
γ = 0.05: max ρ_t in 2022-23 = 1.036, max recommended rate = 11.9%
```

The best fit is close to the paper's $\gamma = 0.03$.

Small gains make beliefs too sluggish to follow the drift.

Large gains make them chase noise.

At $\gamma = 0.05$, the 2022 surprises push perceived persistence above one: the Fed's model becomes explosive, and its Phelps problem calls for an enormous tightening.

The larger the gain, the more a few quarters of surprises can transform the Fed's model.

This criterion is a least-squares fit of the policy rate that treats the loss parameters as known, not Chung's likelihood for the whole system.

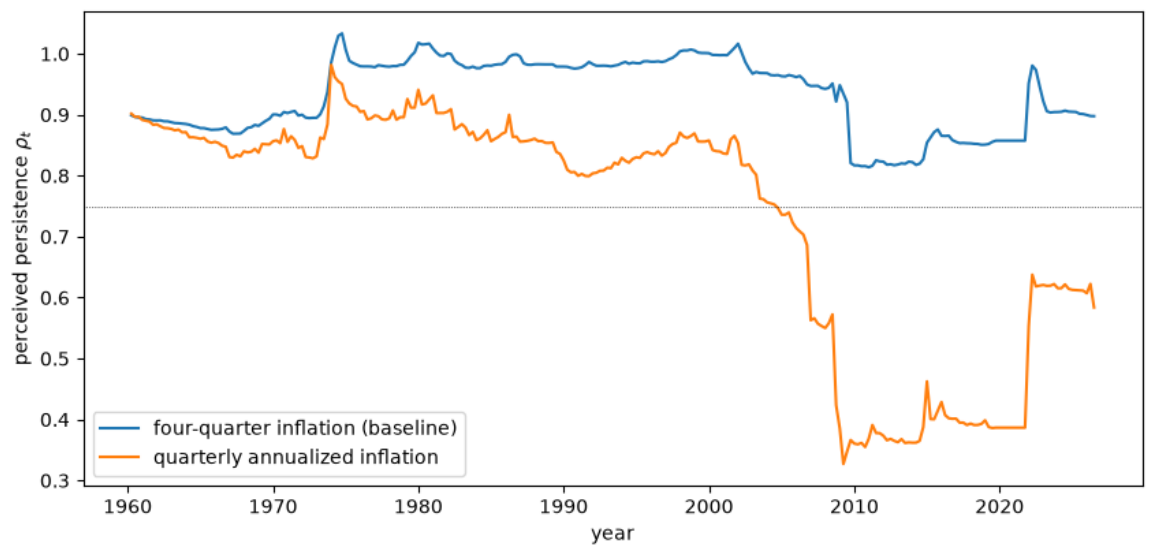
Exercise 110.10.5

This exercise reconciles the persistence measure of this lecture with the one in *Drifts and Volatilities* (*Inflation persistence*).

1. Show by simulation that if quarterly inflation were serially uncorrelated, a regression of four-quarter inflation on its one-quarter lag would give a coefficient near 0.75.
2. Rerun `estimate_beliefs` with quarterly annualized inflation $400 \log(P_t / P_{t-1})$ in place of four-quarter inflation, and compare the two paths of ρ_t.
3. When does persistence fall under each measure?

Solution

We start with the overlap, then rerun the beliefs on quarterly data.



```
rng = np.random.default_rng(0)
quarterly = rng.standard_normal(100_000)
four_quarter = np.convolve(quarterly, np.ones(4) / 4, mode='valid')
coef = np.polyfit(four_quarter[:-1], four_quarter[1:], 1)[0]
print(f"regression coefficient with IID quarterly inflation: {coef:.3f}")

data_q = data.copy()
data_q['pi'] = 400 * np.log(pce / pce.shift(1))[data.index]
beliefs_q = estimate_beliefs(data_q)

fig, ax = plt.subplots(figsize=(10, 4.5))
ax.plot(beliefs['rho'], label='four-quarter inflation (baseline)')
ax.plot(beliefs_q['rho'], label='quarterly annualized inflation')
ax.axhline(0.75, color='k', lw=0.5, ls=':')
ax.set_xlabel('year')
ax.set_ylabel(r'perceived persistence $\rho_t$')
ax.legend()
plt.show()

dates = ['1980-01-01', '1985-01-01', '1995-01-01', '2005-01-01',
         '2015-01-01', '2019-10-01', '2022-04-01']
print(pd.DataFrame({'four-quarter': beliefs['rho'], 'quarterly': beliefs_q['rho']})
        .loc[dates].rename(index=qtr).round(2).T.to_string())
```

```
regression coefficient with IID quarterly inflation: 0.749
              1980Q1  1985Q1  1995Q1  2005Q1  2015Q1  2019Q4  2022Q2
four-quarter    1.02    0.98    0.98    0.96    0.85    0.86    0.98
quarterly       0.94    0.86    0.83    0.74    0.46    0.39    0.64
```

The overlap of four-quarter rates builds in a coefficient of about 0.75 even without any persistence in quarterly inflation, so the baseline ρ_t cannot fall far.

With quarterly inflation, persistence falls modestly after 1980, further by the mid-2000s, and to around 0.4 in the 2010s.

It rises again in 2022, but to a level far below one.

The overlap thus both inflates the level of the baseline measure and hides the early part of its decline.

The quarterly measure is closer to *Drifts and Volatilities*, which finds persistence falling soon after 1980.

Both measures agree on the main fact this lecture uses: by 2019 inflation was much less persistent than it had been.

Part XIV

Optimal Growth

CHAPTER

ONE

CASS-KOOPMANS MODEL

111.1 Overview

This lecture and *Cass-Koopmans Competitive Equilibrium* describe a model that Tjalling Koopmans [Koopmans, 1965] and David Cass [Cass, 1965] used to analyze optimal growth.

The model extends the model of Robert Solow described in an earlier lecture.

It does so by making saving rate be a decision, instead of a hard-wired constant.

(Solow assumed a constant saving rate determined outside the model.)

We describe two versions of the model, a planning problem in this lecture, and a competitive equilibrium in this lecture *Cass-Koopmans Competitive Equilibrium*.

Together, the two lectures illustrate what is, in fact, a more general connection between a **planned economy** and a decentralized economy organized as a **competitive equilibrium**.

This lecture is devoted to the planned economy version.

In the planned economy, there are

- no prices
- no budget constraints

Instead there is a dictator that tells people

- what to produce
- what to invest in physical capital
- who is to consume what and when

The lecture uses important ideas including

- A min-max problem for solving a planning problem.
- A **shooting algorithm** for solving difference equations subject to initial and terminal conditions.
- A **turnpike** property of optimal paths for long but finite-horizon economies.
- A **stable manifold** and a **phase plane**

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

Let's start with some standard imports:

```
import matplotlib.pyplot as plt
from numba import jit, float64
from numba.experimental import jitclass
import numpy as np
from quantecon.optimize import brentq
```

111.2 The Model

Time is discrete and takes values $t = 0, 1, \ldots, T$ where T is finite.

(We'll eventually study a limiting case in which $T = +\infty$)

A single good can either be consumed or invested in physical capital.

The consumption good is not durable and depreciates completely if not consumed immediately.

The capital good is durable but depreciates.

We let C_t be the total consumption of a nondurable consumption good at time t.

Let K_t be the stock of physical capital at time t.

Let $\vec{C} = \{C_0, \ldots, C_T\}$ and $\vec{K} = \{K_0, \ldots, K_{T+1}\}$.

111.2.1 Digression: Aggregation Theory

We use a concept of a representative consumer to be thought of as follows.

There is a unit mass of identical consumers indexed by $\omega \in [0, 1]$.

Consumption of consumer ω is $c(\omega)$.

Aggregate consumption is

$$C = \int_0^1 c(\omega) d\omega$$

Consider a welfare problem that chooses an allocation $\{c(\omega)\}$ across consumers to maximize

$$\int_0^1 u(c(\omega)) d\omega$$

where $u(\cdot)$ is a concave utility function with $u' > 0, u'' < 0$ and maximization is subject to

$$C = \int_0^1 c(\omega) d\omega. \tag{111.1}$$

Form a Lagrangian $L = \int_0^1 u(c(\omega)) d\omega + \lambda[C - \int_0^1 c(\omega) d\omega]$.

Differentiate under the integral signs with respect to each ω to obtain the first-order necessary conditions

$$u'(c(\omega)) = \lambda.$$

These conditions imply that $c(\omega)$ equals a constant c that is independent of ω.

To find c, use feasibility constraint (111.1) to conclude that

$$c(\omega) = c = C.$$

This line of argument indicates the special *aggregation theory* that lies beneath outcomes in which a representative consumer consumes amount C.

It appears often in aggregate economics.

We shall use this aggregation theory here and also in this lecture *Cass-Koopmans Competitive Equilibrium*.

An Economy

A representative household is endowed with one unit of labor at each t and likes the consumption good at each t.

The representative household inelastically supplies a single unit of labor N_t at each t, so that $N_t = 1$ for all $t \in \{0, 1, \dots, T\}$.

The representative household has preferences over consumption bundles ordered by the utility functional:

$$U(\vec{C}) = \sum_{t=0}^{T} \beta^t \frac{C_t^{1-\gamma}}{1-\gamma} \tag{111.2}$$

where $\beta \in (0, 1)$ is a discount factor and $\gamma > 0$ governs the curvature of the one-period utility function.

Larger γ's imply more curvature.

Note that

$$u(C_t) = \frac{C_t^{1-\gamma}}{1-\gamma} \tag{111.3}$$

satisfies $u' > 0, u'' < 0$.

$u' > 0$ asserts that the consumer prefers more to less.

$u'' < 0$ asserts that marginal utility declines with increases in C_t.

We assume that $K_0 > 0$ is an exogenous initial capital stock.

There is an economy-wide production function

$$F(K_t, N_t) = AK_t^{\alpha} N_t^{1-\alpha} \tag{111.4}$$

with $0 < \alpha < 1$, $A > 0$.

A feasible allocation $\vec{C}, \vec{K}$ satisfies

$$C_t + K_{t+1} \leq F(K_t, N_t) + (1-\delta)K_t \quad \text{for all } t \in \{0, 1, \dots, T\} \tag{111.5}$$

where $\delta \in (0, 1)$ is a depreciation rate of capital.

111.3 Planning Problem

A planner chooses an allocation $\{\vec{C}, \vec{K}\}$ to maximize (111.2) subject to (111.5).

Let $\vec{\mu} = \{\mu_0, \dots, \mu_T\}$ be a sequence of nonnegative **Lagrange multipliers**.

To find an optimal allocation, form a Lagrangian

$$\mathcal{L}(\vec{C}, \vec{K}, \vec{\mu}) = \sum_{t=0}^{T} \beta^t \left\{ u(C_t) + \mu_t \left(F(K_t, 1) + (1-\delta)K_t - C_t - K_{t+1} \right) \right\} \tag{111.6}$$

and pose the following min-max problem:

$$\min_{\vec{\mu}} \max_{\vec{C},\vec{K}} \mathcal{L}(\vec{C},\vec{K},\vec{\mu}) \tag{111.7}$$

- **Extremization** means maximization with respect to $\vec{C},\vec{K}$ and minimization with respect to $\vec{\mu}$.
- Our problem satisfies conditions that assure that second-order conditions are satisfied at an allocation that satisfies the first-order necessary conditions that we are about to compute.

Before computing first-order conditions, we present some handy formulas.

111.3.1 Useful Properties of Linearly Homogeneous Production Function

The following technicalities will help us.

Notice that

$$F(K_t,N_t) = AK_t^{\alpha}N_t^{1-\alpha} = N_t A\left(\frac{K_t}{N_t}\right)^{\alpha}$$

Define the **output per-capita production function**

$$\frac{F(K_t,N_t)}{N_t} \equiv f\left(\frac{K_t}{N_t}\right) = A\left(\frac{K_t}{N_t}\right)^{\alpha}$$

whose argument is **capital per-capita**.

It is useful to recall the following calculations for the marginal product of capital

$$\begin{aligned}
\frac{\partial F(K_t,N_t)}{\partial K_t} &= \frac{\partial N_t f\left(\frac{K_t}{N_t}\right)}{\partial K_t} \\
&= N_t f'\left(\frac{K_t}{N_t}\right)\frac{1}{N_t} \quad \text{(Chain rule)} \\
&= f'\left(\frac{K_t}{N_t}\right)\Big|_{N_t=1} \\
&= f'(K_t)
\end{aligned} \tag{111.8}$$

and the marginal product of labor

$$\begin{aligned}
\frac{\partial F(K_t,N_t)}{\partial N_t} &= \frac{\partial N_t f\left(\frac{K_t}{N_t}\right)}{\partial N_t} \quad \text{(Product rule)} \\
&= f\left(\frac{K_t}{N_t}\right) + N_t f'\left(\frac{K_t}{N_t}\right)\frac{-K_t}{N_t^2} \quad \text{(Chain rule)} \\
&= f\left(\frac{K_t}{N_t}\right) - \frac{K_t}{N_t} f'\left(\frac{K_t}{N_t}\right)\Big|_{N_t=1} \\
&= f(K_t) - f'(K_t)K_t
\end{aligned}$$

(Here we are using that $N_t = 1$ for all t, so that $K_t = \frac{K_t}{N_t}$.)

111.3.2 First-order necessary conditions

We now compute **first-order necessary conditions** for extremization of Lagrangian (111.6):

$$C_t: \quad u'(C_t) - \mu_t = 0 \quad \text{for all} \quad t = 0, 1, \ldots, T \tag{111.9}$$

$$K_t: \quad \beta\mu_t \left[(1-\delta) + f'(K_t)\right] - \mu_{t-1} = 0 \quad \text{for all} \quad t = 1, 2, \ldots, T \tag{111.10}$$

$$\mu_t: \quad F(K_t, 1) + (1-\delta)K_t - C_t - K_{t+1} = 0 \quad \text{for all} \quad t = 0, 1, \ldots, T \tag{111.11}$$

$$K_{T+1}: \quad -\mu_T \leq 0, \ \leq 0 \text{ if } K_{T+1} = 0; \ = 0 \text{ if } K_{T+1} > 0 \tag{111.12}$$

In computing (111.10) we recognize that K_t appears in both the time t and time $t-1$ feasibility constraints (111.5).

Restrictions (111.12) come from differentiating with respect to K_{T+1} and applying the following **Karush-Kuhn-Tucker condition** (KKT) (see Karush-Kuhn-Tucker conditions):

$$\mu_T K_{T+1} = 0 \tag{111.13}$$

Combining (111.9) and (111.10) gives

$$\beta u'\left(C_t\right)\left[(1-\delta) + f'\left(K_t\right)\right] - u'\left(C_{t-1}\right) = 0 \quad \text{for all } t = 1, 2, \ldots, T+1$$

which can be rearranged to become

$$\beta u'\left(C_{t+1}\right)\left[(1-\delta) + f'\left(K_{t+1}\right)\right] = u'\left(C_t\right) \quad \text{for all } t = 0, 1, \ldots, T \tag{111.14}$$

Applying the inverse marginal utility of consumption function on both sides of the above equation gives

$$C_{t+1} = u'^{-1}\left(\left(\frac{\beta}{u'(C_t)}[f'(K_{t+1}) + (1-\delta)]\right)^{-1}\right)$$

which for our utility function (111.3) becomes the consumption **Euler equation**

$$C_{t+1} = \left(\beta C_t^{\gamma}[f'(K_{t+1}) + (1-\delta)]\right)^{1/\gamma} \tag{111.15}$$

which we can combine with the feasibility constraint (111.5) to get

$$\begin{aligned} C_{t+1} &= C_t\left(\beta[f'(F(K_t, 1) + (1-\delta)K_t - C_t) + (1-\delta)]\right)^{1/\gamma} \\ K_{t+1} &= F(K_t, 1) + (1-\delta)K_t - C_t. \end{aligned} \tag{111.16}$$

This is a pair of non-linear first-order difference equations that map C_t, K_t into C_{t+1}, K_{t+1} and that an optimal sequence $\vec{C}, \vec{K}$ must satisfy.

It must also satisfy the initial condition that K_0 is given and $K_{T+1} = 0$.

Below we define a `jitclass` that stores parameters and functions that define our economy.

```
planning_data = [
    ('γ', float64),     # Coefficient of relative risk aversion
    ('β', float64),     # Discount factor
    ('δ', float64),     # Depreciation rate on capital
    ('α', float64),     # Return to capital per capita
    ('A', float64)      # Technology
]
```

```
@jitclass(planning_data)
class PlanningProblem():

    def __init__(self, γ=2, β=0.95, δ=0.02, α=0.33, A=1):

        self.γ, self.β = γ, β
        self.δ, self.α, self.A = δ, α, A

    def u(self, c):
        '''
        Utility function
        ASIDE: If you have a utility function that is hard to solve by hand
        you can use automatic or symbolic differentiation
        See https://github.com/HIPS/autograd
        '''
        γ = self.γ

        return c ** (1 - γ) / (1 - γ) if γ!= 1 else np.log(c)

    def u_prime(self, c):
        'Derivative of utility'
        γ = self.γ

        return c ** (-γ)

    def u_prime_inv(self, c):
        'Inverse of derivative of utility'
        γ = self.γ

        return c ** (-1 / γ)

    def f(self, k):
        'Production function'
        α, A = self.α, self.A

        return A * k ** α

    def f_prime(self, k):
        'Derivative of production function'
        α, A = self.α, self.A

        return α * A * k ** (α - 1)

    def f_prime_inv(self, k):
        'Inverse of derivative of production function'
        α, A = self.α, self.A

        return (k / (A * α)) ** (1 / (α - 1))

    def next_k_c(self, k, c):
        ''''
        Given the current capital Kt and an arbitrary feasible
        consumption choice Ct, computes Kt+1 by state transition law
        and optimal Ct+1 by Euler equation.
        '''
        β, δ = self.β, self.δ
        u_prime, u_prime_inv = self.u_prime, self.u_prime_inv
```

(continues on next page)

(continued from previous page)

```
        f, f_prime = self.f, self.f_prime

        k_next = f(k) + (1 - δ) * k - c
        c_next = u_prime_inv(u_prime(c) / (β * (f_prime(k_next) + (1 - δ))))

        return k_next, c_next
```

We can construct an economy with the Python code:

```
pp = PlanningProblem()
```

111.4 Shooting Algorithm

We use **shooting** to compute an optimal allocation $\vec{C}, \vec{K}$ and an associated Lagrange multiplier sequence $\vec{\mu}$.

First-order necessary conditions (111.9), (111.10), and (111.11) for the planning problem form a system of **difference equations** with two boundary conditions:

- K_0 is a given **initial condition** for capital
- $K_{T+1} = 0$ is a **terminal condition** for capital that we deduced from the first-order necessary condition for K_{T+1} the KKT condition (111.13)

We have no initial condition for the Lagrange multiplier μ_0.

If we did, our job would be easy:

- Given μ_0 and k_0, we could compute c_0 from equation (111.9) and then k_1 from equation (111.11) and μ_1 from equation (111.10).
- We could continue in this way to compute the remaining elements of $\vec{C}, \vec{K}, \vec{\mu}$.

However, we woujld not be assured that the Kuhn-Tucker condition (111.13) would be satisfied.

Furthermore, we don't have an initial condition for μ_0.

So this won't work.

Indeed, part of our task is to compute the **optimal** value of μ_0.

To compute μ_0 and the other objects we want, a simple modification of the above procedure will work.

It is called the **shooting algorithm**.

It is an instance of a **guess and verify** algorithm that consists of the following steps:

- Guess an initial Lagrange multiplier μ_0.
- Apply the **simple algorithm** described above.
- Compute K_{T+1} and check whether it equals zero.
- If $K_{T+1} = 0$, we have solved the problem.
- If $K_{T+1} > 0$, lower μ_0 and try again.
- If $K_{T+1} < 0$, raise μ_0 and try again.

The following Python code implements the shooting algorithm for the planning problem.

(Actually, we modified the preceding algorithm slightly by starting with a guess for c_0 instead of μ_0 in the following code.)

```
@jit
def shooting(pp, c0, k0, T=10):
    '''
    Given the initial condition of capital k0 and an initial guess
    of consumption c0, computes the whole paths of c and k
    using the state transition law and Euler equation for T periods.
    '''
    if c0 > pp.f(k0) + (1 - pp.δ) * k0:
        print("initial consumption is not feasible")

        return None

    # initialize vectors of c and k
    c_vec = np.empty(T+1)
    k_vec = np.empty(T+2)

    c_vec[0] = c0
    k_vec[0] = k0

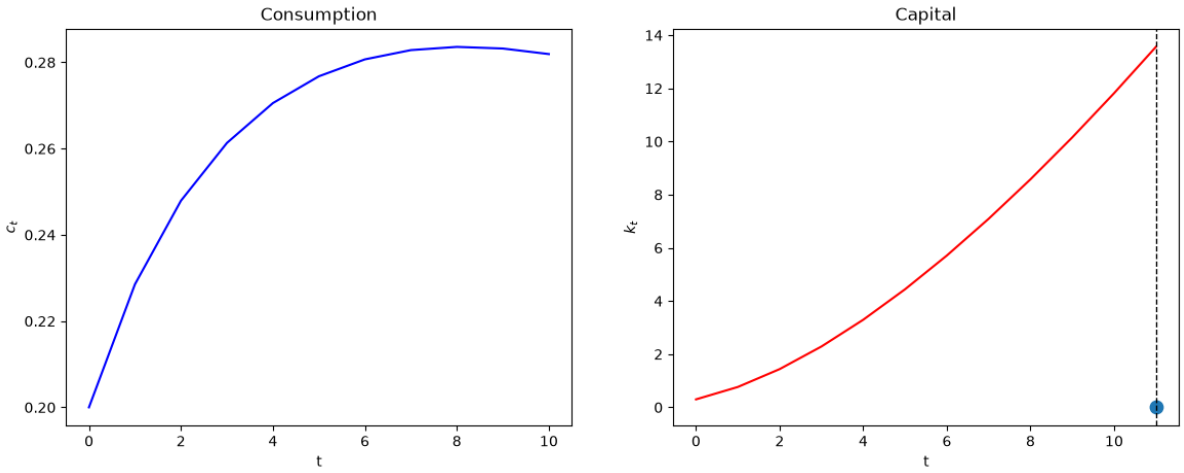
    for t in range(T):
        k_vec[t+1], c_vec[t+1] = pp.next_k_c(k_vec[t], c_vec[t])

    k_vec[T+1] = pp.f(k_vec[T]) + (1 - pp.δ) * k_vec[T] - c_vec[T]

    return c_vec, k_vec
```

We'll start with an incorrect guess.

```
paths = shooting(pp, 0.2, 0.3, T=10)
```



```
fig, axs = plt.subplots(1, 2, figsize=(14, 5))

colors = ['blue', 'red']
titles = ['Consumption', 'Capital']
ylabels = ['$c_t$', '$k_t$']

T = paths[0].size - 1
for i in range(2):
    axs[i].plot(paths[i], c=colors[i])
    axs[i].set(xlabel='t', ylabel=ylabels[i], title=titles[i])

axs[1].scatter(T+1, 0, s=80)
axs[1].axvline(T+1, color='k', ls='--', lw=1)

plt.show()
```

Evidently, our initial guess for μ_0 is too high, so initial consumption too low.

We know this because we miss our $K_{T+1} = 0$ target on the high side.

Now we automate things with a search-for-a-good μ_0 algorithm that stops when we hit the target $K_{t+1} = 0$.

We use a **bisection method**.

We make an initial guess for C_0 (we can eliminate μ_0 because C_0 is an exact function of μ_0).

We know that the lowest C_0 can ever be is 0 and that the largest it can be is initial output $f(K_0)$.

Guess C_0 and shoot forward to $T + 1$.

If $K_{T+1} > 0$, we take it to be our new **lower** bound on C_0.

If $K_{T+1} < 0$, we take it to be our new **upper** bound.

Make a new guess for C_0 that is halfway between our new upper and lower bounds.

Shoot forward again, iterating on these steps until we converge.

When K_{T+1} gets close enough to 0 (i.e., within an error tolerance bounds), we stop.

```
@jit
def bisection(pp, c0, k0, T=10, tol=1e-4, max_iter=500, k_ter=0, verbose=True):

    # initial boundaries for guess c0
    c0_upper = pp.f(k0) + (1 - pp.δ) * k0
    c0_lower = 0

    i = 0
    while True:
        c_vec, k_vec = shooting(pp, c0, k0, T)
        error = k_vec[-1] - k_ter

        # check if the terminal condition is satisfied
        if np.abs(error) < tol:
            if verbose:
                print('Converged successfully on iteration ', i+1)
            return c_vec, k_vec

        i += 1
        if i == max_iter:
            if verbose:
```

(continues on next page)

(continued from previous page)

```
                print('Convergence failed.')
            return c_vec, k_vec

        # if iteration continues, updates boundaries and guess of c0
        if error > 0:
            c0_lower = c0
        else:
            c0_upper = c0

        c0 = (c0_lower + c0_upper) / 2
```

```
def plot_paths(pp, c0, k0, T_arr, k_ter=0, k_ss=None, axs=None):

    if axs is None:
        fix, axs = plt.subplots(1, 3, figsize=(16, 4))
    ylabels = ['$c_t$', '$k_t$', r'$\mu_t$']
    titles = ['Consumption', 'Capital', 'Lagrange Multiplier']

    c_paths = []
    k_paths = []
    for T in T_arr:
        c_vec, k_vec = bisection(pp, c0, k0, T, k_ter=k_ter, verbose=False)
        c_paths.append(c_vec)
        k_paths.append(k_vec)

        μ_vec = pp.u_prime(c_vec)
        paths = [c_vec, k_vec, μ_vec]

        for i in range(3):
            axs[i].plot(paths[i])
            axs[i].set(xlabel='t', ylabel=ylabels[i], title=titles[i])

        # Plot steady state value of capital
        if k_ss is not None:
            axs[1].axhline(k_ss, c='k', ls='--', lw=1)

        axs[1].axvline(T+1, c='k', ls='--', lw=1)
        axs[1].scatter(T+1, paths[1][-1], s=80)

    return c_paths, k_paths
```

Now we can solve the model and plot the paths of consumption, capital, and Lagrange multiplier.

```
plot_paths(pp, 0.3, 0.3, [10]);
```

111.5 Setting Initial Capital to Steady State Capital

When $T \to +\infty$, the optimal allocation converges to steady state values of C_t and K_t.

It is instructive to set K_0 equal to the $\lim_{T \to +\infty} K_t$, which we'll call steady state capital.

In a steady state $K_{t+1} = K_t = \bar{K}$ for all very large t.

Evalauating feasibility constraint (111.5) at $\bar{K}$ gives

$$f(\bar{K}) - \delta \bar{K} = \bar{C} \tag{111.17}$$

Substituting $K_t = \bar{K}$ and $C_t = \bar{C}$ for all t into (111.14) gives

$$1 = \beta \frac{u'(\bar{C})}{u'(\bar{C})} [f'(\bar{K}) + (1 - \delta)]$$

Defining $\beta = \frac{1}{1+\rho}$, and cancelling gives

$$1 + \rho = 1[f'(\bar{K}) + (1 - \delta)]$$

Simplifying gives

$$f'(\bar{K}) = \rho + \delta$$

and

$$\bar{K} = f'^{-1}(\rho + \delta)$$

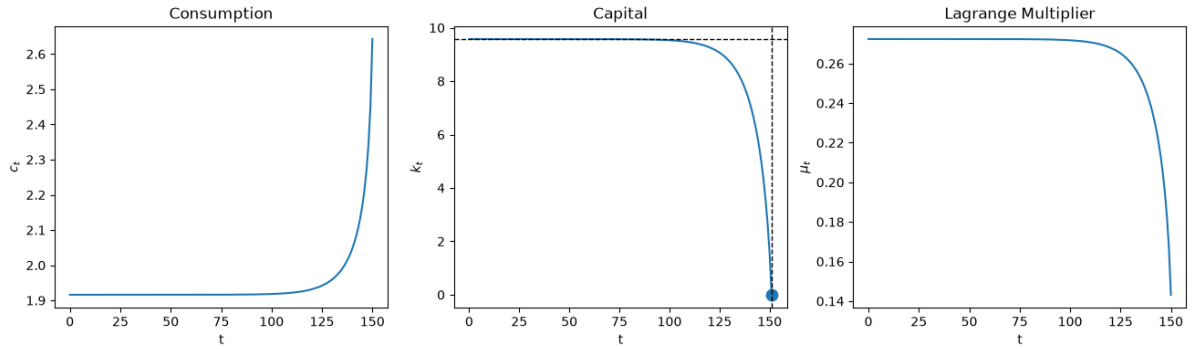
For production function (111.4), this becomes

$$\alpha \bar{K}^{\alpha - 1} = \rho + \delta$$

As an example, after setting $\alpha = .33$, $\rho = 1/\beta - 1 = 1/(19/20) - 1 = 20/19 - 19/19 = 1/19$, $\delta = 1/50$, we get

$$\bar{K} = \left(\frac{\frac{33}{100}}{\frac{1}{50} + \frac{1}{19}} \right)^{\frac{67}{100}} \approx 9.57583$$

Let's verify this with Python and then use this steady state $\bar{K}$ as our initial capital stock K_0.

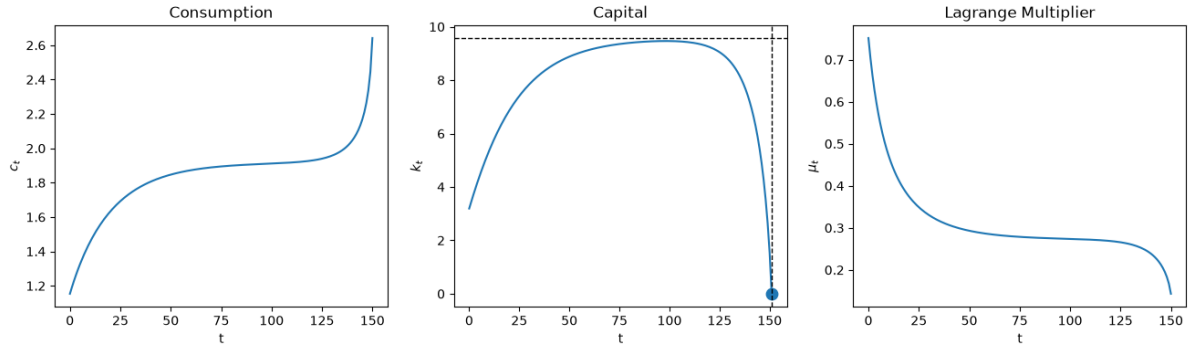


```
ρ = 1 / pp.β - 1
k_ss = pp.f_prime_inv(ρ+pp.δ)

print(f'steady state for capital is: {k_ss}')
```

```
steady state for capital is: 9.57583816331462
```

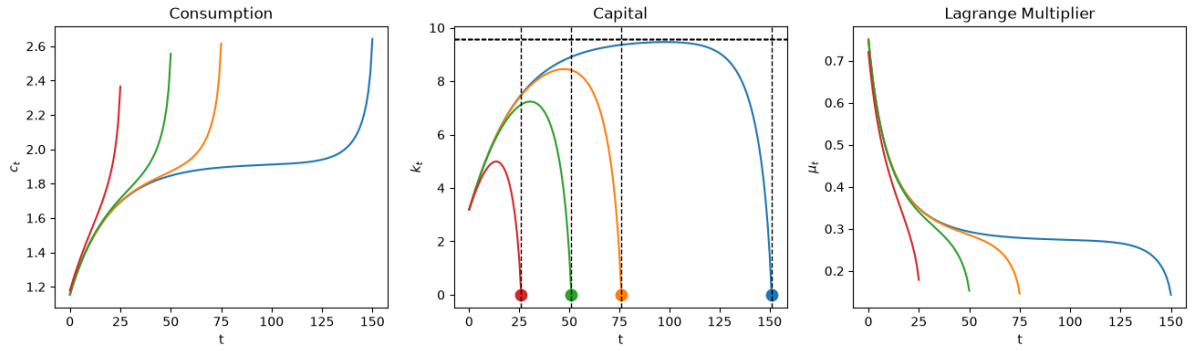
Now we plot



```
plot_paths(pp, 0.3, k_ss, [150], k_ss=k_ss);
```

Evidently, with a large value of T, K_t stays near K_0 until t approaches T closely.

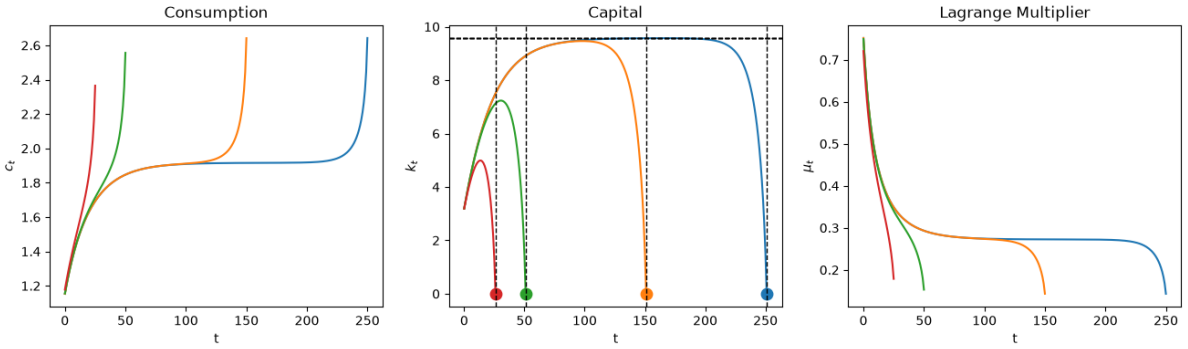
Let's see what the planner does when we set K_0 below $\bar{K}$.



```
plot_paths(pp, 0.3, k_ss/3, [150], k_ss=k_ss);
```

Notice how the planner pushes capital toward the steady state, stays near there for a while, then pushes K_t toward the terminal value $K_{T+1} = 0$ when t closely approaches T.

The following graphs compare optimal outcomes as we vary T.



```
plot_paths(pp, 0.3, k_ss/3, [150, 75, 50, 25], k_ss=k_ss);
```

111.6 A Turnpike Property

The following calculation indicates that when T is very large, the optimal capital stock stays close to its steady state value most of the time.

```
plot_paths(pp, 0.3, k_ss/3, [250, 150, 50, 25], k_ss=k_ss);
```

In the above graphs, different colors are associated with different horizons T.

Notice that as the horizon increases, the planner keeps K_t closer to the steady state value $\bar{K}$ for longer.

This pattern reflects a **turnpike** property of the steady state.

A rule of thumb for the planner is

- from K_0, push K_t toward the steady state and stay close to the steady state until time approaches T.

The planner accomplishes this by adjusting the saving rate $\frac{f(K_t)-C_t}{f(K_t)}$ over time.

Exercise 111.6.1

The turnpike property is independent of the initial condition K_0 provided that T is sufficiently large.

Expand the `plot_paths` function so that it plots trajectories for multiple initial points using `k0s = [k_ss*2, k_ss*3, k_ss/3]`.

Solution

Here is one solution

```
def plot_multiple_paths(pp, c0, k0s, T_arr, k_ter=0, k_ss=None, axs=None):
    if axs is None:
        fig, axs = plt.subplots(1, 3, figsize=(16, 4))

    ylabels = ['$c_t$', '$k_t$', r'$\mu_t$']
    titles = ['Consumption', 'Capital', 'Lagrange Multiplier']

    colors = plt.cm.viridis(np.linspace(0, 1, len(k0s)))

    all_c_paths = []
    all_k_paths = []

    for i, k0 in enumerate(k0s):
        k0_c_paths = []
        k0_k_paths = []
```

```
        for T in T_arr:
            c_vec, k_vec = bisection(pp, c0, k0, T, k_ter=k_ter, verbose=False)
            k0_c_paths.append(c_vec)
            k0_k_paths.append(k_vec)

            μ_vec = pp.u_prime(c_vec)
            paths = [c_vec, k_vec, μ_vec]

            for j in range(3):
                axs[j].plot(paths[j], color=colors[i],
                            label=f'$k_0 = {k0:.2f}$' if j == 0 and T == T_arr[0]␣
↪else "", alpha=0.7)
                axs[j].set(xlabel='t', ylabel=ylabels[j], title=titles[j])

            if k_ss is not None and i == 0 and T == T_arr[0]:
                axs[1].axhline(k_ss, c='k', ls='--', lw=1)

            axs[1].axvline(T+1, c='k', ls='--', lw=1)
            axs[1].scatter(T+1, paths[1][-1], s=80, color=colors[i])

        all_c_paths.append(k0_c_paths)
        all_k_paths.append(k0_k_paths)

    # Add legend if multiple initial points
    if len(k0s) > 1:
        axs[0].legend()

    return all_c_paths, all_k_paths
```

```
_ = plot_multiple_paths(pp, 0.3, [k_ss*2, k_ss*3, k_ss/3], [250, 150, 75, 50], k_
↪ss=k_ss)
```

We see that the turnpike property holds for various initial values of K_0.

Let's calculate and plot the saving rate.

```
@jit
def saving_rate(pp, c_path, k_path):
    'Given paths of c and k, computes the path of saving rate.'
    production = pp.f(k_path[:-1])

    return (production - c_path) / production
```

```
def plot_saving_rate(pp, c0, k0, T_arr, k_ter=0, k_ss=None, s_ss=None):

    fix, axs = plt.subplots(2, 2, figsize=(12, 9))

    c_paths, k_paths = plot_paths(pp, c0, k0, T_arr, k_ter=k_ter, k_ss=k_ss, axs=axs.
↪flatten())

    for i, T in enumerate(T_arr):
        s_path = saving_rate(pp, c_paths[i], k_paths[i])
        axs[1, 1].plot(s_path)

    axs[1, 1].set(xlabel='t', ylabel='$s_t$', title='Saving rate')

    if s_ss is not None:
        axs[1, 1].hlines(s_ss, 0, np.max(T_arr), linestyle='--')
```

```
plot_saving_rate(pp, 0.3, k_ss/3, [250, 150, 75, 50], k_ss=k_ss)
```

111.7 A Limiting Infinite Horizon Economy

We want to set $T = +\infty$.

The appropriate thing to do is to replace terminal condition (111.12) with

$$\lim_{T \to +\infty} \beta^T u'(C_T) K_{T+1} = 0,$$

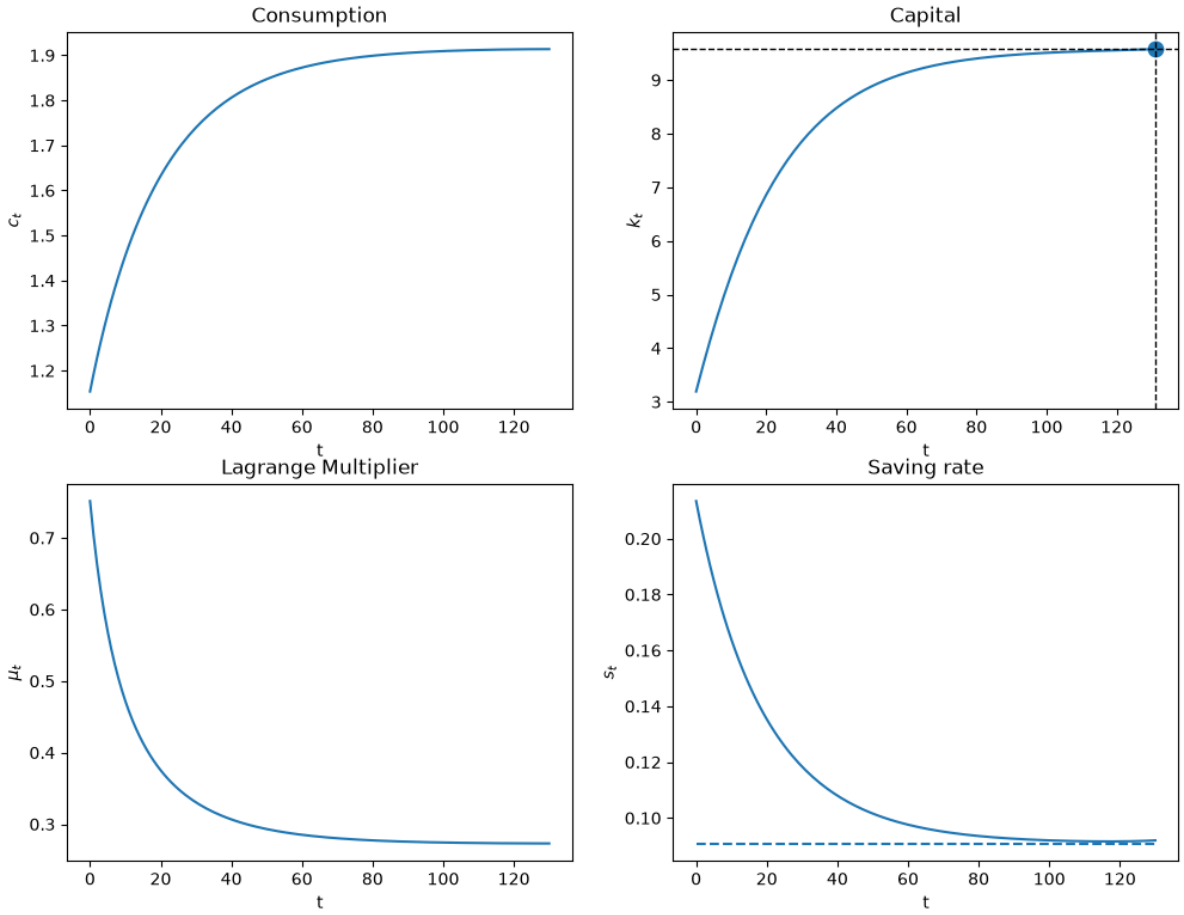
a condition that will be satisfied by a path that converges to an optimal steady state.

We can approximate the optimal path by starting from an arbitrary initial K_0 and shooting towards the optimal steady state K at a large but finite $T + 1$.

In the following code, we do this for a large T and plot consumption, capital, and the saving rate.

We know that in the steady state that the saving rate is constant and that $\bar{s} = \frac{f(\bar{K}) - \bar{C}}{f(\bar{K})}$.

From (111.17) the steady state saving rate equals



$$\bar{s} = \frac{\delta \bar{K}}{f(\bar{K})}$$

The steady state saving rate $\bar{S} = \bar{s} f(\bar{K})$ is the amount required to offset capital depreciation each period.

We first study optimal capital paths that start below the steady state.

```
# steady state of saving rate
s_ss = pp.δ * k_ss / pp.f(k_ss)

plot_saving_rate(pp, 0.3, k_ss/3, [130], k_ter=k_ss, k_ss=k_ss, s_ss=s_ss)
```

Since $K_0 < \bar{K}$, $f'(K_0) > \rho + \delta$.

The planner chooses a positive saving rate that is higher than the steady state saving rate.

Note that $f''(K) < 0$, so as K rises, $f'(K)$ declines.

The planner slowly lowers the saving rate until reaching a steady state in which $f'(K) = \rho + \delta$.

111.8 Stable Manifold and Phase Diagram

We now describe a classic diagram that describes an optimal (K_{t+1}, C_t) path.

The diagram has K on the ordinate axis and C on the coordinate axis.

Given an arbitrary and fixed K, a fixed point C of the consumption Euler equation (111.15) satisfies

$$C = C\left(\beta\left[f'\left(f\left(K\right) + \left(1-\delta\right)K - C\right) + \left(1-\delta\right)\right]\right)^{1/\gamma}$$

which implies

$$\begin{aligned} C &= f\left(K\right) + \left(1-\delta\right)K - f'^{-1}\left(\frac{1}{\beta} - \left(1-\delta\right)\right) \\ &\equiv \tilde{C}\left(K\right) \end{aligned} \tag{111.18}$$

A positive fixed point $C = \tilde{C}(K)$ exists only if $f\left(K\right) + \left(1-\delta\right)K - f'^{-1}\left(\frac{1}{\beta} - \left(1-\delta\right)\right) > 0$

```
@jit
def C_tilde(K, pp):

    return pp.f(K) + (1 - pp.δ) * K - pp.f_prime_inv(1 / pp.β - 1 + pp.δ)
```

Next note that given a time-invariant arbitrary C, a fixed point K of the feasibility condition (111.5) solves the following equation

$$K = f(K) + (1 - \delta K) - C.$$

A fixed point of the above equation is described by a function

$$K = \tilde{K}(C) \tag{111.19}$$

```
@jit
def K_diff(K, C, pp):
    return pp.f(K) - pp.δ * K - C

@jit
def K_tilde(C, pp):

    res = brentq(K_diff, 1e-6, 100, args=(C, pp))

    return res.root
```

A steady state (K_s, C_s) is a pair (K, C) that satisfies both equations (111.18) and (111.19).

It is thus the intersection of the two curves $\tilde{C}$ and $\tilde{K}$ that we'll plot in Figure Fig. 111.1 below.

We can compute K_s by solving the equation $K_s = \tilde{K}\left(\tilde{C}\left(K_s\right)\right)$

```
@jit
def K_tilde_diff(K, pp):

    K_out = K_tilde(C_tilde(K, pp), pp)

    return K - K_out
```

```
res = brentq(K_tilde_diff, 8, 10, args=(pp,))

Ks = res.root
Cs = C_tilde(Ks, pp)

Ks, Cs
```

```
(9.575838163314447, 1.9160839808123402)
```

We can use the shooting algorithm to compute trajectories that approach (K_s, C_s).

For a given K, let's compute $\vec{C}$ and $\vec{K}$ for a large T , e.g., $= 200$.

We compute C_0 by the bisection algorithm that assures that $K_T = K_s$.

Let's compute two trajectories towards (K_s, C_s) that start from different sides of K_s: $\bar{K}_0 = 1e-3 < K_s < \bar{K}_1 = 15$.

```
c_vec1, k_vec1 = bisection(pp, 5, 15, T=200, k_ter=Ks)
c_vec2, k_vec2 = bisection(pp, 1e-3, 1e-3, T=200, k_ter=Ks)
```

```
Converged successfully on iteration  46
Converged successfully on iteration  51
```

The following code generates Figure Fig. 111.1, which is patterned on a graph that appears on page 411 of [Intriligator, 2002].

Figure Fig. 111.1 is a classic "phase plane" with "state" variable K on the ordinate axis and "co-state" variable C on the coordinate axis.

Figure Fig. 111.1 plots three curves:

- the blue line graphs $C = \tilde{C}(K)$ of fixed points described by equation (111.18).
- the red line graphs $K = \tilde{K}(C)$ of fixed points described by equation (111.19)
- the green line graphs the stable traced out by paths that converge to the steady state starting from an arbitrary K_0 at time 0.
  - for a given K_0, the shooting algorithm sets C_0 to the coordinate on the green line in order to initiate a path that converges to the optimal steady state
  - the arrows on the green line show the direction in which dynamics (111.16) push successive (K_{t+1}, C_t) pairs.

In addition to the three curves, Figure Fig. 111.1 plots arrows that point where the dynamics (111.16) drive the system when, for a given K_0, C_0 is not on the stable manifold depicted in the green line.

- If C_0 is set below the green line for a given K_0, too much capital is accumulated
- If C_0 is set above the green line for a given K_0, too little capital is accumulated

111.9 Concluding Remarks

In *Cass-Koopmans Competitive Equilibrium*, we study a decentralized version of an economy with exactly the same technology and preference structure as deployed here.

In that lecture, we replace the planner of this lecture with Adam Smith's **invisible hand**.

In place of quantity choices made by the planner, there are market prices that are set by a *deus ex machina* from outside the model, a so-called invisible hand.

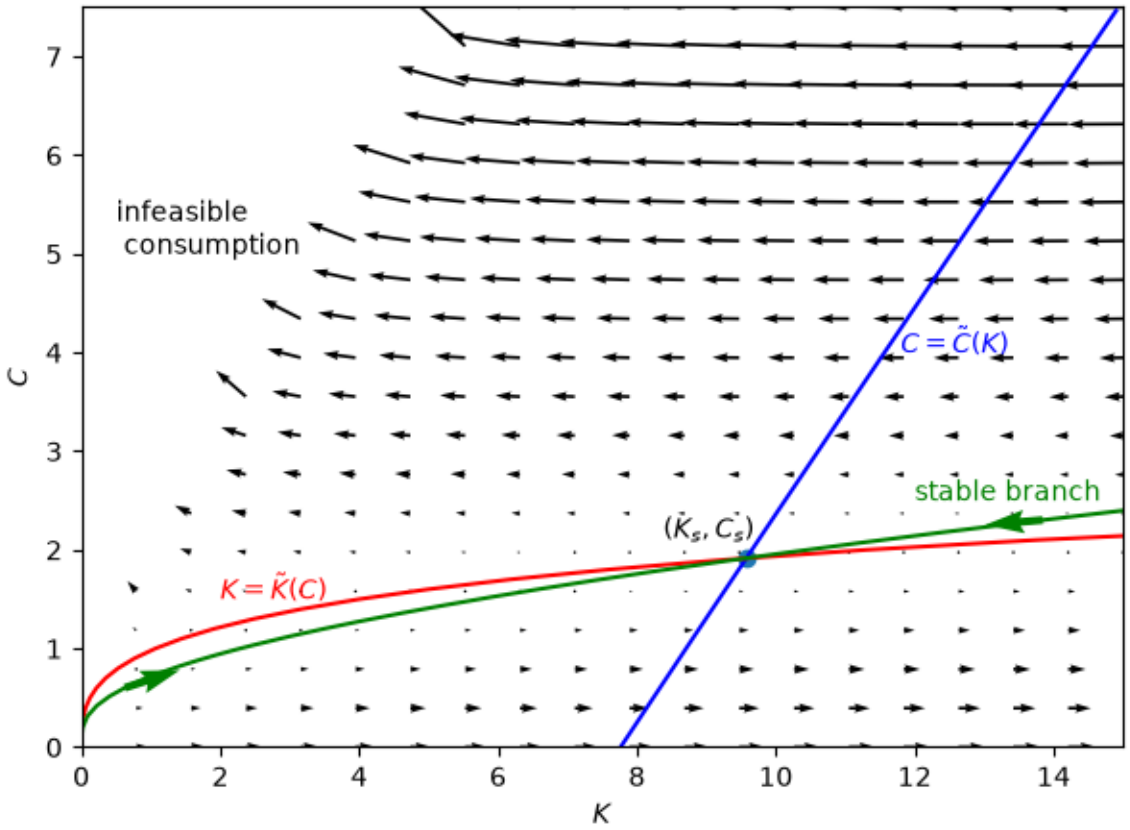
Equilibrium market prices must reconcile distinct decisions that are made independently by a representative household and a representative firm.

The relationship between a command economy like the one studied in this lecture and a market economy like that studied in *Cass-Koopmans Competitive Equilibrium* is a foundational topic in general equilibrium theory and welfare economics.

111.9.1 Exercise

Exercise 111.9.1

- Plot the optimal consumption, capital, and saving paths when the initial capital level begins at 1.5 times the steady state level as we shoot towards the steady state at $T = 130$.
- Why does the saving rate respond as it does?



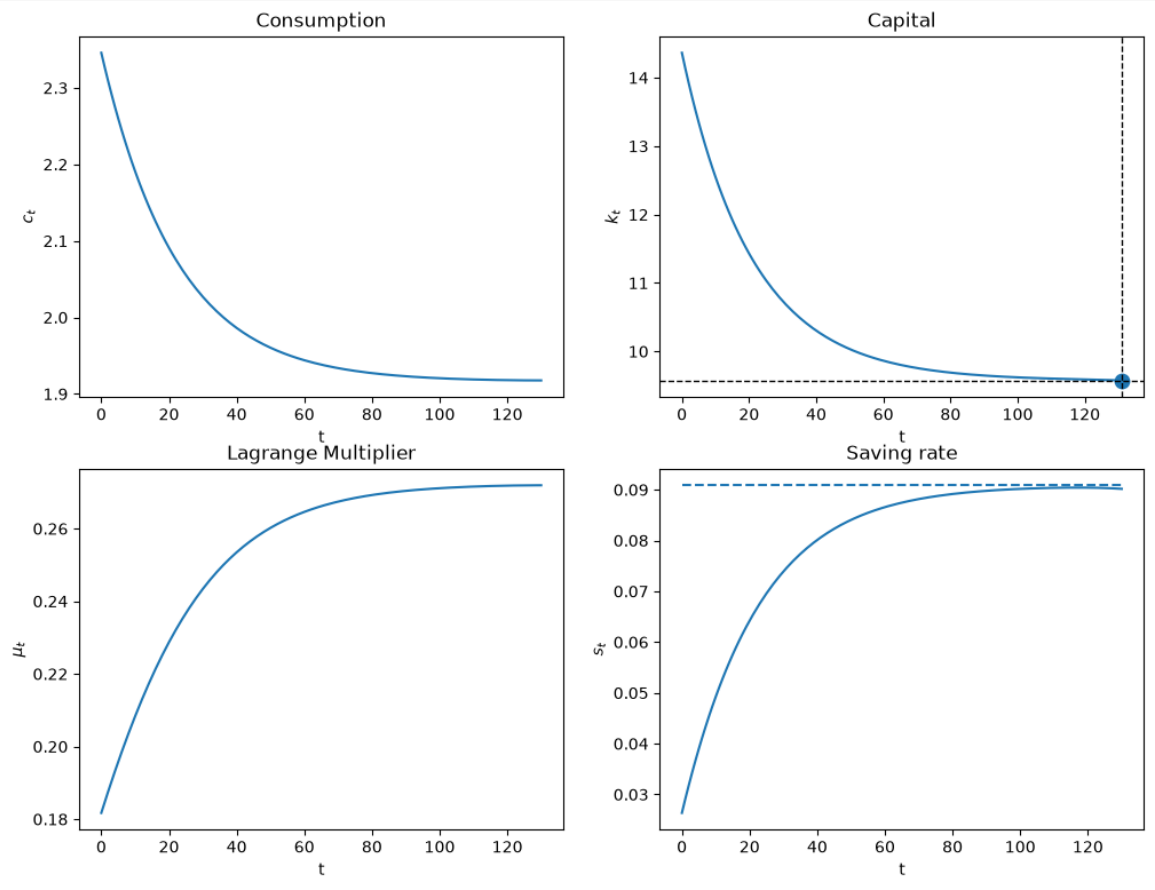


Fig. 111.1: Stable Manifold and Phase Plane

Solution

```
plot_saving_rate(pp, 0.3, k_ss*1.5, [130], k_ter=k_ss, k_ss=k_ss, s_ss=s_ss)
```

112.1 Overview

This lecture continues our analysis in this lecture *Cass-Koopmans Planning Model* about the model that Tjalling Koopmans [Koopmans, 1965] and David Cass [Cass, 1965] used to study optimal capital accumulation.

This lecture illustrates what is, in fact, a more general connection between a **planned economy** and an economy organized as a competitive equilibrium or a **market economy**.

The earlier lecture *Cass-Koopmans Planning Model* studied a planning problem and used ideas including

- A Lagrangian formulation of the planning problem that leads to a system of difference equations.
- A **shooting algorithm** for solving difference equations subject to initial and terminal conditions.
- A **turnpike** property that describes optimal paths for long-but-finite horizon economies.

The present lecture uses additional ideas including

- Hicks-Arrow prices, named after John R. Hicks and Kenneth Arrow.
- A connection between some Lagrange multipliers from the planning problem and the Hicks-Arrow prices.
- A **Big** K **, little** k trick widely used in macroeconomic dynamics.
  - We shall encounter this trick in this lecture and also in this lecture.

- A non-stochastic version of a theory of the **term structure of interest rates**.
- An intimate connection between two ways to organize an economy, namely:
  - **socialism** in which a central planner commands the allocation of resources, and
  - **competitive markets** in which competitive equilibrium **prices** induce individual consumers and producers to choose a socially optimal allocation as unintended consequences of their selfish decisions

Let's start with some standard imports:

```
import matplotlib.pyplot as plt
from numba import jit, float64
from numba.experimental import jitclass
import numpy as np
```

112.2 Review of Cass-Koopmans Model

The physical setting is identical with that in *Cass-Koopmans Planning Model*.

Time is discrete and takes values $t = 0, 1, \ldots, T$.

Output of a single good can either be consumed or invested in physical capital.

The capital good is durable but partially depreciates each period at a constant rate.

We let C_t be a nondurable consumption good at time t.

Let K_t be the stock of physical capital at time t.

Let $\vec{C} = \{C_0, \ldots, C_T\}$ and $\vec{K} = \{K_0, \ldots, K_{T+1}\}$.

A representative household is endowed with one unit of labor at each t and likes the consumption good at each t.

The representative household inelastically supplies a single unit of labor N_t at each t, so that $N_t = 1$ for all $t \in \{0, 1, \ldots, T\}$.

The representative household has preferences over consumption bundles ordered by the utility functional:

$$U(\vec{C}) = \sum_{t=0}^{T} \beta^t \frac{C_t^{1-\gamma}}{1-\gamma}$$

where $\beta \in (0, 1)$ is a discount factor and $\gamma > 0$ governs the curvature of the one-period utility function.

We assume that $K_0 > 0$.

There is an economy-wide production function

$$F(K_t, N_t) = AK_t^{\alpha} N_t^{1-\alpha}$$

with $0 < \alpha < 1$, $A > 0$.

A feasible allocation $\vec{C}, \vec{K}$ satisfies

$$C_t + K_{t+1} \leq F(K_t, N_t) + (1-\delta)K_t \quad \text{for all } t \in \{0, 1, \ldots, T\}$$

where $\delta \in (0, 1)$ is a depreciation rate of capital.

112.2.1 Planning Problem

In this lecture *Cass-Koopmans Planning Model*, we studied a problem in which a planner chooses an allocation $\{\vec{C}, \vec{K}\}$ to maximize (111.2) subject to (111.5).

The allocation that solves the planning problem reappears in a competitive equilibrium, as we shall see below.

112.3 Competitive Equilibrium

We now study a decentralized version of the economy.

It shares the same technology and preference structure as the planned economy studied in this lecture *Cass-Koopmans Planning Model*.

But now there is no planner.

There are (unit masses of) price-taking consumers and firms.

Market prices are set to reconcile distinct decisions that are made separately by a representative consumer and a representative firm.

There is a representative consumer who has the same preferences over consumption plans as did a consumer in the planned economy.

Instead of being told what to consume and save by a planner, a consumer (also known as a *household*) chooses for itself subject to a budget constraint.

- At each time t, the consumer receives wages and rentals of capital from a firm – these comprise its **income** at time t.
- The consumer decides how much income to allocate to consumption or to savings.
- The household can save either by acquiring additional physical capital (it trades one for one with time t consumption) or by acquiring claims on consumption at dates other than t.
- The household owns physical capital and labor and rents them to the firm.
- The household consumes, supplies labor, and invests in physical capital.
- A profit-maximizing representative firm operates the production technology.
- The firm rents labor and capital each period from the representative household and sells its output each period to the household.
- The representative household and the representative firm are both **price takers** who believe that prices are not affected by their choices

Note

Again, we can think of there being unit measures of identical representative consumers and identical representative firms.

112.4 Market Structure

The representative household and the representative firm are both price takers.

The household owns both factors of production, namely, labor and physical capital.

Each period, the firm rents both factors from the household.

There is a **single** grand competitive market in which a household trades date 0 goods for goods at all other dates $t = 1, 2, \ldots, T$.

112.4.1 Prices

There are sequences of prices $\{w_t, \eta_t\}_{t=0}^T = \{\vec{w}, \vec{\eta}\}$ where

- w_t is a wage, i.e., a rental rate, for labor at time t
- η_t is a rental rate for capital at time t

In addition there is a vector $\{q_t^0\}$ of intertemporal prices where

- q_t^0 is the price at time 0 of one unit of the good at date t.

We call $\{q_t^0\}_{t=0}^T$ a vector of **Hicks-Arrow prices**, named after the 1972 economics Nobel prize winners.

Because is a **relative price**. the unit of account in terms of which the prices q_t^0 are stated is; we are free to re-normalize them by multiplying all of them by a positive scalar, say $\lambda > 0$.

Units of q_t^0 could be set so that they are

$$\frac{\text{number of time 0 goods}}{\text{number of time t goods}}$$

In this case, we would be taking the time 0 consumption good to be the **numeraire**.

112.5 Firm Problem

At time t a representative firm hires labor $\tilde{n}_t$ and capital $\tilde{k}_t$.

The firm's profits at time t are

$$F(\tilde{k}_t, \tilde{n}_t) - w_t \tilde{n}_t - \eta_t \tilde{k}_t$$

where w_t is a wage rate at t and η_t is the rental rate on capital at t.

As in the planned economy model

$$F(\tilde{k}_t, \tilde{n}_t) = A \tilde{k}_t^\alpha \tilde{n}_t^{1-\alpha}$$

112.5.1 Zero Profit Conditions

Zero-profits conditions for capital and labor are

$$F_k(\tilde{k}_t, \tilde{n}_t) = \eta_t$$

and

$$F_n(\tilde{k}_t, \tilde{n}_t) = w_t \tag{112.1}$$

These conditions emerge from a no-arbitrage requirement.

To describe this no-arbitrage profits reasoning, we begin by applying a theorem of Euler about linearly homogenous functions.

The theorem applies to the Cobb-Douglas production function because we it displays constant returns to scale:

$$\alpha F(\tilde{k}_t, \tilde{n}_t) = F(\alpha\tilde{k}_t, \alpha\tilde{n}_t)$$

for $\alpha \in (0, 1)$.

Taking partial derivatives $\frac{\partial}{\partial\alpha}$ on both sides of the above equation gives

$$F(\tilde{k}_t, \tilde{n}_t) = \frac{\partial F}{\partial \tilde{k}_t}\tilde{k}_t + \frac{\partial F}{\partial \tilde{n}_t}\tilde{n}_t$$

Rewrite the firm's profits as

$$\frac{\partial F}{\partial \tilde{k}_t}\tilde{k}_t + \frac{\partial F}{\partial \tilde{n}_t}\tilde{n}_t - w_t\tilde{n}_t - \eta_t k_t$$

or

$$\left(\frac{\partial F}{\partial \tilde{k}_t} - \eta_t\right)\tilde{k}_t + \left(\frac{\partial F}{\partial \tilde{n}_t} - w_t\right)\tilde{n}_t$$

Because F is homogeneous of degree 1, it follows that $\frac{\partial F}{\partial \tilde{k}_t}$ and $\frac{\partial F}{\partial \tilde{n}_t}$ are homogeneous of degree 0 and therefore fixed with respect to $\tilde{k}_t$ and $\tilde{n}_t$.

If $\frac{\partial F}{\partial \tilde{k}_t} > \eta_t$, then the firm makes positive profits on each additional unit of $\tilde{k}_t$, so it would want to make $\tilde{k}_t$ arbitrarily large.

But setting $\tilde{k}_t = +\infty$ is not physically feasible, so **equilibrium** prices must take values that present the firm with no such arbitrage opportunity.

A similar argument applies if $\frac{\partial F}{\partial \tilde{n}_t} > w_t$.

If $\frac{\partial \tilde{k}_t}{\partial \tilde{k}_t} < \eta_t$, the firm would want to set $\tilde{k}_t$ to zero, which is not feasible.

It is convenient to define $\vec{w} = \{w_0, \ldots, w_T\}$ and $\vec{\eta} = \{\eta_0, \ldots, \eta_T\}$.

112.6 Household Problem

A representative household lives at $t = 0, 1, \ldots, T$.

At t, the household rents 1 unit of labor and k_t units of capital to a firm and receives income

$$w_t 1 + \eta_t k_t$$

At t the household allocates its income to the following purchases between the following two categories:

- consumption c_t
- net investment $k_{t+1} - (1-\delta)k_t$

Here $(k_{t+1} - (1-\delta)k_t)$ is the household's net investment in physical capital and $\delta \in (0,1)$ is again a depreciation rate of capital.

In period t, the consumer is free to purchase more goods to be consumed and invested in physical capital than its income from supplying capital and labor to the firm, provided that in some other periods its income exceeds its purchases.

A consumer's net excess demand for time t consumption goods is the gap

$$e_t \equiv (c_t + (k_{t+1} - (1-\delta)k_t)) - (w_t 1 + \eta_t k_t)$$

Let $\vec{c} = \{c_0, \ldots, c_T\}$ and let $\vec{k} = \{k_1, \ldots, k_{T+1}\}$.

k_0 is given to the household.

The household faces a **single** budget constraint that requires that the present value of the household's net excess demands must be zero:

$$\sum_{t=0}^{T} q_t^0 e_t \leq 0$$

or

$$\sum_{t=0}^{T} q_t^0 \left(c_t + (k_{t+1} - (1-\delta)k_t)\right) \leq \sum_{t=0}^{T} q_t^0 (w_t 1 + \eta_t k_t)$$

The household faces price system $\{q_t^0, w_t, \eta_t\}$ as a price-taker and chooses an allocation to solve the constrained optimization problem:

$$\max_{\vec{c},\vec{k}} \sum_{t=0}^{T} \beta^t u(c_t)$$

$$\text{subject to } \sum_{t=0}^{T} q_t^0 \left(c_t + (k_{t+1} - (1-\delta)k_t) - (w_t - \eta_t k_t)\right) \leq 0$$

Components of a **price system** have the following units:

- w_t is measured in units of the time t good per unit of time t labor hired
- η_t is measured in units of the time t good per unit of time t capital hired
- q_t^0 is measured in units of a numeraire per unit of the time t good

112.6.1 Definitions

- A **price system** is a sequence $\{q_t^0, \eta_t, w_t\}_{t=0}^T = \{\vec{q}, \vec{\eta}, \vec{w}\}$.
- An **allocation** is a sequence $\{c_t, k_{t+1}, n_t = 1\}_{t=0}^T = \{\vec{c}, \vec{k}, \vec{n}\}$.
- A **competitive equilibrium** is a price system and an allocation with the following properties:
  - Given the price system, the allocation solves the household's problem.
  - Given the price system, the allocation solves the firm's problem.

The vision here is that an equilibrium price system and allocation are determined once and for all.

In effect, we imagine that all trades occur just before time 0.

112.7 Computing a Competitive Equilibrium

We compute a competitive equilibrium by using a **guess and verify** approach.

- We **guess** equilibrium price sequences $\{\vec{q}, \vec{\eta}, \vec{w}\}$.
- We then **verify** that at those prices, the household and the firm choose the same allocation.

112.7.1 Guess for Price System

In this lecture *Cass-Koopmans Planning Model*, we computed an allocation $\{\vec{C}, \vec{K}, \vec{N}\}$ that solves a planning problem.

We use that allocation to construct a guess for the equilibrium price system.

> **Note**
>
> This allocation will constitute the **Big** K to be in the present instance of the **Big** K **, little** k trick that we'll apply to a competitive equilibrium in the spirit of this lecture and this lecture.

In particular, we shall use the following procedure:

- obtain first-order conditions for the representative firm and the representative consumer.
- from these equations, obtain a new set of equations by replacing the firm's choice variables $\tilde{k}, \tilde{n}$ and the consumer's choice variables with the quantities $\vec{C}, \vec{K}$ that solve the planning problem.
- solve the resulting equations for $\{\vec{q}, \vec{\eta}, \vec{w}\}$ as functions of $\vec{C}, \vec{K}$.
- verify that at these prices, $c_t = C_t, k_t = \tilde{k}_t = K_t, \tilde{n}_t = 1$ for $t = 0, 1, \ldots, T$.

Thus, we guess that for $t = 0, \ldots, T$:

$$q_t^0 = \beta^t u'(C_t) \tag{112.2}$$

$$w_t = f(K_t) - K_t f'(K_t) \tag{112.3}$$

$$\eta_t = f'(K_t) \tag{112.4}$$

At these prices, let capital chosen by the household be

$$k_t^*(\vec{q}, \vec{w}, \vec{\eta}), \quad t \geq 0 \tag{112.5}$$

and let the allocation chosen by the firm be

$$\tilde{k}_t^*(\vec{q}, \vec{w}, \vec{\eta}), \quad t \geq 0$$

and so on.

If our guess for the equilibrium price system is correct, then it must occur that

$$k_t^* = \tilde{k}_t^* \tag{112.6}$$

$$1 = \tilde{n}_t^* \tag{112.7}$$

$$c_t^* + k_{t+1}^* - (1-\delta)k_t^* = F(\tilde{k}_t^*, \tilde{n}_t^*)$$

We shall verify that for $t = 0, \ldots, T$ allocations chosen by the household and the firm both equal the allocation that solves the planning problem:

$$k_t^* = \tilde{k}_t^* = K_t, \tilde{n}_t = 1, c_t^* = C_t \tag{112.8}$$

112.7.2 Verification Procedure

Our approach is firsts to stare at first-order necessary conditions for optimization problems of the household and the firm.

At the price system we have guessed, we'll then verify that both sets of first-order conditions are satisfied at the allocation that solves the planning problem.

112.7.3 Household's Lagrangian

To solve the household's problem, we formulate the Lagrangian

$$\mathcal{L}(\vec{c}, \vec{k}, \lambda) = \sum_{t=0}^{T} \beta^t u(c_t) + \lambda \left(\sum_{t=0}^{T} q_t^0 \left(((1-\delta)k_t - w_t) + \eta_t k_t - c_t - k_{t+1} \right) \right)$$

and attack the min-max problem:

$$\min_{\lambda} \max_{\vec{c}, \vec{k}} \mathcal{L}(\vec{c}, \vec{k}, \lambda)$$

First-order conditions are

$$c_t : \quad \beta^t u'(c_t) - \lambda q_t^0 = 0 \quad t = 0, 1, \ldots, T \tag{112.9}$$

$$k_t : \quad -\lambda q_t^0 \left[(1-\delta) + \eta_t \right] + \lambda q_{t-1}^0 = 0 \quad t = 1, 2, \ldots, T+1 \tag{112.10}$$

$$\lambda : \quad \left(\sum_{t=0}^{T} q_t^0 \left(c_t + (k_{t+1} - (1-\delta)k_t) - w_t - \eta_t k_t \right) \right) \leq 0 \tag{112.11}$$

$$k_{T+1} : \quad -\lambda q_0^{T+1} \leq 0, \ \leq 0 \text{ if } k_{T+1} = 0; \ = 0 \text{ if } k_{T+1} > 0 \tag{112.12}$$

Now we plug in our guesses of prices and do some algebra in the hope of recovering all first-order necessary conditions (111.9)-(111.12) for the planning problem from this lecture *Cass-Koopmans Planning Model*.

Combining (112.9) and (112.2), we get:

$$u'(C_t) = \mu_t$$

which is (111.9).

Combining (112.10), (112.2), and (112.4), we get:

$$-\lambda \beta^t \mu_t \left[(1-\delta) + f'(K_t) \right] + \lambda \beta^{t-1} \mu_{t-1} = 0 \tag{112.13}$$

Rewriting (112.13) by dividing by λ on both sides (which is nonzero since u'>0) we get:

$$\beta^t \mu_t [(1 - \delta + f'(K_t)] = \beta^{t-1} \mu_{t-1}$$

or

$$\beta \mu_t [(1 - \delta + f'(K_t)] = \mu_{t-1}$$

which is (111.10).

Combining (112.11), (112.2), (112.3) and (112.4) after multiplying both sides of (112.11) by λ, we get

$$\sum_{t=0}^{T} \beta^t \mu_t \left(C_t + (K_{t+1} - (1-\delta)K_t) - f(K_t) + K_t f'(K_t) - f'(K_t) K_t \right) \leq 0$$

which simplifies to

$$\sum_{t=0}^{T} \beta^t \mu_t \left(C_t + K_{t+1} - (1-\delta) K_t - F(K_t, 1) \right) \leq 0$$

Since $\beta^t \mu_t > 0$ for $t = 0, \ldots, T$, it follows that

$$C_t + K_{t+1} - (1-\delta) K_t - F(K_t, 1) = 0 \quad \text{for all } t \text{ in } \{0, 1, \ldots, T\}$$

which is (111.11).

Combining (112.12) and (112.2), we get:

$$-\beta^{T+1} \mu_{T+1} \leq 0$$

Dividing both sides by β^{T+1} gives

$$-\mu_{T+1} \leq 0$$

which is (111.12) for the planning problem.

Thus, at our guess of the equilibrium price system, the allocation that solves the planning problem also solves the problem faced by a representative household living in a competitive equilibrium.

112.7.4 Representative Firm's Problem

We now turn to the problem faced by a firm in a competitive equilibrium:

If we plug (112.8) into (112.1) for all t, we get

$$\frac{\partial F(K_t, 1)}{\partial K_t} = f'(K_t) = \eta_t$$

which is (112.4).

If we now plug (112.8) into (112.1) for all t, we get:

$$\frac{\partial F(\tilde{K}_t, 1)}{\partial \tilde{L}_t} = f(K_t) - f'(K_t) K_t = w_t$$

which is exactly (112.5).

Thus, at our guess for the equilibrium price system, the allocation that solves the planning problem also solves the problem faced by a firm within a competitive equilibrium.

By (112.6) and (112.7) this allocation is identical to the one that solves the consumer's problem.

Note

Because budget sets are affected only by relative prices, $\{q_t^0\}$ is determined only up to multiplication by a positive constant.

Normalization: We are free to choose a $\{q_t^0\}$ that makes $\lambda = 1$ so that we are measuring q_t^0 in units of the marginal utility of time 0 goods.

We will plot q, w, η below to show these equilibrium prices induce the same aggregate movements that we saw earlier in the planning problem.

To proceed, we bring in Python code that *Cass-Koopmans Planning Model* used to solve the planning problem

First let's define a `jitclass` that stores parameters and functions the characterize an economy.

```
planning_data = [
    ('γ', float64),     # Coefficient of relative risk aversion
    ('β', float64),     # Discount factor
    ('δ', float64),     # Depreciation rate on capital
    ('α', float64),     # Return to capital per capita
    ('A', float64)      # Technology
]
```

```
@jitclass(planning_data)
class PlanningProblem():

    def __init__(self, γ=2, β=0.95, δ=0.02, α=0.33, A=1):

        self.γ, self.β = γ, β
        self.δ, self.α, self.A = δ, α, A

    def u(self, c):
        '''
        Utility function
        ASIDE: If you have a utility function that is hard to solve by hand
        you can use automatic or symbolic differentiation
        See https://github.com/HIPS/autograd
        '''
        γ = self.γ

        return c ** (1 - γ) / (1 - γ) if γ!= 1 else np.log(c)

    def u_prime(self, c):
        'Derivative of utility'
        γ = self.γ

        return c ** (-γ)

    def u_prime_inv(self, c):
        'Inverse of derivative of utility'
        γ = self.γ

        return c ** (-1 / γ)

    def f(self, k):
        'Production function'
        α, A = self.α, self.A

        return A * k ** α

    def f_prime(self, k):
        'Derivative of production function'
        α, A = self.α, self.A

        return α * A * k ** (α - 1)

    def f_prime_inv(self, k):
        'Inverse of derivative of production function'
        α, A = self.α, self.A

        return (k / (A * α)) ** (1 / (α - 1))
```

(continues on next page)

(continued from previous page)

```
    def next_k_c(self, k, c):
        '''
        Given the current capital Kt and an arbitrary feasible
        consumption choice Ct, computes Kt+1 by state transition law
        and optimal Ct+1 by Euler equation.
        '''
        β, δ = self.β, self.δ
        u_prime, u_prime_inv = self.u_prime, self.u_prime_inv
        f, f_prime = self.f, self.f_prime

        k_next = f(k) + (1 - δ) * k - c
        c_next = u_prime_inv(u_prime(c) / (β * (f_prime(k_next) + (1 - δ))))

        return k_next, c_next
```

```
@jit
def shooting(pp, c0, k0, T=10):
    '''
    Given the initial condition of capital k0 and an initial guess
    of consumption c0, computes the whole paths of c and k
    using the state transition law and Euler equation for T periods.
    '''
    if c0 > pp.f(k0):
        print("initial consumption is not feasible")

        return None

    # initialize vectors of c and k
    c_vec = np.empty(T+1)
    k_vec = np.empty(T+2)

    c_vec[0] = c0
    k_vec[0] = k0

    for t in range(T):
        k_vec[t+1], c_vec[t+1] = pp.next_k_c(k_vec[t], c_vec[t])

    k_vec[T+1] = pp.f(k_vec[T]) + (1 - pp.δ) * k_vec[T] - c_vec[T]

    return c_vec, k_vec
```

```
@jit
def bisection(pp, c0, k0, T=10, tol=1e-4, max_iter=500, k_ter=0, verbose=True):

    # initial boundaries for guess c0
    c0_upper = pp.f(k0)
    c0_lower = 0

    i = 0
    while True:
        c_vec, k_vec = shooting(pp, c0, k0, T)
        error = k_vec[-1] - k_ter

        # check if the terminal condition is satisfied
        if np.abs(error) < tol:
            if verbose:
```

(continues on next page)

(continued from previous page)

```
                print('Converged successfully on iteration ', i+1)
            return c_vec, k_vec

        i += 1
        if i == max_iter:
            if verbose:
                print('Convergence failed.')
            return c_vec, k_vec

        # if iteration continues, updates boundaries and guess of c0
        if error > 0:
            c0_lower = c0
        else:
            c0_upper = c0

        c0 = (c0_lower + c0_upper) / 2
```

```
pp = PlanningProblem()

# Steady states
ρ = 1 / pp.β - 1
k_ss = pp.f_prime_inv(ρ+pp.δ)
c_ss = pp.f(k_ss) - pp.δ * k_ss
```

The above code from this lecture *Cass-Koopmans Planning Model* lets us compute an optimal allocation for the planning problem.

- from the preceding analysis, we know that it will also be an allocation associated with a competitive equilibium.

Now we're ready to bring in Python code that we require to compute additional objects that appear in a competitive equilibrium.

```
@jit
def q(pp, c_path):
    # Here we choose numeraire to be u'(c_0) -- this is q^(t_0)_t
    T = len(c_path) - 1
    q_path = np.ones(T+1)
    q_path[0] = 1
    for t in range(1, T+1):
        q_path[t] = pp.β ** t * pp.u_prime(c_path[t])
    return q_path

@jit
def w(pp, k_path):
    w_path = pp.f(k_path) - k_path * pp.f_prime(k_path)
    return w_path

@jit
def η(pp, k_path):
    η_path = pp.f_prime(k_path)
    return η_path
```

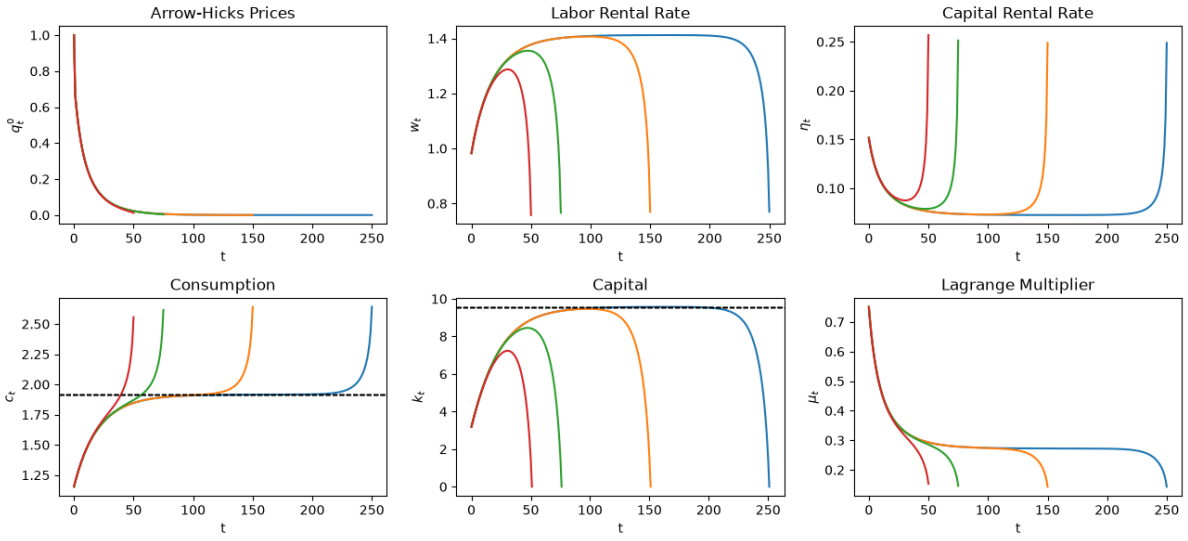
Now we calculate and plot for each T

```
T_arr = [250, 150, 75, 50]

fix, axs = plt.subplots(2, 3, figsize=(13, 6))
```

(continues on next page)

(continued from previous page)



```
titles = ['Arrow-Hicks Prices', 'Labor Rental Rate', 'Capital Rental Rate',
          'Consumption', 'Capital', 'Lagrange Multiplier']
ylabels = ['$q_t^0$', '$w_t$', r'$\eta_t$', '$c_t$', '$k_t$', r'$\mu_t$']

for T in T_arr:
    c_path, k_path = bisection(pp, 0.3, k_ss/3, T, verbose=False)
    μ_path = pp.u_prime(c_path)

    q_path = q(pp, c_path)
    w_path = w(pp, k_path)[:-1]
    η_path = η(pp, k_path)[:-1]
    paths = [q_path, w_path, η_path, c_path, k_path, μ_path]

    for i, ax in enumerate(axs.flatten()):
        ax.plot(paths[i])
        ax.set(title=titles[i], ylabel=ylabels[i], xlabel='t')
        if titles[i] == 'Capital':
            ax.axhline(k_ss, lw=1, ls='--', c='k')
        if titles[i] == 'Consumption':
            ax.axhline(c_ss, lw=1, ls='--', c='k')

plt.tight_layout()
plt.show()
```

Varying Curvature

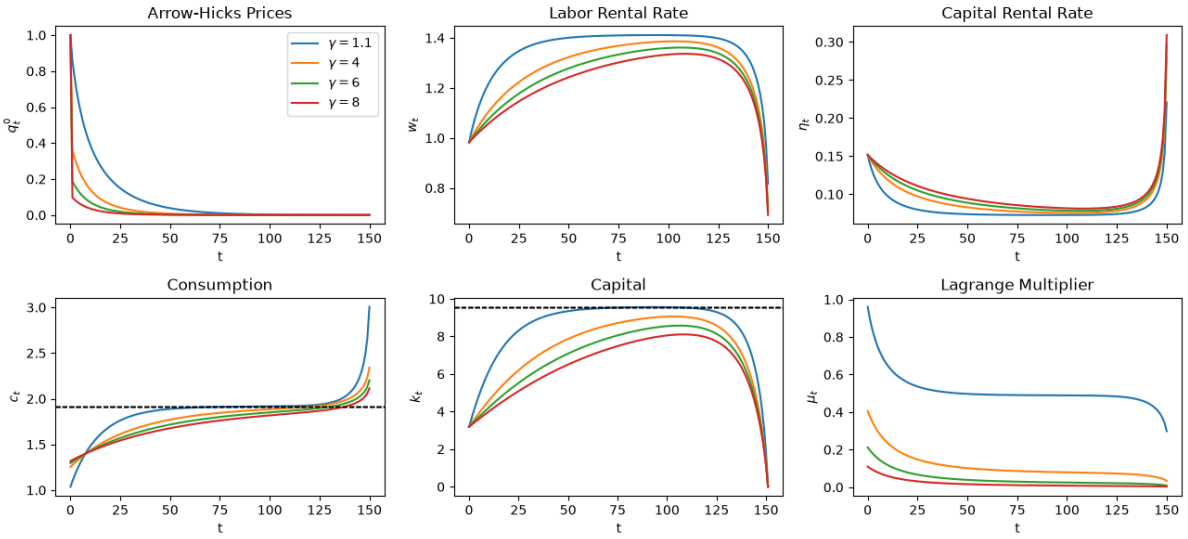
Now we see how our results change if we keep T constant, but allow the curvature parameter, γ to vary, starting with K_0 below the steady state.

We plot the results for $T = 150$

```
T = 150
γ_arr = [1.1, 4, 6, 8]

fix, axs = plt.subplots(2, 3, figsize=(13, 6))
```

(continues on next page)



(continued from previous page)

```
for γ in γ_arr:
    pp_γ = PlanningProblem(γ=γ)
    c_path, k_path = bisection(pp_γ, 0.3, k_ss/3, T, verbose=False)
    μ_path = pp_γ.u_prime(c_path)

    q_path = q(pp_γ, c_path)
    w_path = w(pp_γ, k_path)[:-1]
    η_path = η(pp_γ, k_path)[:-1]
    paths = [q_path, w_path, η_path, c_path, k_path, μ_path]

    for i, ax in enumerate(axs.flatten()):
        ax.plot(paths[i], label=fr'$\gamma = {γ}$')
        ax.set(title=titles[i], ylabel=ylabels[i], xlabel='t')
        if titles[i] == 'Capital':
            ax.axhline(k_ss, lw=1, ls='--', c='k')
        if titles[i] == 'Consumption':
            ax.axhline(c_ss, lw=1, ls='--', c='k')

axs[0, 0].legend()
plt.tight_layout()
plt.show()
```

Adjusting γ means adjusting how much individuals prefer to smooth consumption.

Higher γ means individuals prefer to smooth more resulting in slower convergence to a steady state allocation.

Lower γ means individuals prefer to smooth less, resulting in faster convergence to a steady state allocation.

112.8 Yield Curves and Hicks-Arrow Prices

We return to Hicks-Arrow prices and calculate how they are related to **yields** on loans of alternative maturities.

This will let us plot a **yield curve** that graphs yields on bonds of maturities $j = 1, 2, ...$ against $j = 1, 2, ...$

We use the following formulas.

A **yield to maturity** on a loan made at time t_0 that matures at time $t > t_0$

$$r_{t_0,t} = -\frac{\log q_t^{t_0}}{t - t_0}$$

A Hicks-Arrow price system for a base-year $t_0 \leq t$ satisfies

$$q_t^{t_0} = \beta^{t-t_0} \frac{u'(c_t)}{u'(c_{t_0})} = \beta^{t-t_0} \frac{c_t^{-\gamma}}{c_{t_0}^{-\gamma}}$$

We redefine our function for q to allow arbitrary base years, and define a new function for r, then plot both.

We begin by continuing to assume that $t_0 = 0$ and plot things for different maturities $t = T$, with K_0 below the steady state

```
@jit
def q_generic(pp, t0, c_path):
    # simplify notations
    β = pp.β
    u_prime = pp.u_prime

    T = len(c_path) - 1
    q_path = np.zeros(T+1-t0)
    q_path[0] = 1
    for t in range(t0+1, T+1):
        q_path[t-t0] = β ** (t-t0) * u_prime(c_path[t]) / u_prime(c_path[t0])
    return q_path

@jit
def r(pp, t0, q_path):
    '''Yield to maturity'''
    r_path = - np.log(q_path[1:]) / np.arange(1, len(q_path))
    return r_path

def plot_yield_curves(pp, t0, c0, k0, T_arr):

    fig, axs = plt.subplots(1, 2, figsize=(10, 5))

    for T in T_arr:
        c_path, k_path = bisection(pp, c0, k0, T, verbose=False)
        q_path = q_generic(pp, t0, c_path)
        r_path = r(pp, t0, q_path)

        axs[0].plot(range(t0, T+1), q_path)
        axs[0].set(xlabel='t', ylabel='$q_t^0$', title='Hicks-Arrow Prices')

        axs[1].plot(range(t0+1, T+1), r_path)
        axs[1].set(xlabel='t', ylabel='$r_t^0$', title='Yields')
```

```
T_arr = [150, 75, 50]
plot_yield_curves(pp, 0, 0.3, k_ss/3, T_arr)
```

Now we plot when $t_0 = 20$

```
plot_yield_curves(pp, 20, 0.3, k_ss/3, T_arr)
```

CHAPTER

THREE

CASS-KOOPMANS MODEL WITH DISTORTING TAXES

113.1 Overview

This lecture studies effects of foreseen fiscal and technology shocks on competitive equilibrium prices and quantities in a nonstochastic version of a Cass-Koopmans growth model with features described in this QuantEcon lecture *Cass-Koopmans Competitive Equilibrium*.

This model is discussed in more detail in chapter 11 of [Ljungqvist and Sargent, 2018].

We use the model as a laboratory to experiment with numerical techniques for approximating equilibria and to display the structure of dynamic models in which decision makers have perfect foresight about future government decisions.

Following a classic paper by Robert E. Hall [Hall, 1971], we augment a nonstochastic version of the Cass-Koopmans optimal growth model with a government that purchases a stream of goods and that finances its purchases with an sequences of several distorting flat-rate taxes.

Distorting taxes prevent a competitive equilibrium allocation from solving a planning problem.

Therefore, to compute an equilibrium allocation and price system, we solve a system of nonlinear difference equations consisting of the first-order conditions for decision makers and the other equilibrium conditions.

We present two ways to approximate an equilibrium:

- The first is a shooting algorithm like the one that we deployed in *Cass-Koopmans Competitive Equilibrium*.
- The second method is a root-finding algorithm that minimizes residuals from the first-order conditions of the consumer and representative firm.

113.2 The Economy

113.2.1 Technology

Feasible allocations satisfy

$$g_t + c_t + x_t \leq F(k_t, n_t), \tag{113.1}$$

where

- g_t is government purchases of the time t good
- x_t is gross investment, and
- $F(k_t, n_t)$ is a linearly homogeneous production function with positive and decreasing marginal products of capital k_t and labor n_t.

Physical capital evolves according to

$$k_{t+1} = (1-\delta)k_t + x_t,$$

where $\delta \in (0,1)$ is a depreciation rate.

It is sometimes convenient to eliminate x_t from (113.1) and to represent it as as

$$g_t + c_t + k_{t+1} \leq F(k_t, n_t) + (1-\delta)k_t.$$

113.2.2 Components of a competitive equilibrium

All trades occurring at time 0.

The representative household owns capital, makes investment decisions, and rents capital and labor to a representative production firm.

The representative firm uses capital and labor to produce goods with the production function $F(k_t, n_t)$.

A **price system** is a triple of sequences $\{q_t, \eta_t, w_t\}_{t=0}^{\infty}$, where

- q_t is the time 0 pretax price of one unit of investment or consumption at time t (x_t or c_t),
- η_t is the pretax price at time t that the household receives from the firm for renting capital at time t, and
- w_t is the pretax price at time t that the household receives for renting labor to the firm at time t.

The prices w_t and η_t are expressed in terms of time t goods, while q_t is expressed in terms of a numeraire at time 0, as in *Cass-Koopmans Competitive Equilibrium*.

The presence of a government distinguishes this lecture from *Cass-Koopmans Competitive Equilibrium*.

Government purchases of goods at time t are $g_t \geq 0$.

A government expenditure plan is a sequence $g = \{g_t\}_{t=0}^{\infty}$.

A government tax plan is a 4-tuple of sequences $\{\tau_{ct}, \tau_{kt}, \tau_{nt}, \tau_{ht}\}_{t=0}^{\infty}$, where

- τ_{ct} is a tax rate on consumption at time t,
- τ_{kt} is a tax rate on rentals of capital at time t,
- τ_{nt} is a tax rate on wage earnings at time t, and
- τ_{ht} is a lump sum tax on a consumer at time t.

Because lump-sum taxes τ_{ht} are available, the government actually should not use any distorting taxes.

Nevertheless, we include all of these taxes because, like [Hall, 1971], they allow us to analyze how various taxes distort production and consumption decisions.

In the *experiment section*, we shall see how variations in government tax plan affect the transition path and equilibrium.

113.2.3 Representative Household

A representative household has preferences over nonnegative streams of a single consumption good c_t and leisure $1 - n_t$ that are ordered by:

$$\sum_{t=0}^{\infty} \beta^t U(c_t, 1-n_t), \quad \beta \in (0,1), \tag{113.2}$$

where

- U is strictly increasing in c_t, twice continuously differentiable, and strictly concave with $c_t \geq 0$ and $n_t \in [0, 1]$.

The representative hßousehold maximizes (113.2) subject to the single budget constraint:

$$\begin{aligned}\sum_{t=0}^{\infty} q_t \left\{ (1+\tau_{ct})c_t + \underbrace{[k_{t+1} - (1-\delta)k_t]}_{\text{no tax when investing}} \right\} \\ \leq \sum_{t=0}^{\infty} q_t \left\{ \eta_t k_t - \underbrace{\tau_{kt}(\eta_t - \delta)k_t}_{\text{tax on rental return}} + (1-\tau_{nt})w_t n_t - \tau_{ht} \right\}.\end{aligned} \tag{113.3}$$

Here we have assumed that the government gives a depreciation allowance δk_t from the gross rentals on capital $\eta_t k_t$ and so collects taxes $\tau_{kt}(\eta_t - \delta)k_t$ on rentals from capital.

113.2.4 Government

Government plans $\{g_t\}_{t=0}^{\infty}$ for government purchases and taxes $\{\tau_{ct}, \tau_{kt}, \tau_{nt}, \tau_{ht}\}_{t=0}^{\infty}$ must respect the budget constraint

$$\sum_{t=0}^{\infty} q_t g_t \leq \sum_{t=0}^{\infty} q_t \left\{ \tau_{ct} c_t + \tau_{kt}(\eta_t - \delta)k_t + \tau_{nt} w_t n_t + \tau_{ht} \right\}. \tag{113.4}$$

Given a budget-feasible government policy $\{g_t\}_{t=0}^{\infty}$ and $\{\tau_{ct}, \tau_{kt}, \tau_{nt}, \tau_{ht}\}_{t=0}^{\infty}$ subject to (113.4),

- **Household** chooses $\{c_t\}_{t=0}^{\infty}$, $\{n_t\}_{t=0}^{\infty}$, and $\{k_{t+1}\}_{t=0}^{\infty}$ to maximize utility(113.2) subject to budget constraint(113.3), and
- **Firm** chooses sequences of capital $\{k_t\}_{t=0}^{\infty}$ and $\{n_t\}_{t=0}^{\infty}$ to maximize profits

$$\sum_{t=0}^{\infty} q_t [F(k_t, n_t) - \eta_t k_t - w_t n_t] \tag{113.5}$$

- A **feasible allocation** is a sequence $\{c_t, x_t, n_t, k_t\}_{t=0}^{\infty}$ that satisfies feasibility condition (113.1).

113.3 Equilibrium

Definition 113.3.1

A **competitive equilibrium with distorting taxes** is a **budget-feasible government policy**, **a feasible allocation**, and **a price system** for which, given the price system and the government policy, the allocation solves the household's problem and the firm's problem.

113.4 No-arbitrage Condition

A no-arbitrage argument implies a restriction on prices and tax rates across time.

By rearranging (113.3) and group k_t at the same t, we can get

$$\begin{aligned}\sum_{t=0}^{\infty} q_t \left[(1+\tau_{ct})c_t\right] \leq \sum_{t=0}^{\infty} q_t (1-\tau_{nt}) w_t n_t - \sum_{t=0}^{\infty} q_t \tau_{ht} \\ + \sum_{t=1}^{\infty} \left\{ \left[(1-\tau_{kt})(\eta_t - \delta) + 1\right] q_t - q_{t-1} \right\} k_t \\ + \left[(1-\tau_{k0})(\eta_0 - \delta) + 1\right] q_0 k_0 - \lim_{T \to \infty} q_T k_{T+1}\end{aligned} \tag{113.6}$$

The household inherits a given k_0 that it takes as initial condition and is free to choose $\{c_t, n_t, k_{t+1}\}_{t=0}^{\infty}$.

The household's budget constraint (113.3) must be bounded in equilibrium due to finite resources.

This imposes a restriction on price and tax sequences.

Specifically, for $t \geq 1$, the terms multiplying k_t must equal zero.

If they were strictly positive (negative), the household could arbitrarily increase (decrease) the right-hand side of (113.3) by selecting an arbitrarily large positive (negative) k_t, leading to unbounded profit or arbitrage opportunities:

- For strictly positive terms, the household could purchase large capital stocks k_t and profit from their rental services and undepreciated value.
- For strictly negative terms, the household could engage in "short selling" synthetic units of capital. Both cases would make (113.3) unbounded.

Hence, by setting the terms multiplying k_t to 0 we have the non-arbitrage condition:

$$\frac{q_t}{q_{t+1}} = \left[(1 - \tau_{kt+1})(\eta_{t+1} - \delta) + 1\right]. \tag{113.7}$$

Moreover, we have terminal condition:

$$-\lim_{T \to \infty} q_T k_{T+1} = 0. \tag{113.8}$$

Zero-profit conditions for the representative firm impose additional restrictions on equilibrium prices and quantities.

The present value of the firm's profits is

$$\sum_{t=0}^{\infty} q_t \left[F(k_t, n_t) - w_t n_t - \eta_t k_t\right].$$

Applying Euler's theorem on linearly homogeneous functions to $F(k, n)$, the firm's present value is:

$$\sum_{t=0}^{\infty} q_t \left[(F_{kt} - \eta_t)k_t + (F_{nt} - w_t)n_t\right].$$

No-arbitrage (or zero-profit) conditions are:

$$\eta_t = F_{kt}, \quad w_t = F_{nt}. \tag{113.9}$$

113.5 Household's First Order Condition

Household maximize (113.2) under (113.3).

Let $U_1 = \frac{\partial U}{\partial c}, U_2 = \frac{\partial U}{\partial (1-n)} = -\frac{\partial U}{\partial n}$., we can derive FOC from the Lagrangian

$$\mathcal{L} = \sum_{t=0}^{\infty} \beta^t U(c_t, 1 - n_t) + \mu \left(\sum_{t=0}^{\infty} q_t \left[(1 + \tau_{ct})c_t - (1 - \tau_{nt})w_t n_t + ...\right] \right),$$

First-order necessary conditions for the representative household's problem are

$$\frac{\partial \mathcal{L}}{\partial c_t} = \beta^t U_1(c_t, 1 - n_t) - \mu q_t (1 + \tau_{ct}) = 0 \tag{113.10}$$

and

$$\frac{\partial \mathcal{L}}{\partial n_t} = \beta^t \left(-U_{2t}(c_t, 1 - n_t)\right) - \mu q_t (1 - \tau_{nt}) w_t = 0 \tag{113.11}$$

Rearranging (113.10) and (113.11), we have

$$\beta^t U_1(c_t, 1-n_t) = \beta^t U_{1t} = \mu q_t (1+\tau_{ct}), \tag{113.12}$$

$$\beta^t U_2(c_t, 1-n_t) = \beta^t U_{2t} = \mu q_t (1-\tau_{nt}) w_t. \tag{113.13}$$

Plugging (113.12) into (113.8) and replacing q_t, we get terminal condition

$$-\lim_{T\to\infty} \beta^T \frac{U_{1T}}{(1+\tau_{cT})} k_{T+1} = 0. \tag{113.14}$$

113.6 Computing Equilibria

To compute an equilibrium, we seek a price system $\{q_t, \eta_t, w_t\}$, a budget feasible government policy $\{g_t, \tau_t\} \equiv \{g_t, \tau_{ct}, \tau_{nt}, \tau_{kt}, \tau_{ht}\}$, and an allocation $\{c_t, n_t, k_{t+1}\}$ that solve a system of nonlinear difference equations consisting of

- feasibility condition (113.1), no-arbitrage condition for household (113.7) and firms (113.9), household's first order conditions (113.12) and (113.13).
- an initial condition k_0 and a terminal condition (113.14).

113.7 Python Code

We require the following imports

```
import numpy as np
from scipy.optimize import root
import matplotlib.pyplot as plt
from collections import namedtuple
from mpmath import mp, mpf
from warnings import warn

# Set the precision
mp.dps = 40
mp.pretty = True
```

We use the `mpmath` library to perform high-precision arithmetic in the shooting algorithm in cases where the solution diverges due to numerical instability.

Note

In the functions below, we include routines to handle the growth component, which will be discussed further in the section *Exogenous growth*.

We include them here to avoid code duplication.

We set the following parameters

```
# Create a namedtuple to store the model parameters
Model = namedtuple("Model",
                   ["β", "γ", "δ", "α", "A"])
```

(continues on next page)

(continued from previous page)

```
def create_model(β=0.95,  # discount factor
                 γ=2.0,   # relative risk aversion coefficient
                 δ=0.2,   # depreciation rate
                 α=0.33,  # capital share
                 A=1.0    # TFP
                 ):
    """Create a model instance."""
    return Model(β=β, γ=γ, δ=δ, α=α, A=A)

model = create_model()

# Total number of periods
S = 100
```

113.7.1 Inelastic Labor Supply

In this lecture, we consider the special case where $U(c, 1-n) = u(c)$ and $f(k) := F(k, 1)$.

We rewrite (113.1) with $f(k) := F(k, 1)$,

$$k_{t+1} = f(k_t) + (1-\delta)k_t - g_t - c_t. \tag{113.15}$$

```
def next_k(k_t, g_t, c_t, model, μ_t=1):
    """
    Capital next period: k_{t+1} = f(k_t) + (1 - δ) * k_t - c_t - g_t
    with optional growth adjustment: k_{t+1} = (f(k_t) + (1 - δ) * k_t - c_t - g_t) /␣
↪μ_{t+1}
    """
    return (f(k_t, model) + (1 - model.δ) * k_t - g_t - c_t) / μ_t
```

By the properties of a linearly homogeneous production function, we have $F_k(k, n) = f'(k)$ and $F_n(k, 1) = f(k, 1) - f'(k)k$.

Substituting (113.12), (113.9), and (113.15) into (113.7), we obtain the Euler equation

$$\begin{aligned}
&\frac{u'(f(k_t) + (1-\delta)k_t - g_t - k_{t+1})}{(1+\tau_{ct})} \\
&- \beta \frac{u'(f(k_{t+1}) + (1-\delta)k_{t+1} - g_{t+1} - k_{t+2})}{(1+\tau_{ct+1})} \\
&\times [(1-\tau_{kt+1})(f'(k_{t+1}) - \delta) + 1] = 0.
\end{aligned} \tag{113.16}$$

This can be simplified to:

$$u'(c_t) = \beta u'(c_{t+1}) \frac{(1+\tau_{ct})}{(1+\tau_{ct+1})} [(1-\tau_{kt+1})(f'(k_{t+1}) - \delta) + 1]. \tag{113.17}$$

Equation (113.17) will appear prominently in our equilibrium computation algorithms.

113.7.2 Steady state

Tax rates and government expenditures act as **forcing functions** for difference equations (113.15) and (113.17).

Define $z_t = [g_t, \tau_{kt}, \tau_{ct}]'$.

Represent the second-order difference equation as:

$$H(k_t, k_{t+1}, k_{t+2}; z_t, z_{t+1}) = 0. \tag{113.18}$$

We assume that a government policy reaches a steady state such that $\lim_{t\to\infty} z_t = \bar{z}$ and that the steady state prevails for $t > T$.

The terminal steady-state capital stock $\bar{k}$ satisfies:

$$H(\bar{k}, \bar{k}, \bar{k}, \bar{z}, \bar{z}) = 0.$$

From difference equation (113.17), we can infer a restriction on the steady-state:

$$\begin{aligned} u'(\bar{c}) &= \beta u'(\bar{c}) \frac{(1+\bar{\tau}_c)}{(1+\bar{\tau}_c)} [(1-\bar{\tau}_k)(f'(\bar{k}) - \delta) + 1]. \\ \implies 1 &= \beta[(1-\bar{\tau}_k)(f'(\bar{k}) - \delta) + 1]. \end{aligned} \tag{113.19}$$

113.7.3 Other equilibrium quantities and prices

Price:

$$q_t = \frac{\beta^t u'(c_t)}{u'(c_0)} \tag{113.20}$$

```
def compute_q_path(c_path, model, S=100, A_path=None):
    """
    Compute q path: q_t = (β^t * u'(c_t)) / u'(c_0)
    with optional A_path for growth models.
    """
    A = np.ones_like(c_path) if A_path is None else np.asarray(A_path)
    q_path = np.zeros_like(c_path)
    for t in range(S):
        q_path[t] = (model.β ** t *
                     u_prime(c_path[t], model, A[t])) / u_prime(c_path[0], model,␣
↪A[0])
    return q_path
```

Capital rental rate

$$\eta_t = f'(k_t)$$

```
def compute_η_path(k_path, model, S=100, A_path=None):
    """
    Compute η path: η_t = f'(k_t)
    with optional A_path for growth models.
    """
    A = np.ones_like(k_path) if A_path is None else np.asarray(A_path)
    η_path = np.zeros_like(k_path)
    for t in range(S):
        η_path[t] = f_prime(k_path[t], model, A[t])
    return η_path
```

Labor rental rate:

$$w_t = f(k_t) - k_t f'(k_t)$$

```
def compute_w_path(k_path, η_path, model, S=100, A_path=None):
    """
    Compute w path: w_t = f(k_t) - k_t * f'(k_t)
    with optional A_path for growth models.
    """
    A = np.ones_like(k_path) if A_path is None else np.asarray(A_path)
    w_path = np.zeros_like(k_path)
    for t in range(S):
        w_path[t] = f(k_path[t], model, A[t]) - k_path[t] * η_path[t]
    return w_path
```

Gross one-period return on capital:

$$\bar{R}_{t+1} = \frac{(1+\tau_{ct})}{(1+\tau_{ct+1})}\left[(1-\tau_{kt+1})(f'(k_{t+1})-\delta)+1\right] = \frac{(1+\tau_{ct})}{(1+\tau_{ct+1})}R_{t,t+1} \tag{113.21}$$

```
def compute_R_bar(τ_ct, τ_ctp1, τ_ktp1, k_tp1, model):
    """
    Gross one-period return on capital:
    R_bar = [(1 + τ_c_t) / (1 + τ_c_{t+1})]
        * { [1 - τ_k_{t+1}] * [f'(k_{t+1}) - δ] + 1 }
    """
    return ((1 + τ_ct) / (1 + τ_ctp1)) * (
        (1 - τ_ktp1) * (f_prime(k_tp1, model) - model.δ) + 1)
```

```
def compute_R_bar_path(shocks, k_path, model, S=100):
    """
    Compute R_bar path over time.
    """
    R_bar_path = np.zeros(S + 1)
    for t in range(S):
        R_bar_path[t] = compute_R_bar(
            shocks['τ_c'][t], shocks['τ_c'][t + 1], shocks['τ_k'][t + 1],
            k_path[t + 1], model)
    R_bar_path[S] = R_bar_path[S - 1]
    return R_bar_path
```

One-period discount factor:

$$R_{t,t+1}^{-1} = \frac{q_{t+1}}{q_t} = m_{t,t+1} = \beta\frac{u'(c_{t+1})}{u'(c_t)}\frac{(1+\tau_{ct})}{(1+\tau_{ct+1})} \tag{113.22}$$

Net one-period rate of interest:

$$r_{t,t+1} \equiv R_{t,t+1} - 1 = (1-\tau_{k,t+1})(f'(k_{t+1})-\delta) \tag{113.23}$$

By (113.22) and $r_{t,t+1} = -\ln(\frac{q_{t+1}}{q_t})$, we have

$$R_{t,t+s} = e^{s\cdot r_{t,t+s}}.$$

Then by (113.23), we have

$$\frac{q_{t+s}}{q_t} = e^{-s\cdot r_{t,t+s}}.$$

Rearranging the above equation, we have

$$r_{t,t+s} = -\frac{1}{s} \ln \left(\frac{q_{t+s}}{q_t} \right).$$

```
def compute_rts_path(q_path, S, t):
    """
    Compute r path:
    r_t,t+s = - (1/s) * ln(q_{t+s} / q_t)
    """
    s = np.arange(1, S + 1)
    q_path = np.array([float(q) for q in q_path])

    with np.errstate(divide='ignore', invalid='ignore'):
        rts_path = - np.log(q_path[t + s] / q_path[t]) / s
    return rts_path
```

113.8 Some functional forms

We assume that the representative household' period utility has the following CRRA (constant relative risk aversion) form

$$u(c) = \frac{c^{1-\gamma}}{1-\gamma}$$

```
def u_prime(c, model, A_t=1):
    """
    Marginal utility: u'(c) = c^{-γ}
    with optional technology adjustment: u'(cA) = (cA)^{-γ}
    """
    return (c * A_t) ** (-model.γ)
```

By substituting (113.21) into (113.17), we obtain

$$c_{t+1} = c_t \left[\beta \frac{(1+\tau_{ct})}{(1+\tau_{ct+1})} \left[(1-\tau_{k,t+1})(f'(k_{t+1}) - \delta) + 1 \right] \right]^{\frac{1}{\gamma}} = c_t \left[\beta \overline{R}_{t+1} \right]^{\frac{1}{\gamma}} \tag{113.24}$$

```
def next_c(c_t, R_bar, model, μ_t=1):
    """
    Consumption next period: c_{t+1} = c_t * (β * R̄)^{1/γ}
    with optional growth adjustment: c_{t+1} = c_t * (β * R_bar)^{1/γ} * μ_{t+1}^{-1}
    """
    return c_t * (model.β * R_bar) ** (1 / model.γ) / μ_t
```

For the production function we assume a Cobb-Douglas form:

$$F(k, 1) = Ak^{\alpha}$$

```
def f(k, model, A=1):
    """
    Production function: f(k) = A * k^{α}
    """
    return A * k ** model.α

def f_prime(k, model, A=1):
```

(continues on next page)

(continued from previous page)

```
    """

```

113.9 Computation

We describe two ways to compute an equilibrium:

- a shooting algorithm
- a residual-minimization method that focuses on imposing Euler equation (113.17) and the feasibility condition (113.15).

113.9.1 Shooting Algorithm

This algorithm deploys the following steps.

1. Solve the equation (113.19) for the terminal steady-state capital $\bar{k}$ that corresponds to the permanent policy vector $\bar{z}$.
2. Select a large time index $S \gg T$, guess an initial consumption rate c_0, and use the equation (113.15) to solve for k_1.
3. Use the equation (113.24) to determine c_{t+1}. Then, apply the equation (113.15) to compute k_{t+2}.
4. Iterate step 3 to compute candidate values $\hat{k}_t$ for $t = 1, \ldots, S$.
5. Compute the difference $\hat{k}_S - \bar{k}$. If $\left|\hat{k}_S - \bar{k}\right| > \epsilon$ for some small ϵ, adjust c_0 and repeat steps 2-5.
6. Adjust c_0 iteratively using the bisection method to find a value that ensures $\left|\hat{k}_S - \bar{k}\right| < \epsilon$.

The following code implements these steps.

```
# Steady-state calculation
def steady_states(model, g_ss, τ_k_ss=0.0, μ_ss=None):
    """
    Calculate steady state values for capital and
    consumption with optional A_path for growth models.
    """

    β, δ, α, γ = model.β, model.δ, model.α, model.γ

    A = model.A or 1.0

    # growth-adjustment in the numerator: μ^γ or 1
    μ_eff = μ_ss**γ if μ_ss is not None else 1.0

    num = δ + (μ_eff/β - 1) / (1 - τ_k_ss)
    k_ss = (num / (α * A)) ** (1 / (α - 1))

    c_ss = (
        A * k_ss**α - δ * k_ss - g_ss
        if μ_ss is None
        else k_ss**α + (1 - δ - μ_ss) * k_ss - g_ss
```

(continues on next page)

113.9.2 Experiments

Let's run some experiments.

1. A foreseen once-and-for-all increase in g from 0.2 to 0.4 occurring in period 10,
2. A foreseen once-and-for-all increase in τ_c from 0.0 to 0.2 occurring in period 10,
3. A foreseen once-and-for-all increase in τ_k from 0.0 to 0.2 occurring in period 10, and
4. A foreseen one-time increase in g from 0.2 to 0.4 in period 10, after which g reverts to 0.2 permanently.

To start, we prepare sequences that we'll used to initialize our iterative algorithm.

We will start from an initial steady state and apply shocks at an the indicated time.

```

The above figures indicate that an equilibrium **consumption smoothing** mechanism is at work, driven by the representative consumer's preference for smooth consumption paths coming from the curvature of its one-period utility function.

- The steady-state value of the capital stock remains unaffected:
  - This follows from the fact that g disappears from the steady state version of the Euler equation ((113.19)).
- Consumption begins to decline gradually before time T due to increased government consumption:
  - Households reduce consumption to offset government spending, which is financed through increased lump-sum taxes.
  - The competitive economy signals households to consume less through an increase in the stream of lump-sum taxes.
  - Households, caring about the present value rather than the timing of taxes, experience an adverse wealth effect on consumption, leading to an immediate response.
- Capital gradually accumulates between time 0 and T due to increased savings and reduces gradually after time T:
  - This temporal variation in capital stock smooths consumption over time, driven by the representative consumer's consumption-smoothing motive.

Let's collect the procedures used above into a function that runs the solver and draws plots for a given experiment

The following figure compares responses to a foreseen increase in g at $t = 10$ for two economies:

- our original economy with $\gamma = 2$, shown in the solid line, and

- an otherwise identical economy with $\gamma = 0.2$.

This comparison interest us because the utility curvature parameter γ governs the household's willingness to substitute consumption over time, and thus it preferences about smoothness of consumption paths over time.

```
# Solve the model using shooting
solution = run_shooting(shocks, S, model)

# Compute the initial steady states
k_ss_initial, c_ss_initial = steady_states(model,
                                           shocks['g'][0],
                                           shocks['τ_k'][0])

# Plot the solution for γ=2
fig, axes = plt.subplots(2, 3, figsize=(10, 8))

plot_results(solution, k_ss_initial, c_ss_initial,
             shocks, 'g', axes, model_γ2,
             label=fr"$\gamma = {model_γ2.γ}$",
             linestyle='-.', T=40)

handles, labels = axes[0].get_legend_handles_labels()
fig.legend(handles, labels, loc='lower right',
           ncol=3, fontsize=14, bbox_to_anchor=(1, 0.1))

for ax in axes[5:]:
    fig.delaxes(ax)

plt.tight_layout()
plt.show()
```

```
Model: Model(β=0.95, γ=2.0, δ=0.2, α=0.33, A=1.0)
Optimal initial consumption c0 = 0.60924195288792396453121856997271325335517
Model: Model(β=0.95, γ=0.2, δ=0.2, α=0.33, A=1.0)
Optimal initial consumption c0 = 0.64203304129879029264147687246076236817745
```

The outcomes indicate that lowering γ affects both the consumption and capital stock paths because - it increases the representative consumer's willingness to substitute consumption across time:

- Consumption path:
  - When $\gamma = 0.2$, consumption becomes less smooth compared to $\gamma = 2$.
  - For $\gamma = 0.2$, consumption mirrors the government expenditure path more closely, staying higher until $t = 10$.
- Capital stock path:
  - With $\gamma = 0.2$, there are smaller build-ups and drawdowns of capital stock.
  - There are also smaller fluctuations in $\bar{R}$ and η.

Let's write another function that runs the solver and draws plots for these two experiments

Now we plot other equilibrium quantities:

```
def plot_prices(solution, c_ss, shock_param, axes,
                model, label='', linestyle='-', T=40):
    """
    Compares and plots prices
    """
    α, β, δ, γ, A = model.α, model.β, model.δ, model.γ, model.A

    k_path = solution[:, 0]
    c_path = solution[:, 1]
```

(continues on next page)

(continued from previous page)

```
    # Plot for c
    axes[0].plot(c_path[:T], linestyle=linestyle, label=label)
    axes[0].axhline(c_ss, linestyle='--', color='black')
    axes[0].set_title('c')

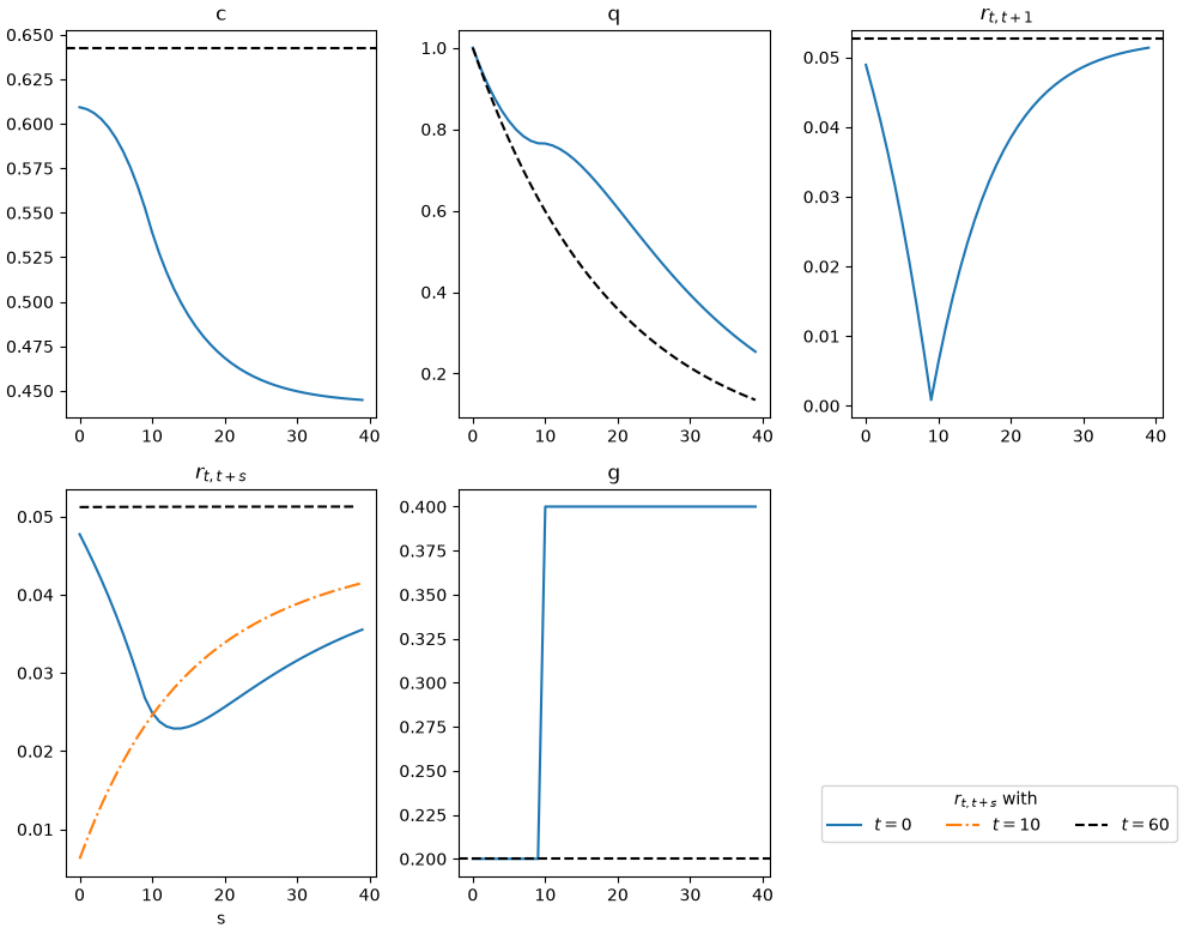
    axes[4].axhline(shocks[shock_param][0], linestyle='--', color='black')
    axes[4].set_title(shock_param)
```

For $\gamma = 2$ again, the next figure describes the response of q_t and the term structure of interest rates to a foreseen increase in g_t at $t = 10$

```
solution = run_shooting(shocks, S, model)



fig, axes = plt.subplots(2, 3, figsize=(10, 8))
axes = axes.flatten()

plot_prices(solution, c_ss_initial, 'g', axes, model, T=40)

for ax in axes[5:]:
    fig.delaxes(ax)

handles, labels = axes[3].get_legend_handles_labels()
fig.legend(handles, labels, title=r"$r_{t,t+s}$ with ", loc='lower right',
           ncol=3, fontsize=10, bbox_to_anchor=(1, 0.1))
plt.tight_layout()
plt.show()
```

```
Model: Model(β=0.95, γ=2.0, δ=0.2, α=0.33, A=1.0)
Optimal initial consumption c0 = 0.6092419528879239645312185699727132533517
```

The second panel on the top compares q_t for the initial steady state with q_t after the increase in g is foreseen at $t = 0$, while the third panel compares the implied short rate r_t.

The fourth panel shows the term structure of interest rates at $t = 0$, $t = 10$, and $t = 60$.

Notice that, by $t = 60$, the system has converged to the new steady state, and the term structure of interest rates becomes flat.

At $t = 10$, the term structure of interest rates is upward sloping.

This upward slope reflects the expected increase in the rate of growth of consumption over time, as shown in the consumption panel.

At $t = 0$, the term structure of interest rates exhibits a "U-shaped" pattern:

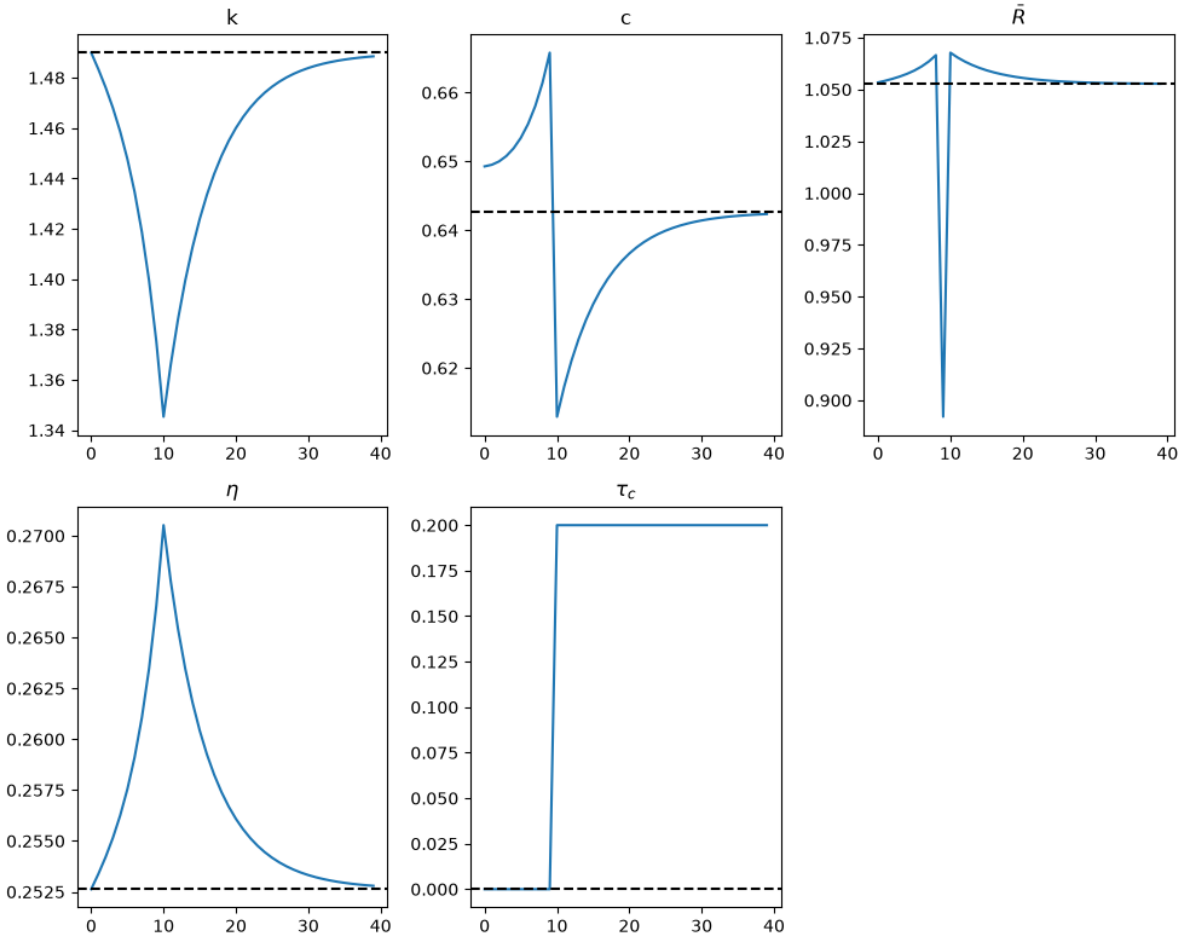
- It declines until maturity at $s = 10$.
- After $s = 10$, it increases for longer maturities.

This pattern aligns with the pattern of consumption growth in the first two figures, which declines at an increasing rate until $t = 10$ and then declines at a decreasing rate afterward.

Experiment 2: Foreseen once-and-for-all increase in τ_c from 0.0 to 0.2 in period 10

With an inelastic labor supply, the Euler equation (113.16) and the other equilibrium conditions show that

- constant consumption taxes do not distort decisions, but
- anticipated changes in them do.



Indeed, (113.16) or (113.17) indicates that a foreseen in- crease in τ_{ct} (i.e., a decrease in $(1+\tau_{ct})\ (1+\tau_{ct+1})$) operates like an increase in τ_{kt}.

The following figure portrays the response to a foreseen increase in the consumption tax τ_c.

```
shocks = {
    'g': np.repeat(0.2, S + 1),
    'τ_c': np.concatenate((np.repeat(0.0, 10), np.repeat(0.2, S - 9))),
    'τ_k': np.repeat(0.0, S + 1)
}

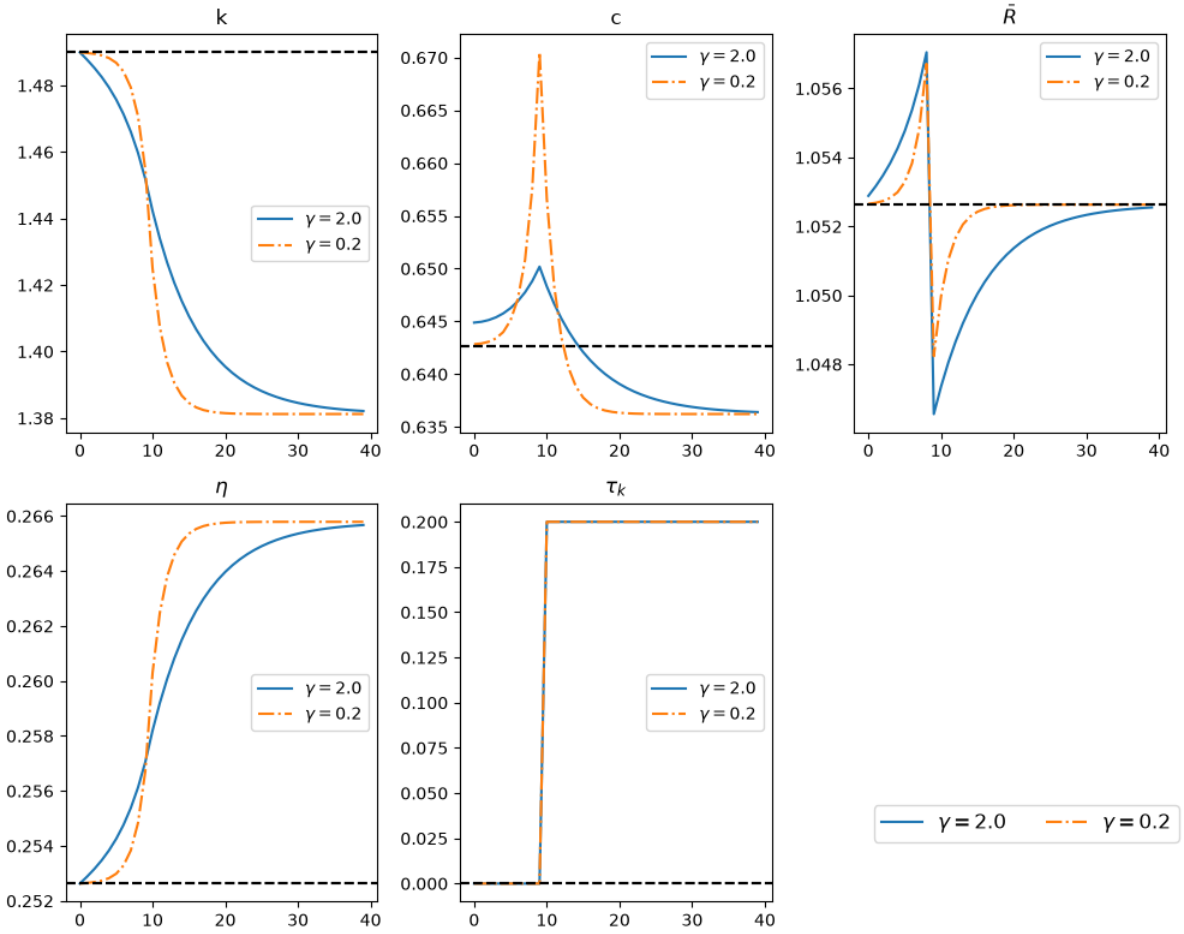
experiment_model(shocks, S, model,
                 solver=run_shooting,
                 plot_func=plot_results,
                 policy_shock='τ_c')
```

```
Steady-state capital: 1.4900
Steady-state consumption: 0.6426
----------------------------------------------------------------
Model: Model(β=0.95, γ=2.0, δ=0.2, α=0.33, A=1.0)
Optimal initial consumption c0 = 0.64927956146815433723018647051957883983 96
```

Evidently all variables in the figures above eventually return to their initial steady-state values.

The anticipated increase in τ_{ct} leads to variations in consumption and capital stock across time:

- At $t = 0$:
  - Anticipation of the increase in τ_c causes an *immediate jump in consumption*.
  - This is followed by a *consumption binge* that sends the capital stock downward until $t = T = 10$.
- Between $t = 0$ and $t = T = 10$:
  - The decline in the capital stock raises $\bar{R}$ over time.
  - The equilibrium conditions require the growth rate of consumption to rise until $t = T$.
- At $t = T = 10$:
  - The jump in τ_c depresses $\bar{R}$ below 1, causing a *sharp drop in consumption*.
- After $T = 10$:
  - The effects of anticipated distortion are over, and the economy gradually adjusts to the lower capital stock.
  - Capital must now rise, requiring *austerity* –consumption plummets after $t = T$, indicated by lower levels of consumption.
  - The interest rate gradually declines, and consumption grows at a diminishing rate along the path to the terminal steady-state.



Experiment 3: Foreseen once-and-for-all increase in τ_k from 0.0 to 0.2 in period 10

For the two γ values 2 and 0.2, the next figure shows the response to a foreseen permanent jump in τ_{kt} at $t = T = 10$.

```
shocks = {
    'g': np.repeat(0.2, S + 1),
    'τ_c': np.repeat(0.0, S + 1),
    'τ_k': np.concatenate((np.repeat(0.0, 10), np.repeat(0.2, S - 9)))
}

experiment_two_models(shocks, S, model, model_γ2,
                solver=run_shooting,
                 plot_func=plot_results,
                 policy_shock='τ_k')
```

```
Model 1 (γ=2.0): steady state k=1.4900, c=0.6426
Model 2 (γ=0.2): steady state k=1.4900, c=0.6426
----------------------------------------------------------------
Model: Model(β=0.95, γ=2.0, δ=0.2, α=0.33, A=1.0)
Optimal initial consumption c0 = 0.64488564003186084609963008227070148901 99
Model: Model(β=0.95, γ=0.2, δ=0.2, α=0.33, A=1.0)
Optimal initial consumption c0 = 0.64284077722405067274641526959215137674 15
```

The path of government expenditures remains fixed

- the increase in τ_{kt} is offset by a reduction in the present value of lump-sum taxes to keep the budget balanced.

The figure shows that:

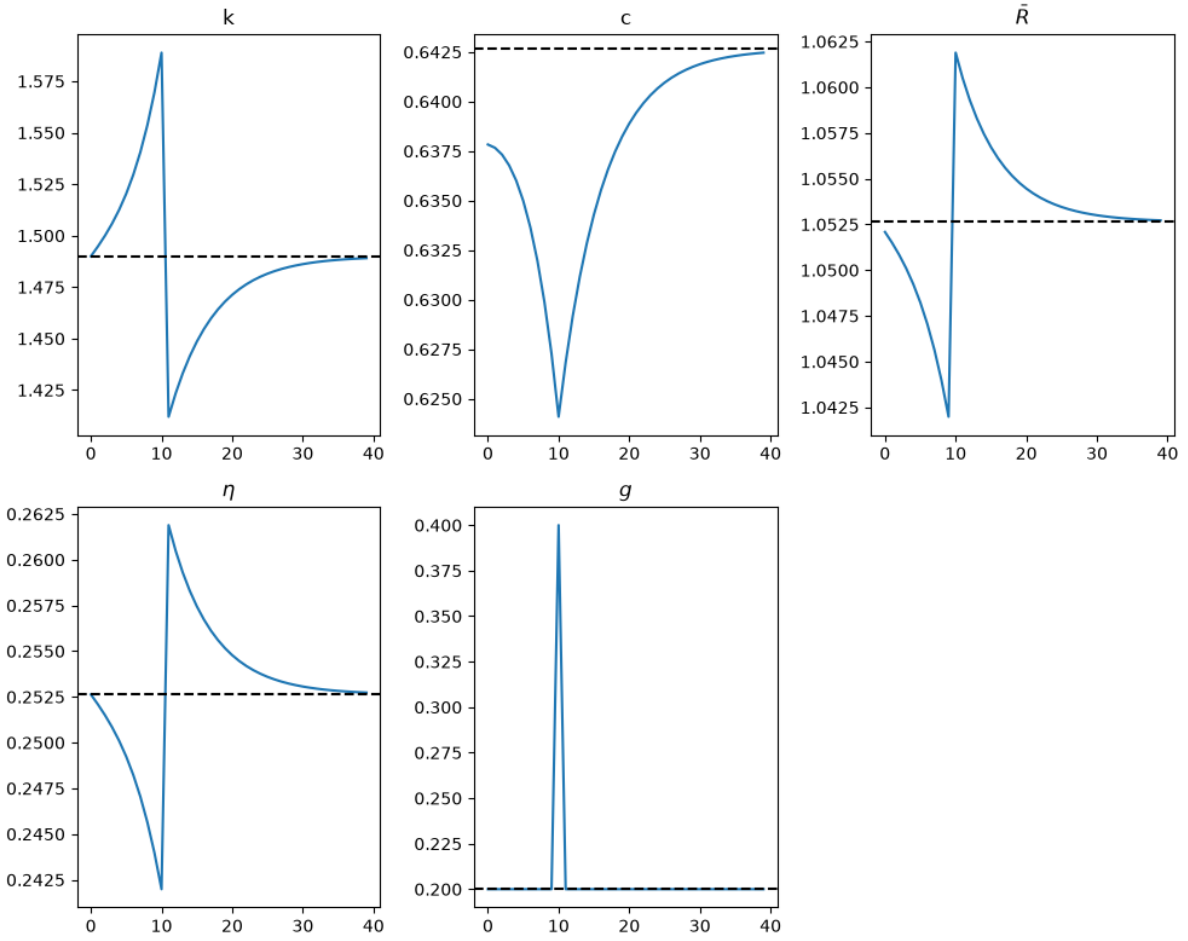
- Anticipation of the increase in τ_{kt} leads to immediate decline in capital stock due to increased current consumption and a growing consumption flow.
- $\bar{R}$ starts rising at $t = 0$ and peaks at $t = 9$, and at $t = 10$, $\bar{R}$ drops sharply due to the tax change.
  - Variations in $\bar{R}$ align with the impact of the tax increase at $t = 10$ on consumption across time.
- Transition dynamics push k_t (capital stock) toward a new, lower steady-state level. In the new steady state:
  - Consumption is lower due to reduced output from the lower capital stock.
  - Smoother consumption paths occur when $\gamma = 2$ than when $\gamma = 0.2$.

So far we have explored consequences of foreseen once-and-for-all changes in government policy. Next we describe some experiments in which there is a foreseen one-time change in a policy variable (a "pulse").

Experiment 4: Foreseen one-time increase in g from 0.2 to 0.4 in period 10, after which g returns to 0.2 forever

```
g_path = np.repeat(0.2, S + 1)
g_path[10] = 0.4

shocks = {
```



(continues on next page)

(continued from previous page)

```
    'g': g_path,
    'τ_c': np.repeat(0.0, S + 1),
    'τ_k': np.repeat(0.0, S + 1)
}

experiment_model(shocks, S, model,
                 solver=run_shooting,
                 plot_func=plot_results,
                 policy_shock='g')
```

```
Steady-state capital: 1.4900
Steady-state consumption: 0.6426
------------------------------------------------------------
Model: Model(β=0.95, γ=2.0, δ=0.2, α=0.33, A=1.0)
Optimal initial consumption c0 = 0.6378298012463969247674771825320030214755
```

The figure indicates how:

- Consumption:
  - Drops immediately upon announcement of the policy and continues to decline over time in anticipation of the one-time surge in g.
  - After the shock at $t = 10$, consumption begins to recover, rising at a diminishing rate toward its steady-state value.

- Capital and $\bar{R}$:
  - Before $t = 10$, capital accumulates as interest rate changes induce households to prepare for the anticipated increase in government spending.
  - At $t = 10$, the capital stock sharply decreases as the government consumes part of it.
  - $\bar{R}$ jumps above its steady-state value due to the capital reduction and then gradually declines toward its steady-state level.

113.9.3 Method 2: Residual Minimization

The second method involves minimizing residuals (i.e., deviations from equalities) of the following equations:

- The Euler equation (113.17):

$$1 = \beta \left(\frac{c_{t+1}}{c_t} \right)^{-\gamma} \frac{(1 + \tau_{ct})}{(1 + \tau_{ct+1})} \left[(1 - \tau_{kt+1})(\alpha A k_{t+1}^{\alpha - 1} - \delta) + 1 \right]$$

- The feasibility condition (113.15):

$$k_{t+1} = A k_t^{\alpha} + (1 - \delta) k_t - g_t - c_t.$$

```
# Euler's equation and feasibility condition
def euler_residual(c_t, c_tp1, τ_c_t, τ_c_tp1, τ_k_tp1, k_tp1, model, μ_tp1=1):
    """
    Computes the residuals for Euler's equation
    with optional growth model parameters μ_tp1.
    """
    R_bar = compute_R_bar(τ_c_t, τ_c_tp1, τ_k_tp1, k_tp1, model)

    c_expected = next_c(c_t, R_bar, model, μ_tp1)

    return c_expected / c_tp1 - 1.0

def feasi_residual(k_t, k_tm1, c_tm1, g_t, model, μ_t=1):
    """
    Computes the residuals for feasibility condition
    with optional growth model parameter μ_t.
    """
    k_t_expected = next_k(k_tm1, g_t, c_tm1, model, μ_t)
    return k_t_expected - k_t
```

The algorithm proceeds follows:

1. Find initial steady state k_0 based on the government plan at $t = 0$.
2. Initialize a sequence of initial guesses $\{\hat{c}_t, \hat{k}_t\}_{t=0}^{S}$.
3. Compute residuals l_a and l_k for $t = 0, \ldots, S$, as well as l_{k_0} for $t = 0$ and l_{k_S} for $t = S$:
   - Compute the Euler equation residual for $t = 0, \ldots, S$ using (113.17):

$$l_{ta} = \beta u'(c_{t+1}) \frac{(1 + \tau_{ct})}{(1 + \tau_{ct+1})} \left[(1 - \tau_{kt+1})(f'(k_{t+1}) - \delta) + 1 \right] - 1$$

   - Compute the feasibility condition residual for $t = 1, \ldots, S - 1$ using (113.15):

$$l_{tk} = k_{t+1} - f(k_t) - (1 - \delta) k_t + g_t + c_t$$

- Compute the residual for the initial condition for k_0 using (113.19) and the initial capital k_0:

$$l_{k_0} = 1 - \beta \left[(1 - \tau_{k0}) \left(f'(k_0) - \delta \right) + 1 \right]$$

- Compute the residual for the terminal condition for $t = S$ using (113.17) under the assumptions $c_t = c_{t+1} = c_S$, $k_t = k_{t+1} = k_S$, $\tau_{ct} = \tau_{ct+1} = \tau_{c_s}$, and $\tau_{kt} = \tau_{kt+1} = \tau_{k_s}$:

$$l_{k_S} = \beta u'(c_S) \frac{(1 + \tau_{c_s})}{(1 + \tau_{c_s})} \left[(1 - \tau_{k_s})(f'(k_S) - \delta) + 1 \right] - 1$$

4. Iteratively adjust guesses for $\{\hat{c}_t, \hat{k}_t\}_{t=0}^{S}$ to minimize residuals l_{k_0}, l_{ta}, l_{tk}, and l_{k_S} for $t = 0, \ldots, S$.

```
def compute_residuals(vars_flat, k_init, S, shock_paths, model):
    """
    Compute the residuals for the Euler equation and feasibility condition.
    """
    g, τ_c, τ_k, μ = (shock_paths[key] for key in ('g','τ_c','τ_k','μ'))
    k, c = vars_flat.reshape((S+1, 2)).T
    res = np.empty(2*S+2, dtype=float)

    # boundary condition on initial capital
    res[0] = k[0] - k_init

    # interior Euler and feasibility
    for t in range(S):
        res[2*t + 1] = euler_residual(
            c[t],    c[t+1],
            τ_c[t],  τ_c[t+1],
            τ_k[t+1],k[t+1],
            model, μ[t+1])
        res[2*t + 2] = feasi_residual(
            k[t+1], k[t], c[t],
            g[t],  model,
            μ[t+1])

    # terminal Euler condition at t=S
    res[-1] = euler_residual(
        c[S],   c[S],
        τ_c[S], τ_c[S],
        τ_k[S], k[S],
        model,
        μ[S])

    return res

def run_min(shocks, S, model, A_path=None):
    """
    Solve for the full (k,c) path by root-finding the residuals.
    """
    shocks['μ'] = shocks['μ'] if 'μ' in shocks else np.ones_like(shocks['g'])

    # compute the steady-state to serve as both initial capital and guess
    k_ss, c_ss = steady_states(
        model,
        shocks['g'][0],
```

(continues on next page)

(continued from previous page)

```
        shocks['τ_k'][0],
        shocks['μ'][0]  # =1 if no growth
    )

    # initial guess: flat at the steady-state
    guess = np.column_stack([
        np.full(S+1, k_ss),
        np.full(S+1, c_ss)
    ]).flatten()

    sol = root(
        compute_residuals,
        guess,
        args=(k_ss, S, shocks, model),
        tol=1e-8
    )

    return sol.x.reshape((S+1, 2))
```

We found that method 2 did not encounter numerical stability issues, so using `mp.mpf` is not necessary.

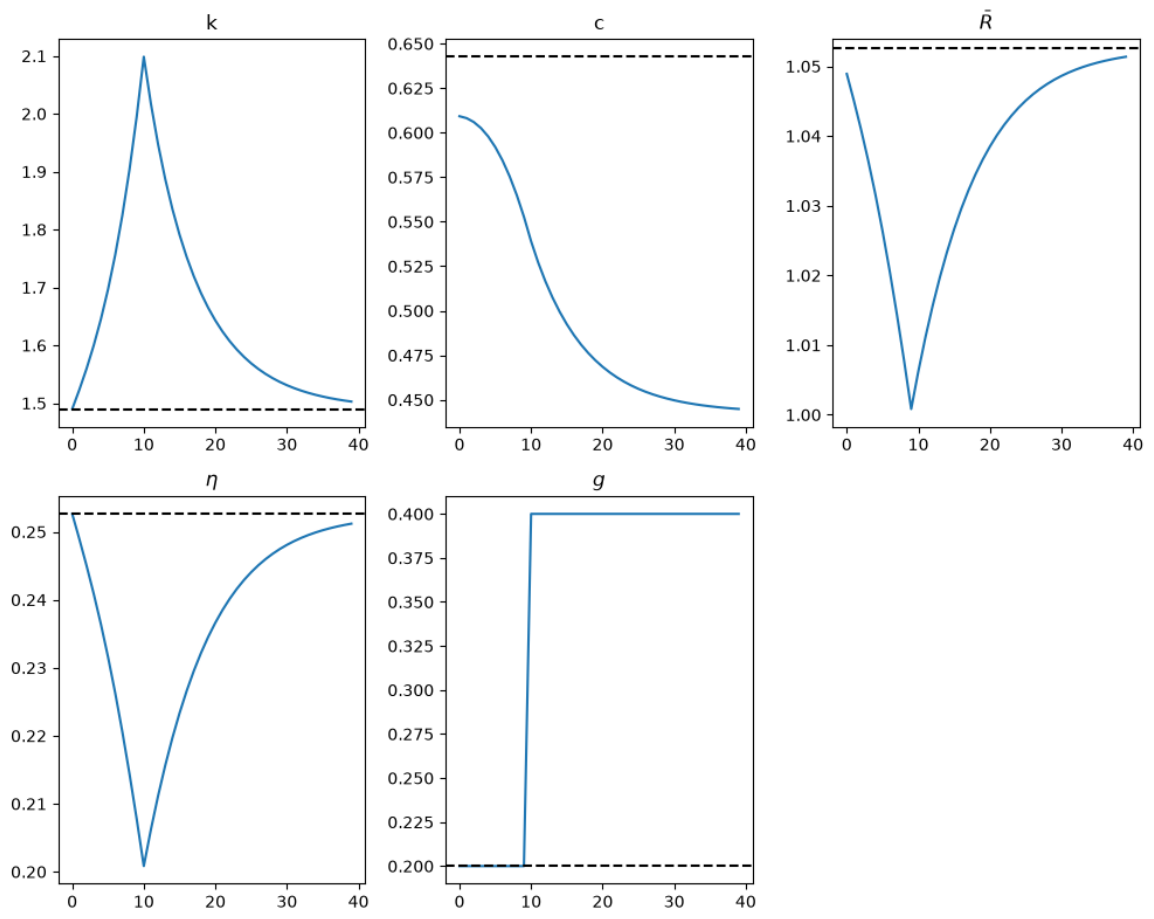
We leave as exercises replicating some of our experiments by using the second method.

Exercise 113.9.1

Replicate the plots of our four experiments using the second method of residual minimization:

1. A foreseen once-and-for-all increase in g from 0.2 to 0.4 occurring in period 10,
2. A foreseen once-and-for-all increase in τ_c from 0.0 to 0.2 occurring in period 10,
3. A foreseen once-and-for-all increase in τ_k from 0.0 to 0.2 occurring in period 10, and
4. A foreseen one-time increase in g from 0.2 to 0.4 in period 10, after which g reverts to 0.2 permanently,

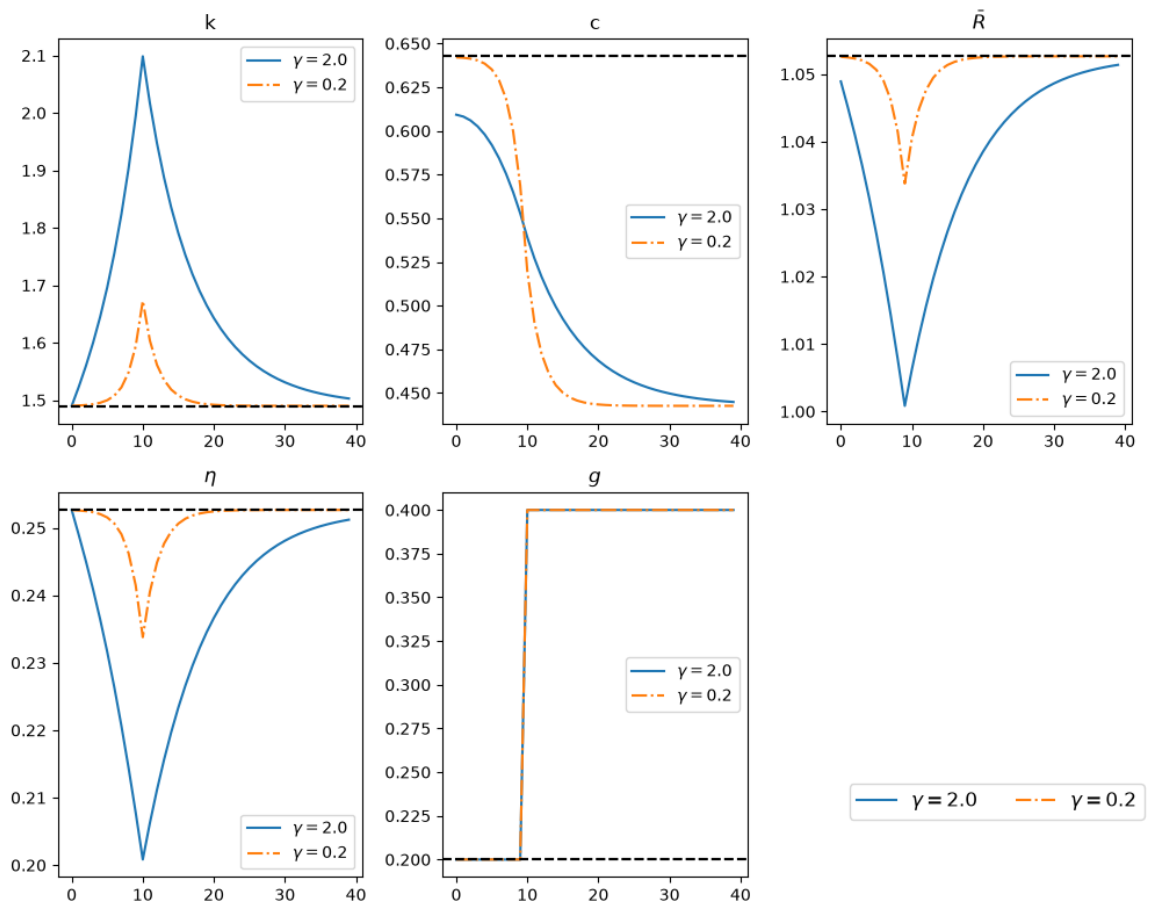
Solution



Here is one solution:

Experiment 1: Foreseen once-and-for-all increase in g from 0.2 to 0.4 in period 10

```
shocks = {
    'g': np.concatenate((np.repeat(0.2, 10), np.repeat(0.4, S - 9))),
    'τ_c': np.repeat(0.0, S + 1),
    'τ_k': np.repeat(0.0, S + 1)
}

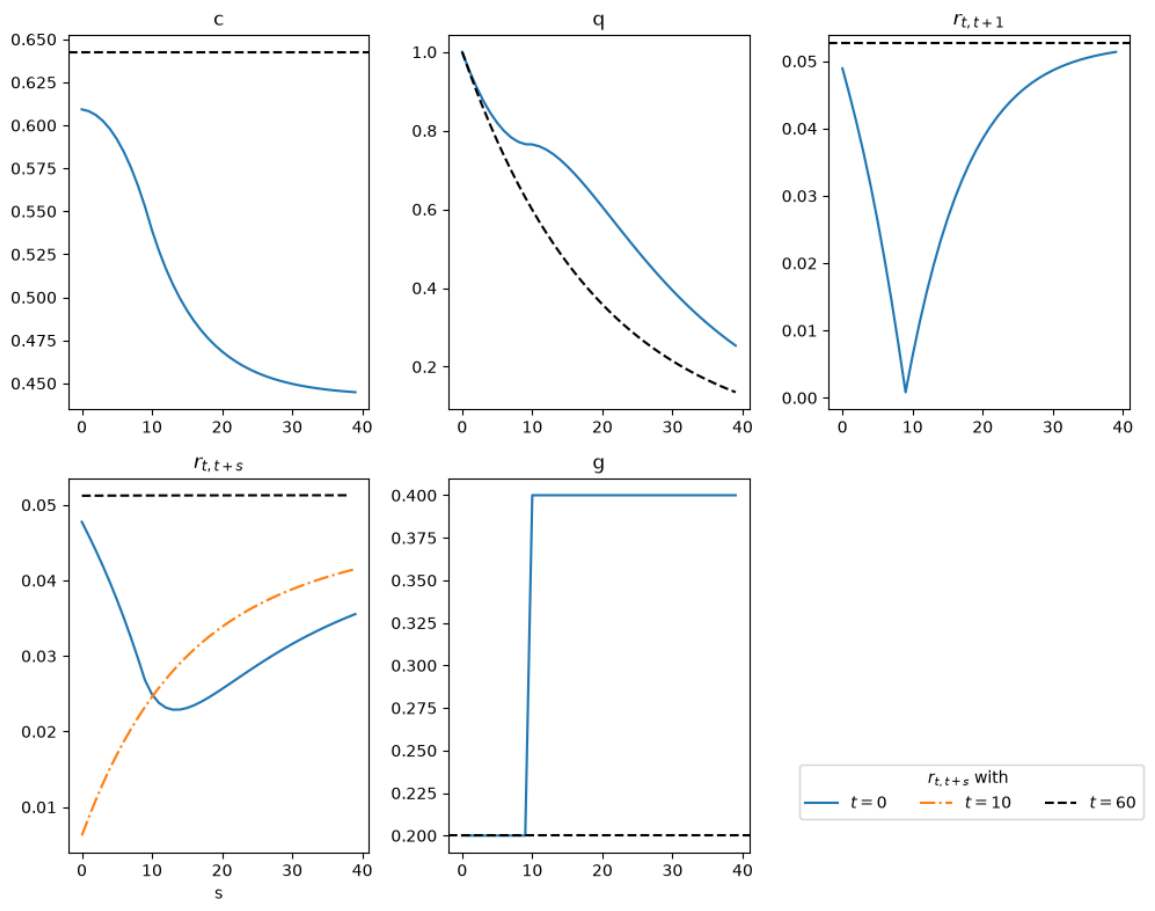


experiment_model(shocks, S, model, solver=run_min,
                 plot_func=plot_results,
                 policy_shock='g')
```

```
Steady-state capital: 1.4900
Steady-state consumption: 0.6426
----------------------------------------------------------------
```

```
experiment_two_models(shocks, S, model, model_y2,
                run_min, plot_results, 'g')
```

```
Model 1 (y=2.0): steady state k=1.4900, c=0.6426
Model 2 (y=0.2): steady state k=1.4900, c=0.6426
----------------------------------------------------------------
```



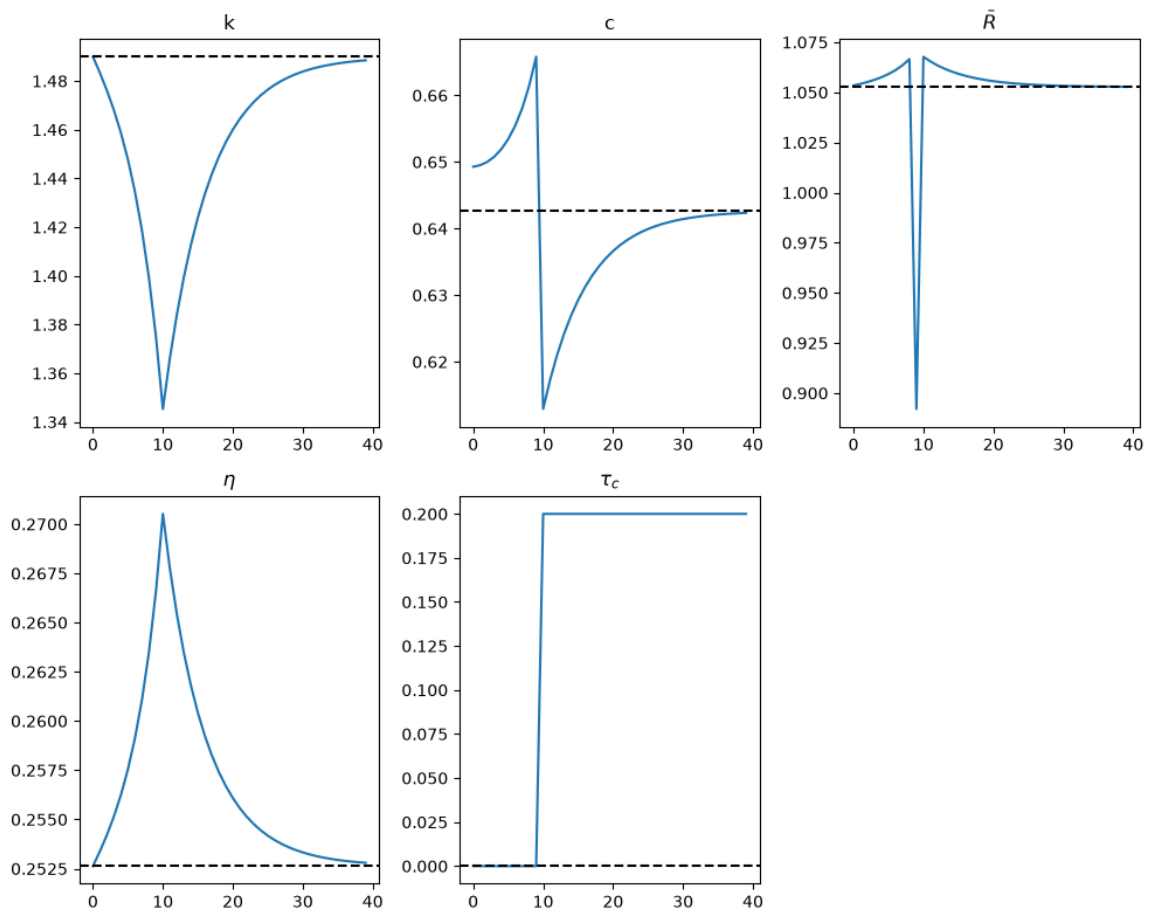
```
solution = run_min(shocks, S, model)

fig, axes = plt.subplots(2, 3, figsize=(10, 8))
axes = axes.flatten()

plot_prices(solution, c_ss_initial, 'g', axes, model, T=40)

for ax in axes[5:]:
    fig.delaxes(ax)

handles, labels = axes[3].get_legend_handles_labels()
fig.legend(handles, labels, title=r"$r_{t,t+s}$ with ", loc='lower right', ncol=3,␣
↪fontsize=10, bbox_to_anchor=(1, 0.1))
plt.tight_layout()
plt.show()
```

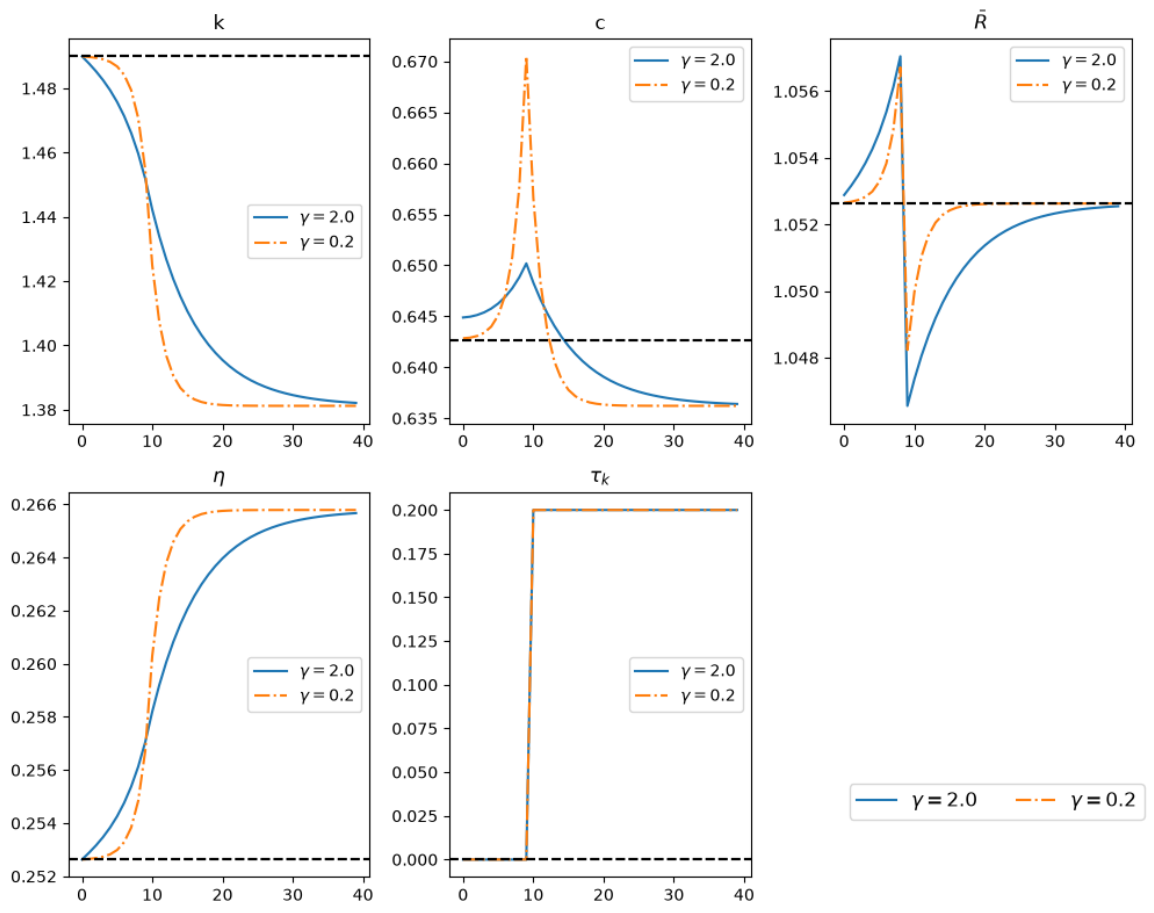


Experiment 2: Foreseen once-and-for-all increase in τ_c from 0.0 to 0.2 in period 10.

```
shocks = {
    'g': np.repeat(0.2, S + 1),
    'τ_c': np.concatenate((np.repeat(0.0, 10), np.repeat(0.2, S - 9))),
    'τ_k': np.repeat(0.0, S + 1)
}

experiment_model(shocks, S, model, solver=run_min,
                 plot_func=plot_results,
                 policy_shock='τ_c')
```

```
Steady-state capital: 1.4900
Steady-state consumption: 0.6426
----------------------------------------------------------------
```

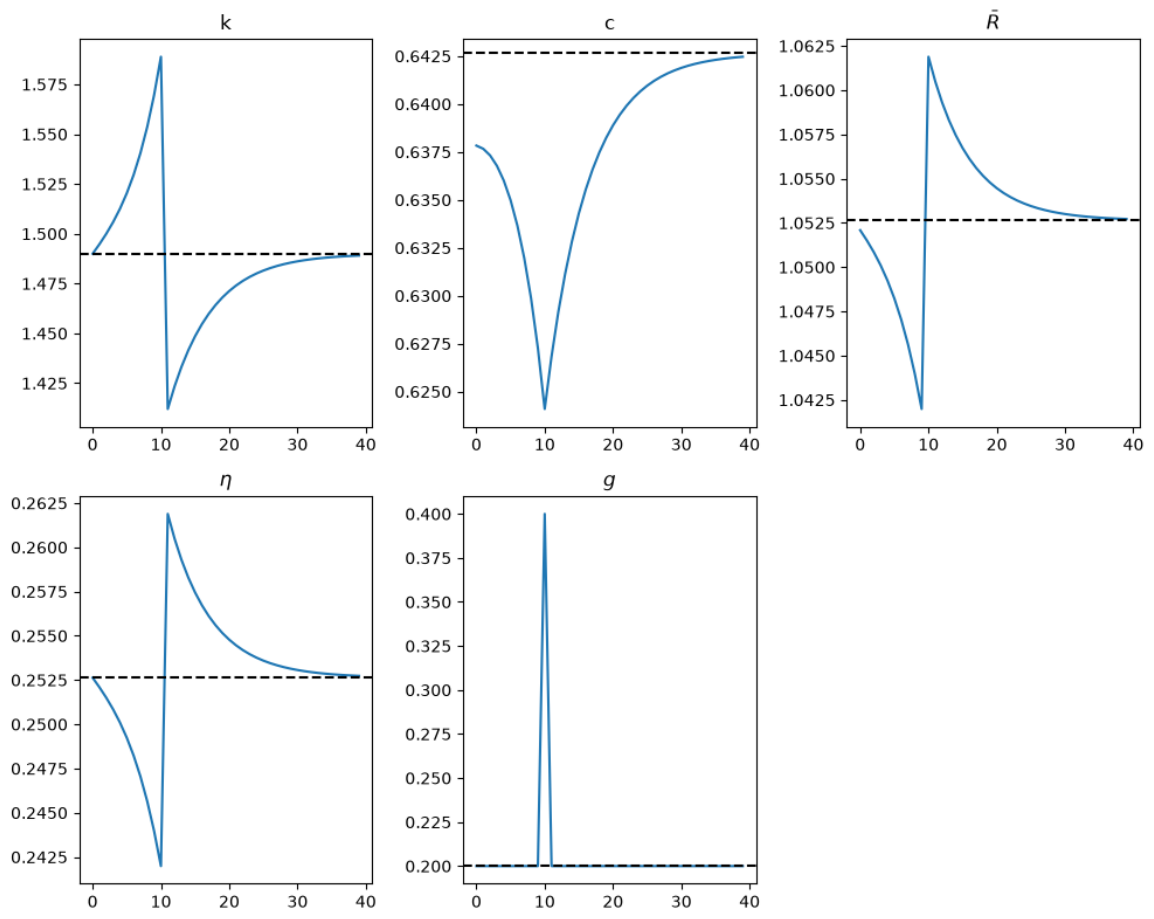


Experiment 3: Foreseen once-and-for-all increase in τ_k from 0.0 to 0.2 in period 10.

```
shocks = {
    'g': np.repeat(0.2, S + 1),
    'τ_c': np.repeat(0.0, S + 1),
    'τ_k': np.concatenate((np.repeat(0.0, 10), np.repeat(0.2, S - 9)))
}

experiment_two_models(shocks, S, model, model_γ2,
                solver=run_min,
                 plot_func=plot_results,
                 policy_shock='τ_k')
```

```
Model 1 (γ=2.0): steady state k=1.4900, c=0.6426
Model 2 (γ=0.2): steady state k=1.4900, c=0.6426
----------------------------------------------------------------
```



Experiment 4: Foreseen one-time increase in g from 0.2 to 0.4 in period 10, after which g returns to 0.2 forever

```
g_path = np.repeat(0.2, S + 1)
g_path[10] = 0.4

shocks = {
    'g': g_path,
    'τ_c': np.repeat(0.0, S + 1),
    'τ_k': np.repeat(0.0, S + 1)
}

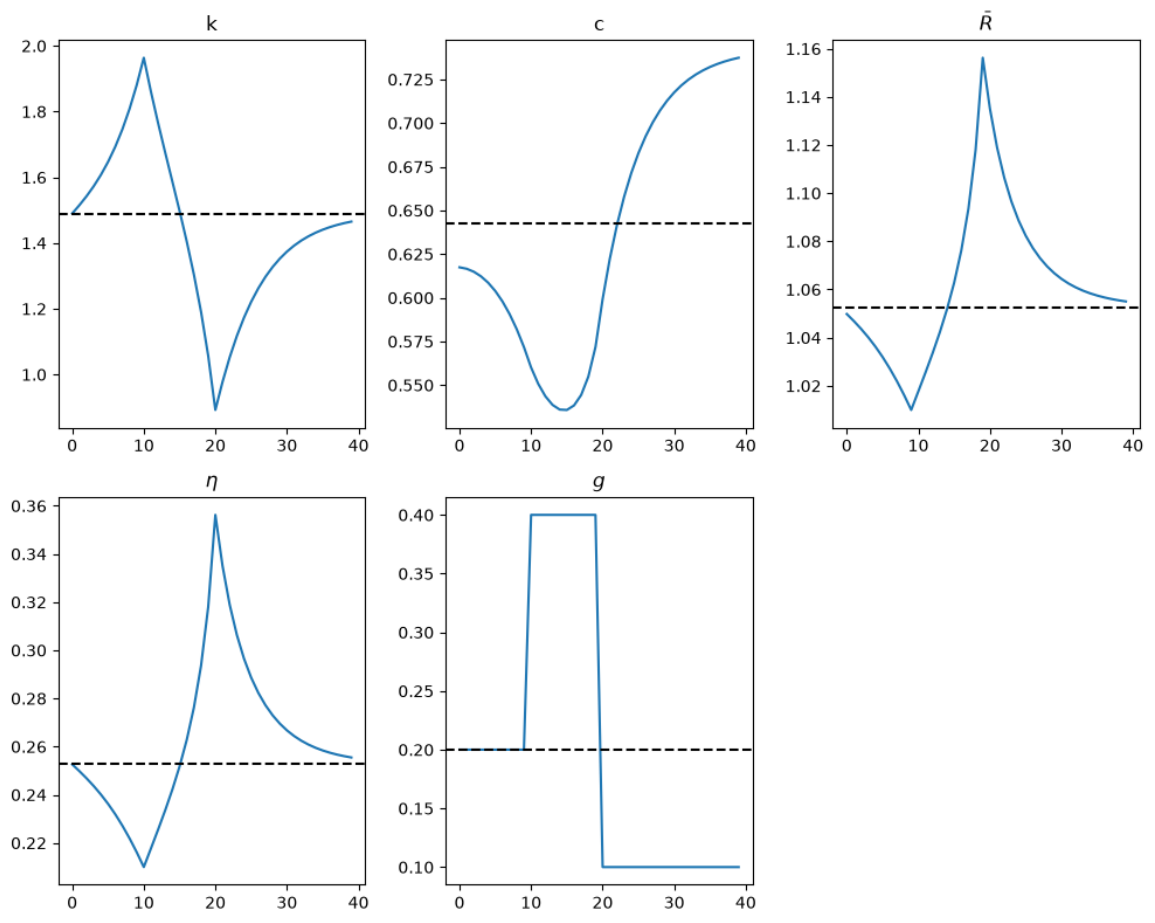
experiment_model(shocks, S, model, solver=run_min,
                 plot_func=plot_results,
                 policy_shock='g')
```

```
Steady-state capital: 1.4900
Steady-state consumption: 0.6426
------------------------------------------------------------------
```

Exercise 113.9.2

Design a new experiment where the government expenditure g increases from 0.2 to 0.4 in period 10, and then decreases to 0.1 in period 20 permanently.

Solution



Here is one solution:

```
g_path = np.repeat(0.2, S + 1)
g_path[10:20] = 0.4
g_path[20:] = 0.1

shocks = {
    'g': g_path,
    'τ_c': np.repeat(0.0, S + 1),
    'τ_k': np.repeat(0.0, S + 1)
}

experiment_model(shocks, S, model, solver=run_min,
                 plot_func=plot_results,
                 policy_shock='g')
```

```
Steady-state capital: 1.4900
Steady-state consumption: 0.6426
------------------------------------------------------------------
```

113.10 Exogenous growth

In the previous section, we considered a model without exogenous growth.

We set the term A_t in the production function to a constant by setting $A_t = 1$ for all t.

Now we are ready to consider growth.

To incorporate growth, we modify the production function to be

$$Y_t = F(K_t, A_t n_t)$$

where Y_t is aggregate output, N_t is total employment, A_t is labor-augmenting technical change, and $F(K, AN)$ is the same linearly homogeneous production function as before.

We assume that A_t follows the process

$$A_{t+1} = \mu_{t+1} A_t \tag{113.25}$$

and that $\mu_{t+1} = \bar{\mu} > 1$.

```
# Set the constant A parameter to None
model = create_model(A=None)
```

```
def compute_A_path(A0, shocks, S=100):
    """
    Compute A path over time.
    """
    A_path = np.full(S + 1, A0)
    for t in range(1, S + 1):
        A_path[t] = A_path[t-1] * shocks['μ'][t-1]
    return A_path
```

113.10.1 Inelastic Labor Supply

By linear homogeneity, the production function can be expressed as

$$y_t = f(k_t)$$

where $f(k) = F(k, 1) = k^\alpha$ and $k_t = \frac{K_t}{n_t A_t}$, $y_t = \frac{Y_t}{n_t A_t}$.

k_t and y_t are measured per unit of "effective labor" $A_t n_t$.

We also let $c_t = \frac{C_t}{A_t n_t}$ and $g_t = \frac{G_t}{A_t n_t}$, where C_t and G_t are total consumption and total government expenditures.

We continue to consider the case of inelastic labor supply.

Based on this, feasibility can be summarized by the following modified version of equation (113.15):

$$k_{t+1} = \mu_{t+1}^{-1}[f(k_t) + (1 - \delta)k_t - g_t - c_t] \tag{113.26}$$

Again, by the properties of a linearly homogeneous production function, we have

$$\eta_t = F_k(k_t, 1) = f'(k_t), w_t = F_n(k_t, 1) = f(k_t) - f'(k_t)k_t$$

Since per capita consumption is now $c_t A_t$, the counterpart to the Euler equation (113.17) is

$$u'(c_t A_t) = \beta u'(c_{t+1} A_{t+1}) \frac{(1 + \tau_{ct})}{(1 + \tau_{ct+1})}[(1 - \tau_{kt+1})(f'(k_{t+1}) - \delta) + 1]. \tag{113.27}$$

$\bar{R}_{t+1}$ continues to be defined by (113.21), except that now k_t is capital per effective unit of labor.

Thus, substituting (113.21), (113.27) becomes

$$u'(c_t A_t) = \beta u'(c_{t+1} A_{t+1}) \bar{R}_{t+1}$$

Assuming that the household's utility function is the same as before, we have

$$(c_t A_t)^{-\gamma} = \beta (c_{t+1} A_{t+1})^{-\gamma} \bar{R}_{t+1}$$

Thus, the counterpart to (113.24) is

$$c_{t+1} = c_t \left[\beta \bar{R}_{t+1}\right]^{\frac{1}{\gamma}} \mu_{t+1}^{-1} \tag{113.28}$$

113.10.2 Steady State

In a steady state, $c_{t+1} = c_t$. Then (113.27) becomes

$$1 = \mu^{-\gamma}\beta[(1-\tau_k)(f'(k)-\delta)+1] \tag{113.29}$$

from which we can compute that the steady-state level of capital per unit of effective labor satisfies

$$f'(k) = \delta + (\frac{\frac{1}{\beta}\mu^{\gamma}-1}{1-\tau_k}) \tag{113.30}$$

and that

$$\bar{R} = \frac{\mu^{\gamma}}{\beta} \tag{113.31}$$

The steady-state level of consumption per unit of effective labor can be found using (113.26):

$$c = f(k) + (1-\delta-\mu)k - g$$

Since the algorithm and plotting routines are the same as before, we include the steady-state calculations and shooting routine in the section *Python Code*.

113.10.3 Shooting Algorithm

Now we can apply the shooting algorithm to compute equilibrium. We augment the vector of shock variables by including μ_t, then proceed as before.

113.10.4 Experiments

Let's run some experiments:

1. A foreseen once-and-for-all increase in μ from 1.02 to 1.025 in period 10
2. An unforeseen once-and-for-all increase in μ to 1.025 in period 0

Experiment 1: A foreseen increase in μ from 1.02 to 1.025 at t=10

The figures below show the effects of a permanent increase in productivity growth μ from 1.02 to 1.025 at t=10.

They now measure c and k in effective units of labor.

```
shocks = {
    'g': np.repeat(0.2, S + 1),
    'τ_c': np.repeat(0.0, S + 1),
    'τ_k': np.repeat(0.0, S + 1),
    'μ': np.concatenate((np.repeat(1.02, 10), np.repeat(1.025, S - 9)))
}

A_path = compute_A_path(1.0, shocks, S)

k_ss_initial, c_ss_initial = steady_states(model,
                                           shocks['g'][0],
                                           shocks['τ_k'][0],
                                           shocks['μ'][0]
```

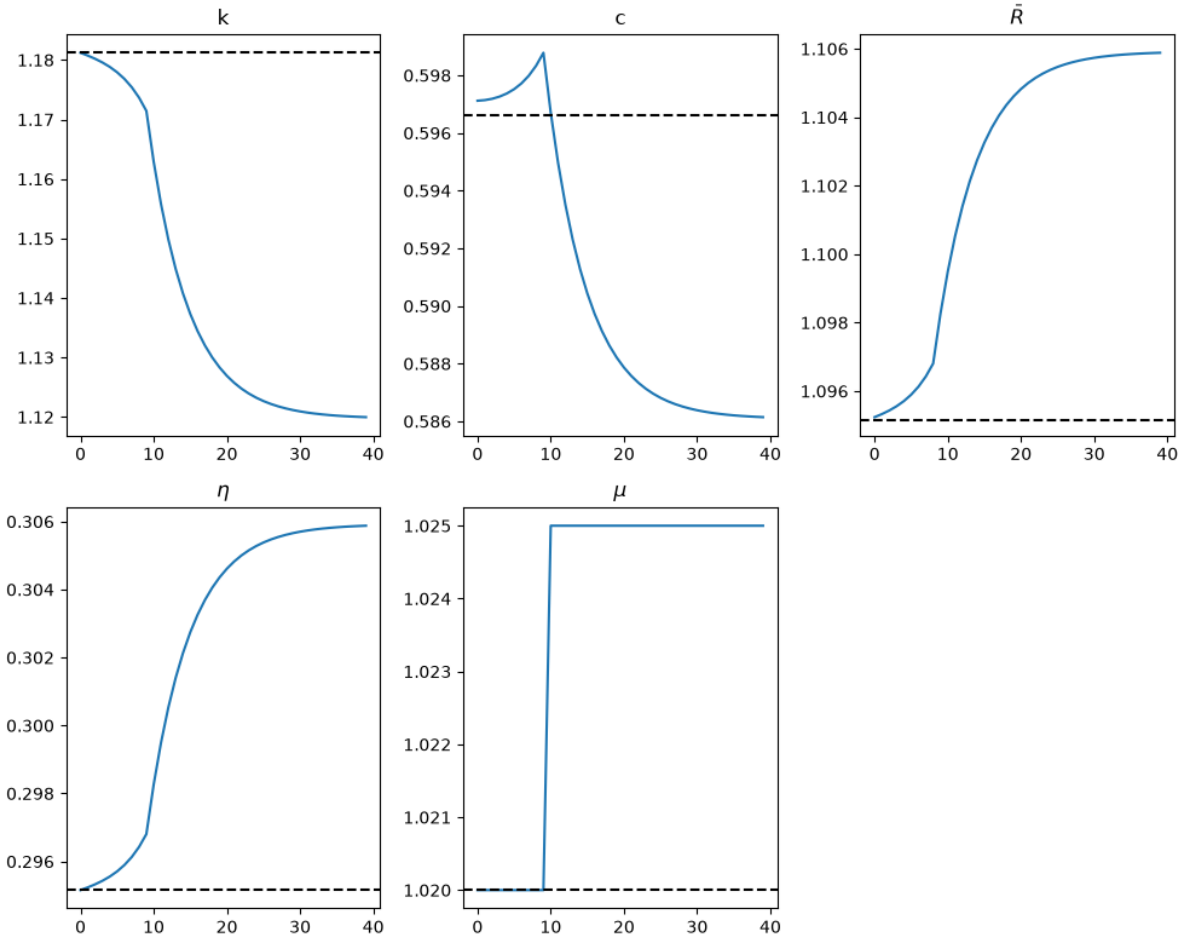
(continues on next page)

(continued from previous page)

```
                                        )

print(f"Steady-state capital: {k_ss_initial:.4f}")
print(f"Steady-state consumption: {c_ss_initial:.4f}")

# Run the shooting algorithm with the A_path parameter
solution = run_shooting(shocks, S, model, A_path)



fig, axes = plt.subplots(2, 3, figsize=(10, 8))
axes = axes.flatten()

plot_results(solution, k_ss_initial,
             c_ss_initial, shocks, 'μ', axes, model,
             A_path, T=40)

for ax in axes[5:]:
    fig.delaxes(ax)

plt.tight_layout()
plt.show()
```

```
Steady-state capital: 1.1812
Steady-state consumption: 0.5966
Model: Model(β=0.95, γ=2.0, δ=0.2, α=0.33, A=None)
Optimal initial consumption c0 = 0.597118474934446239627091833718360733991 9
```

The results in the figures are mainly driven by (113.29) and imply that a permanent increase in μ will lead to a decrease in the steady-state value of capital per unit of effective labor.

The figures indicate the following:

- As capital becomes more efficient, even with less of it, consumption per capita can be raised.
- Consumption smoothing drives an *immediate jump in consumption* in anticipation of the increase in μ.
- The increased productivity of capital leads to an increase in the gross return $\bar{R}$.
- Perfect foresight makes the effects of the increase in the growth of capital precede it, with the effect visible at $t = 0$.

Experiment 2: An unforeseen increase in μ from 1.02 to 1.025 at t=0

The figures below show the effects of an immediate jump in μ to 1.025 at t=0.

```
shocks = {
    'g': np.repeat(0.2, S + 1),
    'τ_c': np.repeat(0.0, S + 1),
    'τ_k': np.repeat(0.0, S + 1),
    'μ': np.concatenate((np.repeat(1.02, 1), np.repeat(1.025, S)))
}

A_path = compute_A_path(1.0, shocks, S)
```

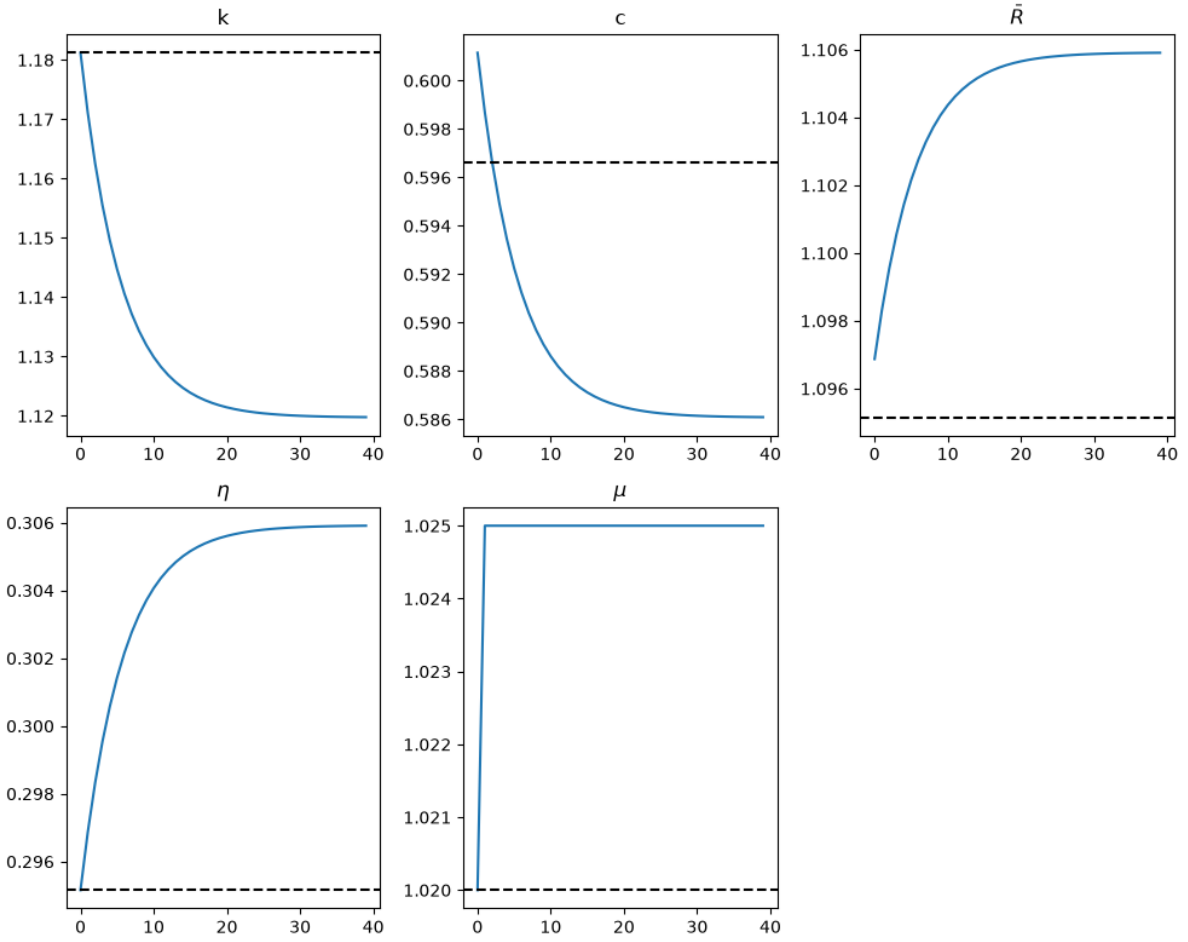
(continues on next page)

(continued from previous page)

```
k_ss_initial, c_ss_initial = steady_states(model,
                                           shocks['g'][0],
                                           shocks['τ_k'][0],
                                           shocks['μ'][0]
                                          )

print(f"Steady-state capital: {k_ss_initial:.4f}")
print(f"Steady-state consumption: {c_ss_initial:.4f}")

# Run the shooting algorithm with the A_path parameter
solution = run_shooting(shocks, S, model, A_path)



fig, axes = plt.subplots(2, 3, figsize=(10, 8))
axes = axes.flatten()

plot_results(solution, k_ss_initial,
             c_ss_initial, shocks, 'μ', axes, model, A_path, T=40)

for ax in axes[5:]:
    fig.delaxes(ax)

plt.tight_layout()
plt.show()
```

```
Steady-state capital: 1.1812
Steady-state consumption: 0.5966
Model: Model(β=0.95, γ=2.0, δ=0.2, α=0.33, A=None)
Optimal initial consumption c0 = 0.601149493043064115039588375310958831663 8
```

Again, we can collect the procedures used above into a function that runs the solver and draws plots for a given experiment.

```
def experiment_model(shocks, S, model, A_path, solver, plot_func, policy_shock, T=40):
    """
    Run the shooting algorithm given a model and plot the results.
    """
    k0, c0 = steady_states(model, shocks['g'][0], shocks['τ_k'][0], shocks['μ'][0])

    print(f"Steady-state capital: {k0:.4f}")
    print(f"Steady-state consumption: {c0:.4f}")
    print('-'*64)

    fig, axes = plt.subplots(2, 3, figsize=(10, 8))
    axes = axes.flatten()

    solution = solver(shocks, S, model, A_path)
    plot_func(solution, k0, c0,
              shocks, policy_shock, axes, model, A_path, T=T)

    for ax in axes[5:]:
        fig.delaxes(ax)

    plt.tight_layout()
    plt.show()
```

```
shocks = {
    'g': np.repeat(0.2, S + 1),
    'τ_c': np.repeat(0.0, S + 1),
    'τ_k': np.repeat(0.0, S + 1),
    'μ': np.concatenate((np.repeat(1.02, 1), np.repeat(1.025, S)))
}

experiment_model(shocks, S, model, A_path, run_shooting, plot_results, 'μ')
```

```
Steady-state capital: 1.1812
Steady-state consumption: 0.5966
----------------------------------------------------------------------
Model: Model(β=0.95, γ=2.0, δ=0.2, α=0.33, A=None)
Optimal initial consumption c0 = 0.601149493043064115039588375310958831663 8
```

The figures show that:

- The paths of all variables are now smooth due to the absence of feedforward effects.
- Capital per effective unit of labor gradually declines to a lower steady-state level.
- Consumption per effective unit of labor jumps immediately and then declines smoothly toward its lower steady-state value.
- The after-tax gross return $\bar{R}$ once again co-moves with the consumption growth rate, verifying the Euler equation (113.29).

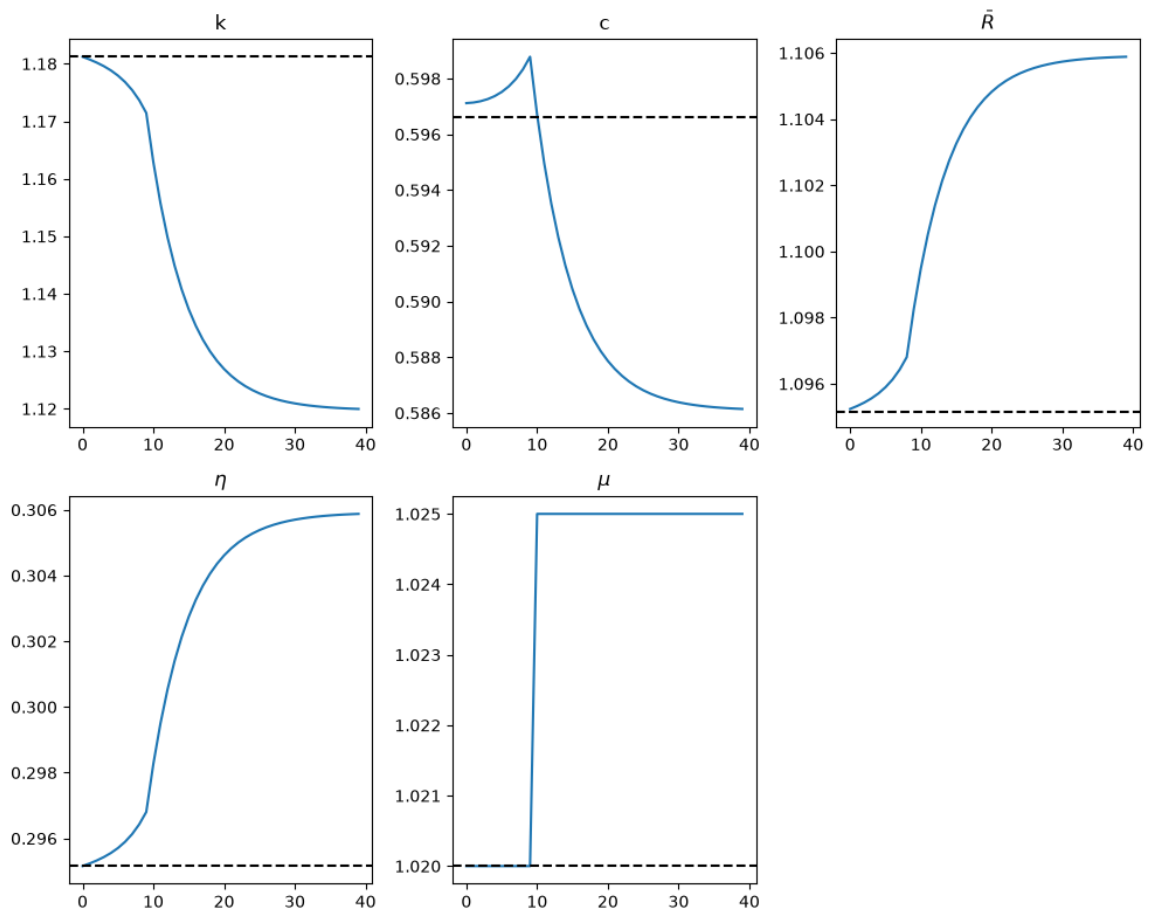
Exercise 113.10.1

Replicate the plots of our two experiments using the second method of residual minimization:

1. A foreseen increase in μ from 1.02 to 1.025$ at t=10
2. An unforeseen increase in μ from 1.02 to 1.025$ at t=0

Solution

Here is one solution:



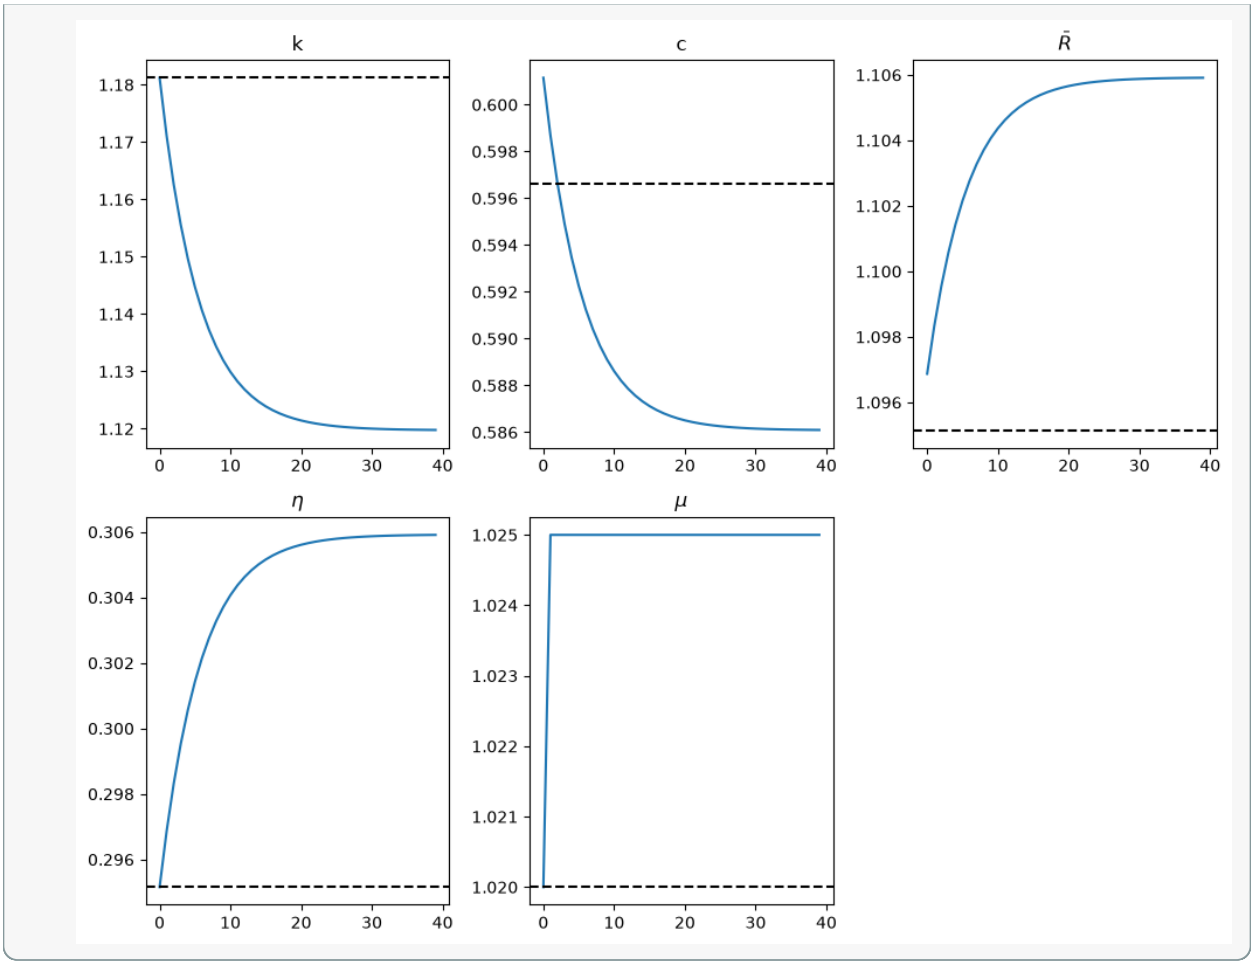
Experiment 1: A foreseen increase in μ from 1.02 to 1.025 at $t = 10$

```
shocks = {
    'g': np.repeat(0.2, S + 1),
    'τ_c': np.repeat(0.0, S + 1),
    'τ_k': np.repeat(0.0, S + 1),
    'μ': np.concatenate((np.repeat(1.02, 10), np.repeat(1.025, S - 9)))
}

A_path = compute_A_path(1.0, shocks, S)

experiment_model(shocks, S, model, A_path, run_min, plot_results, 'μ')
```

```
Steady-state capital: 1.1812
Steady-state consumption: 0.5966
----------------------------------------------------------------------
```



Experiment 2: An unforeseen increase in μ from 1.02 to 1.025 at $t = 0$

```
shocks = {
    'g': np.repeat(0.2, S + 1),
    'τ_c': np.repeat(0.0, S + 1),
    'τ_k': np.repeat(0.0, S + 1),
    'μ': np.concatenate((np.repeat(1.02, 1), np.repeat(1.025, S)))
}

experiment_model(shocks, S, model, A_path, run_min, plot_results, 'μ')
```

```
Steady-state capital: 1.1812
Steady-state consumption: 0.5966
------------------------------------------------------------------
```

In this this sequel *Two-Country Model with Distorting Taxes*, we study a two-country version of our one-country model that is closely related to Mendoza and Tesar [1998].

CHAPTER

FOUR

TWO-COUNTRY MODEL WITH DISTORTING TAXES

114.1 Overview

This lecture is a sequel to this QuantEcon lecture *Cass-Koopmans Model with Distorting Taxes* in which we studied consequences of foreseen fiscal and technology shocks on competitive equilibrium prices and quantities in a nonstochastic version of a Cass-Koopmans growth model like the one described in this QuantEcon lecture *Cass-Koopmans Competitive Equilibrium*.

Here we study a two-country version of that model.

We construct it by putting instances of two *Cass-Koopmans Competitive Equilibrium* economies together back to back, and then opening international trade in some commodities, but not in others.

This lets us focus on some of the issues studied by Mendoza and Tesar [1998].

Let's start with some imports:

```
import numpy as np
from scipy.optimize import root
import matplotlib.pyplot as plt
from collections import namedtuple
from mpmath import mp, mpf
from warnings import warn

# Set the precision
mp.dps = 40
mp.pretty = True
```

114.2 A Two-Country Cass-Koopmans Model

This section describes a two-country version of the basic model of *The Economy*.

The model has a structure similar to ones used in the international real business cycle literature and is in the spirit of an analysis of distorting taxes by Mendoza and Tesar [1998].

We allow two countries to trade goods and claims on future goods, but not labor.

Both countries have production technologies, and consumers in each country can hold capital in either country, subject to different tax treatments.

We denote variables in the second country with asterisks (*).

Households in both countries maximize lifetime utility:

$$\sum_{t=0}^{\infty} \beta^t u(c_t) \quad \text{and} \quad \sum_{t=0}^{\infty} \beta^t u(c_t^*),$$

where $u(c) = \frac{c^{1-\gamma}}{1-\gamma}$ with $\gamma > 0$.

There are Cobb-Douglas functions with identical technology parameters in the two countries.

The world resource constraint in this two-country economy is:

$$(c_t + c_t^*) + (g_t + g_t^*) + (k_{t+1} - (1-\delta)k_t) + (k_{t+1}^* - (1-\delta)k_t^*) = f(k_t) + f(k_t^*)$$

which combines the feasibility constraints for the two countries.

Later, we will use this constraint as a global feasibility constraint in our computation.

To connect the two countries, we need to specify how capital flows across borders and how taxes are levied in different jurisdictions.

114.2.1 Capital Mobility and Taxation

A consumer in country one can hold capital in either country but pays taxes on rentals from foreign holdings of capital at the rate set by the foreign country.

Residents in both countries can purchase consumption at date t at a common Arrow-Debreu price q_t. We assume capital markets are complete.

Let B_t^f be the amount of time t goods that the representative domestic consumer raises by issuing a one-period IOU to the representative foreign consumer.

So $B_t^f > 0$ indicates the domestic consumer is borrowing from abroad at t, and $B_t^f < 0$ indicates the domestic consumer is lending abroad at t.

Hence, the budget constraint of a representative consumer in country one is:

$$\sum_{t=0}^{\infty} q_t \left(c_t + (k_{t+1} - (1-\delta)k_t) + (\tilde{k}_{t+1} - (1-\delta)\tilde{k}_t) + R_{t-1,t} B_{t-1}^f \right) \leq$$

$$\sum_{t=0}^{\infty} q_t \left((\eta_t - \tau_{kt}(\eta_t - \delta))k_t + (\eta_t^* - \tau_{kt}^*(\eta_t^* - \delta))\tilde{k}_t + (1-\tau_{nt}) w_t n_t - \tau_{ht} + B_t^f \right).$$

No-arbitrage conditions for k_t and $\tilde{k}_t$ for $t \geq 1$ imply

$$q_{t-1} = [(1-\tau_{kt})(\eta_t - \delta) + 1] q_t,$$
$$q_{t-1} = [(1-\tau_{kt}^*)(\eta_t^* - \delta) + 1] q_t,$$

which together imply that after-tax rental rates on capital are equalized across the two countries:

$$(1-\tau_{kt}^*)(\eta_t^* - \delta) = (1-\tau_{kt})(\eta_t - \delta).$$

The no-arbitrage conditions for B_t^f for $t \geq 0$ are $q_t = q_{t+1} R_{t+1,t}$, which implies that

$$q_{t-1} = q_t R_{t-1,t}$$

for $t \geq 1$.

Since domestic capital, foreign capital, and consumption loans bear the same rates of return, portfolios are indeterminate.

We can set holdings of foreign capital equal to zero in each country if we allow B_t^f to be nonzero.

This way of resolving portfolio indeterminacy is convenient because it reduces the number of initial conditions we need to specify.

Therefore, we set holdings of foreign capital equal to zero in both countries while allowing international lending.

Given an initial level B_{-1}^f of debt from the domestic country to the foreign country, and where $R_{t-1,t} = \frac{q_{t-1}}{q_t}$, international debt dynamics satisfy

$$B_t^f = R_{t-1,t} B_{t-1}^f + c_t + (k_{t+1} - (1-\delta)k_t) + g_t - f(k_t)$$

```
def Bf_path(k, c, g, model):
    """
    Compute B^{f}_t:
      Bf_t = R_{t-1} Bf_{t-1} + c_t + (k_{t+1}-(1-δ)k_t) + g_t - f(k_t)
    with Bf_0 = 0.
    """
    S = len(c) - 1
    R = c[:-1]**(-model.γ) / (model.β * c[1:]**(-model.γ))

    Bf = np.zeros(S + 1)
    for t in range(1, S + 1):
        inv = k[t] - (1 - model.δ) * k[t-1]
        Bf[t] = (
            R[t-1] * Bf[t-1] + c[t] + inv + g[t-1]
            - f(k[t-1], model))
    return Bf

def Bf_ss(c_ss, k_ss, g_ss, model):
    """
    Compute the steady-state B^f
    """
    R_ss   = 1.0 / model.β
    inv_ss = model.δ * k_ss
    num    = c_ss + inv_ss + g_ss - f(k_ss, model)
    den    = 1.0 - R_ss
    return num / den
```

and

$$c_t^* + (k_{t+1}^* - (1-\delta)k_t^*) + g_t^* - R_{t-1,t} B_{t-1}^f = f(k_t^*) - B_t^f.$$

The firms' first-order conditions in the two countries are:

$$\begin{aligned} \eta_t &= f'(k_t), \quad w_t = f(k_t) - k_t f'(k_t) \\ \eta_t^* &= f'(k_t^*), \quad w_t^* = f(k_t^*) - k_t^* f'(k_t^*). \end{aligned}$$

International trade in goods establishes:

$$\frac{q_t}{\beta^t} = \frac{u'(c_t)}{1+\tau_{ct}} = \mu^* \frac{u'(c_t^*)}{1+\tau_{ct}^*},$$

where μ^* is a nonnegative number that is a function of the Lagrange multiplier on the budget constraint for a consumer in country $*$.

We have normalized the Lagrange multiplier on the budget constraint of the domestic country to set the corresponding μ for the domestic country to unity.

```
def compute_rs(c_t, c_tp1, c_s_t, c_s_tp1, τc_t,
               τc_tp1, τc_s_t, τc_s_tp1, model):
    """
    Compute international risk sharing after trade starts.
    """

    return (c_t**(-model.γ)/(1+τc_t)) * ((1+τc_s_t)/c_s_t**(-model.γ)) - (
        c_tp1**(-model.γ)/(1+τc_tp1)) * ((1+τc_s_tp1)/c_s_tp1**(-model.γ))
```

Equilibrium requires that the following two national Euler equations be satisfied for $t \geq 0$:

$$u'(c_t) = \beta u'(c_{t+1}) \left[(1 - \tau_{kt+1})(f'(k_{t+1}) - \delta) + 1\right] \left[\frac{1 + \tau_{ct+1}}{1 + \tau_{ct}}\right],$$

$$u'(c_t^*) = \beta u'(c_{t+1}^*) \left[(1 - \tau_{kt+1}^*)(f'(k_{t+1}^*) - \delta) + 1\right] \left[\frac{1 + \tau_{ct+1}^*}{1 + \tau_{ct}^*}\right].$$

The following code computes both the domestic and foreign Euler equations.

Since they have the same form but use different variables, we can write a single function that handles both cases.

```
def compute_euler(c_t, c_tp1, τc_t,
                  τc_tp1, τk_tp1, k_tp1, model):
    """
    Compute the Euler equation.
    """
    Rbar = (1 - τk_tp1)*(f_prime(k_tp1, model) - model.δ) + 1
    return model.β * (c_tp1/c_t)**(-model.γ) * (1+τc_t)/(1+τc_tp1) * Rbar - 1
```

114.2.2 Initial condition and steady state

For the initial conditions, we choose the pre-trade allocation of capital (k_0, k_0^*) and the initial level B_{-1}^f of international debt owed by the unstarred (domestic) country to the starred (foreign) country.

114.2.3 Equilibrium steady state values

The steady state of the two-country model is characterized by two sets of equations.

First, the following equations determine the steady-state capital-labor ratios $\bar{k}$ and $\bar{k}^*$ in each country:

$$f'(\bar{k}) = \delta + \frac{\rho}{1 - \tau_k} \tag{114.1}$$

$$f'(\bar{k}^*) = \delta + \frac{\rho}{1 - \tau_k^*} \tag{114.2}$$

Given these steady-state capital-labor ratios, the domestic and foreign consumption values $\bar{c}$ and $\bar{c}^*$ are determined by:

$$(\bar{c} + \bar{c}^*) = f(\bar{k}) + f(\bar{k}^*) - \delta(\bar{k} + \bar{k}^*) - (\bar{g} + \bar{g}^*) \tag{114.3}$$

$$\bar{c} = f(\bar{k}) - \delta\bar{k} - \bar{g} - \rho\bar{B}^f \tag{114.4}$$

Equation (114.3) expresses feasibility at the steady state, while equation (114.4) represents the trade balance, including interest payments, at the steady state.

The steady-state level of debt $\bar{B}^f$ from the domestic country to the foreign country influences the consumption allocation between countries but not the total world capital stock.

We assume $\bar{B}^f = 0$ in the steady state, which gives us the following function to compute the steady-state values of capital and consumption

```
def compute_steady_state_global(model, g_ss=0.2):
    """
    Calculate steady state values for capital, consumption, and investment.
    """
    k_ss = ((1/model.β - (1-model.δ)) / (model.A * model.α)) ** (1/(model.α-1))
    c_ss = f(k_ss, model) - model.δ * k_ss - g_ss
    return k_ss, c_ss
```

Now, we can apply the residual minimization method to compute the steady-state values of capital and consumption.

Again, we minimize the residuals of the Euler equation, the global resource constraint, and the no-arbitrage condition.

```
def compute_residuals_global(z, model, shocks, T, k0_ss, k_star, Bf_star):
    """
    Compute residuals for the two-country model.
    """
    k, c, k_s, c_s = z.reshape(T+1, 4).T
    g, gs = shocks['g'], shocks['g_s']
    τc, τk = shocks['τ_c'], shocks['τ_k']
    τc_s, τk_s = shocks['τ_c_s'], shocks['τ_k_s']

    res = [k[0] - k0_ss, k_s[0] - k0_ss]

    for t in range(T):
        e_d = compute_euler(
            c[t], c[t+1],
            τc[t], τc[t+1], τk[t+1],
            k[t+1], model)

        e_f = compute_euler(
            c_s[t], c_s[t+1],
            τc_s[t], τc_s[t+1], τk_s[t+1],
            k_s[t+1], model)

        rs = compute_rs(
            c[t], c[t+1], c_s[t], c_s[t+1],
            τc[t], τc[t+1], τc_s[t], τc_s[t+1],
            model)

        # Global resource constraint
        grc = k[t+1] + k_s[t+1] - (
            f(k[t], model) + f(k_s[t], model) +
            (1-model.δ)*(k[t] + k_s[t]) -
            c[t] - c_s[t] - g[t] - gs[t]
        )

        res.extend([e_d, e_f, rs, grc])

    Bf_term = Bf_path(k, c, shocks['g'], model)[-1]
    res.append(k[T] - k_star)
    res.append(Bf_term - Bf_star)
    return np.array(res)
```

Now we plot the results

```
# Function to plot global two-country model results
def plot_global_results(k, k_s, c, c_s, shocks, model,
                        k0_ss, c0_ss, g_ss, S, T=40, shock='g',
                        # a dictionary storing sequence for lower left panel
                        ll_series='None'):
    """
    Plot results for the two-country model.
    """
    fig, axes = plt.subplots(2, 3, figsize=(10, 8))
    x = np.arange(T)
    τc, τk = shocks['τ_c'], shocks['τ_k']

    axes[1,2].set_xlim(0, T-1)

    plt.tight_layout()
    return fig, axes
```

As in our in the one-country model in *Cass-Koopmans Model with Distorting Taxes*, we assume a Cobb-Douglas production function:

$$F(k, 1) = Ak^{\alpha}$$

```
def f(k, model, A=1):
    """
    Production function: f(k) = A * k^{α}
    """
    return A * k ** model.α

def f_prime(k, model, A=1):
    """
    Marginal product of capital: f'(k) = α * A * k^{α - 1}
    """
    return model.α * A * k ** (model.α - 1)
```

Similarly, we define the capital rental rate

$$\eta_t = f'(k_t)$$

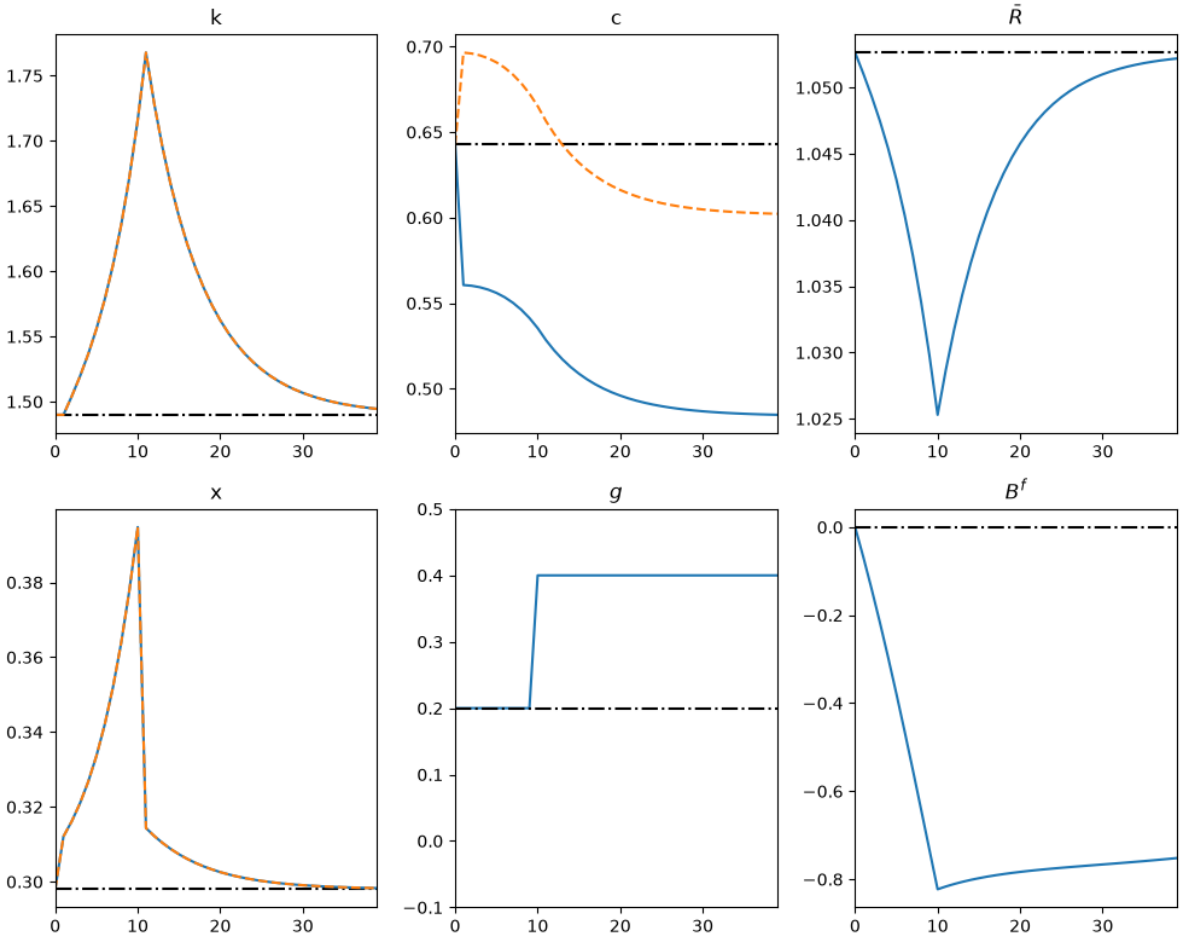
```
def compute_η_path(k_path, model, S=100, A_path=None):
    """
    Compute η path: η_t = f'(k_t)
    with optional A_path for growth models.
    """
    A = np.ones_like(k_path) if A_path is None else np.asarray(A_path)
    η_path = np.zeros_like(k_path)
    for t in range(S):
        η_path[t] = f_prime(k_path[t], model, A[t])
    return η_path
```

Experiment 1: A foreseen increase in g from 0.2 to 0.4 at t=10

The figure below presents transition dynamics after an increase in g in the domestic economy from 0.2 to 0.4 that is announced ten periods in advance.

We start both economies from a steady state with $B_0^f = 0$.

In the figure below, the blue lines represent the domestic economy and orange dotted lines represent the foreign economy.



```
Model = namedtuple("Model", ["β", "γ", "δ", "α", "A"])
model = Model(β=0.95, γ=2.0, δ=0.2, α=0.33, A=1.0)
S = 100

shocks_global = {
    'g': np.concatenate((np.full(10, 0.2), np.full(S-9, 0.4))),
    'g_s': np.full(S+1, 0.2),
    'τ_c': np.zeros(S+1),
    'τ_k': np.zeros(S+1),
    'τ_c_s': np.zeros(S+1),
    'τ_k_s': np.zeros(S+1)
}
g_ss = 0.2
k0_ss, c0_ss = compute_steady_state_global(model, g_ss)

k_star = k0_ss
Bf_star = Bf_ss(c0_ss, k_star, g_ss, model)

init_glob = np.tile([k0_ss, c0_ss, k0_ss, c0_ss], S+1)
sol_glob = root(
    lambda z: compute_residuals_global(z, model, shocks_global,
                                       S, k0_ss, k_star, Bf_star),
    init_glob, tol=1e-12
)
k, c, k_s, c_s = sol_glob.x.reshape(S+1, 4).T

# Plot global results via function
plot_global_results(k, k_s, c, c_s,
                        shocks_global, model,
                        k0_ss, c0_ss, g_ss,
                        S)
plt.show()
```

At time 1, the government announces that domestic government purchases g will rise ten periods later, cutting into future private resources.

To smooth consumption, domestic households immediately increase saving, offsetting the anticipated hit to their future wealth.

In a closed economy, they would save solely by accumulating extra domestic capital; with open capital markets, they can also lend to foreigners.

Once the capital flow opens up at time 1, the no-arbitrage conditions connect adjustments of both types of saving: the increase in savings by domestic households will reduce the equilibrium return on bonds and capital in the foreign economy to prevent arbitrage opportunities.

Because no-arbitrage equalizes the ratio of marginal utilities, the resulting paths of consumption and capital are synchronized across the two economies.

Up to the date the higher g takes effect, both countries continue to build their capital stocks.

When government spending finally rises 10 periods later, domestic households begin to draw down part of that capital to cushion consumption.

Again by no-arbitrage conditions, when g actually increases, both countries reduce their investment rates.

The domestic economy, in turn, starts running current-account deficits partially to fund the increase in g.

This means that foreign households begin repaying part of their external debt by reducing their capital stock.

Experiment 2: A foreseen increase in g from 0.2 to 0.4 at t=10

We now explore the impact of an increase in capital taxation in the domestic economy 10 periods after its announcement at $t = 1$.

Because the change is anticipated, households in both countries adjust immediately–even though the tax does not take effect until period $t = 11$.

```
shocks_global = {
    'g': np.full(S+1, g_ss),
    'g_s': np.full(S+1, g_ss),

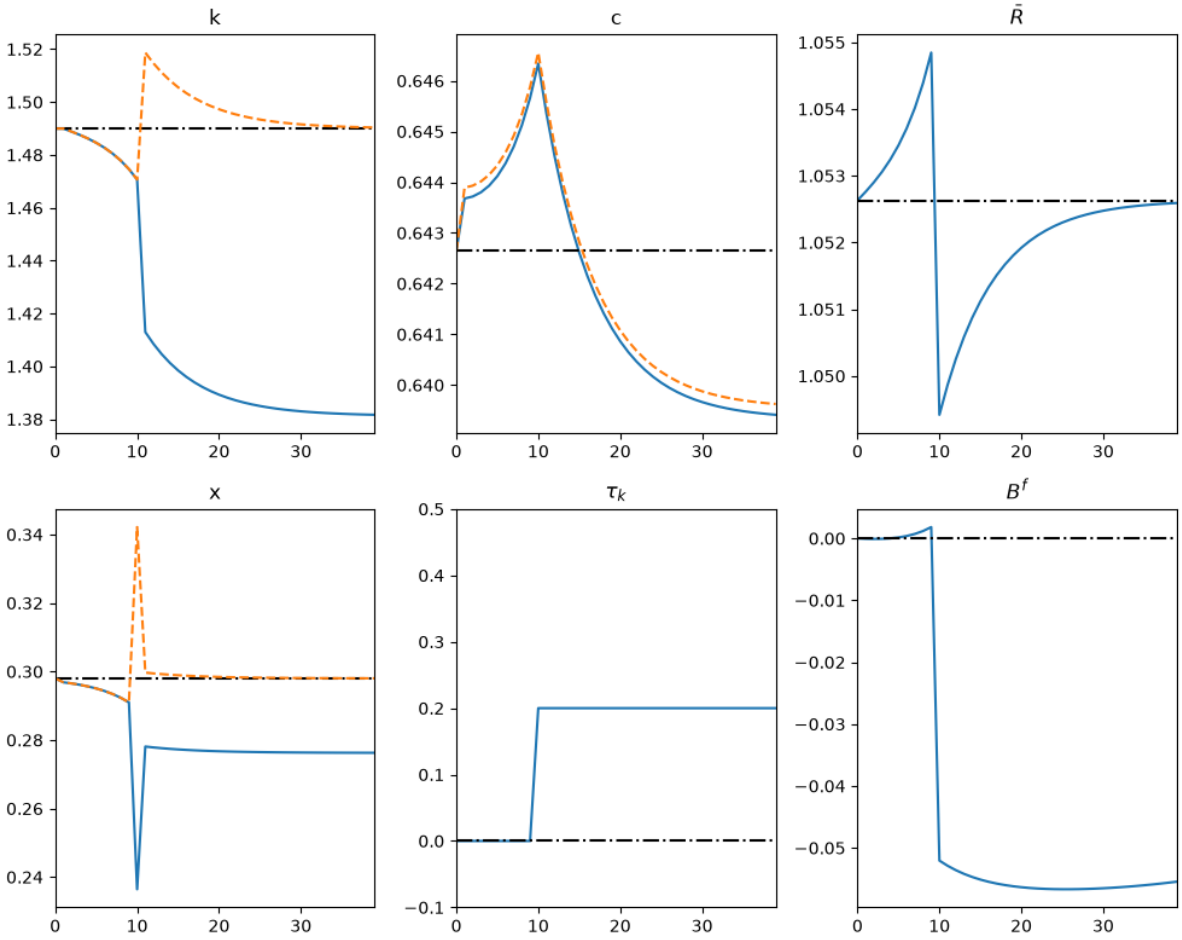
    'τ_k_s': np.zeros(S+1),
}



k0_ss, c0_ss = compute_steady_state_global(model, g_ss)
k_star = k0_ss
Bf_star = Bf_ss(c0_ss, k_star, g_ss, model)

init_glob = np.tile([k0_ss, c0_ss, k0_ss, c0_ss], S+1)

sol_glob = root(
    lambda z: compute_residuals_global(z, model,
            shocks_global, S, k0_ss, k_star, Bf_star),
            init_glob, tol=1e-12)

k, c, k_s, c_s = sol_glob.x.reshape(S+1, 4).T

# plot
fig, axes = plot_global_results(k, k_s, c, c_s, shocks_global, model,
                                k0_ss, c0_ss, g_ss, S, shock='τ_k')
plt.tight_layout()
plt.show()
```

After the tax increase is announced, domestic households foresee lower after-tax returns on capital, so they shift toward higher present consumption and allow the domestic capital stock to decline.

This shrinkage of the world capital supply drives the global real interest rate upward, prompting foreign households to raise current consumption as well.

Prior to the actual tax hike, the domestic economy finances part of its consumption by importing capital, generating a current-account deficit.

When τ_k finally rises, international arbitrage leads investors to reallocate capital quickly toward the untaxed foreign market, compressing the yield on bonds everywhere.

The bond-rate drop reflects the lower after-tax return on domestic capital and the higher foreign capital stock, which depresses its marginal product.

Foreign households fund their capital purchases by borrowing abroad, creating a pronounced current-account deficit and a buildup of external debt.

After the policy change, both countries move smoothly toward a new steady state in which:

- Consumption levels in each economy settle below their pre-announcement paths.
- Capital stocks differ just enough to equalize after-tax returns across borders.

Despite carrying positive net liabilities, the foreign country enjoys higher steady-state consumption because its larger capital stock yields greater output.

The episode demonstrates how open capital markets transmit a domestic tax shock internationally: capital flows and

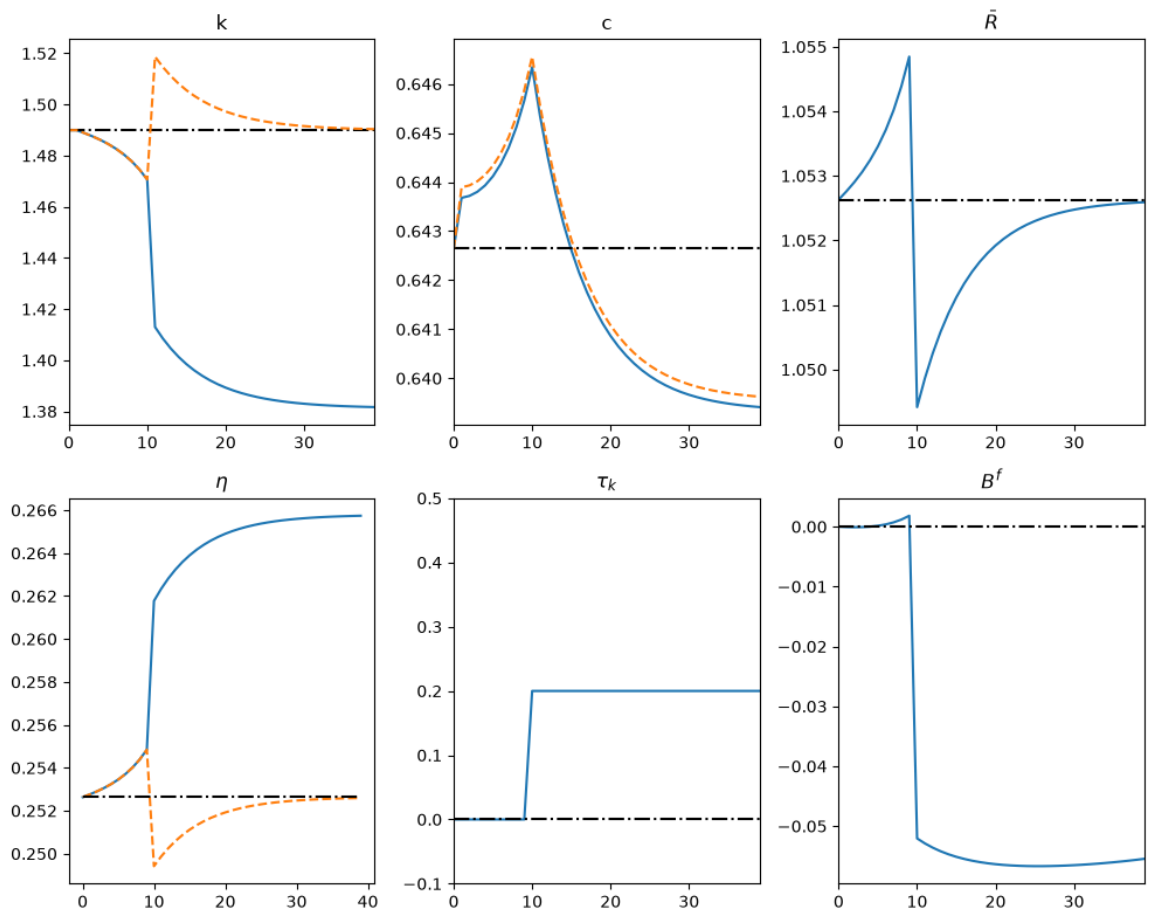
interest-rate movements share the burden, smoothing consumption adjustments in both the taxed and untaxed economies over time.

Exercise 114.2.1

In this exercise, replace the plot for x_t with η_t to replicate the figure in [Ljungqvist and Sargent, 2018].

Compare the figures for k_t and η_t and discuss the economic intuition.

Solution



Here is one solution.

```
fig, axes = plot_global_results(k, k_s, c, c_s, shocks_global, model,
                                k0_ss, c0_ss, g_ss, S, shock='τ_k')

# Clear the plot for x_t
axes[1,0].cla()

# Plot η_t
axes[1,0].plot(compute_η_path(k, model)[:40])
axes[1,0].plot(compute_η_path(k_s, model)[:40], '--')
axes[1,0].plot(np.full(40, f_prime(k_s, model)[0]), 'k-.', lw=1.5)
axes[1,0].set_title(r'$\eta$')

plt.tight_layout()
plt.show()
```

When capital k_t decreases in the domestic country after the tax shock, the rental rate η_t increases in that country.

This happens because when capital becomes scarcer, its marginal product rises.

Multiple Agent Models

CHAPTER

FIVE

A LAKE MODEL OF EMPLOYMENT AND UNEMPLOYMENT

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

Contents

- *A Lake Model of Employment and Unemployment*
  - *Overview*
  - *The model*
  - *Implementation*
  - *Dynamics of an individual worker*
  - *Exercises*

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon jax
```

115.1 Overview

This lecture describes what has come to be called a *lake model*.

The lake model is a basic tool for modeling unemployment.

It allows us to analyze

- flows between unemployment and employment
- how these flows influence steady state employment and unemployment rates

It is a good model for interpreting monthly labor department reports on gross and net jobs created and destroyed.

The "lakes" in the model are the pools of employed and unemployed.

The "flows" between the lakes are caused by

- firing and hiring
- entry and exit from the labor force

For the first part of this lecture, the parameters governing transitions into and out of unemployment and employment are exogenous.

Later, we'll determine some of these transition rates endogenously using the *McCall search model*.

We'll also use some nifty concepts like ergodicity, which provides a fundamental link between *cross-sectional* and *long run time series* distributions.

These concepts will help us build an equilibrium model of ex-ante homogeneous workers whose different luck generates variations in their ex post experiences.

Let's start with some imports:

```
import matplotlib.pyplot as plt
import jax
import jax.numpy as jnp
from typing import NamedTuple
from quantecon.distributions import BetaBinomial
from functools import partial
import jax.scipy.stats as stats
```

115.1.1 Prerequisites

Before working through what follows, we recommend you read the *lecture on finite Markov chains*.

You will also need some basic *linear algebra* and probability.

115.2 The model

The economy is inhabited by a very large number of ex-ante identical workers.

The workers live forever, spending their lives moving between unemployment and employment.

Their rates of transition between employment and unemployment are governed by the following parameters:

- λ, the job finding rate for currently unemployed workers
- α, the dismissal rate for currently employed workers
- b, the entry rate into the labor force
- d, the exit rate from the labor force

The growth rate of the labor force evidently equals $g = b - d$.

115.2.1 Aggregate variables

We want to derive the dynamics of the following aggregates:

- E_t, the total number of employed workers at date t
- U_t, the total number of unemployed workers at t
- N_t, the number of workers in the labor force at t

115.2.2 Laws of motion for stock variables

We begin by constructing laws of motion for the aggregate variables E_t, U_t, N_t.

Of the mass of workers E_t who are employed at date t,

- $(1-d)E_t$ will remain in the labor force
- of these, $(1-\alpha)(1-d)E_t$ will remain employed

Of the mass of workers U_t workers who are currently unemployed,

- $(1-d)U_t$ will remain in the labor force
- of these, $(1-d)\lambda U_t$ will become employed

Therefore, the number of workers who will be employed at date $t+1$ will be

$$E_{t+1} = (1-d)(1-\alpha)E_t + (1-d)\lambda U_t$$

A similar analysis implies

$$U_{t+1} = (1-d)\alpha E_t + (1-d)(1-\lambda)U_t + b(E_t + U_t)$$

The value $b(E_t + U_t)$ is the mass of new workers entering the labor force unemployed.

The total stock of workers $N_t = E_t + U_t$ evolves as

$$N_{t+1} = (1+b-d)N_t = (1+g)N_t$$

Letting $X_t := \begin{pmatrix} U_t \\ E_t \end{pmatrix}$, the law of motion for X is

$$X_{t+1} = AX_t \quad \text{where} \quad A := \begin{bmatrix} (1-d)(1-\lambda) + b & (1-d)\alpha + b \\ (1-d)\lambda & (1-d)(1-\alpha) \end{bmatrix}$$

This law tells us how total employment and unemployment evolve over time.

115.2.3 Laws of motion for rates

Now let's derive the law of motion for rates.

We want to track the values of the following objects:

- The employment rate $e_t := E_t/N_t$.
- The unemployment rate $u_t := U_t/N_t$.

(Here and below, capital letters represent aggregates and lowercase letters represent rates)

To get these we can divide both sides of $X_{t+1} = AX_t$ by N_{t+1} to get

$$\begin{bmatrix} U_{t+1}/N_{t+1} \\ E_{t+1}/N_{t+1} \end{bmatrix} = \frac{1}{1+g} A \begin{bmatrix} U_t/N_t \\ E_t/N_t \end{bmatrix}$$

Letting

$$x_t := \begin{pmatrix} u_t \\ e_t \end{pmatrix} = \begin{pmatrix} U_t/N_t \\ E_t/N_t \end{pmatrix}$$

we can also write this as

$$x_{t+1} = Rx_t \quad \text{where} \quad R := \frac{1}{1+g} A$$

You can check that $e_t + u_t = 1$ implies that $e_{t+1} + u_{t+1} = 1$.

This follows from the fact that the columns of R sum to 1.

115.3 Implementation

Let's code up these equations.

115.3.1 Model

To begin, we set up a class called `LakeModel` that stores the primitives α, λ, b, d.

```
class LakeModel(NamedTuple):
    """
    Parameters for the lake model
    """
    λ: float
    α: float
    b: float
    d: float
    A: jnp.ndarray
    R: jnp.ndarray
    g: float

def create_lake_model(
        λ: float = 0.283,      # job finding rate
        α: float = 0.013,      # separation rate
        b: float = 0.0124,     # birth rate
        d: float = 0.00822     # death rate
    ) -> LakeModel:
    """
    Create a LakeModel instance with default parameters.

    Computes and stores the transition matrices A and R,
    and the labor force growth rate g.

    """
    # Compute growth rate
```

(continues on next page)

(continued from previous page)

```
    g = b - d

    # Compute transition matrix A
    A = jnp.array([
        [(1-d) * (1-λ) + b,  (1-d) * α + b],
        [(1-d) * λ,          (1-d) * (1-α)]
    ])

    # Compute normalized transition matrix R
    R = A / (1 + g)

    return LakeModel(λ=λ, α=α, b=b, d=d, A=A, R=R, g=g)
```

The default parameter values are:

- $\alpha = 0.013$ and $\lambda = 0.283$ are based on [Davis *et al.*, 2006]
- $b = 0.0124$ and $d = 0.00822$ are set to match monthly birth and death rates, respectively, in the U.S. population

As an experiment, let's create two instances, one with $\alpha = 0.013$ and another with $\alpha = 0.03$

```
model = create_lake_model()
print(f"Default α: {model.α}")
print(f"A matrix:\n{model.A}")
print(f"R matrix:\n{model.R}")
```

```
Default α: 0.013
A matrix:
[[0.7235063  0.02529314]
 [0.28067374 0.97888684]]
R matrix:
[[0.7204946  0.02518786]
 [0.27950543 0.97481215]]
```

```
model_new = create_lake_model(α=0.03)
print(f"New α: {model_new.α}")
print(f"New A matrix:\n{model_new.A}")
print(f"New R matrix:\n{model_new.R}")
```

```
New α: 0.03
New A matrix:
[[0.7235063  0.0421534 ]
 [0.28067374 0.9620266 ]]
New R matrix:
[[0.7204946  0.04197793]
 [0.27950543 0.9580221 ]]
```

115.3.2 Code for dynamics

We will also use a specialized function to generate time series in an efficient JAX-compatible manner.

Iteratively generating time series is somewhat nontrivial in JAX because arrays are immutable.

Here we use `lax.scan`, which allows the function to be jit-compiled.

Readers who prefer to skip the details can safely continue reading after the function definition.

```
@partial(jax.jit, static_argnames=['f', 'num_steps'])
def generate_path(f, initial_state, num_steps, **kwargs):
    """
    Generate a time series by repeatedly applying an update rule.

    Given a map f, initial state x_0, and model parameters, this
    function computes and returns the sequence {x_t}_{t=0}^{T-1} when

        x_{t+1} = f(x_t, **kwargs)

    Args:
        f: Update function mapping (x_t, **kwargs) -> x_{t+1}
        initial_state: Initial state x_0
        num_steps: Number of time steps T to simulate
        **kwargs: Optional extra arguments passed to f

    Returns:
        Array of shape (dim(x), T) containing the time series path
        [x_0, x_1, x_2, ..., x_{T-1}]
    """

    def update_wrapper(state, t):
        """
        Wrapper function that adapts f for use with JAX scan.
        """
        next_state = f(state, **kwargs)
        return next_state, state

    _, path = jax.lax.scan(update_wrapper,
                    initial_state, jnp.arange(num_steps))
    return path.T
```

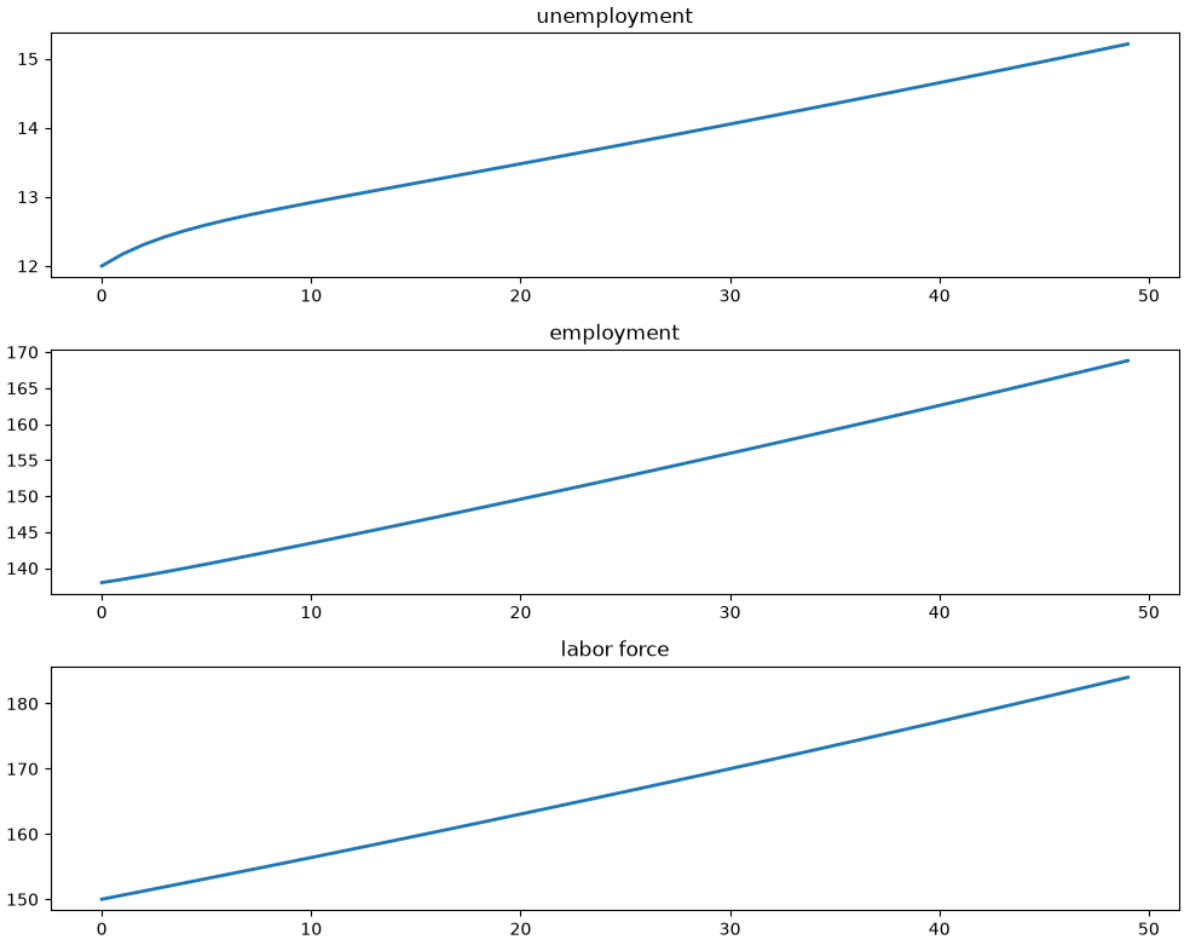
Here are functions to update X_t and x_t.

```
def stock_update(X: jnp.ndarray, model: LakeModel) -> jnp.ndarray:
    """Apply transition matrix to get next period's stocks."""
    λ, α, b, d, A, R, g = model
    return A @ X

def rate_update(x: jnp.ndarray, model: LakeModel) -> jnp.ndarray:
    """Apply normalized transition matrix for next period's rates."""
    λ, α, b, d, A, R, g = model
    return R @ x
```

115.3.3 Aggregate dynamics

Let's run a simulation under the default parameters starting from $X_0 = (12, 138)$.



We will plot the sequences $\{E_t\}$, $\{U_t\}$ and $\{N_t\}$.

```
N_0 = 150       # Population
e_0 = 0.92      # Initial employment rate
u_0 = 1 - e_0   # Initial unemployment rate
T = 50          # Simulation length

U_0 = u_0 * N_0
E_0 = e_0 * N_0

# Generate X path
X_0 = jnp.array([U_0, E_0])
X_path = generate_path(stock_update, X_0, T, model=model)

# Plot
fig, axes = plt.subplots(3, 1, figsize=(10, 8))
titles = ['unemployment', 'employment', 'labor force']
data = [X_path[0, :], X_path[1, :], X_path.sum(0)]
for ax, title, series in zip(axes, titles, data):
    ax.plot(series, lw=2)
    ax.set_title(title)
plt.tight_layout()
plt.show()
```

The aggregates E_t and U_t don't converge because their sum $E_t + U_t$ grows at rate g.

115.3.4 Rate dynamics

On the other hand, the vector of employment and unemployment rates x_t can be in a steady state $\bar{x}$ if there exists an $\bar{x}$ such that

- $\bar{x} = R\bar{x}$
- the components satisfy $\bar{e} + \bar{u} = 1$

This equation tells us that a steady state level $\bar{x}$ is an eigenvector of R associated with a unit eigenvalue.

The following function can be used to compute the steady state.

```
@jax.jit
def rate_steady_state(model: LakeModel) -> jnp.ndarray:
    r"""
    Finds the steady state of the system :math:`x_{t+1} = R x_{t}`
    by computing the eigenvector corresponding to the largest eigenvalue.

    By the Perron-Frobenius theorem, since :math:`R` is a non-negative
    matrix with columns summing to 1 (a stochastic matrix), the largest
    eigenvalue equals 1 and the corresponding eigenvector gives the steady state.
    """
```

(continues on next page)

(continued from previous page)

```
    λ, α, b, d, A, R, g = model
    eigenvals, eigenvec = jnp.linalg.eig(R)

    # Find the eigenvector corresponding to the largest eigenvalue
    # (which is 1 for a stochastic matrix by Perron-Frobenius theorem)
    max_idx = jnp.argmax(jnp.abs(eigenvals))

    # Get the corresponding eigenvector
    steady_state = jnp.real(eigenvec[:, max_idx])

    # Normalize to ensure positive values and sum to 1
    steady_state = jnp.abs(steady_state)
    steady_state = steady_state / jnp.sum(steady_state)

    return steady_state
```

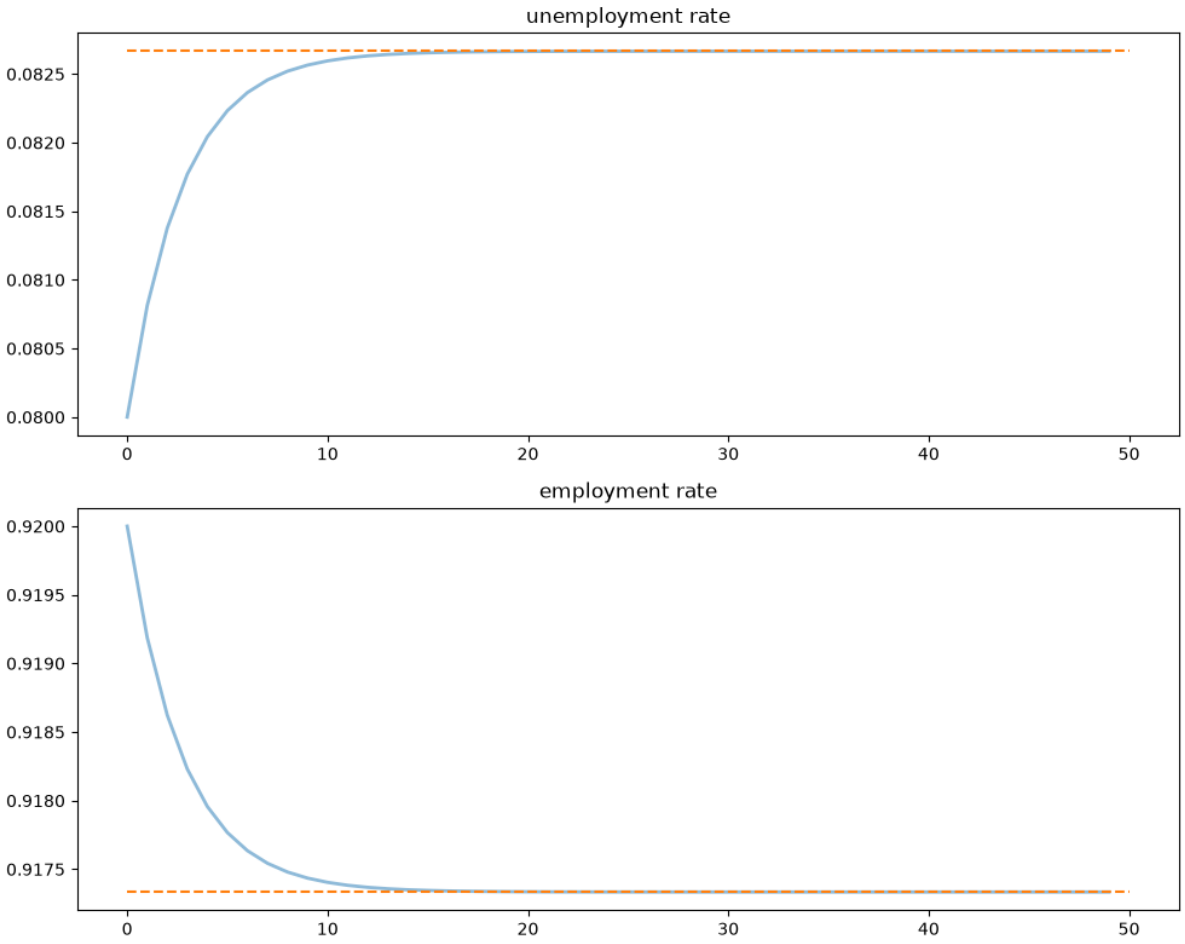
We also have $x_t \to \bar{x}$ as $t \to \infty$ provided that the remaining eigenvalue of R has modulus less than 1.

This is the case for our default parameters:

```
model = create_lake_model()
e, f = jnp.linalg.eigvals(model.R)
print(f"Eigenvalue magnitudes: {abs(e):.2f}, {abs(f):.2f}")
```

```
Eigenvalue magnitudes: 0.70, 1.00
```

Let's look at the convergence of the unemployment and employment rates to steady state levels (dashed line)



```
xbar = rate_steady_state(model)

fig, axes = plt.subplots(2, 1, figsize=(10, 8))
x_0 = jnp.array([u_0, e_0])
x_path = generate_path(rate_update, x_0, T, model=model)

titles = ['unemployment rate', 'employment rate']

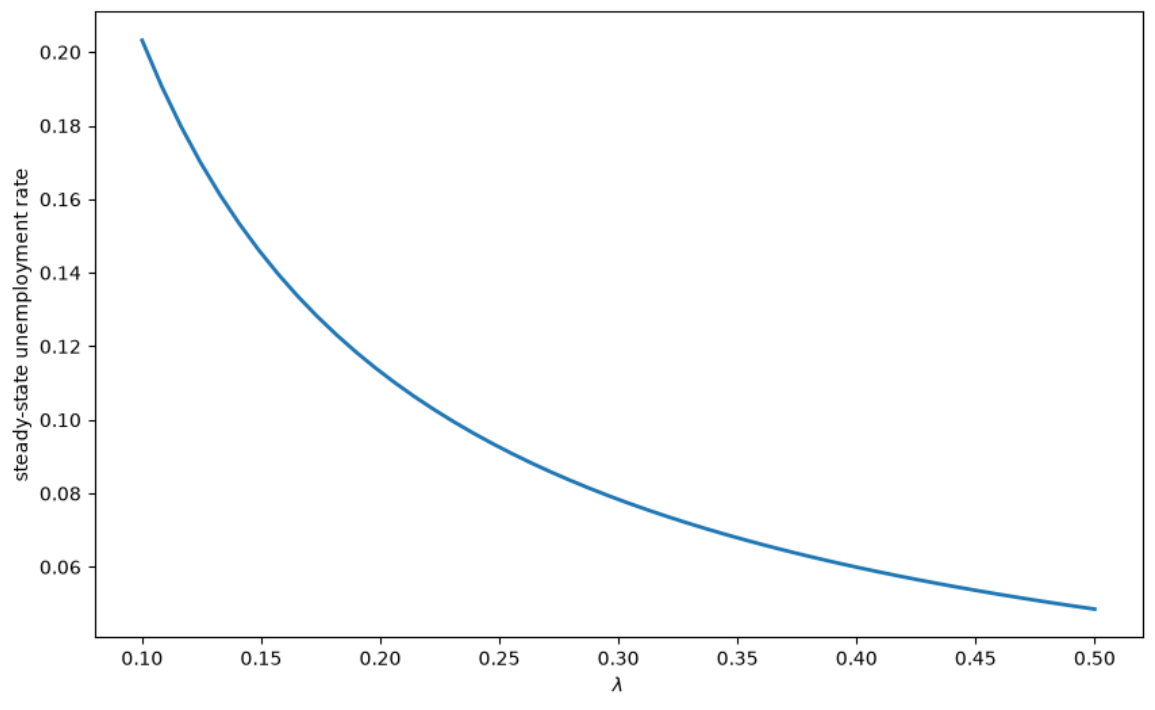
for i, title in enumerate(titles):
    axes[i].plot(x_path[i, :], lw=2, alpha=0.5)
    axes[i].hlines(xbar[i], 0, T, color='C1', linestyle='--')
    axes[i].set_title(title)

plt.tight_layout()
plt.show()
```

Exercise 115.3.1

Use JAX's `vmap` to compute steady-state unemployment rates for a range of job finding rates λ (from 0.1 to 0.5), and plot the relationship.

Solution



Here is one solution

```
@jax.jit
def compute_unemployment_rate(λ_val):
    """Computes steady-state unemployment for a given λ"""
    model = create_lake_model(λ=λ_val)
    steady_state = rate_steady_state(model)
    return steady_state[0]

# Use vmap to compute for multiple λ values
λ_values = jnp.linspace(0.1, 0.5, 50)
unemployment_rates = jax.vmap(compute_unemployment_rate)(λ_values)

# Plot the results
fig, ax = plt.subplots(figsize=(10, 6))
ax.plot(λ_values, unemployment_rates, lw=2)
```

```
ax.set_xlabel(r'$\lambda$')
ax.set_ylabel('steady-state unemployment rate')
plt.show()
```

115.4 Dynamics of an individual worker

An individual worker's employment dynamics are governed by a *finite state Markov process*.

The worker can be in one of two states:

- $s_t = 0$ means unemployed
- $s_t = 1$ means employed

Let's start off under the assumption that $b = d = 0$.

The associated transition matrix is then

$$P = \begin{pmatrix} 1 - \lambda & \lambda \\ \alpha & 1 - \alpha \end{pmatrix}$$

Let ψ_t denote the *marginal distribution* over employment/unemployment states for the worker at time t.

As usual, we regard it as a row vector.

We know *from an earlier discussion* that ψ_t follows the law of motion

$$\psi_{t+1} = \psi_t P$$

We also know from the *lecture on finite Markov chains* that if $\alpha \in (0, 1)$ and $\lambda \in (0, 1)$, then P has a unique stationary distribution, denoted here by ψ^*.

The unique stationary distribution satisfies

$$\psi^*[0] = \frac{\alpha}{\alpha + \lambda}$$

Not surprisingly, probability mass on the unemployment state increases with the dismissal rate and falls with the job finding rate.

115.4.1 Ergodicity

Let's look at a typical lifetime of employment-unemployment spells.

We want to compute the average amounts of time an infinitely lived worker would spend employed and unemployed.

Let

$$\bar{s}_{u,T} := \frac{1}{T} \sum_{t=1}^{T} \mathbb{1}\{s_t = 0\}$$

and

$$\bar{s}_{e,T} := \frac{1}{T} \sum_{t=1}^{T} \mathbb{1}\{s_t = 1\}$$

(As usual, $\mathbb{1}\{Q\} = 1$ if statement Q is true and 0 otherwise)

These are the fraction of time a worker spends unemployed and employed, respectively, up until period T.

If $\alpha \in (0, 1)$ and $\lambda \in (0, 1)$, then P is *ergodic*, and hence we have

$$\lim_{T \to \infty} \bar{s}_{u,T} = \psi^*[0] \quad \text{and} \quad \lim_{T \to \infty} \bar{s}_{e,T} = \psi^*[1]$$

with probability one.

Inspection tells us that P is exactly the transpose of R under the assumption $b = d = 0$.

Thus, the percentages of time that an infinitely lived worker spends employed and unemployed equal the fractions of workers employed and unemployed in the steady state distribution.

115.4.2 Convergence rate

How long does it take for time series sample averages to converge to cross-sectional averages?

We can investigate this by simulating the Markov chain.

Let's plot the path of the sample averages over 5,000 periods

```
def markov_update(state, P, key):
    """
    Sample next state from transition probabilities.
    """
    probs = P[state]
    state_new = jax.random.choice(key,
                        a=jnp.arange(len(probs)),
                        p=probs)
    return state_new

model_markov = create_lake_model(d=0, b=0)
```

(continues on next page)

(continued from previous page)

```
T = 5000  # Simulation length

α, λ = model_markov.α, model_markov.λ

P = jnp.array([[1 - λ,         λ],
               [    α,     1 - α]])

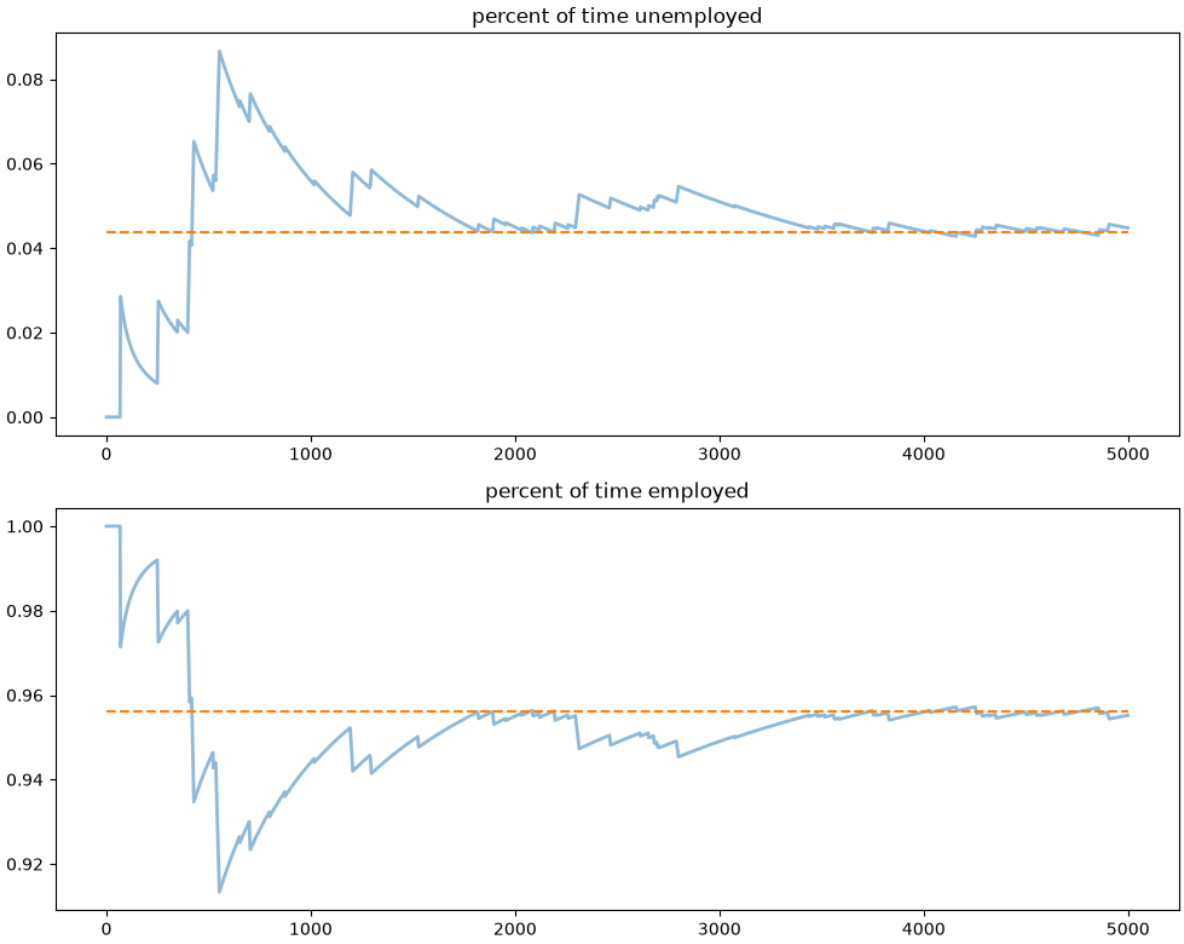
xbar = rate_steady_state(model_markov)

# Simulate the Markov chain - we need a different approach for random updates
key = jax.random.key(0)

def simulate_markov(P, initial_state, T, key):
    """Simulate Markov chain for T periods"""
    keys = jax.random.split(key, T)

    def scan_fn(state, key):
        next_state = markov_update(state, P, key)
        return next_state, state

    _, path = jax.lax.scan(scan_fn, initial_state, keys)
    return path



s_path = simulate_markov(P, 1, T, key)

fig, axes = plt.subplots(2, 1, figsize=(10, 8))
s_bar_e = jnp.cumsum(s_path) / jnp.arange(1, T+1)
s_bar_u = 1 - s_bar_e

to_plot = [s_bar_u, s_bar_e]
titles = ['percent of time unemployed', 'percent of time employed']

for i, plot in enumerate(to_plot):
    axes[i].plot(plot, lw=2, alpha=0.5)
    axes[i].hlines(xbar[i], 0, T, color='C1', linestyle='--')
    axes[i].set_title(titles[i])

plt.tight_layout()
plt.show()
```

The stationary probabilities are given by the dashed line.

In this case it takes much of the sample for these two objects to converge.

This is largely due to the high persistence in the Markov chain.

115.5 Exercises

Exercise 115.5.1

Consider an economy with an initial stock of workers $N_0 = 100$ at the steady state level of employment in the baseline parameterization.

Suppose that in response to new legislation the hiring rate reduces to $\lambda = 0.2$.

Plot the transition dynamics of the unemployment and employment stocks for 50 periods.

Plot the transition dynamics for the rates.

How long does the economy take to converge to its new steady state?

What is the new steady state level of employment?

Solution

We begin by constructing the model with default parameters and finding the initial steady state

```
model_initial = create_lake_model()
x0 = rate_steady_state(model_initial)
print(f"Initial Steady State: {x0}")
```

```
Initial Steady State: [0.08266623 0.9173338 ]
```

Initialize the simulation values

```
N0 = 100
T = 50
```

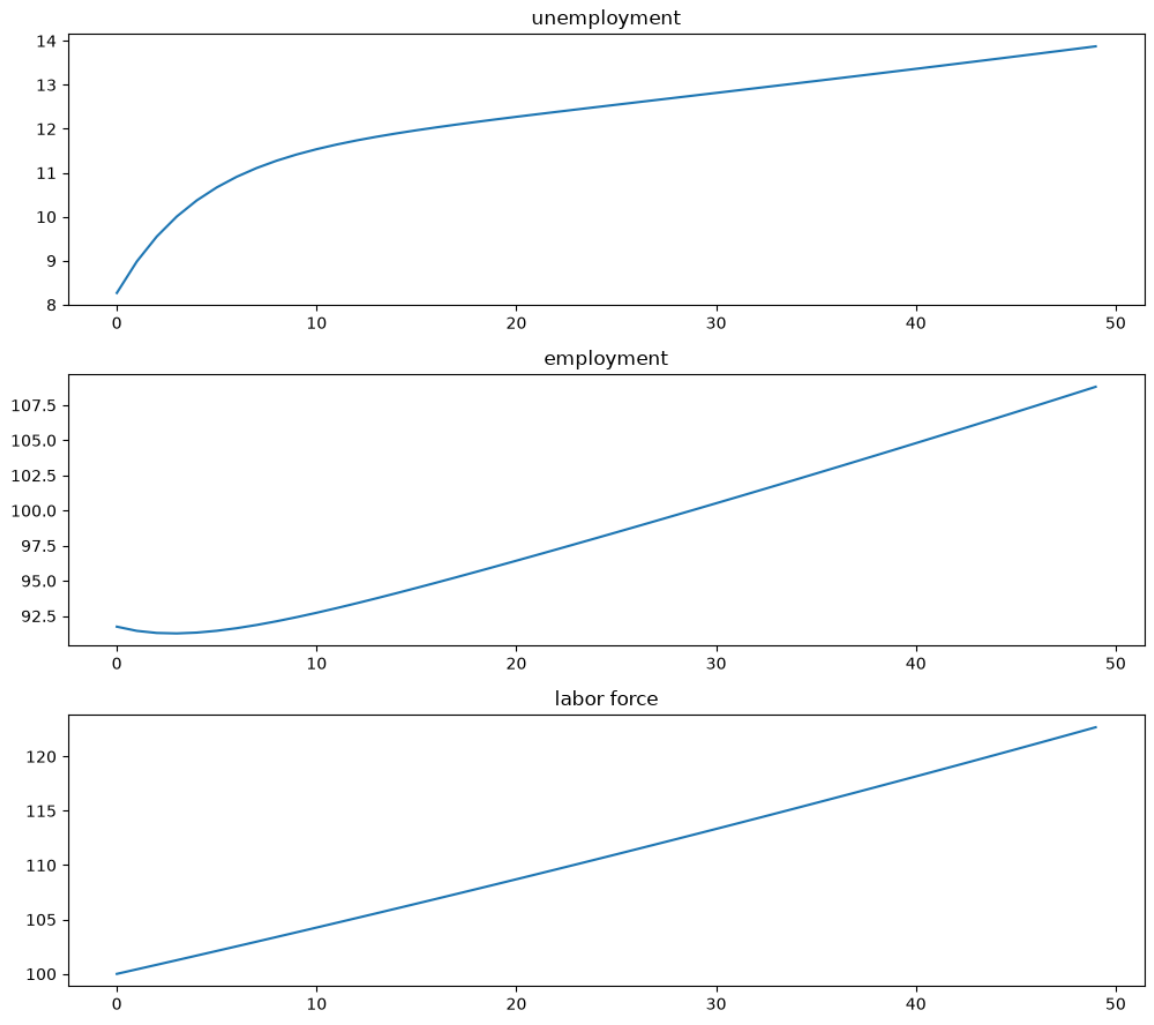
New legislation changes λ to 0.2

```
model_ex2 = create_lake_model(λ=0.2)
xbar = rate_steady_state(model_ex2)  # new steady state

# Simulate paths
X_path = generate_path(stock_update, x0 * N0, T, model=model_ex2)
x_path = generate_path(rate_update, x0, T, model=model_ex2)
print(f"New Steady State: {xbar}")
```

```
New Steady State: [0.11309288 0.8869071 ]
```

Now plot stocks



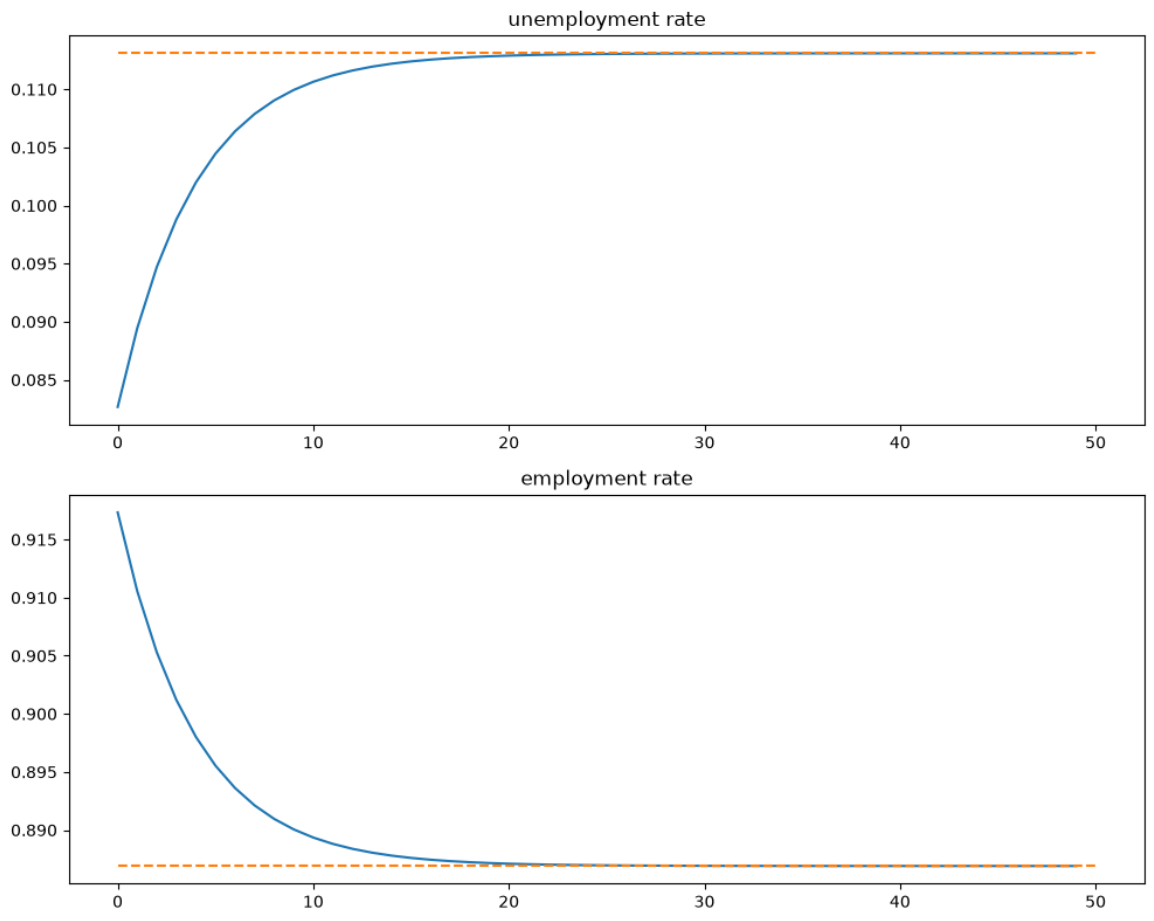
```
fig, axes = plt.subplots(3, 1, figsize=[10, 9])

axes[0].plot(X_path[0, :])
axes[0].set_title('unemployment')

axes[1].plot(X_path[1, :])
axes[1].set_title('employment')

axes[2].plot(X_path.sum(0))
axes[2].set_title('labor force')

plt.tight_layout()
plt.show()
```



And how the rates evolve

```
fig, axes = plt.subplots(2, 1, figsize=(10, 8))

titles = ['unemployment rate', 'employment rate']

for i, title in enumerate(titles):
    axes[i].plot(x_path[i, :])
    axes[i].hlines(xbar[i], 0, T, color='C1', linestyle='--')
    axes[i].set_title(title)

plt.tight_layout()
plt.show()
```

We see that it takes 20 periods for the economy to converge to its new steady state levels.

Exercise 115.5.2

Consider an economy with an initial stock of workers $N_0 = 100$ at the steady state level of employment in the baseline parameterization.

Suppose that for 20 periods the birth rate was temporarily high ($b = 0.025$) and then returned to its original level.

Plot the transition dynamics of the unemployment and employment stocks for 50 periods.

Plot the transition dynamics for the rates.

How long does the economy take to return to its original steady state?

Solution

This exercise has the economy experiencing a boom in entrances to the labor market and then later returning to the original levels.

For 20 periods the economy has a new entry rate into the labor market.

Let's start off at the baseline parameterization and record the steady state

```
model_baseline = create_lake_model()
x0 = rate_steady_state(model_baseline)
N0 = 100
T = 50
```

Here are the other parameters:

```
b_hat = 0.025
T_hat = 20
```

Let's increase b to the new value and simulate for 20 periods

```
model_high_b = create_lake_model(b=b_hat)

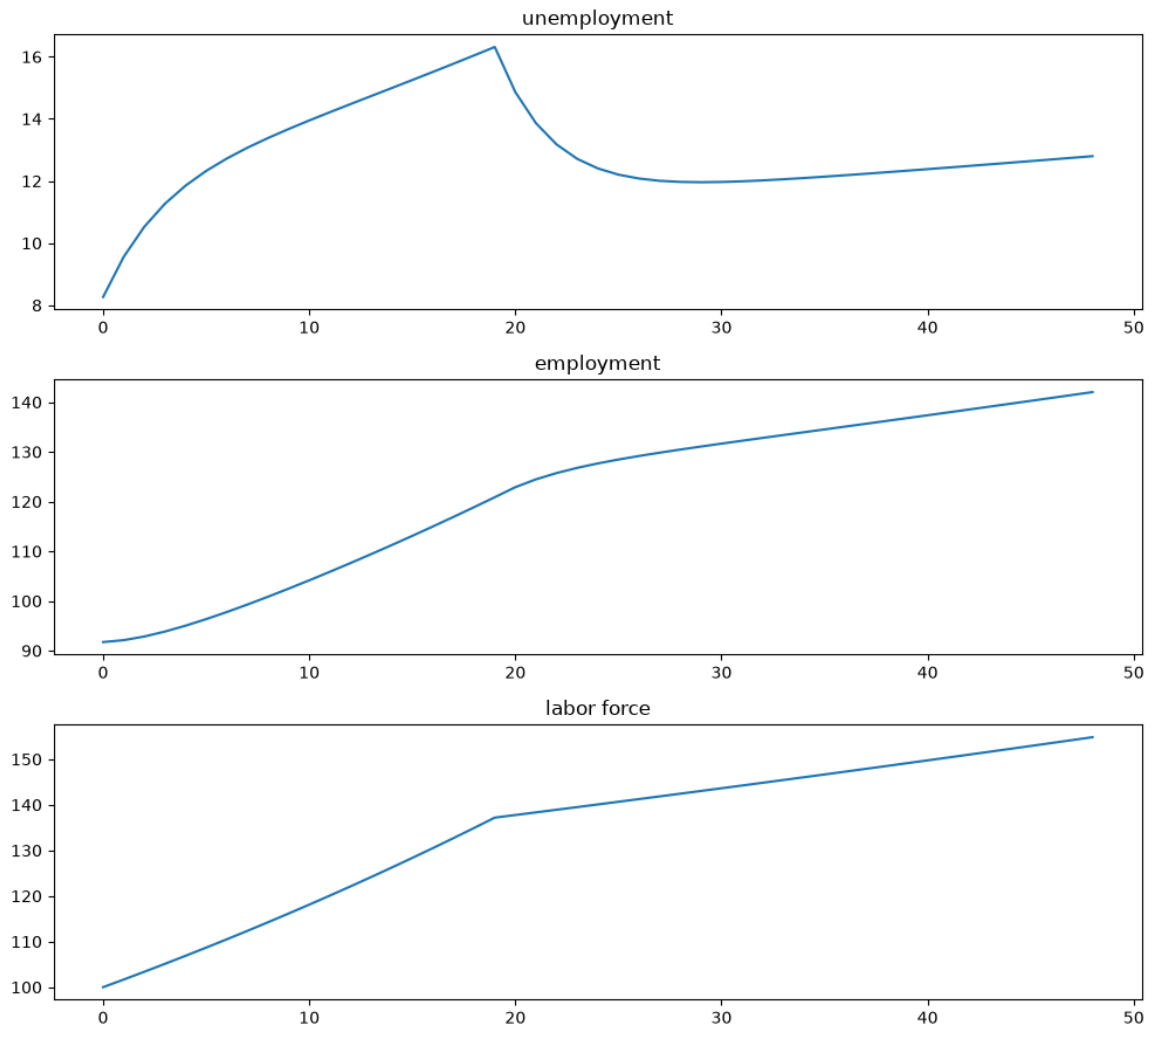
# Simulate stocks and rates for first 20 periods
X_path1 = generate_path(stock_update, x0 * N0, T_hat, model=model_high_b)
x_path1 = generate_path(rate_update, x0, T_hat, model=model_high_b)
```

Now we reset b to the original value and then, using the state after 20 periods for the new initial conditions, we simulate for the additional 30 periods

```
# Use final state from period 20 as initial condition
X_path2 = generate_path(stock_update, X_path1[:, -1], T-T_hat,
                        model=model_baseline)
x_path2 = generate_path(rate_update, x_path1[:, -1], T-T_hat,
                        model=model_baseline)
```

Finally, we combine these two paths and plot

```
# Combine paths
X_path = jnp.hstack([X_path1, X_path2[:, 1:]])
x_path = jnp.hstack([x_path1, x_path2[:, 1:]])



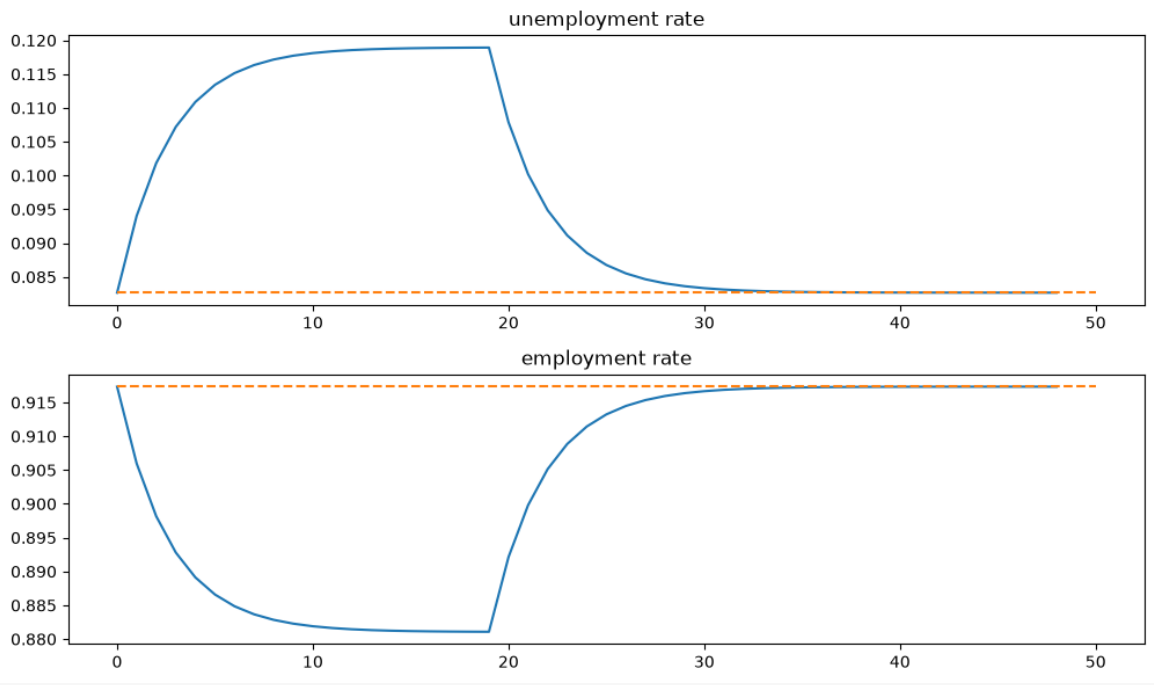
fig, axes = plt.subplots(3, 1, figsize=[10, 9])

axes[0].plot(X_path[0, :])
axes[0].set_title('unemployment')

axes[1].plot(X_path[1, :])
axes[1].set_title('employment')

axes[2].plot(X_path.sum(0))
axes[2].set_title('labor force')

plt.tight_layout()
plt.show()
```



And the rates

```
fig, axes = plt.subplots(2, 1, figsize=[10, 6])

titles = ['unemployment rate', 'employment rate']

for i, title in enumerate(titles):
    axes[i].plot(x_path[i, :])
    axes[i].hlines(x0[i], 0, T, color='C1', linestyle='--')
    axes[i].set_title(title)

plt.tight_layout()
plt.show()
```

LAKE MODEL WITH AN ENDOGENOUS JOB FINDING RATE

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

Contents

- *Lake Model with an Endogenous Job Finding Rate*
  - *Overview*
  - *Set Up*
  - *Fiscal policy*
  - *Exercises*

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon jax
```

116.1 Overview

This lecture is a continuation of the *lake model lecture*.

We recommend you read that lecture first before proceeding with this one.

In the previous lecture, we studied a lake model of unemployment and employment where the transition rates between states were exogenous parameters.

In this lecture, we extend the model by making the job finding rate endogenous.

Specifically, the transition rate from unemployment to employment will be determined by the McCall search model [McCall, 1970].

Let's start with some imports:

```
import matplotlib.pyplot as plt
import jax
import jax.numpy as jnp
from typing import NamedTuple
from quantecon.distributions import BetaBinomial
from functools import partial
import jax.scipy.stats as stats
```

116.2 Set Up

The basic structure of the model will be as discussed in the *lake model lecture*.

The only difference is that the hiring rate is endogenous, determined by the decisions of optimizing agents inhabiting a McCall search model [McCall, 1970] with IID wage offers and job separation at rate α.

116.2.1 Reservation wage

In the model, the optimal policy is characterized by a reservation wage $\bar{w}$

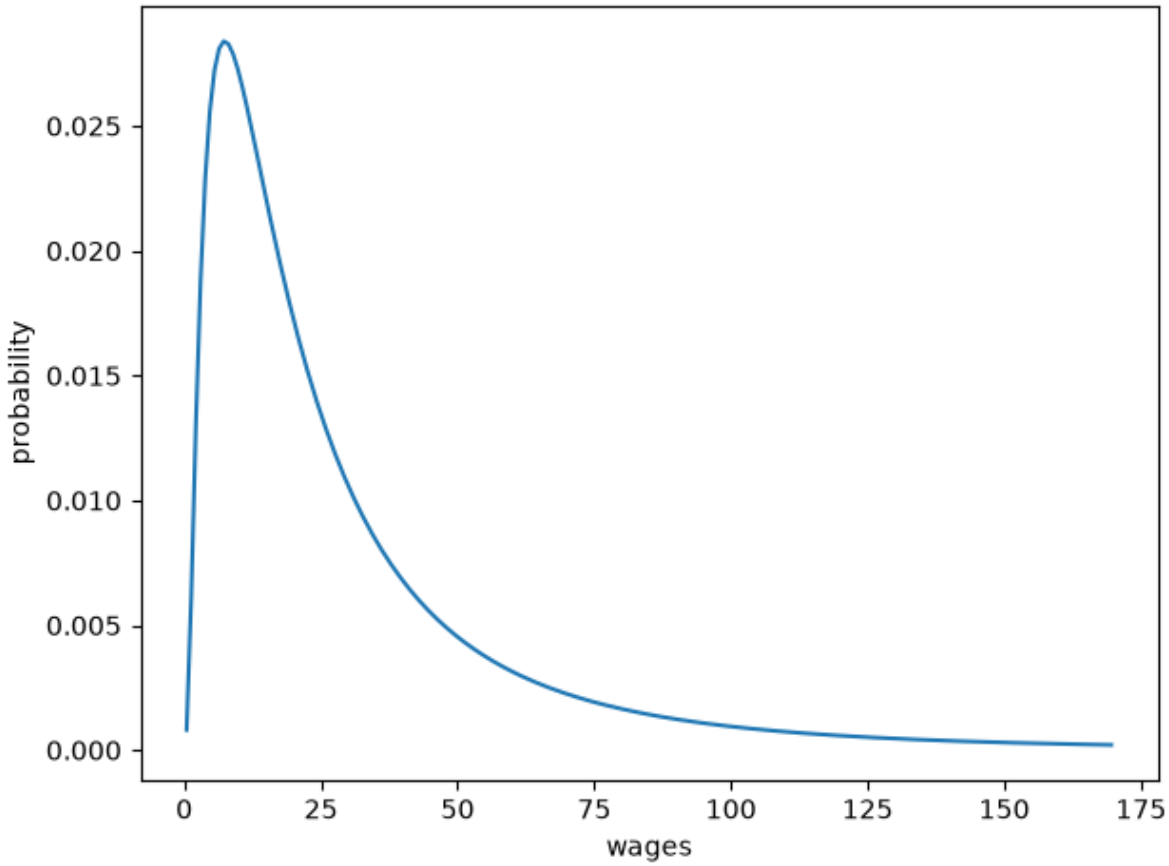
- If the wage offer w in hand is greater than or equal to $\bar{w}$, then the worker accepts.
- Otherwise, the worker rejects.

The reservation wage depends on the wage offer distribution and the parameters

- α, the separation rate
- β, the discount factor
- γ, the offer arrival rate
- c, unemployment compensation

The wage offer distribution will be a discretized version of a lognormal distribution.

We first define a function to create such a discrete distribution.



```
def create_wage_distribution(
        max_wage: float,
        wage_grid_size: int,
        log_wage_mean: float
    ):
    """
    Creates a discretized version of a lognormal density LN(log(m),1), where
    m is log_wage_mean.

    """
    w_vec_temp = jnp.linspace(1e-8, max_wage, wage_grid_size + 1)
    cdf = stats.norm.cdf(
        jnp.log(w_vec_temp), loc=jnp.log(log_wage_mean), scale=1
    )
    pdf = cdf[1:] - cdf[:-1]
    p_vec = pdf / pdf.sum()
    w_vec = (w_vec_temp[1:] + w_vec_temp[:-1]) / 2
    return w_vec, p_vec
```

The cell below creates a discretized $LN(\log(20), 1)$ wage distribution and plots it.

```
w_vec, p_vec = create_wage_distribution(170, 200, 20)

fig, ax = plt.subplots()
ax.plot(w_vec, p_vec)
ax.set_xlabel('wages')
ax.set_ylabel('probability')
plt.tight_layout()
plt.show()
```

Now we organize the code for solving the McCall model, given a set of parameters.

For background on the model and our solution method, see the *lecture on the McCall model with separation*

Our first step is to define the utility function and the McCall model data structure.

```
def u(c, σ=2.0):
    return jnp.where(c > 0, (c**(1 - σ) - 1) / (1 - σ), -10e6)

class McCallModel(NamedTuple):
    """
    Stores the parameters for the McCall search model
    """
    α: float            # Job separation rate
    β: float            # Discount rate
    γ: float            # Job offer rate
```

(continues on next page)

(continued from previous page)

```
    c: float            # Unemployment compensation
    σ: float            # Utility parameter
    w_vec: jnp.ndarray  # Possible wage values
    p_vec: jnp.ndarray  # Probabilities over w_vec

def create_mccall_model(
        α=0.2, β=0.98, γ=0.7, c=6.0, σ=2.0,
        w_vec=None,
        p_vec=None
    ) -> McCallModel:
    if w_vec is None:
        n = 60  # Number of possible outcomes for wage
        # Wages between 10 and 20
        w_vec = jnp.linspace(10, 20, n)
        a, b = 600, 400  # Shape parameters
        dist = BetaBinomial(n-1, a, b)
        p_vec = jnp.array(dist.pdf())
    return McCallModel(
        α=α, β=β, γ=γ, c=c, σ=σ, w_vec=w_vec, p_vec=p_vec
    )
```

Next, we implement the Bellman operator

```
def T(mcm: McCallModel, V, U):
    """
    Update the Bellman equations.
    """
    α, β, γ, c, σ = mcm.α, mcm.β, mcm.γ, mcm.c, mcm.σ
    w_vec, p_vec = mcm.w_vec, mcm.p_vec

    V_new = u(w_vec, σ) + β * ((1 - α) * V + α * U)
    U_new = u(c, σ) + β * (1 - γ) * U + β * γ * (jnp.maximum(U, V) @ p_vec)

    return V_new, U_new
```

Now we define the value function iteration solver.

We'll use a compiled while loop for extra speed.

```
@jax.jit
def solve_mccall_model(mcm: McCallModel, tol=1e-5, max_iter=2000):
    """
    Iterates to convergence on the Bellman equations.
    """
    def cond(state):
        V, U, i, error = state
        return jnp.logical_and(error > tol, i < max_iter)

    def update(state):
        V, U, i, error = state
        V_new, U_new = T(mcm, V, U)
        error_1 = jnp.max(jnp.abs(V_new - V))
        error_2 = jnp.abs(U_new - U)
        error_new = jnp.maximum(error_1, error_2)
        return V_new, U_new, i + 1, error_new
```

(continues on next page)

(continued from previous page)

```
    # Initial state
    V_init = jnp.ones(len(mcm.w_vec))
    U_init = 1.0
    i_init = 0
    error_init = tol + 1

    init_state = (V_init, U_init, i_init, error_init)
    V_final, U_final, _, _ = jax.lax.while_loop(
        cond, update, init_state
    )
    return V_final, U_final
```

116.2.2 Lake model code

We also need the lake model functions from the previous lecture to compute steady state unemployment rates:

```
class LakeModel(NamedTuple):
    """
    Parameters for the lake model
    """
    λ: float
    α: float
    b: float
    d: float
    A: jnp.ndarray
    R: jnp.ndarray
    g: float

def create_lake_model(
        λ: float = 0.283,      # job finding rate
        α: float = 0.013,      # separation rate
        b: float = 0.0124,     # birth rate
        d: float = 0.00822     # death rate
    ) -> LakeModel:
    """
    Create a LakeModel instance with default parameters.

    Computes and stores the transition matrices A and R,
    and the labor force growth rate g.

    """
    # Compute growth rate
    g = b - d

    # Compute transition matrix A
    A = jnp.array([
        [(1-d) * (1-λ) + b, (1-d) * α + b],
        [(1-d) * λ,         (1-d) * (1-α)]
    ])

    # Compute normalized transition matrix R
    R = A / (1 + g)

    return LakeModel(λ=λ, α=α, b=b, d=d, A=A, R=R, g=g)
```

(continues on next page)

(continued from previous page)

```
@jax.jit
def rate_steady_state(model: LakeModel) -> jnp.ndarray:
    r"""
    Finds the steady state of the system :math:`x_{t+1} = R x_{t}`
    by computing the eigenvector corresponding to the largest eigenvalue.

    By the Perron-Frobenius theorem, since :math:`R` is a non-negative
    matrix with columns summing to 1 (a stochastic matrix), the largest
    eigenvalue equals 1 and the corresponding eigenvector gives the steady state.
    """
    λ, α, b, d, A, R, g = model
    eigenvals, eigenvec = jnp.linalg.eig(R)

    # Find the eigenvector corresponding to the largest eigenvalue
    # (which is 1 for a stochastic matrix by Perron-Frobenius theorem)
    max_idx = jnp.argmax(jnp.abs(eigenvals))

    # Get the corresponding eigenvector
    steady_state = jnp.real(eigenvec[:, max_idx])

    # Normalize to ensure positive values and sum to 1
    steady_state = jnp.abs(steady_state)
    steady_state = steady_state / jnp.sum(steady_state)

    return steady_state
```

116.2.3 Linking the McCall search model to the lake model

Suppose that all workers inside a lake model behave according to the McCall search model.

The exogenous probability of leaving employment remains α.

But their optimal decision rules determine the probability λ of leaving unemployment.

This is now

$$\lambda = \gamma \mathbb{P}\{w_t \geq \bar{w}\} = \gamma \sum_{w' \geq \bar{w}} p(w') \tag{116.1}$$

Here

- $\bar{w}$ is the reservation wage determined by the parameters and
- p is the wage offer distribution.

Wage offers across the population of workers are independent draws from p.

Here we calculate λ at the default parameters:

```
mcm = create_mccall_model(w_vec=w_vec, p_vec=p_vec)
V, U = solve_mccall_model(mcm)
w_idx = jnp.searchsorted(V - U, 0)
w_bar = jnp.where(w_idx == len(V), jnp.inf, mcm.w_vec[w_idx])
λ = mcm.γ * jnp.sum(p_vec * (w_vec > w_bar))
print(f"Job finding rate at default paramters ={λ}.")
```

```
Job finding rate at default paramters =0.4510621726512909.
```

116.3 Fiscal policy

In this section, we will put the lake model to work, examining outcomes associated with different levels of unemployment compensation.

Our aim is to find an optimal level of unemployment insurance.

We assume that the government sets unemployment compensation c.

The government imposes a lump-sum tax τ sufficient to finance total unemployment payments.

To attain a balanced budget at a steady state, taxes, the steady state unemployment rate u, and the unemployment compensation rate must satisfy

$$\tau = uc$$

The lump-sum tax applies to everyone, including unemployed workers.

- The post-tax income of an employed worker with wage w is $w - \tau$.
- The post-tax income of an unemployed worker is $c - \tau$.

For each specification (c, τ) of government policy, we can solve for the worker's optimal reservation wage.

This determines λ via (116.1) evaluated at post tax wages, which in turn determines a steady state unemployment rate $u(c, \tau)$.

For a given level of unemployment benefit c, we can solve for a tax that balances the budget in the steady state

$$\tau = u(c, \tau)c$$

To evaluate alternative government tax-unemployment compensation pairs, we require a welfare criterion.

We use a steady state welfare criterion

$$W := e\,\mathbb{E}[V \,|\, \text{employed}] + u\,U$$

where the notation V and U is as defined above and the expectation is at the steady state.

116.3.1 Computing optimal unemployment insurance

Now we set up the infrastructure to compute optimal unemployment insurance levels.

First, we define a container for the economy's parameters:

```
class Economy(NamedTuple):
    """Parameters for the economy"""
    α: float
    b: float
    d: float
    β: float
    γ: float
    σ: float
    log_wage_mean: float
    wage_grid_size: int
```

(continues on next page)

(continued from previous page)

```
    max_wage: float

def create_economy(
        α=0.013,
        b=0.0124,
        d=0.00822,
        β=0.98,
        γ=1.0,
        σ=2.0,
        log_wage_mean=20,
        wage_grid_size=200,
        max_wage=170
    ) -> Economy:
    """
    Create an economy with a set of default values"""
    return Economy(α=α, b=b, d=d, β=β, γ=γ, σ=σ,
                           log_wage_mean=log_wage_mean,
                           wage_grid_size=wage_grid_size,
                           max_wage=max_wage)
```

Next, we define a function that computes optimal worker behavior given policy parameters:

```
@jax.jit
def compute_optimal_quantities(
        c: float,
        τ: float,
        economy: Economy,
        w_vec: jnp.array,
        p_vec: jnp.array
    ):
    """
    Compute the reservation wage, job finding rate and value functions
    of the workers given c and τ.

    """
    mcm = create_mccall_model(
        α=economy.α,
        β=economy.β,
        γ=economy.γ,
        c=c-τ,          # Post tax compensation
        σ=economy.σ,
        w_vec=w_vec-τ,  # Post tax wages
        p_vec=p_vec
    )

    # Compute reservation wage under given parameters
    V, U = solve_mccall_model(mcm)
    w_idx = jnp.searchsorted(V - U, 0)
    w_bar = jnp.where(w_idx == len(V), jnp.inf, mcm.w_vec[w_idx])

    # Compute job finding rate
    λ = economy.γ * jnp.sum(p_vec * (w_vec - τ > w_bar))

    return w_bar, λ, V, U
```

This function computes the steady state outcomes given unemployment insurance and tax levels:

```
@jax.jit
def compute_steady_state_quantities(
        c, τ, economy: Economy, w_vec, p_vec
    ):
    """
    Compute the steady state unemployment rate given c and τ using optimal
    quantities from the McCall model and computing corresponding steady
    state quantities

    """

    # Find optimal values and policies by solving the McCall model, as well
    # as the corresponding job finding rate.
    w_bar, λ, V, U = compute_optimal_quantities(c, τ, economy, w_vec, p_vec)

    # Set up a lake model using the given parameters and the job finding rate.
    model = create_lake_model(λ=λ, α=economy.α, b=economy.b, d=economy.d)

    # Compute steady state employment and unemployment rates from this lake
    # model.
    u, e = rate_steady_state(model)

    # Compute expected lifetime value conditional on being employed.
    mask = (w_vec - τ > w_bar)
    w = jnp.sum(V * p_vec * mask) / jnp.sum(p_vec * mask)
    # Compute steady state welfare.
    welfare = e * w + u * U

    return e, u, welfare
```

We need a function to find the tax rate that balances the government budget:

```
def find_balanced_budget_tax(c, economy: Economy, w_vec, p_vec):
    """
    Find the tax rate that will induce a balanced budget given unemployment
    compensation c.

    """

    def steady_state_budget(t):
        """
        For given tax rate t, compute the budget surplus.

        """
        e, u, w = compute_steady_state_quantities(c, t, economy, w_vec, p_vec)
        return t - u * c

    # Use a simple bisection method to find the tax rate that balances the
    # budget (but setting the surplus to zero

    t_low, t_high = 0.0, 0.9 * c
    tol = 1e-6
    max_iter = 100
    for i in range(max_iter):
        t_mid = (t_low + t_high) / 2
        budget = steady_state_budget(t_mid)
        if abs(budget) < tol:
```

(continues on next page)

(continued from previous page)

```
            return t_mid
        elif budget < 0:
            t_low = t_mid
        else:
            t_high = t_mid

    return t_mid
```

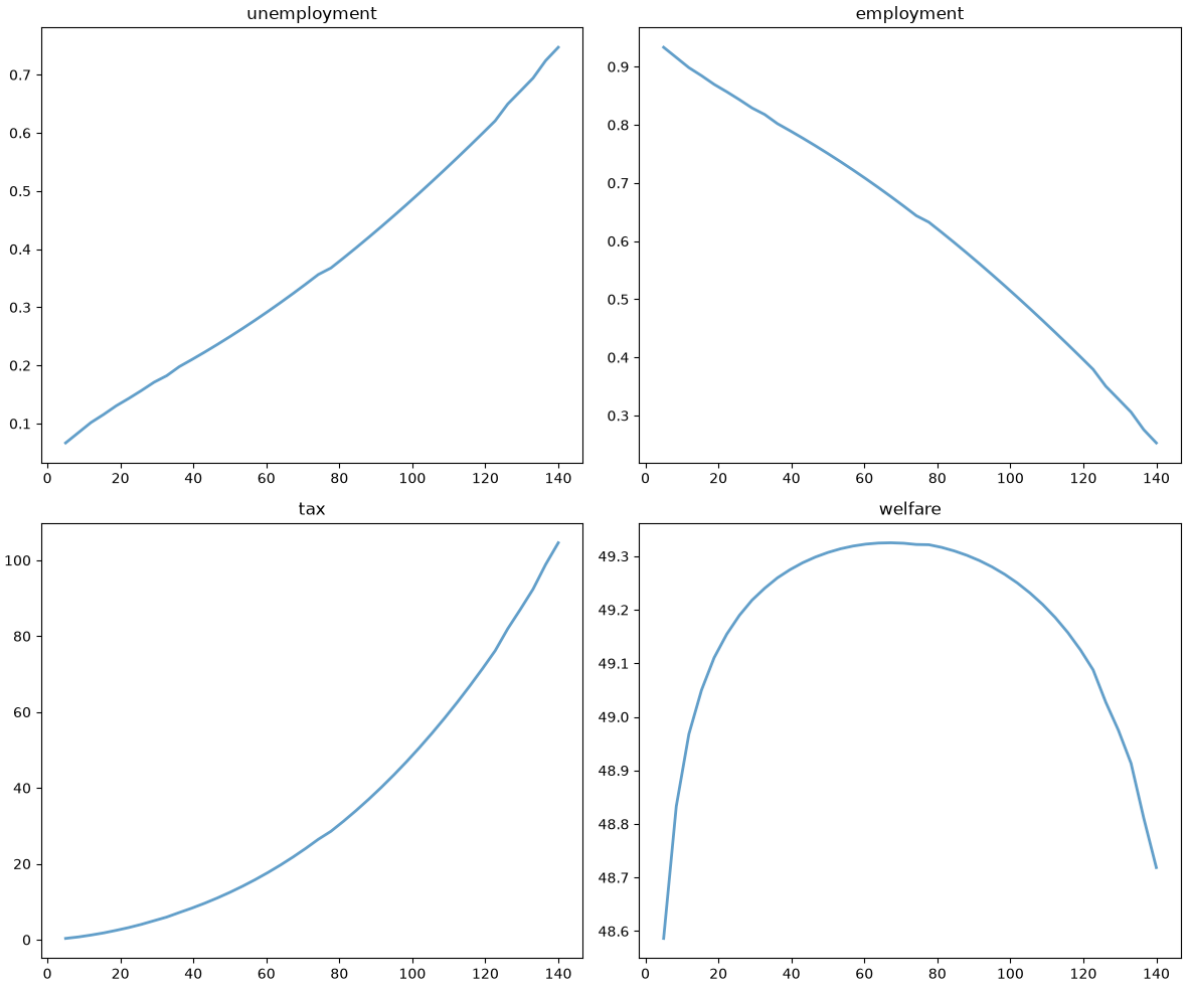
Now we compute how employment, unemployment, taxes, and welfare vary with the unemployment compensation rate:

```
# Create economy and wage distribution
economy = create_economy()
w_vec, p_vec = create_wage_distribution(
    economy.max_wage, economy.wage_grid_size, economy.log_wage_mean
)

# Levels of unemployment insurance we wish to study
c_vec = jnp.linspace(5, 140, 40)

tax_vec = []
unempl_vec = []
empl_vec = []
welfare_vec = []

for c in c_vec:
    t = find_balanced_budget_tax(c, economy, w_vec, p_vec)
    e_rate, u_rate, welfare = compute_steady_state_quantities(
        c, t, economy, w_vec, p_vec
    )
    tax_vec.append(t)
    unempl_vec.append(u_rate)
    empl_vec.append(e_rate)
    welfare_vec.append(welfare)
```



Let's visualize the results:

```
fig, axes = plt.subplots(2, 2, figsize=(12, 10))

plots = [unempl_vec, empl_vec, tax_vec, welfare_vec]
titles = ['unemployment', 'employment', 'tax', 'welfare']

for ax, plot, title in zip(axes.flatten(), plots, titles):
    ax.plot(c_vec, plot, lw=2, alpha=0.7)
    ax.set_title(title)

plt.tight_layout()
plt.show()
```

Welfare first increases and then decreases as unemployment benefits rise.

The level that maximizes steady state welfare is approximately 62.

116.4 Exercises

Exercise 116.4.1

How does the welfare-maximizing level of unemployment compensation c change with the job separation rate α?

Compute and plot the optimal c (the value that maximizes welfare) for a range of separation rates α from 0.01 to 0.04.

For each α value, find the optimal c by computing welfare across the range of c values and selecting the maximum.

Solution

Here is one solution:

```
# Range of separation rates to explore (wider range, fewer points)
α_values = jnp.linspace(0.01, 0.04, 8)

# We'll store the optimal c for each α
optimal_c_values = []

# Use a finer grid for c values to get better resolution
c_vec_fine = jnp.linspace(5, 140, 150)

for α_val in α_values:
    # Create economy parameters with this α
    params_α = create_economy(α=α_val)

    # Create wage distribution
    w_vec_α, p_vec_α = create_wage_distribution(
        params_α.max_wage, params_α.wage_grid_size, params_α.log_wage_mean
    )

    # Compute welfare for each c value
    welfare_values = []
    for c in c_vec_fine:
        t = find_balanced_budget_tax(c, params_α, w_vec_α, p_vec_α)
        e_rate, u_rate, welfare = compute_steady_state_quantities(
            c, t, params_α, w_vec_α, p_vec_α
        )
        welfare_values.append(welfare)

    # The welfare function is very flat near its maximum.
    # Using argmax on a single point can be unstable due to numerical noise.
    # Instead, we find all c values within 99.9% of maximum welfare and
    # compute their weighted average (centroid). This gives a more stable
    # estimate of the optimal unemployment compensation level.
    welfare_array = jnp.array(welfare_values)
    max_welfare = jnp.max(welfare_array)
    threshold = 0.999 * max_welfare
    near_optimal_mask = welfare_array >= threshold

    # Compute weighted average of c values in the near-optimal region
    optimal_c = jnp.sum(c_vec_fine * near_optimal_mask * welfare_array) / \
                jnp.sum(near_optimal_mask * welfare_array)
    optimal_c_values.append(optimal_c)

# Plot the relationship
fig, ax = plt.subplots(figsize=(10, 6))
ax.plot(α_values, optimal_c_values, lw=2, marker='o')
ax.set_xlabel(r'Separation rate $\alpha$')
ax.set_ylabel('Optimal unemployment compensation $c$')
ax.set_title('How optimal unemployment insurance varies with job separation rate')
ax.grid(True, alpha=0.3)
plt.tight_layout()
plt.show()
```

We see that as the separation rate increases (workers lose their jobs more frequently), the welfare-maximizing level of unemployment compensation decreases.

This occurs because higher separation rates increase steady-state unemployment, which raises the tax burden needed to finance unemployment benefits. The optimal policy balances insurance against distortionary taxation.

```

117.1 Overview

This lecture introduces the concept of a *rational expectations equilibrium*.

To illustrate it, we describe a linear quadratic version of a model due to Lucas and Prescott [Lucas and Prescott, 1971].

That 1971 paper is one of a small number of research articles that ignited a *rational expectations revolution*.

You can regard the present lecture as a "baby" version of that paper, and as an introduction to ideas that two sequels study in more general settings.

Investment Under Uncertainty describes the model that Lucas and Prescott actually built, in which demand is shifted by a Markov process, so that the equilibrium is a stochastic process rather than a deterministic path.

Optimal Growth Under Uncertainty and Tobin's q studies a one-sector optimal growth model with random shocks to production, and uses it to think about Tobin's q.

Both sequels ask a question that cannot arise here, because this lecture has no uncertainty: does the equilibrium have an invariant probability distribution to which it converges from any initial condition?

We follow Lucas and Prescott by employing a setting that is readily "Bellmanized" (i.e., susceptible to being formulated as a dynamic programming problems.

Because we use linear quadratic setups for demand and costs, we can deploy the LQ programming techniques described in *this lecture*.

We will learn about how a representative agent's problem differs from a planner's, and how a planning problem can be used to compute quantities and prices in a rational expectations equilibrium.

We will also learn about how a rational expectations equilibrium can be characterized as a fixed point of a mapping from a *perceived law of motion* to an *actual law of motion*.

Equality between a perceived and an actual law of motion for endogenous market-wide objects captures in a nutshell what the rational expectations equilibrium concept is all about.

Finally, we will learn about the important "Big K, little k" trick, a modeling device widely used in macroeconomics.

Except that for us

- Instead of "Big K" it will be "Big Y".
- Instead of "little k" it will be "little y".

Let's start with some standard imports:

```
import matplotlib.pyplot as plt
import numpy as np
```

We'll also use the LQ class from `QuantEcon.py`.

```
from quantecon import LQ
```

117.1.1 The big Y, little y trick

This widely used method applies in contexts in which a **representative firm** or agent is a "price taker" operating within a competitive equilibrium.

The following setting justifies the concept of a representative firm that stands in for a large number of other firms too.

There is a uniform unit measure of identical firms named $\omega \in \Omega = [0, 1]$.

The output of firm ω is $y(\omega)$.

The output of all firms is $Y = \int_0^1 y(\omega) d\,\omega$.

All firms end up choosing to produce the same output, so that at the end of the day $y(\omega) = y$ and $Y = y = \int_0^1 y(\omega) d\,\omega$.

This setting allows us to speak of a representative firm that chooses to produce y.

We want to impose that

- The representative firm or individual firm takes *aggregate* Y as given when it chooses individual $y(\omega)$, but ....
- At the end of the day, $Y = y(\omega) = y$, so that the representative firm is indeed representative.

The Big Y, little y trick accomplishes these two goals by

- Taking Y as beyond control when posing the choice problem of who chooses y; but ....
- Imposing $Y = y$ *after* having solved the individual's optimization problem.

Please watch for how this strategy is applied as the lecture unfolds.

We begin by applying the Big Y, little y trick in a very simple static context.

A simple static example of the big Y, little y trick

Consider a static model in which a unit measure of firms produce a homogeneous good that is sold in a competitive market.

Each of these firms ends up producing and selling output $y(\omega) = y$.

The price p of the good lies on an inverse demand curve

$$p = a_0 - a_1 Y \tag{117.1}$$

where

- $a_i > 0$ for $i = 0, 1$
- $Y = \int_0^1 y(\omega) d\omega$ is the market-wide level of output

For convenience, we'll often just write y instead of $y(\omega)$ when we are describing the choice problem of an individual firm $\omega \in \Omega$.

Each firm has a total cost function

$$c(y) = c_1 y + 0.5 c_2 y^2, \qquad c_i > 0 \text{ for } i = 1, 2$$

The profits of a representative firm are $py - c(y)$.

Using (117.1), we can express the problem of the representative firm as

$$\max_y \left[(a_0 - a_1 Y) y - c_1 y - 0.5 c_2 y^2 \right] \tag{117.2}$$

In posing problem (117.2), we want the firm to be a *price taker*.

We do that by regarding p and therefore Y as exogenous to the firm.

The essence of the Big Y, little y trick is *not* to set $Y = ny$ *before* taking the first-order condition with respect to y in problem (117.2).

This assures that the firm is a price taker.

The first-order condition for problem (117.2) is

$$a_0 - a_1 Y - c_1 - c_2 y = 0 \tag{117.3}$$

At this point, *but not before*, we substitute $Y = y$ into (117.3) to obtain the following linear equation

$$a_0 - c_1 - (a_1 + c_2) Y = 0 \tag{117.4}$$

to be solved for the competitive equilibrium market-wide output Y.

After solving for Y, we can compute the competitive equilibrium price p from the inverse demand curve (117.1).

117.1.2 Related planning problem

Define **consumer surplus** as the area under the inverse demand curve:

$$S_c(Y) = \int_0^Y (a_0 - a_1 s) ds = a_o Y - \frac{a_1}{2} Y^2.$$

Define the social cost of production as

$$S_p(Y) = c_1 Y + \frac{c_2}{2} Y^2$$

Consider the planning problem

$$\max_Y [S_c(Y) - S_p(Y)]$$

The first-order necessary condition for the planning problem is equation (117.4).

Thus, a Y that solves (117.4) is a competitive equilibrium output as well as an output that solves the planning problem.

This type of outcome provides an intellectual justification for liking a competitive equilibrium.

117.1.3 Further reading

References for this lecture include

- [Ljungqvist and Sargent, 2018], chapter 7

The two sequels to this lecture are *Investment Under Uncertainty* and *Optimal Growth Under Uncertainty and Tobin's q*.

117.2 Rational expectations equilibrium

Our first illustration of a rational expectations equilibrium involves a market with a unit measure of identical firms, each of which seeks to maximize the discounted present value of profits in the face of adjustment costs.

The adjustment costs induce the firms to make gradual adjustments, which in turn requires consideration of future prices.

Individual firms understand that, via the inverse demand curve, the price is determined by the amounts supplied by other firms.

Hence each firm wants to forecast future total industry output.

In our context, a forecast is generated by a belief about the law of motion for the aggregate state.

Rational expectations equilibrium prevails when this belief coincides with the actual law of motion generated by production choices induced by this belief.

We formulate a rational expectations equilibrium in terms of a fixed point of an operator that maps beliefs into optimal beliefs.

117.2.1 Competitive equilibrium with adjustment costs

To illustrate, consider a collection of n firms producing a homogeneous good that is sold in a competitive market.

Each firm sell output $y_t(\omega) = y_t$.

The price p_t of the good lies on the inverse demand curve

$$p_t = a_0 - a_1 Y_t \tag{117.5}$$

where

- $a_i > 0$ for $i = 0, 1$
- $Y_t = \int_0^1 y_t(\omega) d\omega = y_t$ is the market-wide level of output

The firm's problem

Each firm is a price taker.

While it faces no uncertainty, it does face adjustment costs

In particular, it chooses a production plan to maximize

$$\sum_{t=0}^{\infty} \beta^t r_t \tag{117.6}$$

where

$$r_t := p_t y_t - \frac{\gamma (y_{t+1} - y_t)^2}{2}, \qquad y_0 \text{ given} \tag{117.7}$$

Regarding the parameters,

- $\beta \in (0, 1)$ is a discount factor
- $\gamma > 0$ measures the cost of adjusting the rate of output

Regarding timing, the firm observes p_t and y_t when it chooses y_{t+1} at time t.

To state the firm's optimization problem completely requires that we specify dynamics for all state variables.

This includes ones that the firm cares about but does not control like p_t.

We turn to this problem now.

Prices and aggregate output

In view of (117.5), the firm's incentive to forecast the market price translates into an incentive to forecast aggregate output Y_t.

Aggregate output depends on the choices of other firms.

The output $y_t(\omega)$ of a single firm ω has a negligible effect on aggregate output $\int_0^1 y_t(\omega) d\omega$.

That justifies firms in regarding their forecasts of aggregate output as being unaffected by their own output decisions.

Representative firm's beliefs

We suppose the firm believes that market-wide output Y_t follows the law of motion

$$Y_{t+1} = H(Y_t) \tag{117.8}$$

where Y_0 is a known initial condition.

The **belief function** H is an equilibrium object, and hence remains to be determined.

Because of this, at this stage Y_{t+1} only means the perceived output in the next period, Y_{t+1}^e.

Optimal behavior given beliefs

For now, let's fix a particular belief H in (117.8) and investigate the firm's response to it.

Let v be the optimal value function for the firm's problem given H.

The value function satisfies the Bellman equation

$$v(y, Y) = \max_{y'} \left\{ a_0 y - a_1 y Y - \frac{\gamma(y' - y)^2}{2} + \beta v(y', H(Y)) \right\} \tag{117.9}$$

Let's denote the firm's optimal policy function by h, so that

$$y_{t+1} = h(y_t, Y_t) \tag{117.10}$$

where

$$h(y, Y) := \text{argmax}_{y'} \left\{ a_0 y - a_1 y Y - \frac{\gamma(y' - y)^2}{2} + \beta v(y', H(Y)) \right\} \tag{117.11}$$

Evidently v and h both depend on H.

Characterization with first-order necessary conditions

In what follows it will be helpful to have a second characterization of h, based on first-order conditions.

The first-order necessary condition for choosing y' is

$$-\gamma(y' - y) + \beta v_y(y', H(Y)) = 0 \tag{117.12}$$

An important useful envelope result of Benveniste-Scheinkman [Benveniste and Scheinkman, 1979] implies that to differentiate v with respect to y we can naively differentiate the right side of (117.9), giving

$$v_y(y, Y) = a_0 - a_1 Y + \gamma(y' - y)$$

and equivalently, $v_y(y', H(Y)) = a_0 - a_1 H(Y) + \gamma(y'' - y')$

Substituting this equation into (117.12) gives the **Euler equation**

$$-\gamma(y_{t+1} - y_t) + \beta[a_0 - a_1 H(Y_t) + \gamma(y_{t+2} - y_{t+1})] = 0 \tag{117.13}$$

The firm optimally sets an output path that satisfies (117.13), taking (117.8) as given, and subject to

- the initial conditions for (y_0, Y_0).
- the terminal condition $\lim_{t \to \infty} \beta^t y_t v_y(y_t, Y_t) = 0$.

This last condition is called the **transversality condition**, and acts as a first-order necessary condition "at infinity".

A representative firm's decision rule solves the difference equation (117.13) subject to the given initial condition y_0 and the transversality condition.

Note that solving the Bellman equation (117.9) for v and then h in (117.11) yields a decision rule that automatically imposes both the Euler equation (117.13) and the transversality condition.

The actual law of motion for output

As we've seen, a given belief translates into a particular decision rule h.

Recalling that in equilbrium $Y_t = y_t$, the **actual law of motion** for market-wide output is then

$$Y_{t+1} = h(Y_t, Y_t) \tag{117.14}$$

Thus, when firms believe that the law of motion for market-wide output is (117.8), their optimizing behavior makes the actual law of motion be (117.14).

117.2.2 Definition of rational expectations equilibrium

Definition

A **rational expectations equilibrium** or **recursive competitive equilibrium** of the model with adjustment costs is a decision rule h and an aggregate law of motion H such that

1. Given belief H, the map h is the firm's optimal policy function.
2. The law of motion H satisfies $H(Y) = h(Y, Y)$ for all Y.

Thus, a rational expectations equilibrium equates the perceived and actual laws of motion (117.8) and (117.14).

Fixed point characterization

As we've seen, the firm's optimum problem induces a mapping Φ from a perceived law of motion H for market-wide output to an actual law of motion $\Phi(H)$.

The mapping Φ is the composition of two mappings, the first of which maps a perceived law of motion into a decision rule via (117.9)–(117.11), the second of which maps a decision rule into an actual law via (117.14).

The H component of a rational expectations equilibrium is a fixed point of Φ.

117.3 Computing an equilibrium

Now let's compute a rational expectations equilibrium.

117.3.1 Failure of contractivity

Readers accustomed to dynamic programming arguments might try to address this problem by choosing some guess H_0 for the aggregate law of motion and then iterating with Φ.

Unfortunately, the mapping Φ is not a contraction.

Indeed, there is no guarantee that direct iterations on Φ converge[1].

There are examples in which these iterations diverge.

[1] A literature that studies whether models populated with agents who learn can converge to rational expectations equilibria features iterations on a modification of the mapping Φ that can be approximated as $\gamma\Phi + (1-\gamma)I$. Here I is the identity operator and $\gamma \in (0, 1)$ is a *relaxation parameter*. See Marcet and Sargent [1989] and Evans and Honkapohja [2001] for statements and applications of this approach to establish conditions under which collections of adaptive agents who use least squares learning to converge to a rational expectations equilibrium.

To see this intuitively, consider Blackwell's sufficient condition and suppose there are two beliefs with $H_a(Y) > H_b(Y)$ for every Y.

By the Euler equation (117.13), the actual law of motion $Y_{t+1} = h(Y_t, Y_t)$ decreases as H increases, so Φ reverses the ordering of beliefs.

Hence the monotonicity required by Blackwell's condition fails.

Fortunately, another method works here.

The method exploits a connection between equilibrium and Pareto optimality expressed in the fundamental theorems of welfare economics (see, e.g, [Mas-Colell *et al.*, 1995]).

Lucas and Prescott [Lucas and Prescott, 1971] used this method to construct a rational expectations equilibrium.

Some details follow.

117.3.2 A planning problem approach

Our plan of attack is to match the Euler equations of the market problem with those for a single-agent choice problem.

As we'll see, this planning problem can be solved by LQ control (*linear regulator*).

Optimal quantities from the planning problem are rational expectations equilibrium quantities.

The rational expectations equilibrium price can be obtained as a shadow price in the planning problem.

We first compute a sum of consumer and producer surplus at time t

$$s(Y_t, Y_{t+1}) := \int_0^{Y_t} (a_0 - a_1 x)\, dx - \frac{\gamma (Y_{t+1} - Y_t)^2}{2} \tag{117.15}$$

The first term is the area under the demand curve, while the second measures the social costs of changing output.

The **planning problem** is to choose a production plan $\{Y_t\}$ to maximize

$$\sum_{t=0}^{\infty} \beta^t s(Y_t, Y_{t+1})$$

subject to an initial condition for Y_0.

117.3.3 Solution of planning problem

Evaluating the integral in (117.15) yields the quadratic form $a_0 Y_t - a_1 Y_t^2/2$.

As a result, the Bellman equation for the planning problem is

$$V(Y) = \max_{Y'} \left\{ a_0 Y - \frac{a_1}{2} Y^2 - \frac{\gamma (Y' - Y)^2}{2} + \beta V(Y') \right\} \tag{117.16}$$

The associated first-order condition is

$$-\gamma (Y' - Y) + \beta V'(Y') = 0 \tag{117.17}$$

Applying the same Benveniste-Scheinkman formula gives

$$V'(Y) = a_0 - a_1 Y + \gamma (Y' - Y)$$

Substituting this into equation (117.17) and rearranging leads to the Euler equation

$$\beta a_0 + \gamma Y_t - [\beta a_1 + \gamma (1 + \beta)] Y_{t+1} + \gamma \beta Y_{t+2} = 0 \tag{117.18}$$

117.3.4 Key insight

Return to equation (117.13) and set $y_t = Y_t$ for all t.

In a rational expectations equilibrium the perceived and actual laws of motion agree, so $H(Y_t) = Y_{t+1}$.

Imposing this alongside $y_t = Y_t$, a small amount of algebra will convince you that equations (117.18) and (117.13) are identical.

Thus, the Euler equation for the planning problem matches the second-order difference equation that we derived by

1. finding the Euler equation of the representative firm and
2. substituting into it the expression $Y_t = y_t$ that "makes the representative firm be representative".

If it is appropriate to apply the same terminal conditions for these two difference equations, which it is, then we have verified that a solution of the planning problem is also a rational expectations equilibrium quantity sequence.

It follows that for this example we can compute equilibrium quantities by forming the optimal linear regulator problem corresponding to the Bellman equation (117.16).

The optimal policy function for the planning problem is the aggregate law of motion H that the representative firm faces within a rational expectations equilibrium.

Structure of the law of motion

As you are asked to show in the exercises, the fact that the planner's problem is an LQ control problem implies an optimal policy — and hence aggregate law of motion — taking the form

$$Y_{t+1} = \kappa_0 + \kappa_1 Y_t \tag{117.19}$$

for some parameter pair κ_0, κ_1.

Now that we know the aggregate law of motion is linear, we can see from the firm's Bellman equation (117.9) that the firm's problem can also be framed as an LQ problem.

As you're asked to show in the exercises, the LQ formulation of the firm's problem implies a law of motion that looks as follows

$$y_{t+1} = h_0 + h_1 y_t + h_2 Y_t \tag{117.20}$$

Hence a rational expectations equilibrium will be defined by the parameters $(\kappa_0, \kappa_1, h_0, h_1, h_2)$ in (117.19)–(117.20).

117.4 Concluding remarks

Three ideas from this lecture recur throughout macroeconomics.

The first is the equilibrium concept itself: a *perceived* law of motion for a market-wide object must coincide with the *actual* law of motion that the resulting decisions generate.

The second is the "Big Y, little y" device that lets a price-taking firm be representative.

The third is the computational strategy: because the mapping from perceived to actual laws of motion is not a contraction, we found an equilibrium by solving a *planning problem* instead, and then read off equilibrium prices as shadow prices.

The two sequels take these ideas into settings with uncertainty.

Investment Under Uncertainty returns to Lucas and Prescott [1971] itself.

There, demand is shifted by a Markov process, firms face a nonlinear technology for converting investment into capacity, and the equilibrium is proved to exist, to be unique, and to solve a planning problem that maximizes discounted consumer surplus.

Because the equilibrium is a Markov process, one can ask whether it converges to an invariant distribution, and whether time averages computed from a single realization converge to population moments.

Affirmative answers are what make such models usable in econometrics.

Optimal Growth Under Uncertainty and Tobin's q pursues the same questions in the one-sector optimal growth model of Brock and Mirman [1972], and then follows Sargent [1980] in adding irreversible investment.

That small change makes the shadow price of installed capital – Tobin's q – diverge from the price of new capital, and it turns the planner's value function into the object on which a theory of investment rests.

The fixed-point idea also survives when beliefs are allowed to be wrong: *Self-Confirming Equilibria* keeps the requirement that perceived and actual laws of motion agree on the outcomes that are actually observed, while letting beliefs be wrong off the equilibrium path.

117.5 Exercises

Exercise 117.5.1

Consider the firm problem *described above*.

Let the firm's belief function H be as given in (117.19).

Formulate the firm's problem as a discounted optimal linear regulator problem, being careful to describe all of the objects needed.

Use the class `LQ` from the QuantEcon.py package to solve the firm's problem for the following parameter values:

$$a_0 = 100, a_1 = 0.05, \beta = 0.95, \gamma = 10, \kappa_0 = 95.5, \kappa_1 = 0.95$$

Express the solution of the firm's problem in the form (117.20) and give the values for each h_j.

If there were a unit measure of identical competitive firms all behaving according to (117.20), what would (117.20) imply for the *actual* law of motion (117.8) for market supply.

Solution

To map a problem into a *discounted optimal linear control problem*, we need to define

- state vector x_t and control vector u_t
- matrices A, B, Q, R that define preferences and the law of motion for the state

For the state and control vectors, we choose

$$x_t = \begin{bmatrix} y_t \\ Y_t \\ 1 \end{bmatrix}, \qquad u_t = y_{t+1} - y_t$$

For B, Q, R we set

$$A = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \kappa_1 & \kappa_0 \\ 0 & 0 & 1 \end{bmatrix}, \quad B = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}, \quad R = \begin{bmatrix} 0 & a_1/2 & -a_0/2 \\ a_1/2 & 0 & 0 \\ -a_0/2 & 0 & 0 \end{bmatrix}, \quad Q = \gamma/2$$

By multiplying out you can confirm that

- $x_t' R x_t + u_t' Q u_t = -r_t$
- $x_{t+1} = Ax_t + Bu_t$

We'll use the module `lqcontrol.py` to solve the firm's problem at the stated parameter values.

This will return an LQ policy F with the interpretation $u_t = -Fx_t$, or

$$y_{t+1} - y_t = -F_0 y_t - F_1 Y_t - F_2$$

Matching parameters with $y_{t+1} = h_0 + h_1 y_t + h_2 Y_t$ leads to

$$h_0 = -F_2, \quad h_1 = 1 - F_0, \quad h_2 = -F_1$$

Here's our solution

```
# Model parameters

a0 = 100
a1 = 0.05
β = 0.95
γ = 10.0

# Beliefs

κ0 = 95.5
κ1 = 0.95

# Formulate the LQ problem

A = np.array([[1, 0, 0], [0, κ1, κ0], [0, 0, 1]])
B = np.array([1, 0, 0])
B.shape = 3, 1
R = np.array([[0, a1/2, -a0/2], [a1/2, 0, 0], [-a0/2, 0, 0]])
Q = 0.5 * γ

# Solve for the optimal policy

lq = LQ(Q, R, A, B, beta=β)
P, F, d = lq.stationary_values()
F = F.flatten()
out1 = f"F = [{F[0]:.3f}, {F[1]:.3f}, {F[2]:.3f}]"
h0, h1, h2 = -F[2], 1 - F[0], -F[1]
out2 = f"(h0, h1, h2) = ({h0:.3f}, {h1:.3f}, {h2:.3f})"

print(out1)
print(out2)
```

```
F = [-0.000, 0.046, -96.949]
(h0, h1, h2) = (96.949, 1.000, -0.046)
```

The implication is that

$$y_{t+1} = 96.949 + y_t - 0.046\, Y_t$$

For the case $n > 1$, recall that $Y_t = n y_t$, which, combined with the previous equation, yields

$$Y_{t+1} = n\,(96.949 + y_t - 0.046\, Y_t) = n96.949 + (1 - n0.046) Y_t$$

For the case of a unit measure of firms,

$$\int_0^1 y_{t+1}(\omega)\, d\omega = h_0 + h_1 \int_0^1 y_t(\omega)\, d\omega + h_2 Y_t$$
$$Y_{t+1} = h_0 + h_1 Y_t + h_2 Y_t$$
$$Y_{t+1} = 96.949 + (1 - 0.046) Y_t$$

Exercise 117.5.2

Consider the following κ_0, κ_1 pairs as candidates for the aggregate law of motion component of a rational expectations equilibrium (see (117.19)).

Extending the program that you wrote for Exercise 117.5.1, determine which if any satisfy *the definition* of a rational expectations equilibrium

- (94.0886298678, 0.923409232937)
- (93.2119845412, 0.984323478873)
- (95.0818452486, 0.952459076301)

Describe an iterative algorithm that uses the program that you wrote for Exercise 117.5.1 to compute a rational expectations equilibrium.

(You are not being asked actually to use the algorithm you are suggesting)

Solution

To determine whether a κ_0, κ_1 pair forms the aggregate law of motion component of a rational expectations equilibrium, we can proceed as follows:

- Determine the corresponding firm law of motion $y_{t+1} = h_0 + h_1 y_t + h_2 Y_t$.
- Test whether the associated aggregate law :$Y_{t+1} = nh(Y_t/n, Y_t)$ evaluates to $Y_{t+1} = \kappa_0 + \kappa_1 Y_t$.

In the second step, we can use $Y_t = n y_t = y_t$, so that $Y_{t+1} = nh(Y_t/n, Y_t)$ becomes

$$Y_{t+1} = h(Y_t, Y_t) = h_0 + (h_1 + h_2) Y_t$$

Hence to test the second step we can test $\kappa_0 = h_0$ and $\kappa_1 = h_1 + h_2$.

The following code implements this test

```
candidates = ((94.0886298678, 0.923409232937),
              (93.2119845412, 0.984323478873),
              (95.0818452486, 0.952459076301))

for κ0, κ1 in candidates:

    # Form the associated law of motion
    A = np.array([[1, 0, 0], [0, κ1, κ0], [0, 0, 1]])

    # Solve the LQ problem for the firm
    lq = LQ(Q, R, A, B, beta=β)
    P, F, d = lq.stationary_values()
    F = F.flatten()
    h0, h1, h2 = -F[2], 1 - F[0], -F[1]

    # Test the equilibrium condition
    if np.allclose((κ0, κ1), (h0, h1 + h2)):
        print(f'Equilibrium pair = {κ0}, {κ1}')
        print('f(h0, h1, h2) = {h0}, {h1}, {h2}')
        break
```

```
Equilibrium pair = 95.0818452486, 0.952459076301
f(h0, h1, h2) = {h0}, {h1}, {h2}
```

The output tells us that the answer is pair (iii), which implies $(h_0, h_1, h_2) = (95.0819, 1.0000, -.0475)$.

(Notice we use `np.allclose` to test equality of floating-point numbers, since exact equality is too strict).

Regarding the iterative algorithm, one could loop from a given (κ_0, κ_1) pair to the associated firm law and then to a new (κ_0, κ_1) pair.

This amounts to implementing the operator Φ described in the lecture.

(There is in general no guarantee that this iterative process will converge to a rational expectations equilibrium)

Exercise 117.5.3

Recall the planner's problem *described above*

1. Formulate the planner's problem as an LQ problem.
2. Solve it using the same parameter values in exercise 1
   - $a_0 = 100, a_1 = 0.05, \beta = 0.95, \gamma = 10$
3. Represent the solution in the form $Y_{t+1} = \kappa_0 + \kappa_1 Y_t$.
4. Compare your answer with the results from exercise 2.

Solution

We are asked to write the planner problem as an LQ problem.

For the state and control vectors, we choose

$$x_t = \begin{bmatrix} Y_t \\ 1 \end{bmatrix}, \quad u_t = Y_{t+1} - Y_t$$

For the LQ matrices, we set

$$A = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad B = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad R = \begin{bmatrix} a_1/2 & -a_0/2 \\ -a_0/2 & 0 \end{bmatrix}, \quad Q = \gamma/2$$

By multiplying out you can confirm that

- $x_t' R x_t + u_t' Q u_t = -s(Y_t, Y_{t+1})$
- $x_{t+1} = A x_t + B u_t$

By obtaining the optimal policy and using $u_t = -F x_t$ or

$$Y_{t+1} - Y_t = -F_0 Y_t - F_1$$

we can obtain the implied aggregate law of motion via $\kappa_0 = -F_1$ and $\kappa_1 = 1 - F_0$.

The Python code to solve this problem is below:

```
# Formulate the planner's LQ problem

A = np.array([[1, 0], [0, 1]])
B = np.array([[1], [0]])
R = np.array([[a1 / 2, -a0 / 2], [-a0 / 2, 0]])
Q = γ / 2

# Solve for the optimal policy

lq = LQ(Q, R, A, B, beta=β)
P, F, d = lq.stationary_values()

# Print the results

F = F.flatten()
κ0, κ1 = -F[1], 1 - F[0]
print(κ0, κ1)
```

```
95.08187459214764 0.952459062703923
```

The output yields the same (κ_0, κ_1) pair obtained as an equilibrium from the previous exercise.

Exercise 117.5.4

A monopolist faces the industry demand curve (117.5) and chooses $\{Y_t\}$ to maximize $\sum_{t=0}^{\infty} \beta^t r_t$ where

$$r_t = p_t Y_t - \frac{\gamma (Y_{t+1} - Y_t)^2}{2}$$

Formulate this problem as an LQ problem.

Compute the optimal policy using the same parameters as Exercise 117.5.2.

In particular, solve for the parameters in

$$Y_{t+1} = m_0 + m_1 Y_t$$

Compare your results with Exercise 117.5.2 – comment.

Solution

The monopolist's LQ problem is almost identical to the planner's problem from the previous exercise, except that

$$R = \begin{bmatrix} a_1 & -a_0/2 \\ -a_0/2 & 0 \end{bmatrix}$$

The problem can be solved as follows

```
A = np.array([[1, 0], [0, 1]])
B = np.array([[1], [0]])
R = np.array([[a1, -a0 / 2], [-a0 / 2, 0]])
Q = γ / 2

lq = LQ(Q, R, A, B, beta=β)
P, F, d = lq.stationary_values()

F = F.flatten()
m0, m1 = -F[1], 1 - F[0]
print(m0, m1)
```

```
73.4729440350284 0.9265270559649701
```

We see that the law of motion for the monopolist is approximately $Y_{t+1} = 73.4729 + 0.9265 Y_t$.

In the rational expectations case, the law of motion was approximately $Y_{t+1} = 95.0818 + 0.9525 Y_t$.

One way to compare these two laws of motion is by their fixed points, which give long-run equilibrium output in each case.

For laws of the form $Y_{t+1} = c_0 + c_1 Y_t$, the fixed point is $c_0/(1 - c_1)$.

If you crunch the numbers, you will see that the monopolist adopts a lower long-run quantity than obtained by the competitive market, implying a higher market price.

This is analogous to the elementary static-case results

```

118.1 Overview

This lecture studies Lucas and Prescott [1971], a paper that helped to ignite a *rational expectations revolution*.

Lucas and Prescott studied a competitive industry in which

- demand shifts randomly each period
- firms face costs of adjusting their capital stocks
- firms must forecast future prices in order to decide how much to invest
- the probability distribution that firms use to forecast prices *equals* the probability distribution that their investment decisions actually generate

That last bullet point is what Muth [1961] called **rational expectations**.

The QuantEcon lecture *Rational Expectations Equilibrium* presents what we might call a "baby" version of the Lucas-Prescott model.

That lecture studies a linear-quadratic industry *without uncertainty*.

The present lecture describes the more ambitious structure that Lucas and Prescott actually built.

Relative to the baby version, Lucas and Prescott

- let demand be shifted by a Markov process $\{u_t\}$, so that the equilibrium is a stochastic process rather than a deterministic path
- allow a nonlinear technology for converting investment into capacity
- prove that a competitive equilibrium *exists* and is *unique*
- show that the equilibrium is the solution of a *planning problem* that maximizes discounted consumer surplus
- show that the equilibrium is a *Markov process* in the state (k_t, u_t)
- provide conditions under which that Markov process has an *invariant probability distribution* to which it converges from any initial condition

The last item is the part of the paper that most influenced later work.

A model whose equilibrium is a Markov process with an invariant distribution is a model that can be taken to time series data.

That observation set the stage for the *rational expectations econometrics* subsequently developed by Lars Peter Hansen and Thomas Sargent [Hansen and Sargent, 1980].

Along the way we'll describe how Prescott and Mehra [1980] later distilled the Lucas-Prescott structure into a general definition of a **recursive competitive equilibrium**.

The sequel *Optimal Growth Under Uncertainty and Tobin's q* studies a paper that asks the same questions about a one-sector optimal growth model, Brock and Mirman [1972], and a paper that uses that model to think about Tobin's q, Sargent [1980].

Let's start with some imports:

```
import numpy as np
import matplotlib.pyplot as plt
import quantecon as qe
from collections import namedtuple
```

118.2 The industry

An industry consists of many small firms.

Each firm produces a single output q_t with a single input, capital k_t.

Production has constant returns to scale, and with a suitable choice of units the production function is

$$0 \leq q_t \leq k_t. \tag{118.1}$$

Because capital is the only input and output is sold at a positive price, every firm produces at capacity, so that $q_t = k_t$.

Let x_t denote gross investment.

Capacity next period is related to capacity this period and investment by

$$k_{t+1} = k_t \, h\left(\frac{x_t}{k_t}\right), \tag{118.2}$$

where h is bounded, continuously differentiable, increasing, and strictly *concave*.

The strict concavity of h is what creates **costs of adjustment**: doubling the rate of investment per unit of capital less than doubles the resulting increment to capacity.

Adjustment costs are why firms change their capital stocks gradually instead of jumping immediately to a long-run target.

Assume that $\delta = h^{-1}(1)$ exists and satisfies $0 < \delta < 1$.

Then $x_t = \delta k_t$ is the investment rate that just maintains capacity, so δ plays the role of a depreciation rate.

Let p_t be the output price and let $\beta = 1/(1+r)$, where $r > 0$ is the cost of capital.

The present value of a firm is

$$V = \sum_{t=0}^{\infty} \beta^t \left[p_t q_t - x_t\right]. \tag{118.3}$$

Because the allocation of a given industry capital stock across firms does not matter, we can use k_t, x_t, q_t interchangeably for firm and industry variables.

Equivalently, we can think of a competitive industry with a single price-taking firm.

Industry demand is subject to random shifts:

$$p_t = D(q_t, u_t), \tag{118.4}$$

where D is continuous and strictly decreasing in q_t and increasing in u_t, so that an increase in u_t shifts the demand curve to the right.

The demand shifter $\{u_t\}$ is a Markov process with transition distribution $p(\cdot, u)$, meaning that the probability that $u_{t+1} \in A$ conditional on $u_t = u$ is $\int_A p(dz, u)$.

118.3 The firm and the price of installed capital

Before studying equilibrium, Lucas and Prescott pause over an instructive question: what does an individual firm actually need to know?

Let w_t be the current market value of a unit of installed capital and let w_t^* be the value per unit expected to prevail next period.

A firm that begins period t with capital k_t and invests x obtains next-period capital worth $\beta k_t h(x/k_t) w_t^*$ at a cost of x, so it solves

$$\max_x \left[-x + \beta k_t h(x/k_t) w_t^*\right].$$

The current value of the firm is

$$w_t k_t = p_t k_t - x + \beta k_t h(x/k_t) w_t^* \tag{118.5}$$

and the first-order condition is

$$0 \geq -1 + \beta h'(x/k_t) w_t^*, \quad \text{with equality if } x > 0. \tag{118.6}$$

Solving (118.5) and (118.6) jointly for x and w_t^* gives an investment function of the form

$$x_t = k_t \, g(w_t - p_t), \qquad g'(\cdot) > 0. \tag{118.7}$$

Lucas and Prescott note that (118.7) is essentially the investment function that Grunfeld had used in empirical work, with the market value of the firm as an explanatory variable.

Their argument is stronger than Grunfeld's, though: a firm does not need to forecast its own future income stream at all.

It needs only to know the value that securities markets place on a unit of installed capital.

Readers will recognize a version of what later became known as Tobin's q theory of investment.

But equation (118.7) is a *consistency requirement*, not yet a theory of capital accumulation, because the path of w_t is still unknown.

To determine w_t we have to study equilibrium.

118.4 Rational expectations equilibrium

Firms must forecast future prices.

Lucas and Prescott describe the usual approach as postulating a forecasting rule – for example "adaptive expectations" – that generates investment behavior, which in conjunction with demand generates an actual price process.

They object that if the underlying disturbance has a regular stochastic character, then, except by coincidence, forecast prices and actual prices will have *different probability distributions*, and the difference will be persistent, costly, and easy to correct.

So they go to the opposite extreme and assume that the actual and anticipated prices have the *same probability distribution*.

To say this precisely, fix an initial state (k_0, u_0).

Because prices depend on the history of demand shocks, an anticipated price process is a sequence $\{p_t\}$ of functions of $(u_1, \ldots, u_t)$.

Similarly, an investment-output plan is a pair of sequences $\{q_t, x_t\}$ of functions of $(u_1, \ldots, u_t)$ – a contingency plan that says in advance what the firm will do after every possible history.

Definition 118.4.1

An **industry equilibrium** for a fixed initial state (k_0, u_0) is a triple of sequences $\{q_t^0, x_t^0, p_t^0\}$ such that

1. the demand curve (118.4) holds for every history, and
2. the plan $\{q_t^0, x_t^0\}$ maximizes expected present value

$$\mathbb{E}\left\{\sum_{t=0}^{\infty} \beta^t \left[p_t^0 q_t - x_t\right]\right\}$$

over all plans $\{q_t, x_t\}$ that satisfy (118.1) and (118.2), *given* the price process $\{p_t^0\}$.

The rational expectations requirement is hiding in plain sight in *Definition 118.4.1*.

The price process $\{p_t^0\}$ that firms take as given when they maximize is the *same* price process that their own decisions generate through the demand curve.

This is exactly the fixed point idea of the lecture *Rational Expectations Equilibrium*, where a **perceived law of motion** H for aggregate output must equal the **actual law of motion** that the resulting decision rule generates.

The difference is that here the fixed point is in a space of sequences of functions of histories rather than in a space of linear decision rules.

Note

Lucas and Prescott are careful about what rationality does and does not assume.

They write that they "surrender, in advance, any hope of shedding light on the process by which firms translate current information into price forecasts."

They also defend the assumption: if the demand shift process really does have a regular, stationary structure, then expectations that are rational in their sense "are surely more plausible than any simple, adaptive scheme"; and if it does not, then adopting some other expectations hypothesis "will certainly not improve matters."

118.5 Equilibrium as a planning problem

How can we compute an object defined by a fixed point in such a large space?

Lucas and Prescott's answer is the device that the lecture *Rational Expectations Equilibrium* also uses: find a **planning problem** whose solution is the equilibrium.

Define **consumer surplus** as the area under the demand curve

$$s(q, u) = \int_0^q D(z, u)\, dz,$$

and define discounted consumer surplus net of investment costs by

$$S = \mathbb{E}\left\{\sum_{t=0}^{\infty} \beta^t \left[s(q_t, u_t) - x_t\right]\right\}. \tag{118.8}$$

Associated with the problem of maximizing S is the functional equation

$$v(k, u) = \sup_{x \geq 0}\left\{s(k, u) - x + \beta \int v\left[kh\left(\frac{x}{k}\right), z\right] p(dz, u)\right\}. \tag{118.9}$$

Theorem 118.5.1

The functional equation (118.9) has a unique bounded solution v, and for each (k, u) the supremum is attained at a unique $x(k, u)$.

In terms of that policy function, the unique industry equilibrium, given (k_0, u_0), is

$$x_t = x(k_t, u_t), \qquad k_{t+1} = k_t h\left(\frac{x(k_t, u_t)}{k_t}\right), \qquad q_t = k_t, \qquad p_t = D(q_t, u_t).$$

The proof has two halves, and both halves matter for later work.

The first half shows that a competitive equilibrium maximizes S, and conversely.

This is an application of the welfare theorems in an infinite-dimensional commodity space, using the valuation equilibria of Debreu and the price systems that Prescott and Lucas developed in a companion paper.

Lucas and Prescott are explicit that they use this connection only as a computational device: "the welfare significance of S is not important. We are interested only in using the connection between the maximization of S and competitive equilibrium in order to determine the properties of the latter."

The second half shows that the planning problem is solved by the functional equation (118.9).

Here they use the operator

$$Tf(k,u) = \sup_{x \geq 0} \left\{ s(k,u) - x + \beta \int f[kh(x/k), z]\, p(dz, u) \right\}$$

and verify that T is monotone and satisfies a discounting property, so that by Blackwell's theorem [Blackwell, 1965] it has a unique fixed point that successive approximations converge to.

They also show that T preserves concavity and monotonicity in k, which delivers a unique and continuous policy function $x(k,u)$.

Note

These arguments are now standard and are treated at length in Stokey *et al.* [1989].

In 1971 they were not standard, which is one reason the paper is hard to read.

Much of its length is devoted to measurability details – Baire functions, Borel sets – that a modern treatment would relegate to an appendix.

Two features of *Theorem 118.5.1* deserve emphasis.

First, the equilibrium is **recursive**: the pair (k_t, u_t) is a Markov process, and equilibrium prices and quantities are time-invariant functions of it.

Second, the equilibrium is computed *without ever iterating on a mapping from beliefs to outcomes*.

The lecture *Rational Expectations Equilibrium* explains why that matters: the mapping Φ from a perceived law of motion to an actual law of motion is *not a contraction*, and iterating on it can diverge.

The planning problem replaces an unreliable fixed point calculation with a dynamic program that is a contraction.

118.6 Recursive competitive equilibrium

Prescott and Mehra [1980] later extracted the general structure that Lucas and Prescott had exploited.

Their goal was to replace a search for equilibrium *sequences of contingency functions*, in the style of Arrow and Debreu, with a search for equilibrium *decision rules*.

Such rules specify current actions as functions of a small number of **state variables** that summarize the effects of past decisions and current information.

As Prescott and Mehra put it, these equilibrium decision rules "must be time invariant in order to apply standard time series methods and this necessitates a recursive structure."

That sentence is the bridge from Lucas and Prescott's theory to econometrics.

In a recursive competitive equilibrium

- the state variables should be of minimal dimension, indexing only the factors that can change over time
- the state is observed, or is an invertible function of observables
- the conditional distribution of next period's state given current decisions and the current state is time invariant

- individual decision rules are optimal given equilibrium pricing functions, and markets clear

Prescott and Mehra note that their structure "subsumes the structure considered in Lucas and Prescott's analysis of equilibrium investment under uncertainty."

Their analysis also establishes optimality of recursive equilibria and supportability of Pareto optima "in a simpler and more direct way" than arguments that pass through equivalence with state-contingent equilibria.

For us, the important point is that *Theorem 118.5.1* produces exactly the objects that rational expectations econometrics needs: time-invariant decision rules, driven by a Markov state, with cross-equation restrictions linking the parameters of the shock process to the parameters of the decision rules.

118.7 A computable version

Let's now compute equilibria of a version of the model.

We take the adjustment technology

$$h(z) = (1 - \delta + z)^{\alpha}, \qquad 0 < \alpha \leq 1,$$

which satisfies the Lucas-Prescott assumptions: h is increasing and strictly concave for $\alpha < 1$, and $h(\delta) = 1$, so δ is the maintenance investment rate.

When $\alpha = 1$ we recover the familiar linear accumulation equation $k_{t+1} = (1 - \delta)k_t + x_t$.

When $\alpha < 1$ there are adjustment costs.

Note that $h'(\delta) = \alpha$, a fact we will use below.

We take a linear inverse demand curve

$$D(q, u) = a_0 + u - a_1 q,$$

which matches the demand curve in the lecture *Rational Expectations Equilibrium* except that it is shifted by u.

Consumer surplus is then

$$s(k, u) = (a_0 + u)k - \frac{a_1}{2}k^2.$$

The demand shifter follows a Gaussian AR(1) process

$$u_{t+1} = \rho u_t + \sigma \epsilon_{t+1}, \qquad \epsilon_{t+1} \sim N(0, 1),$$

which is an example that Lucas and Prescott themselves offer of a process satisfying their assumptions.

We discretize it with the Tauchen method.

Rather than choosing investment x directly, it is convenient to let the planner choose next period's capital k' on a grid, and to invert (118.2) to find the required investment

$$x = k \left[\left(\frac{k'}{k} \right)^{1/\alpha} - (1 - \delta) \right].$$

```
Model = namedtuple("Model", "r β δ α a0 a1 k u P X feasible s")

def create_model(r=0.05, δ=0.10, α=0.70, a0=1.0, a1=0.01,

```

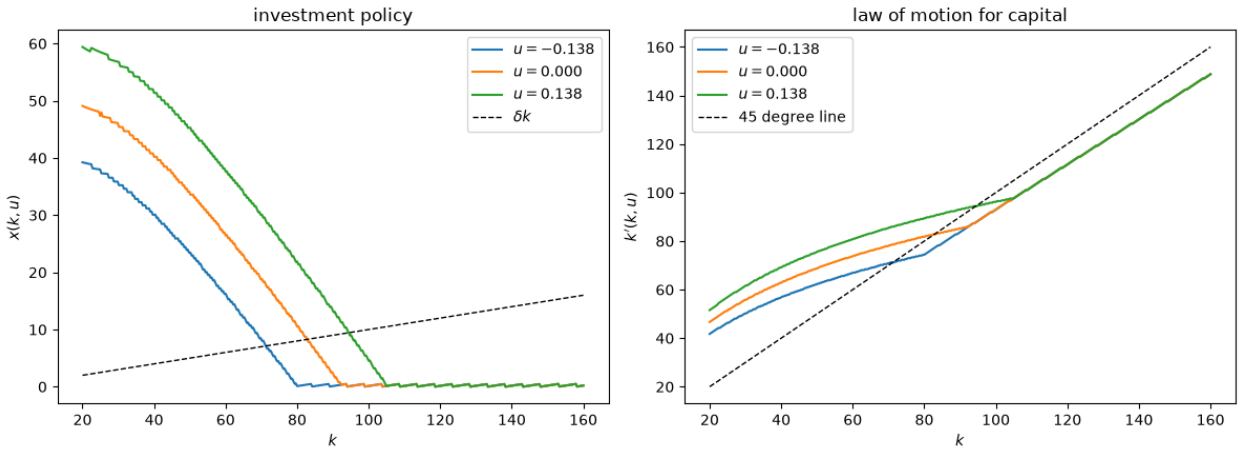

Fig. 118.1: Investment policy and law of motion

Capital rises when $x(k, u)$ lies above the maintenance line δk and falls when it lies below.

Higher demand shifts the investment policy up, so the capital stock that the industry sustains is higher when demand is strong.

118.7.1 The price of installed capital

The planner's problem also delivers the market value w of a unit of installed capital that appeared in (118.5).

Let $z = x/k$ denote the investment rate.

Differentiating the Bellman equation (118.9) and using the envelope condition gives

$$w(k, u) = v_k(k, u) = D(k, u) + \beta \mathbb{E}\left[v_k(k', u') \mid u\right]\left[h(z) - z h'(z)\right],$$

while the first-order condition for x is

$$\beta \mathbb{E}\left[v_k(k', u') \mid u\right] = \frac{1}{h'(z)}. \tag{118.10}$$

Combining them expresses the shadow price in closed form,

$$w(k, u) = D(k, u) + \frac{h(z)}{h'(z)} - z. \tag{118.11}$$

The marginal value of installed capital equals the current price of output plus the value of the capacity that the unit carries into the future.

Notice that (118.10) is the planner's counterpart of the firm's first-order condition (118.6), with $w^* = \mathbb{E}[v_k(k', u') \mid u]$.

That correspondence is the "big K, little k" logic of the lecture *Rational Expectations Equilibrium* in its Lucas-Prescott form.

```
h = lambda z, m: (1 - m.δ + z)**m.α
h_prime = lambda z, m: m.α * (1 - m.δ + z)**(m.α - 1)

z = x / m.k[:, None]
D = m.a0 + m.u[None, :] - m.a1 * m.k[:, None]
w = D + h(z, m) / h_prime(z, m) - z

# check the first-order condition (up to grid error)
Ew = np.take_along_axis(w @ m.P.T, idx, axis=0)
resid = np.abs(m.β * Ew - 1 / h_prime(z, m))
scale = np.median(1 / h_prime(z, m))
near = (m.k > 70) & (m.k < 95)          # capital levels the industry actually visits
print(f"typical size of each side of the FOC: {scale:.3f}")
print(f"median residual, all k:                {np.median(resid):.2e}")
print(f"median residual, 70 < k < 95:          {np.median(resid[near]):.2e}")
```

```
typical size of each side of the FOC: 1.396
median residual, all k:                5.35e-03
median residual, 70 < k < 95:          2.39e-03
```

The residual is a few tenths of one per cent of the magnitude of the terms being compared, which confirms (118.11).

It does not vanish entirely because the planner chooses k' from a finite grid, so the policy function jumps by a whole grid point at a time.

Residuals are much larger at capital levels so extreme that the industry never visits them.

118.8 Long run behavior with serially independent demand

Lucas and Prescott next ask what happens in the long run.

They treat two cases, and the first is the special case in which u_t and u_s are independent for $s \neq t$.

Inspecting the Bellman equation (118.9) when $p(dz, u)$ does not depend on u shows that the optimal investment rate $x(k, u)$ *does not depend on* u.

A demand shift is then a pure windfall: it tells firms nothing about future demand, so it does not change investment.

Consequently the capital stock evolves *deterministically*, according to $k_{t+1} = k_t h(x(k_t)/k_t)$, while output is supplied inelastically and demand shocks move only prices.

Theorem 118.8.1

Under independence, there are two possibilities for the capital stock.

If

$$\int D(0, u)p(du) > \delta + \frac{r}{h'(\delta)}, \tag{118.12}$$

and $k_0 > 0$, then k_t converges monotonically to the unique stationary value k^c given implicitly by

$$\int D(k^c, u)p(du) = \delta + \frac{r}{h'(\delta)}. \tag{118.13}$$

Otherwise capital converges monotonically to zero.

Condition (118.13) has a familiar interpretation.

The left side is expected marginal revenue product of capital, which here is just the expected output price, because the marginal physical product is one.

The right side is a **user cost of capital**: a depreciation term δ plus an interest term $r/h'(\delta)$.

Lucas and Prescott observe that this case corresponds closely to the textbook dichotomy between short-run and long-run supply.

In the short run, capacity is fixed and demand determines price.

In the long run, demand fluctuations play no role at all: capacity is determined entirely by *average* demand.

Let's verify this numerically by setting $\rho = 0$.

```
m_iid = create_model(ρ=0.0)
v_iid, idx_iid, k_next_iid, x_iid = solve_model(m_iid)

# does the policy depend on u?
print("investment policy independent of u:",
      np.allclose(x_iid, x_iid[:, [0]], atol=1e-10))

# stationary capital: where x(k) crosses δ k
def stationary_k(x_col, m):
    "Capital where investment just maintains capacity."
    d = x_col - m.δ * m.k
    i = np.where(np.sign(d[:-1]) != np.sign(d[1:]))[0]
    if len(i) == 0:
        return np.nan
    i = i[0]
    return np.interp(0, [d[i+1], d[i]], [m.k[i+1], m.k[i]])

kc = stationary_k(x_iid[:, 0], m_iid)
user_cost = m_iid.δ + m_iid.r / h_prime(m_iid.δ, m_iid)
print(f"\nstationary capital k^c        = {kc:.3f}")
print(f"expected price at k^c         = {m_iid.a0 - m_iid.a1 * kc:.5f}")
print(f"user cost δ + r / h'(δ)       = {user_cost:.5f}")
```

```
investment policy independent of u: True

stationary capital k^c        = 82.807
expected price at k^c         = 0.17193
user cost δ + r / h'(δ)       = 0.17143
```

The stationary capital stock equates the expected price to the user cost of capital, as (118.13) requires.

Now let's confirm that capital approaches k^c monotonically, and from either direction.

```
def capital_path(m, idx, k0, T=60, u_index=None):
    "Simulate capital, holding the demand state fixed if u_index is given."
    ki = np.abs(m.k - k0).argmin()
    path = np.empty(T)
    j = len(m.u) // 2 if u_index is None else u_index
    for t in range(T):
        path[t] = m.k[ki]
        ki = idx[ki, j]
    return path

fig, ax = plt.subplots(figsize=(8, 4.5))
```

(continues on next page)

(continued from previous page)

```
for k0 in (30.0, 55.0, 110.0, 150.0):
    ax.plot(capital_path(m_iid, idx_iid, k0), lw=2, label=f'$k_0 = {k0:.0f}$')
ax.axhline(kc, color='k', ls='--', lw=1, label='$k^c$')
ax.set_xlabel('$t$'); ax.set_ylabel('$k_t$')
ax.legend()
plt.tight_layout()
plt.show()
```

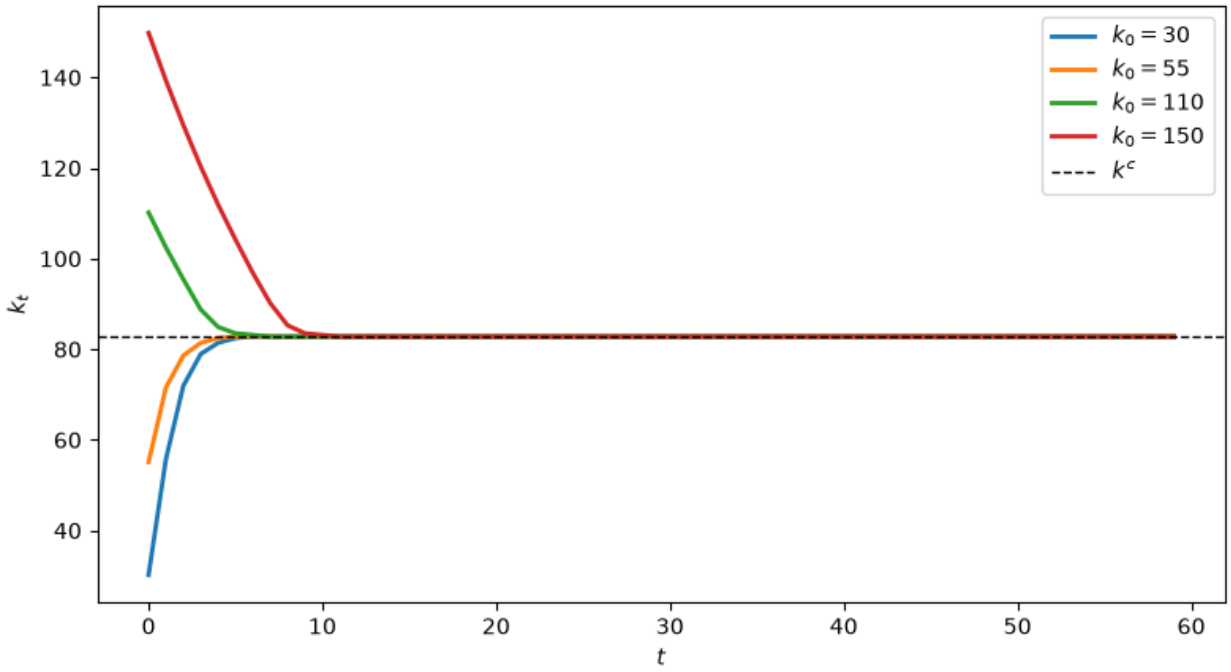

Fig. 118.2: Capital paths under IID demand

Convergence is monotone and the limit does not depend on the initial capital stock.

118.9 Long run behavior with serially correlated demand

The more interesting case allows demand shifts to be positively serially correlated, so that a high demand today signals high demand tomorrow.

Now the current demand state *does* affect investment, and the capital stock is genuinely stochastic.

To characterize the long run, Lucas and Prescott impose additional restrictions on the $\{u_t\}$ process, whose purpose is to guarantee that the distribution of (k_t, u_t) settles down.

In words, they assume that

- from any current u, next period's shock lands in any non-degenerate interval with positive probability
- u_t has a limiting distribution that does not depend on the initial u_0 and that puts positive probability on every non-degenerate interval
- $\mathbb{P}\{u_{t+1} \geq x \mid u_t\}$ is strictly increasing in u_t, so high demand today always signals high demand tomorrow

- consumer surplus $s(k, u)$ converges uniformly as $u \to \pm\infty$

A Gaussian AR(1) process with $0 < \rho < 1$ satisfies these conditions, which is the example they give and the one we simulate.

The analysis then proceeds by bounding the capital stock.

Let $\bar{v}(k)$ and $\underline{v}(k)$ be the limits of the expected value function as $u \to \infty$ and $u \to -\infty$, and let $\bar{x}(k)$ and $\underline{x}(k)$ be the associated investment policies.

Because investment is increasing in u, these bracket the policy for every u.

Let $\bar{k}$ solve $\bar{x}(k) = \delta k$ and let $\underline{k}$ solve $\underline{x}(k) = \delta k$.

These are the capital stocks that would be sustained under permanently maximal and permanently minimal demand.

Lucas and Prescott then prove that

- the sets $(0, \underline{k})$ and $(\bar{k}, \infty)$, paired with any demand state, are **transient**: once the industry leaves them it does not return, and from any starting point it enters $(\underline{k}, \bar{k})$ with probability approaching one
- the set $B = (\underline{k}, \bar{k}) \times E$, where E is the set of possible values of u, is a **single ergodic set**

Theorem 118.9.1

If B is non-empty, then for all (k, u) and every initial state (k_0, u_0),

$$\lim_{t \to \infty} \mathbb{P}\{k_t \leq k, u_t \leq u \mid k_0, u_0\} = P(k, u)$$

exists and *does not depend on* (k_0, u_0).

The function P is a probability distribution that assigns probability zero to the transient sets and positive probability to every subset of B with positive area.

Theorem 118.9.2

If B is non-empty, then for any initial state, with probability one

$$\lim_{T \to \infty} \frac{1}{T} \sum_{t=1}^{T} k_t = k^*,$$

where k^* is the mean of k under the invariant distribution P.

The ergodic set is non-empty – and so this long-run behavior applies – if and only if

$$\lim_{u \to \infty} D(0, u) > \delta + \frac{r}{h'(\delta)}, \tag{118.14}$$

which says that demand must sometimes be strong enough to justify holding any capital at all.

Theorem 118.9.1 and *Theorem 118.9.2* are the results that make this model an object that econometricians can use.

The first says that the model implies a well-defined stationary probability distribution for the observable time series.

The second says that sample averages computed from a single long realization converge to the corresponding population moments of that distribution.

Let's compute the bounds $\underline{k}$ and $\bar{k}$ for our parameterization and check that simulations behave as the theorems say.

```
bounds = np.array([stationary_k(x[:, j], m) for j in range(len(m.u))])
k_lo_star, k_hi_star = bounds.min(), bounds.max()
print(f"conditional stationary capital, lowest demand state:  {k_lo_star:.2f}")
print(f"conditional stationary capital, highest demand state: {k_hi_star:.2f}")
print(f"ergodic set for capital: ({k_lo_star:.2f}, {k_hi_star:.2f})")
```

```
conditional stationary capital, lowest demand state:  71.23
conditional stationary capital, highest demand state: 94.39
ergodic set for capital: (71.23, 94.39)
```

Now we simulate the equilibrium Markov process from two very different initial capital stocks, using the *same* sequence of demand shocks.

```
def simulate(m, idx, k0, T=20_000, seed=0):
    "Simulate the equilibrium Markov process for (k, u)."
    mc = qe.MarkovChain(m.P, m.u)
    u_idx = mc.simulate_indices(T, init=len(m.u)//2, random_state=seed)
    ki = np.abs(m.k - k0).argmin()
    k_path = np.empty(T)
    for t in range(T):
        k_path[t] = m.k[ki]
        ki = idx[ki, u_idx[t]]
    p_path = m.a0 + m.u[u_idx] - m.a1 * k_path
    return k_path, p_path

k_low, p_low = simulate(m, idx, k0=30.0, seed=1)
k_high, p_high = simulate(m, idx, k0=150.0, seed=1)

fig, ax = plt.subplots(figsize=(9, 4.5))
ax.plot(k_low[:250], lw=2, label='$k_0 = 30$')
ax.plot(k_high[:250], lw=2, label='$k_0 = 150$')
ax.axhline(k_lo_star, color='k', ls='--', lw=1)
ax.axhline(k_hi_star, color='k', ls='--', lw=1, label='ergodic set')
ax.set_xlabel('$t$'); ax.set_ylabel('$k_t$')
ax.legend()
plt.tight_layout()
plt.show()
```

Both paths are drawn into the ergodic set and then fluctuate inside it forever.

The next figure compares the long-run distributions of capital computed from the two simulations, after discarding a burn-in sample.

```
burn = 2000
fig, axes = plt.subplots(1, 2, figsize=(12, 4.5))

axes[0].hist(k_low[burn:], bins=60, density=True, alpha=0.5, label='from $k_0 = 30$')
axes[0].hist(k_high[burn:], bins=60, density=True, alpha=0.5, label='from $k_0 = 150$
↪')
axes[0].set_xlabel('$k$'); axes[0].set_ylabel('density')
axes[0].set_title('invariant distribution of capital')
axes[0].legend()

axes[1].hist(p_low[burn:], bins=60, density=True, alpha=0.5)
axes[1].set_xlabel('$p$'); axes[1].set_ylabel('density')
```

(continues on next page)

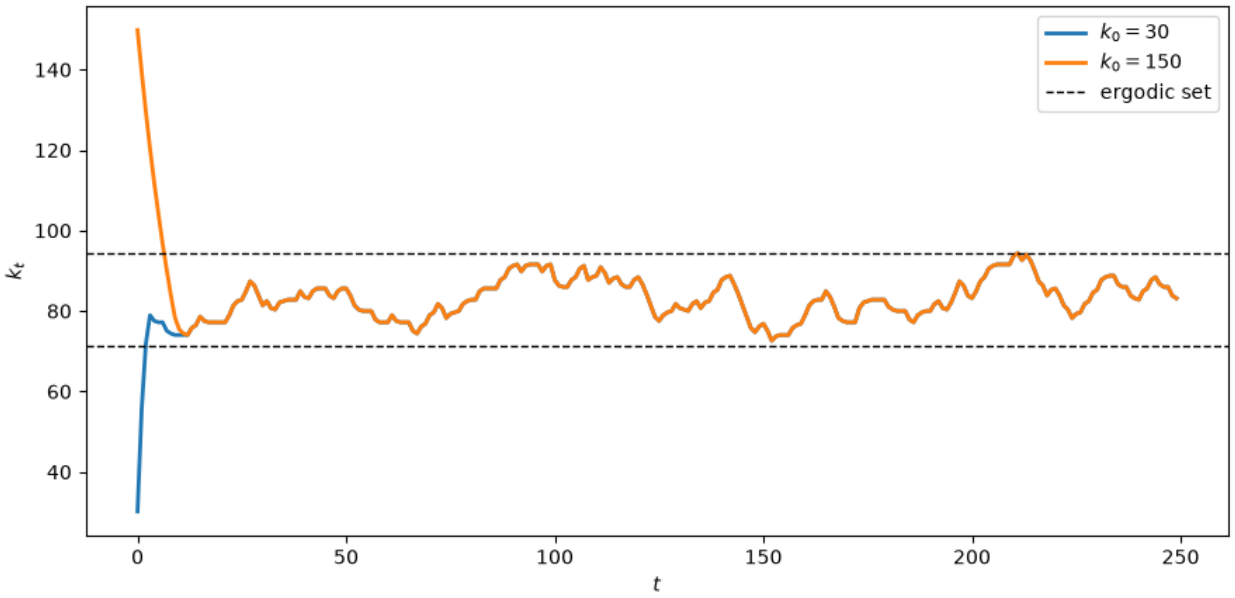

Fig. 118.3: Capital paths entering the ergodic set

(continued from previous page)

```
axes[1].set_title('invariant distribution of price')

plt.tight_layout()
plt.show()

print(f"mean capital from k_0 = 30:  {k_low[burn:].mean():.3f}")
print(f"mean capital from k_0 = 150: {k_high[burn:].mean():.3f}")
print(f"range visited: ({k_low[burn:].min():.2f}, {k_low[burn:].max():.2f})")
```

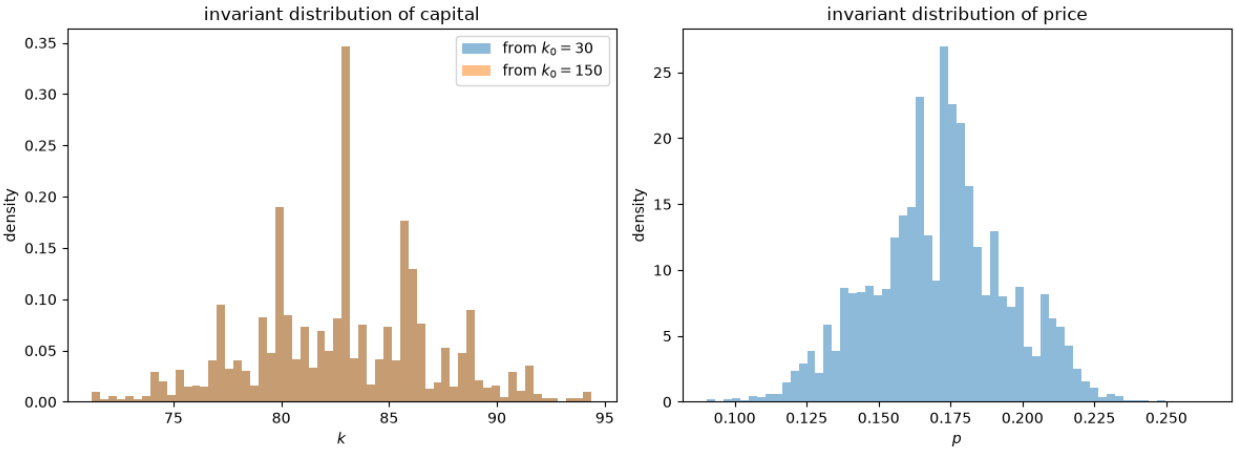

Fig. 118.4: Invariant distributions of capital and price

```
mean capital from k_0 = 30:  82.792
mean capital from k_0 = 150: 82.792
range visited: (71.23, 94.39)
```

The two histograms coincide, as *Theorem 118.9.1* promises, and the capital stock stays inside the ergodic set.

Finally, here is *Theorem 118.9.2* in action: time averages from a single realization converge to the mean of the invariant distribution.

```
running_mean = np.cumsum(k_low) / np.arange(1, len(k_low) + 1)

fig, ax = plt.subplots(figsize=(8, 4.5))
ax.plot(running_mean, lw=2)
ax.axhline(k_low[burn:].mean(), color='k', ls='--', lw=1, label='$k^*$')
ax.set_xlabel('$T$'); ax.set_ylabel(r'$T^{-1}\sum_{t \leq T} k_t$')
ax.set_xscale('log')
ax.legend()
plt.tight_layout()
plt.show()
```

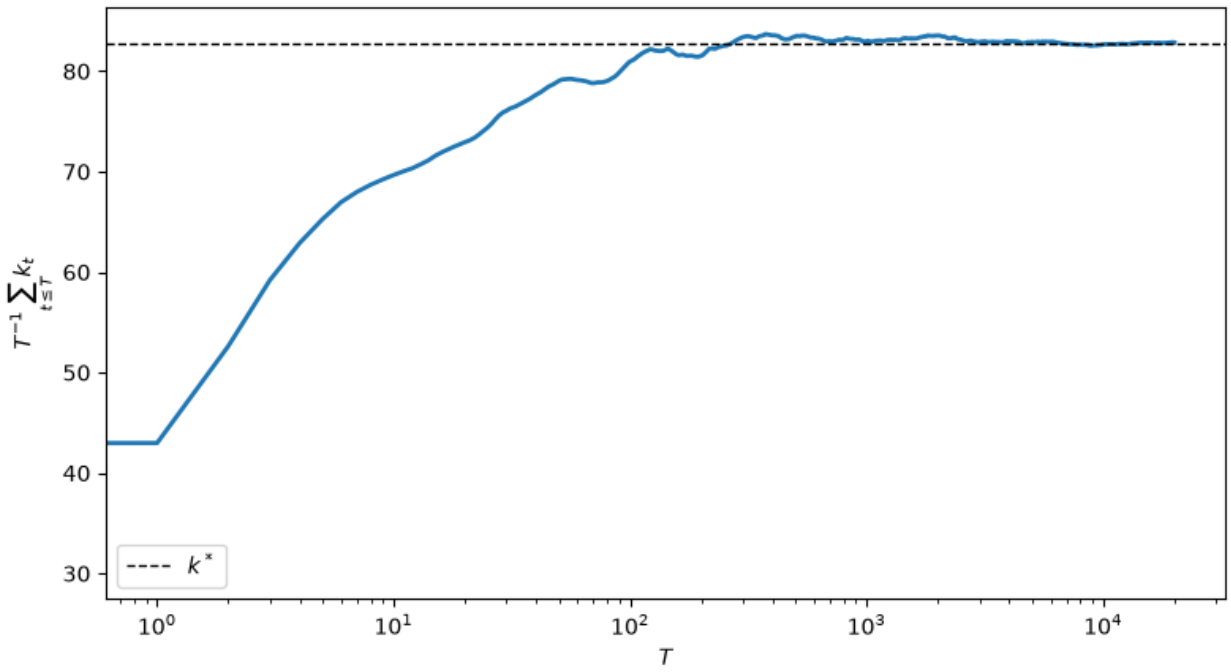

Fig. 118.5: Time average of capital

118.10 Relation to the rational expectations lecture

It is worth collecting the correspondences between this lecture and *Rational Expectations Equilibrium*.

	Rational Expectations Equilibrium	this lecture
uncertainty	none	Markov demand shifter u_t
adjustment costs	quadratic, $\gamma(y' - y)^2/2$	concave technology $k' = kh(x/k)$
equilibrium object	belief H with $Y' = H(Y)$	price process $\{p_t\}$, equivalently policy $x(k, u)$
equilibrium concept	H is a fixed point of Φ	anticipated price distribution equals actual
how it is computed	planning problem, solved as an LQ problem	planning problem, solved by dynamic programming
what the planner maximizes	consumer plus producer surplus	discounted consumer surplus (118.8)
equilibrium dynamics	$Y_{t+1} = \kappa_0 + \kappa_1 Y_t$	Markov process for (k_t, u_t)
long-run behavior	convergence to a steady state	convergence to an invariant distribution

The deepest common element is the strategy for computing an equilibrium.

In both lectures, the direct approach – guess a law of motion, compute the induced best response, and iterate – is unreliable, because that mapping need not be a contraction.

In both lectures, the remedy is to find a planning problem whose Euler equations coincide with the equilibrium conditions, and then to solve the planning problem by dynamic programming.

The lecture *Rational Expectations Equilibrium* verifies this correspondence by matching Euler equations for a particular linear-quadratic example.

Theorem 118.5.1 is the general statement: for this class of economies, the set of competitive equilibria and the set of solutions of the planning problem coincide, and both are singletons.

What the baby version cannot show, because it has no uncertainty, is the payoff that Lucas and Prescott were after: an equilibrium that is a *stationary stochastic process*, with an invariant distribution and ergodic time averages.

That is what makes it possible to confront such a model with data, and what led on to rational expectations econometrics.

The companion lecture *Optimal Growth Under Uncertainty and Tobin's q* pursues exactly this theme in a one-sector growth model.

Brock and Mirman [1972] prove there the counterparts of *Theorem 118.9.1* and *Theorem 118.9.2*: the distribution of capital converges to an invariant distribution that does not depend on initial conditions, and time averages along a single realization converge to population moments.

That lecture also shows what the shadow price of capital in such a planning problem becomes in a competitive equilibrium – namely Tobin's q – and examines a subtle question about the differentiability of the value function that the answer depends on.

118.11 Exercises

Exercise 118.11.1

The user cost of capital in (118.13) depends on the curvature parameter α of the adjustment technology through $h'(\delta) = \alpha$.

1. Explain why a *lower* α – meaning stronger adjustment costs – should reduce the long-run capital stock.
2. For the serially independent case, compute the stationary capital stock k^c for $\alpha \in \{0.4, 0.6, 0.8, 1.0\}$ and verify in each case that the marginal condition (118.13) holds.
3. Confirm that when $\alpha = 1$ the accumulation equation is $k_{t+1} = (1-\delta)k_t + x_t$ and the user cost is the textbook $\delta + r$.

Solution

A lower α makes h more concave, so a unit of investment buys less capacity at the margin.

Since $h'(\delta) = \alpha$, the interest component of the user cost, $r/h'(\delta) = r/\alpha$, rises as α falls.

A higher user cost must be matched by a higher expected price, and since demand slopes down, that means a smaller capital stock.

```
print(f"{'α':>5} {'k^c':>10} {'E[price]':>12} {'user cost':>12}")
for α in (0.4, 0.6, 0.8, 1.0):
    m_α = create_model(ρ=0.0, a=α, k_lo=5.0, k_hi=160.0, n_k=600)
    _, _, _, x_α = solve_model(m_α)
    kc_α = stationary_k(x_α[:, 0], m_α)
    price = m_α.a0 - m_α.a1 * kc_α
    cost = m_α.δ + m_α.r / h_prime(m_α.δ, m_α)
    print(f"{α:>5.1f} {kc_α:>10.3f} {price:>12.5f} {cost:>12.5f}")
```

```
    α        k^c     E[price]    user cost
  0.4     77.454      0.22546      0.22500
  0.6     81.594      0.18406      0.18333
  0.8     83.664      0.16336      0.16250
  1.0     84.958      0.15042      0.15000
```

Stronger adjustment costs (lower α) do indeed lower the long-run capital stock.

With $\alpha = 1$ we have $h(z) = 1 - \delta + z$, so $k' = k(1 - \delta + x/k) = (1-\delta)k + x$, and $h'(\delta) = 1$, so the user cost is $\delta + r$.

Exercise 118.11.2

Theorem 118.5.1 says that the planner's policy *is* the competitive equilibrium.

Verify this numerically, using the "big K, little k" logic of *Rational Expectations Equilibrium*.

Solve the problem of an individual price-taking firm that

- owns capital k_i and chooses k_i' subject to the same accumulation technology
- takes as given the aggregate capital stock K, which evolves according to the planner's policy computed above
- takes as given the price $p = a_0 + u - a_1 K$, which depends on aggregate, not own, capital

Then check that when the firm's own capital equals aggregate capital, $k_i = K$, the firm chooses exactly what the planner chooses.

Use a coarser grid for the firm's own capital to keep the computation small.

Solution

The firm's Bellman equation is

$$v_i(k_i, K, u) = \max_{k_i'} \{p(K,u)k_i - x(k_i, k_i') + \beta \mathbb{E}\left[v_i(k_i', K', u') \mid u\right]\}$$

where K' follows the planner's law of motion.

Note that the firm's own capital affects its revenue but not the price.

```
def firm_problem(m, idx_agg, n_i=80, tol=1e-8, maxit=1000, howard=20):
    "Solve an individual firm's problem taking the aggregate law of motion as␣
↪given."
    sub = np.linspace(0, len(m.k) - 1, n_i).astype(int)    # firm grid ⊂ aggregate␣
↪grid
    ki = m.k[sub]
    n_K, n_u = len(m.k), len(m.u)

    Xi = ki[:, None] * ((ki[None, :] / ki[:, None])**(1/m.α) - (1 - m.δ))
    Ri = np.where(Xi >= 0, Xi, -1e12)                      # (k_i, k_i')
    price = m.a0 + m.u[None, :] - m.a1 * m.k[:, None]      # (K, u)
    revenue = ki[:, None, None] * price[None, :, :]        # (k_i, K, u)

    v_i = np.zeros((n_i, n_K, n_u))
    u_cols = np.arange(n_u)[None, :]
    for it in range(maxit):
        EV = np.tensordot(v_i, m.P, axes=([2], [1]))       # E[v_i(k_i', K', u') |␣
↪u]
        cont = EV[:, idx_agg, u_cols]                      # impose K' = planner's␣
↪choice
        obj = Ri[:, :, None, None] + m.β * cont[None, :, :, :]
        pol = obj.argmax(axis=1)
        v_new = revenue + np.take_along_axis(obj, pol[:, None, :, :], axis=1)[:, 0,
↪ :, :]

        for _ in range(howard):
            EV = np.tensordot(v_new, m.P, axes=([2], [1]))
            cont = EV[:, idx_agg, u_cols]
            v_new = (revenue + Ri[np.arange(n_i)[:, None, None], pol]
                     + m.β * np.take_along_axis(cont, pol, axis=0))

        if np.max(np.abs(v_new - v_i)) < tol:
            v_i = v_new
            break
        v_i = v_new

    return ki, sub, pol

ki, sub, pol_firm = firm_problem(m, idx)

# compare the firm's choice with the planner's, evaluated at k_i = K
gaps = []
```

```
for a, K_i in enumerate(sub):
    for j in range(len(m.u)):
        gaps.append(abs(ki[pol_firm[a, K_i, j]] - m.k[idx[K_i, j]]))
gaps = np.array(gaps)

print(f"firm grid spacing:                    {np.diff(ki).mean():.3f}")
print(f"mean |firm choice - planner choice|: {gaps.mean():.3f}")
print(f"max  |firm choice - planner choice|: {gaps.max():.3f}")
```

```
firm grid spacing:                    1.772
mean |firm choice - planner choice|: 0.590
max  |firm choice - planner choice|: 1.404
```

The discrepancies are smaller than the spacing of the firm's own capital grid.

So the price-taking firm, responding optimally to the price process that the planner's allocation generates, chooses to do exactly what the planner does.

That is the content of *Theorem 118.5.1*, and it is the Lucas-Prescott counterpart of the fixed point condition $H(Y) = h(Y, Y)$ in *Rational Expectations Equilibrium*.

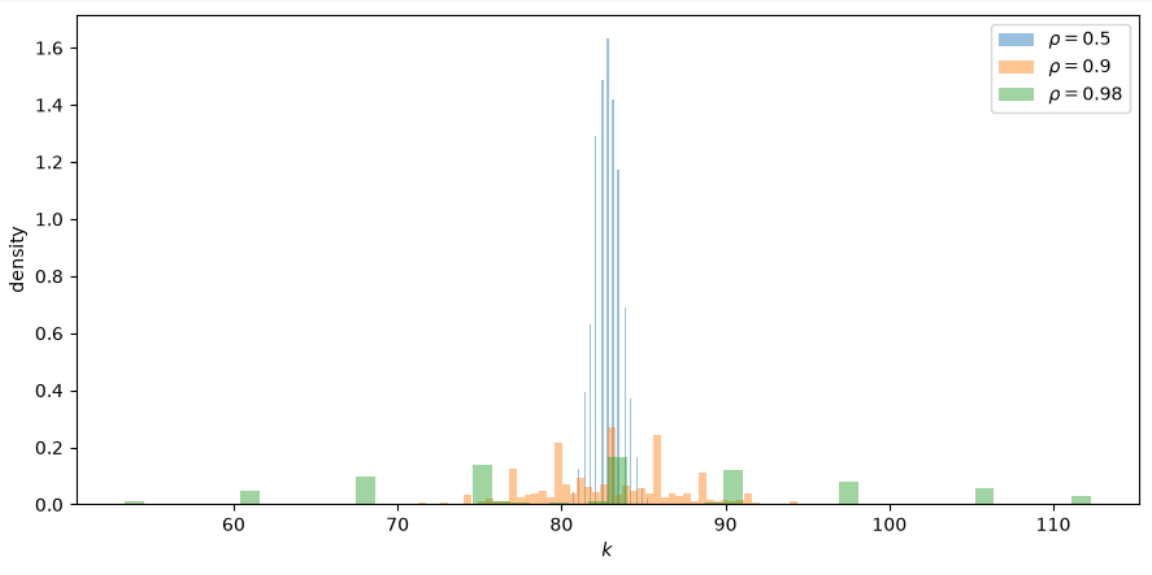
Exercise 118.11.3

Theorem 118.9.1 says that the invariant distribution does not depend on initial conditions, but it says nothing about how *wide* that distribution is.

Investigate how serial correlation in demand affects the ergodic set.

1. For $\rho \in \{0.0, 0.5, 0.9, 0.98\}$, compute the ergodic bounds $\underline{k}$ and $\bar{k}$.
2. Simulate each economy and compare the invariant distributions of capital.
3. Explain the pattern. Why does the $\rho = 0$ case produce a degenerate distribution for capital?

Solution



Here is one solution.

```
fig, ax = plt.subplots(figsize=(9, 4.5))
print(f"{'ρ':>6} {'k_lo':>9} {'k_hi':>9} {'width':>9} {'std(k)':>9}")

for ρ in (0.0, 0.5, 0.9, 0.98):
    m_ρ = create_model(ρ=ρ)
    _, idx_ρ, _, x_ρ = solve_model(m_ρ)
    b = np.array([stationary_k(x_ρ[:, j], m_ρ) for j in range(len(m_ρ.u))])
    k_ρ, _ = simulate(m_ρ, idx_ρ, k0=80.0, seed=3)
    print(f"{ρ:>6.2f} {b.min():>9.2f} {b.max():>9.2f} "
          f"{b.max()-b.min():>9.2f} {k_ρ[2000:].std():>9.3f}")
    if ρ > 0:      # the ρ = 0 distribution is a spike at k^c, so we omit it here
        ax.hist(k_ρ[2000:], bins=50, density=True, alpha=0.45, label=f'$\\rho = {ρ}
↪$')

ax.set_xlabel('$k$'); ax.set_ylabel('density')
ax.legend()
plt.tight_layout()
plt.show()
```

```
     ρ      k_lo      k_hi     width    std(k)
0.00     82.81     82.81      0.00     0.000
0.50     80.00     85.61      5.61     0.797
0.90     71.23     94.39     23.16     4.156
0.98     53.33    112.28     58.95    13.552
```

The more persistent is demand, the wider the ergodic set and the more dispersed the invariant distribution of capital.

(The figure omits $\rho = 0$, whose distribution is a spike at k^c that would dwarf the others.)

The reason is the one Lucas and Prescott emphasize.

Investment responds to *news about future demand*, not to current demand as such.

When $\rho = 0$, a demand shift conveys no information about the future, so investment does not respond at all, and capital converges to the single deterministic value k^c of *Theorem 118.8.1*: the invariant distribution of capital is degenerate even though prices keep fluctuating.

As ρ rises, a high demand state signals a sustained period of high prices, so firms invest more, and the capital stock inherits the persistence of demand.

119.1 Overview

This lecture studies Lucas and Prescott [1974], the labor-market companion to the paper on investment that we studied in *Investment Under Uncertainty*.

The two papers were written by the same authors at the same place within a few years of each other, and they use the same tools: a Bellman equation solved by successive approximations, Blackwell's theorem, and a Markov process whose invariant distribution describes the long run.

What changes is the question.

Lucas and Prescott's target was the natural rate of unemployment of Friedman [1968] and Phelps [1967].

In their words, the language used in discussing the natural rate "suggests that it may have the properties of a competitive equilibrium", yet

> *there exist no theoretical models in which a nonzero equilibrium unemployment rate is determined and its properties studied.*

Without such a model there was no framework in which to pose the welfare questions that unemployment raises, and no account of why average unemployment differs so much from one country to another.

The search literature of the 1960s could not supply one.

Job Search I: The McCall Search Model describes that literature's central problem: a worker draws wage offers from a known distribution and decides when to stop searching.

It is a model of an individual, and it takes the wage distribution as given.

Lucas and Prescott argue that the questions they care about cannot be answered that way:

> *optimal labor supply behavior and the wage distribution on which it is based must be simultaneously determined within a model of market (as opposed to individual) behavior.*

They build an economy of many spatially separate markets, each with its own randomly shifting demand for labor.

The picture comes from Edmund Phelps's "island economy", which they call "the direct ancestor of the present model" [Phelps and others, 1970].

It differs from the islands of Lucas [1972], where employment fluctuates with aggregate demand but unemployment, as an activity, is not distinguished from leisure.

Here it is distinguished.

Workers in a market can work at the wage that clears it, or leave.

Leaving means earning nothing this period and arriving somewhere else next period, so *unemployment is the act of moving between markets*.

Everything is competitive, everyone optimizes, and expectations are rational in the sense of Muth [1961] and of the investment paper, Lucas and Prescott [1971]: the distribution that workers use to evaluate their prospects is the one that their own decisions generate.

The paper's central object is a single number, λ, the expected present value of search.

An individual market takes λ as given, in the way a competitive firm takes a price as given.

Economy-wide, λ adjusts until the workforce that markets want to hold equals the workforce the economy has.

In the paper's equilibrium some markets always have more workers than they want to employ, so unemployment is positive in every period; *Three regions, one transition law* explains when the computable version that we use keeps that property.

Lucas and Prescott also argue that this unemployment need not signal an inefficiency.

Note

There is no congestion externality in the model, and there is no matching function, no bargaining and no wage rigidity: unemployment is there because moving takes a period, and in equilibrium somebody is always moving.

The searching worker who crowds his fellows does so in the same way that any seller of a good crowds other sellers, and λ, like any other equilibrium price, signals what the paper calls "the correct social return" to an additional searcher.

The paper proves no welfare theorem, and it leaves open whether actual labor markets have important external effects.

Efficiency shows that within the model the claim can be made exact: the stationary equilibrium maximizes the expected present value of surplus attainable from its own distribution of workers when moving takes a period, and λ is the present value of a worker added to the pool of searchers.

The lecture first sets out the theory: a worker's problem, the two thresholds that describe a market, and the law of motion of a market's workforce. It then computes an example, closes the economy by finding the equilibrium λ, and asks how workers could learn it.

After a look inside the equilibrium, at markets, workforces and wages, it proves the efficiency claim and relates the model to its descendants. The exercises take up the paper's comparative statics, a moving cost, the paper's own two-state examples, undirected search, the Phillips curve, and a numerical check of efficiency.

Let's start with some imports:

```
import warnings
import numpy as np
import matplotlib.pyplot as plt
import quantecon as qe
from collections import namedtuple
from scipy.optimize import brentq
```

119.2 The economy

There are many markets, each with its own state of demand.

Demand shifts are *independent across markets*, so that aggregate demand is constant, and *persistent within* a market, so that today's demand tells a worker something about tomorrow's.

In each market a competitive industry produces a single good with labor as the only input.

If $p = D(s, Q)$ is the inverse demand curve in demand state s and $q(n)$ is the production function of each of the m identical firms, then profit maximization sets the wage equal to the marginal value product of labor, and the function

$$R(s, n) = D(s, m\, q(n))\, q'(n) \tag{119.1}$$

summarizes everything about the demand side of this labor market.

Lucas and Prescott discard D and q and place assumptions directly on R: it is positive, bounded and differentiable, with

$$R_s(s, n) > 0, \qquad R_n(s, n) < 0.$$

The demand state s follows a Markov process with transition density $f(s', s)$ possessing a unique stationary distribution.

Its conditional distribution function $F(s', s)$ is decreasing in s, so that higher demand today makes higher demand tomorrow more likely.

119.2.1 Timing

A market begins a period with a **workforce** y, which is the most it can employ.

Then, within the period:

1. demand s is realized and the labor market clears, employing $n \leq y$ workers at the wage $w = R(s, n)$
2. the $y - n$ workers who are not employed earn nothing and join the pool of searchers
3. employed workers remain in the market into next period; searchers are allocated across markets and arrive next period

So a worker is *unemployed for exactly one period* each time he moves, and the unemployed are workers in transit.

119.2.2 The value of search

Because demand shifts are independent across markets and there are many of them, the economy-wide distribution of workers across markets is constant once it has settled down, even though each market's workforce fluctuates.

A searcher's prospects therefore do not depend on the market he is leaving, and the expected present value of search is a single number λ.

Searchers are allocated to markets in a way that *equalizes* the expected value of arriving, so no market offers an arriving worker more than λ.

We take λ as given for now and determine it in *Economy-wide equilibrium*.

119.3 A worker's problem

Let $v(s, y, \lambda)$ be the expected present value of the earnings of a worker who finds himself in a market with demand s and workforce y at the start of a period, and let $\beta \in (0, 1)$ be the discount factor.

Lucas and Prescott arrive at a functional equation for v by considering three cases.

Case A: some workers leave. Departing workers get λ. The workers who stay can have no more, since the leavers could have stayed, and no less, since they could have left. So $v = \lambda$.

Case B1: all workers stay and no new workers arrive. Current employment is y, the wage is $R(s, y)$, and next period's workforce is still y:

$$v(s, y, \lambda) = R(s, y) + \beta \int v(s', y, \lambda) f(s', s)\, ds'.$$

Case B2: all workers stay and new workers arrive. Arriving workers are searchers, so the discounted expected value of being in this market next period, $\beta \int v f\, ds'$, must be exactly λ, the value of the search that brought them:

$$v(s, y, \lambda) = R(s, y) + \lambda.$$

When the discounted continuation value at the unchanged workforce is below λ, nobody arrives and case B1 applies; when it would exceed λ, arrivals bring it down to λ and case B2 applies.

Either way the continuation is the smaller of λ and $\beta \int v(s', y, \lambda) f(s', s)\, ds'$, which is the min below.

Case A applies when even that leaves a worker with less than λ, and then he takes λ, which is the max.

All three cases collapse into one equation:

$$v(s, y, \lambda) = \max \left\{ \lambda,\ R(s, y) + \min \left[\lambda,\ \beta \int v(s', y, \lambda) f(s', s)\, ds' \right] \right\}. \tag{119.2}$$

The two operators do different jobs. The *max* is the worker's own option: he can always leave and collect λ.

The *min* is not the worker's choice at all. It is a restriction that competition among searchers imposes: if the continuation value in this market exceeded λ, searchers would flow in until it did not.

Proposition 119.3.1

For each λ, equation (119.2) has a unique bounded continuous solution v, and successive approximations converge to it from any starting point.

The solution is nondecreasing in s and in λ and nonincreasing in y.

The proof of *Proposition 119.3.1* is the one used throughout *Investment Under Uncertainty*: the operator defined by the right side of (119.2) is monotone and satisfies a discounting condition, so Blackwell's theorem [Blackwell, 1965] applies.

Monotonicity in s is where the assumption that $F(s', s)$ decreases in s is used. A worker is worse off the more crowded his market, because a larger workforce means a lower marginal product and a lower wage, which is why v is nonincreasing in y.

119.4 Employment, wages, and two thresholds

With v in hand, the rest of a market's behavior follows from two threshold rules.

119.4.1 How many work

Let $\bar{n}(s, \lambda)$ be the employment at which the marginal worker is just indifferent between staying and searching:

$$R(s, \bar{n}) + \beta \int v(s', \bar{n}, \lambda) f(s', s)\, ds' = \lambda. \tag{119.3}$$

The left side is what a worker gets by staying when employment and next period's workforce are both $\bar{n}$: this period's wage plus the discounted continuation. It is nonincreasing in $\bar{n}$.

If marginal revenue reaches zero at some workforce, as it does in the computable version below, the value of being in a market that crowded has fallen to λ, the left side is flat at $\beta\lambda < \lambda$, and (119.3) cannot hold there.

On an integer workforce grid, (119.3) rarely holds with equality, and employment is the largest $\bar{n}$ at which the left side is at least λ.

Employment is then

$$n(s, y, \lambda) = \min\{\bar{n}(s, \lambda),\ y\}, \qquad w = R(s, n), \tag{119.4}$$

and unemployment in this market is $y - n$, which is positive exactly when the workforce exceeds $\bar{n}$.

119.4.2 How many arrive

A market attracts searchers only when it employs its whole workforce and the continuation value still exceeds λ.

Let $\bar{y}(s, \lambda)$ be the workforce at which that stops being true:

$$\beta \int v(s', \bar{y}, \lambda) f(s', s)\, ds' = \lambda. \tag{119.5}$$

Arrivals fill a market up to $\bar{y}(s, \lambda)$ and no further. Note that $\bar{y} \leq \bar{n}$, since $R \geq 0$ means that any workforce whose continuation alone covers λ also covers it once the wage is added.

The inequality is strict wherever the marginal product is positive: a market just worth entering for a searcher is then strictly inside the range where everyone works.

In the worst demand state of the calibration below, both thresholds are zero at the equilibrium value of λ, and the market employs nobody and attracts nobody.

119.4.3 Three regions, one transition law

Together, (119.4) and (119.5) partition the (s, y) plane into the three regions of the paper's Figure 3:

- region I, where $y > \bar{n}(s, \lambda)$ and the market sheds workers down to $\bar{n}(s, \lambda)$;
- region II, between the two thresholds, where nobody moves;
- region III, where $y < \bar{y}(s, \lambda)$ and the market is filled up to $\bar{y}(s, \lambda)$.

They give the law of motion for the workforce a very simple form:

$$y' = \min\left\{ \max\{y,\ \bar{y}(s, \lambda)\},\ \bar{n}(s, \lambda)\right\}. \tag{119.6}$$

The Bellman equation evaluates the continuation at the *unchanged* workforce y, while the transition law moves the workforce somewhere else.

That is not an inconsistency, because the max and the min have already dealt with the two cases in which the workforce moves.

Where arrivals come, the min replaces the continuation by λ, and a market filled to $\bar{y}$ is worth at least λ to anyone in it: exactly λ with a continuous workforce, and possibly a little more on the integer grid used below. Where workers leave, the max replaces the whole expression by λ.

The continuation at the unchanged y is therefore used only in the region where the workforce really is unchanged.

Note

The paper lets arrivals be random: a market short of workers receives $a(s, y, \lambda)\, x$ of them, where x is a positive random variable with mean one, so that search must "eliminate rents on average" rather than exactly.

Like the numerical examples in the paper's appendix, we set $x \equiv 1$, which gives (119.6).

In the paper, random arrivals give the stationary distribution a strictly positive density (its Proposition 3), so some market is always shedding workers and unemployment is positive in every period.

With $x \equiv 1$, finitely many demand states, and a demand process that can move between any two of them in one period, there are three cases.

- If $\max_s \bar{y}(s) > \min_s \bar{n}(s)$, the stationary distribution is unique and unemployment is positive: a market filled in the state with the highest $\bar{y}$ sheds workers when demand falls to the state with the lowest $\bar{n}$, and those two periods carry a market to $\min_s \bar{n}(s)$ from any starting workforce.
- If $\max_s \bar{y}(s) = \min_s \bar{n}(s)$, the stationary distribution is again unique, every market holds that workforce, and unemployment is zero.
- If $\max_s \bar{y}(s) < \min_s \bar{n}(s)$, any workforce between the two stays where it is in every demand state, so there is a continuum of stationary distributions, and unemployment is zero.

Exercise 119.11.1 meets economies of the third kind.

119.5 A computable version

We follow the appendix of Lucas and Prescott [1974]: a finite number of demand states, an integer workforce, and value function iteration on (119.2).

For the demand process we use the example in the paper's footnote 7, in which $\log s$ follows an AR(1) with persistence between zero and one.

We discretize it with seven states by Rouwenhorst's method.

Unlike the method of Tauchen [1986], it matches the persistence and the stationary variance of $\log s$ exactly, even when persistence is high; the solution to Exercise 119.11.1 shows what goes wrong otherwise.

For R we take a marginal revenue schedule that falls linearly in employment and reaches zero at a capacity N,

$$R(s, n) = s\,(1 - n/N)^{+}.$$

With two demand states and $N = 100$, this is the schedule of the paper's Example 1, drawn in the top left panel of its Figure 5, scaled up by a factor of two.

The capacity is a departure from the theory, which assumes that R is positive everywhere, but it is one that the paper's own examples make. It caps the workforce a market will ever want below N, so the paper's Proposition 5, which promises an equilibrium for every workforce per market, holds here only for workforces below that cap.

It also shapes how unemployment behaves when workers are plentiful, as we will see.

How steeply R falls sets how far employment moves when demand moves, and therefore how much there is to gain from sending a worker from one market to another; Exercise 119.11.3 takes that up.

The function `make_model` builds a market from any demand chain and marginal revenue schedule, and `create_model` builds the lecture's economy with it.

```
Model = namedtuple('Model', ['P', 's', 'y', 'R', 'β'])

def linear_R(s, y, N=200):
    "Marginal revenue s (1 - n/N)^+, which reaches zero at the capacity N."
    return s[:, None]*np.maximum(1 - y[None, :]/N, 0.0)

def make_model(P, s, β=0.9, y_max=260, R=linear_R, **R_args):
    "A market with demand chain (P, s) and marginal revenue R on y = 0, ..., y_max."
    y = np.arange(y_max + 1)
    R_sy = R(s, y, **R_args)
    R_sy[:, 0] = 0.0                                # an empty market pays nothing
    return Model(P=P, s=s, y=y, R=R_sy, β=β)

def create_model(n_s=7, ρ=0.9, sd=0.26, β=0.9, N=200, y_max=260,
                 method='rouwenhorst'):
    """The island economy, with log demand an AR(1) discretized into n_s states.

    ρ and sd are the persistence and the stationary standard deviation of
    log demand, so that changing ρ alone does not change how variable
    demand is.  N is a market's capacity: marginal revenue reaches zero there.
    """
    σ = sd*np.sqrt(1 - ρ**2)
    if method == 'rouwenhorst':
        with warnings.catch_warnings():          # quantecon notes a change in its API
            warnings.filterwarnings('ignore', message='The API of rouwenhorst',
                                    category=UserWarning)
            mc = qe.markov.rouwenhorst(n_s, ρ, σ)
```

(continues on next page)

(continued from previous page)

```
    else:
        mc = qe.markov.tauchen(n_s, ρ, σ)
    return make_model(mc.P, np.exp(mc.state_values), β, y_max, N=N)

model = create_model()
print("demand states:", model.s.round(3))
```

```
demand states: [0.529 0.654 0.809 1.    1.237 1.529 1.891]
```

The Bellman operator is (119.2) with the integral replaced by a sum.

Because the continuation is evaluated at the unchanged workforce, the equation is a separate problem for each y, linked only across demand states, which is why it is cheap to solve and why the convention we adopt for an empty market affects nothing else.

We need some value of search to solve it, so we use $\lambda = 7.1$ here, a value close to the equilibrium that *Economy-wide equilibrium* computes.

The argument `c`, a cost of leaving that is zero until Exercise 119.11.2, changes the worker's outside option from λ to $\lambda - c$.

```
def worker_value(model, λ, c=0.0, tol=1e-11, max_iter=10_000):
    "Solve the worker's functional equation; a worker who leaves collects λ - c."
    P, R, β = model.P, model.R, model.β
    v = np.full(R.shape, λ - c)
    for i in range(max_iter):
        v_new = np.maximum(λ - c, R + np.minimum(λ, β*(P @ v)))
        v_new[:, 0] = λ - c                          # an empty market holds no workers
        if np.max(np.abs(v_new - v)) < tol:
            return v_new, i
        v = v_new
    raise RuntimeError(f"no convergence in {max_iter} iterations at λ = {λ}")

v, iters = worker_value(model, 7.1)
print(f"converged in {iters} iterations")
```

```
converged in 105 iterations
```

The two thresholds are the largest employment, and the largest workforce, at which the relevant value still covers λ.

```
def last_at_least(A, bar):
    "For each row of A, the largest index past 0 at which A ≥ bar, or 0 if none."
    return np.array([np.max(np.where(row >= bar)[0]) if (row[1:] >= bar).any() else 0
                     for row in A])

def thresholds(model, v, λ, c=0.0):
    "The employment threshold n̄(s) and the arrival threshold ȳ(s)."
    EV = model.β*(model.P @ v)                   # the continuation at an unchanged␣
↪workforce
    n_bar = last_at_least(model.R + EV, λ - c)   # staying on as the marginal worker
    y_bar = last_at_least(EV, λ)                 # ≤ n_bar, because R ≥ 0 and c ≥ 0
    return n_bar, y_bar

n_bar, y_bar = thresholds(model, v, 7.1)
print("n̄(s) =", n_bar)
print("ȳ(s) =", y_bar)
```

```
n̄(s) = [  0  16  45  69  90 109 124]
ȳ(s) = [ 0  0  3 33 58 79 97]
```

Employment is capped by $\bar{n}$, arrivals fill up to $\bar{y}$, and (119.6) moves the workforce.

The invariant distribution of that Markov chain on (s, y) can be computed exactly.

One period of (119.6) either leaves a workforce where it is or carries it onto a threshold, so from a threshold the chain never leaves the set of thresholds, and we can solve the small chain on pairs (s, t), with t running over the at most 2×7 threshold values.

A workforce off the thresholds can carry probability in the long run only if it stays put in every demand state.

The ends of such an interval of workforces are themselves thresholds that stay put, so the chain on the thresholds then has more than one invariant distribution: that is the third case of the note in *Three regions, one transition law*.

So we let `qe.MarkovChain` find every invariant distribution of the small chain, and stop with an error, rather than pick one, when there is more than one.

The function also stops if a threshold reaches the top of the grid, where it would be cut off without warning.

```

```

```
workforce 49.92, employment 48.86, unemployment 1.06
```

The small chain has $n_s|T|$ states, where $|T| \leq 2n_s$ is the number of distinct thresholds, and finding its invariant distributions costs about $(n_s|T|)^3$ operations.

That is negligible with seven states and manageable with 25, where a whole equilibrium takes a second or two, but it becomes slow beyond about 35 states.

119.6 Economy-wide equilibrium

So far λ has been a parameter.

Now close the model.

The economy has a fixed workforce, μ per market.

For any λ, the calculation above delivers the stationary distribution $\Psi(s, y; \lambda)$ of a market's demand and workforce, whose probabilities on our grid are the array ψ.

Averaging the workforce across markets with it gives the economy's **demand for workforce**,

$$E(y; \lambda) = \int y \, \Psi(ds, dy; \lambda). \tag{119.7}$$

A higher λ makes every market shed workers sooner and fill up less, so $E(y; \lambda)$ is decreasing.

Equilibrium is the λ^* at which markets want to hold exactly the workers the economy has:

$$E(y; \lambda^*) = \mu. \tag{119.8}$$

Because the schedule is decreasing, bisection finds λ^*.

On the integer grid $E(y; \lambda)$ is a step function of λ, which jumps whenever a threshold moves by one worker, so (119.8) holds only to within a step, and the workforces printed below and in the exercises differ slightly from μ.

`equilibrium_λ` first checks that μ lies between the workforces demanded at the two ends of its bracket, and raises `NotBracketed` if it does not.

```

 ↪%")
print(f"separation rate                 = "
      f"{100*eq['unemployment']/eq['employment']:.2f}% of the employed per period")
print(f"mean wage                       = {eq['wage']:.3f}")
```

```
equilibrium value of search  λ* = 7.096
workforce per market            = 49.94   (target 50)
employment per market           = 48.88
unemployment per market         = 1.06
unemployment rate               = 2.13%
separation rate                 = 2.18% of the employed per period
mean wage                       = 0.774
```

The capacity shows up in the bracket check.

Even at $\lambda = 0.01$ a market wants no more than $N - 1 = 199$ workers, so an economy with $N = 200$ workers per market has no equilibrium, and `equilibrium_λ` says so instead of returning a number.

```
try:
    equilibrium_λ(model, 200)
except NotBracketed as err:
    print(err)
```

```
μ = 200 is not between E(y; 0.01) = 199.00 and E(y; 40.0) = 0.00
```

Lucas and Prescott draw the equilibrium as a demand curve meeting a vertical supply curve, which is exactly what it is.

```
grid = np.linspace(0.6, 15.0, 45)
demand = [market_outcomes(model, λ) for λ in grid]
```

(continues on next page)

(continued from previous page)

plt.show()
```

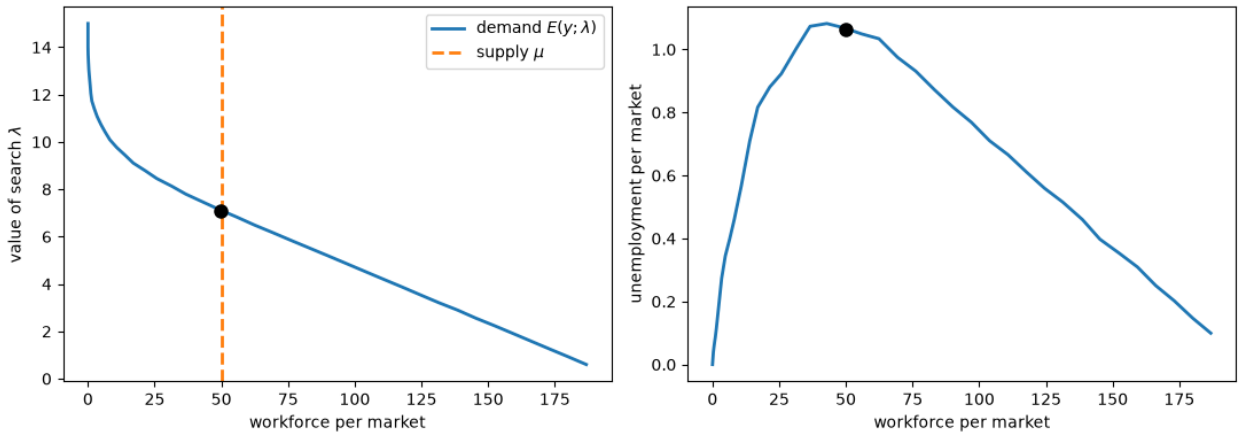

Fig. 119.1: The market for workers, and unemployment along the demand curve

The left panel is the paper's Figure 4. The right panel corresponds to the bottom panels of the paper's Figure 5, which plot average unemployment against λ for two numerical examples; since $E(y;\lambda)$ is decreasing, plotting it against the workforce instead shows the same hump, reflected.

Unemployment per market is *not monotone* in the size of the workforce, a feature that Lucas and Prescott report from their own examples, and the equilibrium sits near the top of the hump.

Where workers are abundant, λ is low, every market is pressed against its capacity, and the two thresholds of every demand state are squeezed together there, so even a large shift in demand moves few workers.

That side of the hump is the work of the capacity.

Where workers are scarce, λ is high, workforces are small, and many markets close altogether. Unemployment per market is small there only because there are so few workers per market; as a *rate* it is high, because the workers who remain are in the best markets and are shed whenever demand falls.

The unemployment rate and the share of empty markets both rise with λ:

```
for λ in (0.6, λ_star, 10.0, 13.0):
    r = market_outcomes(model, λ)
    print(f"λ = {λ:6.3f}:  unemployment rate {100*r['unemployment']/r['workforce']:5.
↪2f}%,"
          f"  markets with no workers {100*r['ψ'][:, 0].sum():5.1f}%")
```

```
λ =  0.600:  unemployment rate  0.05%,  markets with no workers   0.0%
λ =  7.096:  unemployment rate  2.13%,  markets with no workers   3.0%
λ = 10.000:  unemployment rate  5.56%,  markets with no workers  50.0%
λ = 13.000:  unemployment rate 12.02%,  markets with no workers  97.0%
```

119.7 Learning the value of search

Lucas and Prescott devote a section of the paper to a question that the equilibrium itself does not answer: we have assumed that workers know λ, and said nothing about how they would come to know it.

Ultimately, they write, this is "a question for psychological rather than economic theory, so we do not apologize for framing it here in ad hoc 'adaptive' terms".

They also say why the question is manageable here. The distribution Ψ that workers must learn depends on their own behavior, so as their perceptions change, so does the thing they are learning, which "could, in general, raise insuperable analytical difficulties".

It does not here, "since the only feature of Ψ which is relevant to worker decisions is the parameter λ". That is the self-referential structure of *Least Squares Learning in Self-Referential Models*, collapsed to a single number.

Their answer is an adaptive story. Suppose workers believe the value of search is higher than it is; then more of them leave their markets than can be placed at that return.

In the paper the excess searchers are placed by letting the mean of the arrival variable x rise, so that receiving markets get more workers than they expected, and searchers and stayers alike are disappointed in the wages they expected. They revise the number down.

Writing g for a decreasing function that vanishes at zero,

$$\frac{d\lambda}{dt} = g(\lambda - \lambda^*).$$

Stability is built into the sign assumed for g, and what justifies that sign is that the demand schedule slopes down: when λ is too high, markets want fewer workers than the economy has. `equilibrium_λ` rests on the same fact: it brackets the root rather than following the paper's adjustment, but both work because $E(y;\lambda)$ is decreasing.

The story can be put in discrete time: workers hold a belief λ_k, markets act on it, and the belief is revised in the direction of the excess demand for workers,

$$\lambda_{k+1} = \lambda_k + \gamma\,(E(y;\lambda_k) - \mu). \tag{119.9}$$

This is Walrasian tâtonnement, with λ as the price and $E(y;\lambda) - \mu$ as the excess demand. It has the form of the relaxation algorithm (91.3) of *A Peculiar Definition of Bounded Rationality*, applied to $T(\lambda) = \lambda + E(y;\lambda) - \mu$, and the sign structure of E-stability: λ^* is stable because $E(y;\lambda)$ slopes down.

The analogy is only formal, since T adds a number of workers to a present value and is not a map from a perceived to an actual value of λ.

Near λ^* the error $\lambda_k - \lambda^*$ is multiplied each step by $1 + \gamma E'(\lambda^*)$, where E' is the slope of the schedule. So the iteration converges when $0 < \gamma < 2/|E'(\lambda^*)|$, and converges without overshooting when $\gamma < 1/|E'(\lambda^*)|$.

Because $E(y;\lambda)$ is a step function on the integer grid, we estimate its slope by a centered difference wide enough to span many steps.

```
h = 0.5
slope = (workforce_demand(model, λ_star + h) - workforce_demand(model, λ_star - h))/
 ↪(2*h)
print(f"slope of E(y; λ) near λ*: {slope:.1f}")
print(f"monotone convergence for γ < {1/abs(slope):.3f}, "
      f"convergence for γ < {2/abs(slope):.3f}")

def learn_λ(model, μ, γ, λ_0=10.0, n=40):
    "Revise the belief about λ in the direction of the excess demand for workers."
    path = [λ_0]
    for _ in range(n):
        path.append(path[-1] + γ*(workforce_demand(model, path[-1]) - μ))
    return np.array(path)

paths = {γ: learn_λ(model, μ, γ) for γ in (0.01, 0.05, 0.12)}
```

```
slope of E(y; λ) near λ*: -20.1
monotone convergence for γ < 0.050, convergence for γ < 0.100
```

Here are three gains, two below the bound and one above it.

```
fig, axes = plt.subplots(1, 2, figsize=(11, 4), sharey=True)
for ax, gains in zip(axes, ((0.01, 0.05), (0.12,))):
    for γ in gains:
        ax.plot(paths[γ], lw=2, label=fr'$\gamma = {γ}$')
    ax.axhline(λ_star, color='k', lw=0.8, ls='--', label=r'$\lambda^*$')
    ax.set_xlabel('iteration $k$')
    ax.legend(loc='upper right', framealpha=1)
axes[0].set_ylabel(r'belief $\lambda_k$')
plt.tight_layout()
plt.show()
```

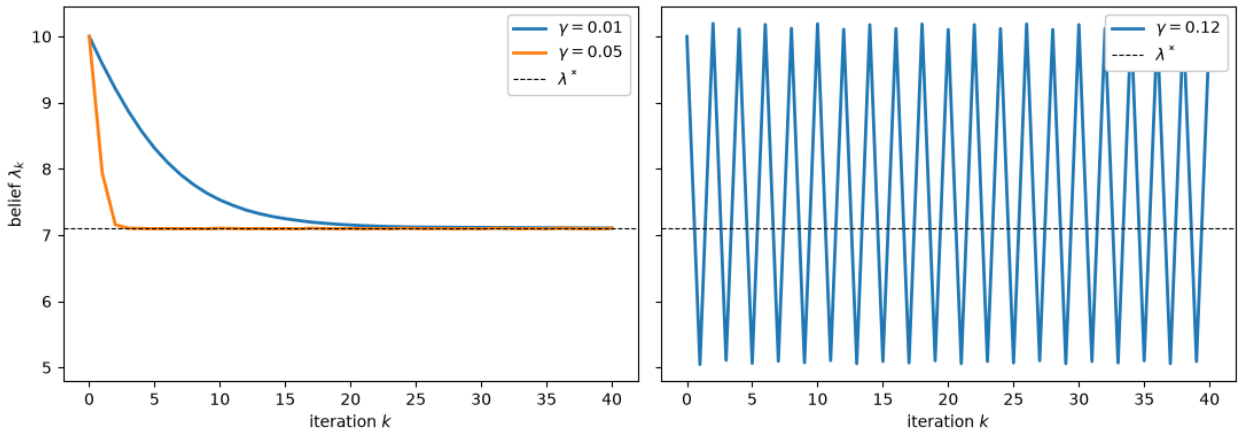

Fig. 119.2: Learning the value of search with gains below and above the bound

With $\gamma = 0.01$ the belief creeps down to λ^*, and with $\gamma = 0.05$, close to $1/|E'|$, it gets there in a few steps.

With $\gamma = 0.12$, above the bound, it does not converge: it jumps back and forth between a high and a low value, where the slope of the schedule is different and the overshooting stops growing.

The bounds are in units of value per worker: if every market were twice as large, E' would double and the stable gains would halve.

Lucas and Prescott are careful to add that this kind of stability "can have no relevance to the dynamic response to regularly recurring shocks", which is the distinction between learning an equilibrium and responding within one. *Least Squares Learning in Self-Referential Models* studies what changes when agents estimate by least squares from data instead of evaluating $E(y;\lambda)$ exactly.

119.8 Inside the equilibrium

Now look inside the equilibrium: at a single market, at the distribution of workforces, and at the wages that identical workers are paid.

119.8.1 What a market looks like

The thresholds describe the whole of a market's behavior.

```
fig, axes = plt.subplots(1, 2, figsize=(11, 4))

axes[0].plot(model.s, eq['n_bar'], 'o-', lw=2, label=r'$\bar n(s)$: employment')
axes[0].plot(model.s, eq['y_bar'], 's--', lw=2, label=r'$\bar y(s)$: arrivals fill to
↪')
axes[0].set_xlabel('demand state $s$')
axes[0].set_ylabel('workers')
axes[0].legend()

employs = eq['n_bar'] > 0                  # a state with n̄(s) = 0 employs nobody
wage_at_nbar = model.R[np.arange(len(model.s)), eq['n_bar']]
axes[1].plot(eq['n_bar'][employs], wage_at_nbar[employs], 'o-', lw=2)
axes[1].set_xlabel(r'employment $\bar n(s)$')
axes[1].set_ylabel('wage')
plt.tight_layout()
plt.show()
```

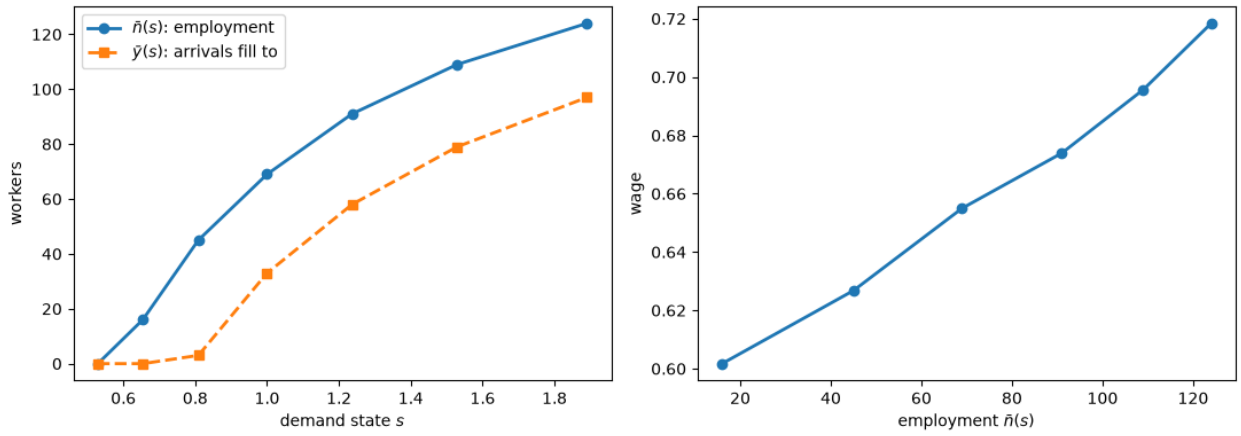

Fig. 119.3: The two thresholds at the equilibrium, and the locus of employment and wages as demand shifts

The right panel is the curve that Lucas and Prescott call SS, the pairs of employment and wages that a market would trace out as demand shifted if its workforce never constrained it.

It leaves out demand states with $\bar{n}(s) = 0$, where a market employs nobody and pays no wage.

The curve is *not flat*. A flat SS would mean that workers had a single reservation wage, accepting work above it and searching below it, which is what the partial-equilibrium search model of *Job Search I: The McCall Search Model derives*.

At $\bar{n}(s)$ the wage is whatever makes staying worth λ, $w = \lambda - \beta \int v(s', \bar{n}, \lambda) f(s', s)\, ds'$ up to the integer grid, so it moves opposite to the continuation value.

A fall in demand changes the continuation value in two ways that work in opposite directions:

1. lower demand today makes lower demand tomorrow more likely, which makes staying worth less;
2. lower employment today means a smaller workforce tomorrow, which makes staying worth more.

The first effect is present in partial-equilibrium models with persistent offers, such as *Job Search VI: Persistent and Transitory Wage Shocks*, where the reservation wage depends on the state.

The second comes from other workers' decisions, and only an equilibrium model has it. Either can dominate, so SS can slope either way.

In this calibration it slopes upward, apart from small wiggles on finer grids among top demand states that markets almost never visit, so the second effect dominates: after a fall in demand, the continuation value in the smaller market is higher, and the wage that keeps its marginal worker is lower.

The equilibrium also shows the absence of a reservation wage directly.

```
ψ, n, w = eq['ψ'], eq['n'], eq['w']
sheds = model.y[None, :] > eq['n_bar'][:, None]          # region I: workers leave
occurs = (ψ > 1e-12) & (n > 0)                           # markets that occur and␣
 ↪employ

print(f"lowest wage in a market that nobody leaves:  {w[occurs & ~sheds].min():.3f}")
print(f"highest wage in a market that workers leave: {w[occurs & sheds].max():.3f}")
```

```
lowest wage in a market that nobody leaves:  0.602
highest wage in a market that workers leave: 0.674
```

Workers stay on, and nobody leaves, in markets paying as little as the first number, while elsewhere workers walk away from markets paying the second, which is higher, so no cutoff between the two sorts the markets a worker accepts from those he leaves.

But the leavers are not turning down an offer in favor of something better, and nobody turns them away from it. At $\bar{n}(s)$ every worker in the market, stayer or leaver, gets λ; the leavers could stay, but then employment would be the whole workforce y, the wage would fall to $R(s, y)$, and staying would be worth less than λ.

So no offer is rejected against a cutoff wage, and nobody is denied a job at the going wage: the margin is the market's level of employment.

119.8.2 The workforce distribution and a sample path

Because arrivals are deterministic and demand takes finitely many values, the workforce moves between a small number of values, each one a threshold of some demand state.

```
fig, axes = plt.subplots(1, 2, figsize=(12, 4))

ψ_y = eq['ψ'].sum(axis=0)                    # the distribution of the workforce
on_support = ψ_y > 1e-10
axes[0].stem(model.y[on_support], ψ_y[on_support], basefmt=' ')
axes[0].set_xlabel('workforce $y$')
axes[0].set_ylabel('probability')

T_path = 60
idx = qe.MarkovChain(model.P).simulate_indices(T_path, init=3, random_state=0)
path_y = np.empty(T_path, dtype=int)
path_y[0] = eq['n_bar'][idx[0]]
for t in range(T_path - 1):
    path_y[t+1] = np.clip(path_y[t], eq['y_bar'][idx[t]], eq['n_bar'][idx[t]])
path_n = np.minimum(path_y, eq['n_bar'][idx])

periods = np.arange(T_path)
axes[1].plot(periods, path_y, lw=2, drawstyle='steps-post', label='workforce')
axes[1].plot(periods, path_n, lw=2, ls='--', drawstyle='steps-post', label='employment
↪')
axes[1].fill_between(periods, path_n, path_y, step='post', alpha=0.3, label=
↪'unemployed')
axes[1].set_xlabel('period')
axes[1].set_ylabel('workers')
axes[1].legend()
plt.tight_layout()
plt.show()

print(f"on this path demand falls {np.sum(idx[1:] < idx[:-1])} times, "
      f"and the market sheds workers in {np.sum(path_n < path_y)} periods")
```

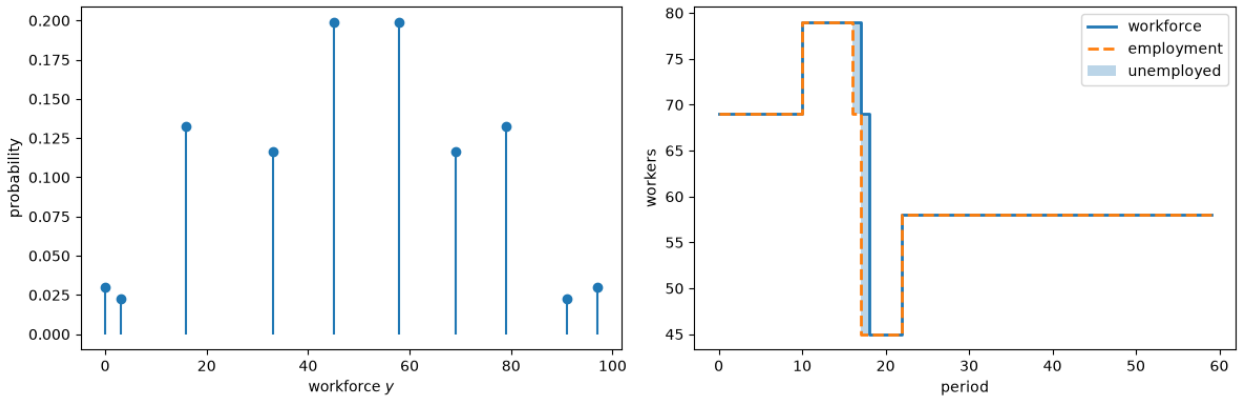

Fig. 119.4: The invariant distribution of the workforce, and one market over sixty periods

```
on this path demand falls 7 times, and the market sheds workers in 2 periods
```

The right panel shows the mechanism of the model in one picture: a market is at rest whenever demand does not move. When demand falls far enough that $\bar{n}(s)$ drops below the workforce, the gap between the two lines opens, for that period

only: that period's leavers are the unemployed, and by the next period they are somewhere else.

A smaller fall need not open it: a market that was filled only to $\bar{y}(s)$ can absorb a fall to a state whose $\bar{n}$ is still above its workforce, and the printed counts show how often that happens on this path.

119.8.3 Where markets sit

The three regions of (119.6) are a partition of the state space, so the invariant distribution says how much of the economy is in each.

```
def where_markets_sit(model, r):
    "Shares of markets in each region, and how often a market's demand stays put."
    y = model.y[None, :]
    sheds, fills = y > r['n_bar'][:, None], y < r['y_bar'][:, None]
    ψ, still = r['ψ'], ~sheds & ~fills
    return {'shedding workers': ψ[sheds].sum(), 'receiving workers': ψ[fills].sum(),
            'neither': ψ[still].sum(), 'with no workers': ψ[:, 0].sum(),
            'still, among the empty': ψ[still[:, 0], 0].sum()/ψ[:, 0].sum(),
            'demand stays put': ψ.sum(axis=1) @ np.diag(model.P)}

for name, share in where_markets_sit(model, eq).items():
    print(f"{name:>24}: {100*share:5.1f}%")
```

```
        shedding workers:   5.6%
       receiving workers:   5.6%
                 neither:  88.8%
          with no workers:   3.0%
  still, among the empty:  88.0%
       demand stays put:  75.0%
```

Most markets are completely still in any given period. A few percent shed workers, and all of the economy's unemployment comes from those; about as many are taking workers in.

What must balance is the flow of workers, and it does: the workers leaving shedding markets are exactly the workers arriving in receiving ones, as Exercise 119.11.4 checks.

The fourth line counts markets that hold no workers at all, and the fifth shows that most of them are still.

Such a market emptied when demand fell to a state where $\bar{n}(s) = 0$, and it stays empty while demand is too low for $\bar{y}(s)$ to be positive; the rest are being refilled because demand has recovered.

These shares depend on the discretization. With seven demand states a market's demand stays where it is three periods in four, as the last line shows; here are the same numbers with 25 states.

```
model_25 = create_model(n_s=25)
eq_25 = market_outcomes(model_25, equilibrium_λ(model_25, μ))
print(f"{'':>24}{'7 states':>10}{'25 states':>11}")
for (name, a), b in zip(where_markets_sit(model, eq).items(),
                        where_markets_sit(model_25, eq_25).values()):
    print(f"{name:>24}{100*a:>9.1f}%{100*b:>10.1f}%")
print(f"{'unemployment rate':>24}{100*eq['unemployment']/eq['workforce']:>9.2f}%"
      f"{100*eq_25['unemployment']/eq_25['workforce']:>10.2f}%")
```

```
                        7 states  25 states
        shedding workers      5.6%       8.2%
       receiving workers      5.6%       8.1%
                 neither     88.8%      83.7%
```

(continues on next page)

(continued from previous page)

```
        with no workers      3.0%       4.0%
  still, among the empty     88.0%      91.9%
       demand stays put      75.0%      41.3%
     unemployment rate       2.13%      2.11%
```

With 25 states demand moves in more periods, by less each time, and somewhat more markets shed and receive workers, but most markets are still still and the unemployment rate is almost unchanged.

119.8.4 The wage distribution

We can now return to the wage distribution, which the Overview said had to be determined together with the behavior of workers. The search literature hands its worker a distribution of wage offers and asks what he should do with it.

Here that distribution is an output: every market pays the marginal product of labor in it, and what a market pays depends on the demand it drew and on how many workers chose to be there.

```
weight = eq['ψ']*eq['n']                    # weight a market by the workers it␣
↪employs
weight = weight/weight.sum()

w, p = eq['w'].ravel(), weight.ravel()
order = np.argsort(w)
w, p = w[order], p[order]
cdf = np.cumsum(p)
quantile = lambda q: w[np.searchsorted(cdf, q)]
mean = (w*p).sum()
flow = λ_star*(1 - model.β)                # the flow value of search

fig, ax = plt.subplots(figsize=(7.5, 4))
ax.hist(w, bins=30, weights=p, color='C0', alpha=0.85)
ax.axvline(mean, color='k', lw=1.5, label=f'mean {mean:.3f}')
ax.axvline(flow, color='C1', lw=1.5, ls='--', label=f'flow value of search {flow:.3f}
↪')
ax.set_xlabel('wage')
ax.set_ylabel('share of workers')
ax.set_xlim(0.5, 1.45)            # a thin tail runs past this; see the print below
ax.legend()
plt.tight_layout()
plt.show()

print(f"mean {mean:.3f}, "
      f"p10 {quantile(0.1):.3f}, median {quantile(0.5):.3f}, p90 {quantile(0.9):.3f}")
print(f"p90/p10 = {quantile(0.9)/quantile(0.1):.2f},  "
      f"highest wage paid {w[p > 1e-12].max():.3f}")
print(f"share paid less than the flow value of search: {100*p[w < flow].sum():.0f}%")
near = np.abs(w - flow) < 0.001*flow
print(f"share paid within 0.1% of it: {100*p[near].sum():.1f}%")
```

```
mean 0.774, p10 0.627, median 0.748, p90 0.925
p90/p10 = 1.48,  highest wage paid 1.862
share paid less than the flow value of search: 31%
share paid within 0.1% of it: 9.2%
```

Workers in this economy are identical: they have the same skills, the same preferences and the same information, and they are free to leave at any time. They are nevertheless paid differently, by about half as much again at the ninetieth percentile as at the tenth.

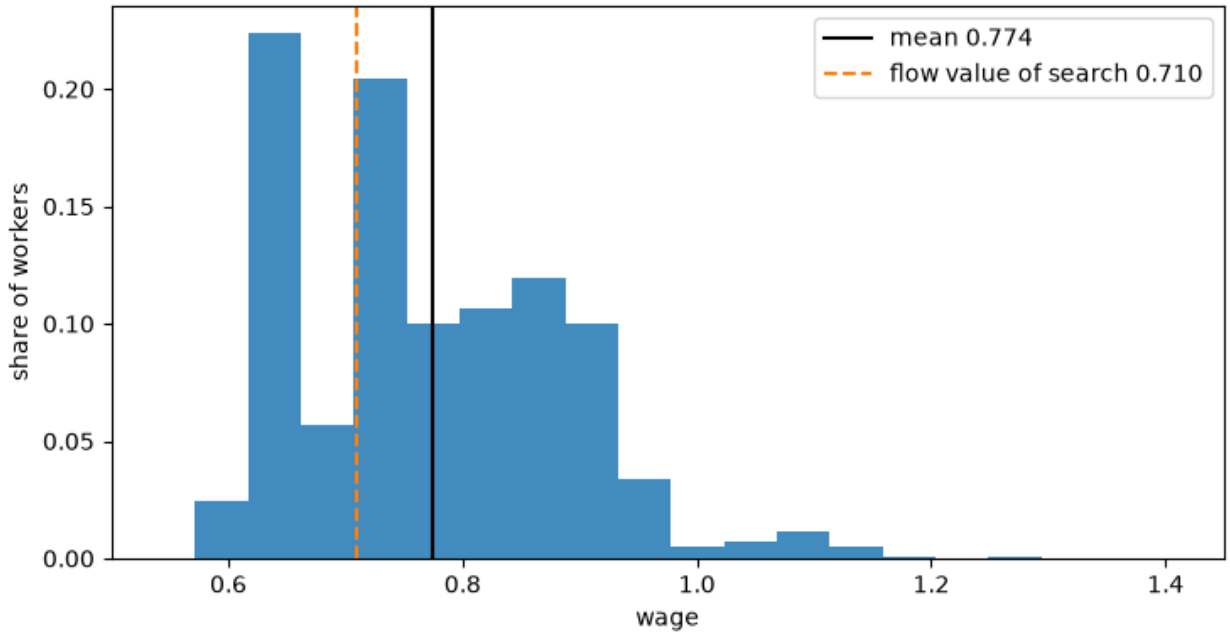

Fig. 119.5: Wages across identical workers, at the equilibrium

The dispersion is not a market failure or a mistake. It is what equalizes the value of *arriving* in any market that takes workers, and of staying or leaving in any market that sheds them.

Everywhere else incumbents earn rents, because new workers take a period to arrive, so the values of positions are dispersed too.

```
held = eq['ψ']*model.y[None, :]              # weight a market by its workforce
print(f"λ* = {λ_star:.3f},  average value of a worker's position = "
      f"{(held*eq['v']).sum()/held.sum():.3f}")
print(f"share of workers whose position is worth more than λ*: "
      f"{100*held[eq['v'] > λ_star + 1e-9].sum()/held.sum():.0f}%")
```

```
λ* = 7.096,  average value of a worker's position = 7.548
share of workers whose position is worth more than λ*: 93%
```

About nine workers in ten hold a position worth more than λ^* to them.

The dashed line in the figure is the flow value of search, $(1-\beta)\lambda^*$, which is what a searcher's position is worth per period.

Roughly a third of workers are paid less than that, and stay. The exact share is fragile.

On this grid a block of about one worker in eleven is paid within a tenth of a percent of the flow value, as the last line of the earlier print shows, so a small change in the grid can move the whole block across the line; across the grids we tried, the share runs from about 30 to 40 percent.

There is no puzzle in it: what a worker holds is not his current wage. It is a position in a particular market, which carries a claim on that market's future and the option to walk away later.

119.9 Efficiency

Lucas and Prescott say that λ signals "the correct social return from an additional unit supplied", but they prove no welfare theorem.

The model has one, and its proof uses the device of the 1971 paper studied in *Investment Under Uncertainty*: find a planning problem that the equilibrium solves.

119.9.1 Surplus

Write

$$\Phi(s, n) = \sum_{m=1}^{n} R(s, m)$$

for the area under the marginal revenue schedule up to employment n.

By (119.1) it is the area under the inverse demand curve $D(s, \cdot)$ up to the industry's output, per firm: gross consumer surplus, the objective of the 1971 paper.

It equals the value of output only when the product price is given, $D(s, Q) = s$, so we call it **surplus**.

119.9.2 A planner for one market

Consider a planner who runs a single market and can move workers in and out of it, and who is credited λ for each worker it releases into the pool of searchers and charged λ for each worker it brings in.

If next period's workforce is y', the planner employs $\min\{y, y'\}$ workers this period and releases or brings in the difference, so its value satisfies

$$W(s, y) = \max_{y'} \left\{ \Phi(s, \min\{y, y'\}) + \lambda (y - y') + \beta \int W(s', y') \, f(s', s) \, ds' \right\}. \tag{119.10}$$

Here is the **marginal-value argument**. $\Phi(s, \cdot)$ is concave because R falls with n, so $\Phi(s, \min\{y, y'\})$ is jointly concave in (y, y'), and maximizing over y' preserves concavity.

So W is concave in y, and the planner's choice is governed by marginal comparisons, made with the marginal value $\Delta W(s, y) = W(s, y) - W(s, y - 1)$.

Keeping one more worker into next period is worth his wage plus $\beta \int \Delta W(s', y') f(s', s) \, ds'$, and releasing him is worth λ; bringing one in costs λ and is worth the discounted continuation alone.

So the planner releases workers down to a threshold defined by (119.3) with ΔW in place of v, fills up to a threshold defined by (119.5) in the same way, and otherwise leaves the workforce alone.

Case by case, the marginal worker is worth λ where the planner releases, $R + \lambda$ where it fills, since he saves the charge for one arrival, and $R + \beta \int \Delta W \, f \, ds'$ in between.

These are cases A, B2 and B1, so ΔW satisfies (119.2). By the uniqueness in *Proposition 119.3.1*, $\Delta W = v$, so the planner's thresholds are the equilibrium thresholds and its policy is (119.6).

Here is the **aggregation argument**. Give every market such a planner, with the same λ, and add their objectives.

The terms $\lambda(y_t - y_{t+1})$ add up to λ times the fall in the economy's total workforce, because every worker released in one period arrives somewhere in the next.

For any feasible plan the total workforce is constant, so these terms add up to zero, and the sum of the planners' objectives is the expected present value of surplus.

The equilibrium policy maximizes each planner's objective, so it maximizes the sum. At $\lambda = \lambda^*$ it is also feasible, because $E(y; \lambda^*) = \mu$ keeps the total workforce constant.

So no feasible way of moving workers produces a higher expected present value of surplus than the stationary equilibrium.

119.9.3 What the theorem says, and what it does not

Stated precisely, the stationary equilibrium maximizes the **expected present value of surplus**

- starting from its own stationary distribution $\Psi(\lambda^*)$,
- among all feasible plans in which moving takes a period, including plans that are not stationary and plans that condition on other markets' histories,
- with a continuum of markets, so that the equilibrium plan keeps the economy's workforce constant period by period,
- up to the slack of the integer grid, on which $E(y; \lambda^*)$ is within a step of μ rather than equal to it.

λ^* is the present value of a worker added to the pool of searchers; per period, the multiplier on the constraint that the economy's workforce is fixed is $(1 - \beta)\lambda^*$, the flow value of search in the wage figure above.

The theorem is about total surplus, whoever receives it, and says nothing about how surplus is divided: Exercise 119.11.2 finds a policy that lowers surplus and still makes workers better off.

Nor does it rank steady states. Its comparison starts from $\Psi(\lambda^*)$ and counts everything that happens along the way to any other allocation.

A policy that leads to a different steady state can raise surplus in that steady state while lowering the present value, because getting there costs surplus first.

Exercise 119.11.6 computes two examples, a small subsidy to moving and the thresholds of a planner more patient than the workers, and both raise steady-state surplus per worker above its equilibrium level.

This is the logic of the **modified golden rule** of growth theory, where a planner who discounts the future chooses less capital than the steady state that maximizes consumption, because building the extra capital costs consumption first.

Here reallocating a worker costs a period of his output now and pays off later, so a planner who discounts reallocates less, and has less unemployment, than one who maximizes steady-state surplus.

The efficiency is relative to the technology of moving, which takes a period, and the equilibrium has exactly as much unemployment as that technology makes worthwhile once the future is discounted at β.

119.10 Relation to other lectures

In the first footnote of Baley *et al.* [2023], there is no "standard model" of frictional unemployment but three workable classes of models: matching models in the Diamond-Mortensen-Pissarides tradition, equilibrium versions of McCall [1970], and search-island models in the tradition of Lucas and Prescott [1974].

Calibrated versions of all three fit data on labor market flows and deliver plausible responses of unemployment to policies like unemployment insurance and layoff taxes.

This lecture is the third class, and the McCall lectures in this series study the worker's problem at the heart of the second, in partial equilibrium. What this model adds to them is everything on the other side of the offer.

The wage a worker is offered is the marginal product of labor in a market whose workforce was determined by where other workers decided to go, and the value of looking elsewhere, λ, is the number that clears the economy-wide market for workers.

One consequence is that there is no reservation wage, as the SS curve showed. Another concerns the flow rates between employment and unemployment.

A Lake Model of Employment and Unemployment takes both rates as parameters: a job finding rate of 0.283 (which that lecture calls λ, not to be confused with the value of search here) and a separation rate of 0.013 go in, and the unemployment rate comes out.

Lake Model with an Endogenous Job Finding Rate makes the job finding rate the outcome of a McCall problem, though still against a wage distribution that is given.

In this lecture the separation rate is an equilibrium object, while the job finding rate is essentially one by construction.

The separation rate printed above, around 2.2 percent of the employed per period, combines how often demand shifts carry a market below its employment threshold with how many workers each such market sheds.

Warning

The job finding rate in this model is *essentially one*.

A worker who leaves is placed in some market at the start of the next period, so a spell of unemployment lasts one period and the model has nothing to say about unemployment *duration*.

Strictly, a market that receives searchers can have its demand fall so far that it sheds more workers than it held before they arrived, so that some of the newcomers must move again; in this calibration that happens to fewer than one searcher in a hundred, even if newcomers are the first to go.

119.10.1 What the island model became

Alvarez and Veracierto [1999] took this model and made it a tool for quantitative policy analysis, in their words by "modifying Lucas and Prescott's (1974) island model to incorporate undirected search and out-of-the-labor-force participation".

Four things change. Search becomes **undirected**: searchers "arrive uniformly across all islands", so an island's workforce next period is its own employment plus the same inflow every other island gets, whether it wants the workers or not.

A searcher can then land in a market that is itself shedding workers and have to move again, so the duration of unemployment becomes an equilibrium object; it averages 2.4 periods in their laissez-faire benchmark.

The nonemployed gain a second option, home production, so that labor force participation is a margin and the model has three states rather than two.

With home production the inflow of searchers is set by the indifference between searching and staying home, so the size of the labor force becomes an outcome, which matters because the policies they study act on whether people look for work at all.

Islands produce with a decreasing returns technology subject to persistent productivity shocks rather than facing a shifting demand curve. And agents trade a complete set of state-contingent securities.

Their laissez-faire equilibrium "is efficient (despite the search frictions)", the analogue for their economy of *Efficiency*, and they use it as the benchmark for evaluating minimum wages, two models of unions, firing taxes and unemployment insurance, at a model period of six weeks.

A firing tax worth twelve months of average wages, for example, takes their unemployment rate *down* from 5.3 to 3.7 percent and pushes the average duration of unemployment *up* from 2.4 to 5.1 periods, while lowering welfare by 2.1 to 2.3 percent of consumption.

Note

Undirected search changes how λ is determined.

Under directed search λ is a *price*: raise it and every market sheds workers sooner and fills up less, so (119.8) pins it down as a market-clearing condition pins down any other price, and the min in (119.2) makes every market that receives workers worth exactly λ to them.

Under undirected search a searcher lands in a market drawn at random, so λ needs a consistency condition of its own, and the common inflow U becomes a second unknown.

With a fixed population the model is still determinate: there are two conditions, the population and the consistency of λ, for the two unknowns.

In this calibration the equilibrium exists and is unique once the inflow can be fractional, but uniqueness no longer follows, in general, from a single decreasing schedule.

Exercise 119.11.4 computes it: undirected search lowers the value of search, and it lowers unemployment too.

119.10.2 Returns to labor mobility

Lucas and Prescott end their discussion of a moving cost with a conjecture, that "differences of this sort in the actual or perceived costs of changing jobs can help to account for the observed differences in average unemployment across occupations and among countries".

Why average unemployment differs across countries became a central question for this class of models; Ljungqvist and Sargent [1998], for example, trace the rise of European unemployment to generous unemployment benefits interacting with a more turbulent economic environment.

Baley *et al.* [2025] call the **returns to labor mobility**, how much more a worker produces where he is going than where he is, "important intermediating forces in all modern macroeconomic models with frictional labour markets".

Baley *et al.* [2023] show that the same quantity decides what a layoff tax does to unemployment, and whether skill losses at the time of a quit can reverse the effect of turbulence on unemployment. It is a property of the shock and of the technology that intermediates it, taken together.

Baley *et al.* [2025] find that calibrations to firm size dynamics, with shocks passed through neoclassical production functions, deliver returns to labor mobility that are robust to perturbations of parameters, while calibrations of per-worker productivity processes to labor market statistics can be fragile.

One of the models they study is that of Alvarez and Veracierto [2001], who calibrated a productivity process to the establishment data on job creation and destruction of Davis and Haltiwanger.

That paper is a different model from Alvarez and Veracierto [1999]: establishments hire at a common labor market whose location changes at random, wage contracts are rigid, and risk-averse agents without insurance markets self-insure and choose how hard to search.

An establishment produces $z\,k^{\theta_k} n^{\theta_n}$ from capital k and labor n, with productivity z and $\theta_k + \theta_n < 1$.

Baley *et al.* [2025] streamline the model, dropping the cost of creating an establishment and a small firing tax, so that every establishment rents capital and hires labor in spot markets and they all equate marginal products, which gives

$$\frac{n_{\text{high}}}{n_{\text{low}}} = \left(\frac{z_{\text{high}}}{z_{\text{low}}}\right)^{1/(1-\theta_k-\theta_n)}, \tag{119.11}$$

so a shock is amplified by an exponent that explodes as returns to scale approach one.

At Alvarez and Veracierto's parameters, they find that a low-productivity establishment employs only 3.81 percent as many workers as a high-productivity one, a ratio of about 26, and that high-productivity establishments hold more than 96 percent of all employment: an exponent of about 4.35 turns a productivity ratio of 2.12 into an employment ratio of about 26.

That is a frictionless allocation, since every establishment hires in the same spot market. In the present model moving takes a period, and Exercise 119.11.3 asks how much of a ratio like 26 survives that friction, holding the technology and the shock like Alvarez and Veracierto's.

119.11 Exercises

Exercise 119.11.1

Lucas and Prescott [1974] report two comparative statics from their own numerical examples:

> *Overall, we found for low and high persistence in demand that unemployment rates were low. In the former case, there was little gained by reallocating workers, while in the latter reallocation occurred infrequently. As expected, the greater the variability of demand, holding the degree of persistence fixed, the greater the level of unemployment.*

Check both in this calibration, holding $\mu = 50$.

1. Compute the equilibrium unemployment rate for persistence $\rho \in \{0.6, 0.8, 0.9, 0.95, 0.99\}$, holding the *stationary* standard deviation of $\log s$ fixed at 0.26, and for stationary standard deviations $\{0.10, 0.18, 0.26, 0.34, 0.45\}$, holding $\rho = 0.9$. Explain the shapes you find.
2. With independent demand, $\rho = 0$, `equilibrium_λ` stops with an error. Show that unemployment is then exactly zero and that the equilibrium λ is not unique. Why does this not contradict the paper's Proposition 5, or its claim that unemployment is positive in every period?
3. Repeat part 2 at $\rho = 0.3$, first with seven demand states and then with 25. What does the comparison say about the low end of part 1?

Solution

Holding the stationary standard deviation fixed as ρ varies is what the argument `sd` of `create_model` already does, so each experiment is one call.

```
def u_rate(model, μ):
    "The equilibrium unemployment rate."
    r = market_outcomes(model, equilibrium_λ(model, μ))
    return r['unemployment']/r['workforce']

for ρ in (0.6, 0.8, 0.9, 0.95, 0.99):
    print(f"ρ = {ρ:<5}  unemployment rate {100*u_rate(create_model(ρ=ρ), μ):.2f}%")
print()
for sd in (0.10, 0.18, 0.26, 0.34, 0.45):
    print(f"sd = {sd:<5} unemployment rate {100*u_rate(create_model(sd=sd), μ):.2f}
↪%")
```

```
ρ = 0.6    unemployment rate 0.86%
ρ = 0.8    unemployment rate 2.08%
ρ = 0.9    unemployment rate 2.13%
ρ = 0.95   unemployment rate 1.44%
ρ = 0.99   unemployment rate 0.50%
sd = 0.1   unemployment rate 0.22%
sd = 0.18  unemployment rate 0.97%
sd = 0.26  unemployment rate 2.13%
sd = 0.34  unemployment rate 3.13%
sd = 0.45  unemployment rate 3.89%
```

Variability does what one expects: demand that moves further moves more workers, and the unemployment rate rises steadily with it.

Persistence does not: unemployment rises to a peak at ρ around 0.8 to 0.9, and falls again to about a quarter of the peak at $\rho = 0.99$. That is the shape Lucas and Prescott describe, and the two ends are low for different reasons.

When demand is nearly independent across periods, a market that is unlucky today expects to be average tomorrow, so the value of staying hardly depends on today's demand, the arrival threshold $\bar{y}(s)$ barely varies with s, and few workers are ever shed; part 2 takes this to its limit.

When demand is nearly permanent, it changes little from one period to the next: on the seven-state chain it changes rarely, by a whole notch, and on finer chains more often, by less. Either way few workers have reason to move in any one period, which is the paper's "reallocation occurred infrequently".

Unemployment needs demand shifts that are *both* worth responding to and frequent, a combination that only intermediate persistence delivers.

For part 2, `equilibrium_λ` stops because the invariant distribution is not unique, the third case of the note in *Three regions, one transition law*. So we look instead for the values of λ at which a market holding μ workers never moves, $\max_s \bar{y}(s) \le \mu \le \min_s \bar{n}(s)$.

Both thresholds fall as λ rises, so each end of that set is found by bisection.

```
def rest_interval(model, μ, lo=0.01, hi=40.0):
    "The interval of λ at which a market holding μ workers never moves, or None."
    def ends(λ):
        n_bar, y_bar = thresholds(model, worker_value(model, λ)[0], λ)
        return y_bar.max(), n_bar.min()
    λ_a = bisect(lambda λ: ends(λ)[0] <= μ, lo, hi)      # no market fills past μ
    λ_b = bisect(lambda λ: ends(λ)[1] < μ, lo, hi)       # some market sheds below μ
    return (λ_a, λ_b) if λ_a < λ_b else None

m_iid = create_model(ρ=0.0)
n_bar_iid, y_bar_iid = thresholds(m_iid, worker_value(m_iid, 7.1)[0], 7.1)
print("rows of P identical:", np.allclose(m_iid.P, m_iid.P[0]))
print("at λ = 7.1:  n̄(s) =", n_bar_iid, "  ȳ(s) =", y_bar_iid)
print("λ at which a market holding μ never moves: from {:.3f} to {:.3f}".format(
      *rest_interval(m_iid, μ)))
```

```
rows of P identical: True
at λ = 7.1:  n̄(s) = [ 55  57  61  71  88 107 124]   ȳ(s) = [47 47 47 47 47 47␣
↪47]
λ at which a market holding μ never moves: from 6.935 to 7.378
```

With independent demand every row of P is the same, so the continuation $\beta \sum_{s'} v(s', y) P(s, s')$ does not depend on s, and neither does $\bar{y}$.

Since $\bar{y}(s) \le \bar{n}(s)$ in every state, the common $\bar{y}$ lies below every employment threshold. So every workforce between $\bar{y}$ and $\min_s \bar{n}(s)$ stays where it is in every demand state, markets drift into that interval and stop, and in the long run nobody moves and unemployment is exactly zero.

Every workforce in the interval is absorbing, so the invariant distribution is not unique, and every λ in the printed interval supports an equilibrium in which every market holds μ workers.

The width of the interval is a property of the discretized chain: it narrows as states are added, because the worst demand state moves further out and its employment threshold comes down toward the common $\bar{y}$. Unemployment stays at zero, though, since every $\bar{n}(s)$ is at least $\bar{y}$.

None of this contradicts the paper, and the operative difference is $x \equiv 1$. The unique λ of Proposition 5 and the claim that unemployment is positive in every period both rest on the unique stationary density of Proposition 3, which

random arrivals deliver by overfilling some markets, and with deterministic arrivals that argument is not available.

Independent demand also violates the strict monotonicity of $F(s', s)$ in s that the paper maintains, and the example in its footnote 7 requires the AR(1) coefficient to be strictly positive.

For part 3, the same check at $\rho = 0.3$ gives different answers on the two grids.

```
for n_s in (7, 25):
    m = create_model(n_s=n_s, ρ=0.3)
    rest = rest_interval(m, μ)
    if rest is not None:
        print(f"{n_s:>2} states: at rest for λ from {rest[0]:.3f} to {rest[1]:.3f}
↪")
    else:
        print(f"{n_s:>2} states: unique λ*, unemployment rate {100*u_rate(m, μ):.
↪3f}%")
```

```
 7 states: at rest for λ from 7.128 to 7.207
25 states: unique λ*, unemployment rate 0.014%
```

With seven states, persistence of 0.3 is not enough to spread the arrival thresholds past the lowest employment threshold, and the economy is at rest, as at $\rho = 0$. With 25 states the extreme demand states are further out, the equilibrium is unique, and unemployment is positive but tiny.

So at $\rho = 0.3$ unemployment is low on either grid, as the paper says, but whether it is exactly zero is a property of the discretized chain.

The method of discretizing matters more at the other end.

```
def chain_moments(m):
    "Standard deviation and autocorrelation of log s, and the chance that s stays␣
↪put."
    π = qe.MarkovChain(m.P).stationary_distributions[0]
    x = np.log(m.s) - π @ np.log(m.s)
    sd = np.sqrt(π @ x**2)
    return sd, (π*x) @ (m.P @ x)/sd**2, π @ np.diag(m.P)

print(f"{'method':>12}{'ρ':>6}{'sd':>8}{'autocorr':>10}{'P(stay)':>9}{'u rate':>9}
↪")
for ρ in (0.9, 0.99):
    for method in ('rouwenhorst', 'tauchen'):
        m = create_model(ρ=ρ, method=method)
        sd, ac, stay = chain_moments(m)
        print(f"{method:>12}{ρ:>6}{sd:>8.3f}{ac:>10.4f}{stay:>9.3f}"
              f"{100*u_rate(m, μ):>8.2f}%")
```

```
      method     ρ      sd  autocorr  P(stay)   u rate
 rouwenhorst   0.9   0.260    0.9000    0.750    2.13%
     tauchen   0.9   0.304    0.9016    0.733    2.68%
 rouwenhorst  0.99   0.260    0.9900    0.971    0.50%
     tauchen  0.99   0.343    0.9999    1.000    0.01%
```

Rouwenhorst's chain has exactly the target standard deviation, 0.26, and the target autocorrelation. Tauchen's seven-state chain is too volatile at $\rho = 0.9$, which raises unemployment by about a quarter.

At $\rho = 0.99$ it is too volatile and also far too persistent: its demand state almost never changes, so markets almost never reallocate, and unemployment nearly vanishes.

With seven states, that would make the right end of part 1 look like the left; with 25 states the two methods nearly agree.

Exercise 119.11.2

In their concluding section, Lucas and Prescott consider a lump-sum cost c of leaving a market to search, so that the right side of (119.3) becomes $\lambda - c$ rather than λ: a worker who leaves collects the value of search net of what it costs him to get there.

The arrival condition (119.5) is unchanged, since it prices the market for workers who are already searching.

They say that the cost "will raise the curve $y = \bar{n}(s, \lambda)$ in Fig. 3 and shift the 'demand curve' in Fig. 4 downward. The result is a decrease in unemployment and a decrease in the equilibrium present value of wages, λ", and remark that this

> *shows that lower average unemployment is not, in general, associated with higher welfare for workers.*

`market_outcomes` and `equilibrium_λ` already take the cost as their argument `c`.

For $c \in \{0, 0.2, 0.5, 1, 2\}$ report the equilibrium λ^* and $\lambda^* - c$, the unemployment rate, surplus per market, the wage bill per market, rents (surplus minus the wage bill), and workers' income per worker per period, the wage bill net of what workers pay to move, divided by the workforce.

1. Does λ^* fall, as the paper says? If not, what does?
2. Does lower unemployment mean better off? Compare what workers gain with what the economy loses, as present values per worker.
3. Who pays? Answer once treating c as a resource, used up in moving, and once treating it as a tax whose revenue is rebated lump sum to workers.
4. Baley *et al.* [2023] use the smallest layoff tax that shuts down all endogenous separations as a diagnostic of a model's returns to labor mobility. Compute the smallest c that does that here, in units of the average wage, with 7, 15 and 25 demand states. Why does it change with the number of states?

Solution

Before sweeping, look at what the cost does to workforce demand at the laissez-faire value of search.

```
λ_0 = equilibrium_λ(model, μ)
for c in (0.0, 2.0):
    n_bar_c, y_bar_c = thresholds(model, worker_value(model, λ_0, c)[0], λ_0, c)
    print(f"c = {c}: workforce demand {workforce_demand(model, λ_0, c):5.1f},  "
          f"n̄(s) = {n_bar_c},  ȳ(s) = {y_bar_c}")
```

```
c = 0.0: workforce demand  49.9,  n̄(s) = [  0  16  45  69  91 109 124],  ȳ(s) =␣
↪[ 0  0  3 33 58 79 97]
c = 2.0: workforce demand  74.8,  n̄(s) = [ 62  78  93 107 121 134 146],  ȳ(s) =␣
↪[ 0  0  2 31 54 72 87]
```

The cost raises workforce demand, so the new λ^* lies above the old one, and we start each bisection there. That also keeps it away from low values of λ, where with a cost the invariant distribution is not unique and the bisection would stop.

In a stationary distribution every unemployed worker left his market once this period, so workers pay c times unemployment per market in moving costs.

```
results = {}
for c in (0.0, 0.2, 0.5, 1.0, 2.0):
    λ_c = equilibrium_λ(model, μ, c, lo=λ_0) if c > 0 else λ_0
    results[c] = (λ_c, market_outcomes(model, λ_c, c))

income = lambda r, c: (r['wage_bill'] - c*r['unemployment'])/r['workforce']
rents = lambda r: r['surplus'] - r['wage_bill']

print(f"{'c':>5}{'λ*':>8}{'λ*-c':>8}{'u rate':>9}{'surplus':>9}{'wages':>8}"
      f"{'rents':>8}{'income':>9}")
for c, (λ_c, r) in results.items():
    print(f"{c:>5}{λ_c:>8.3f}{λ_c - c:>8.3f}"
          f"{100*r['unemployment']/r['workforce']:>8.2f}%{r['surplus']:>9.3f}"
          f"{r['wage_bill']:>8.3f}{rents(r):>8.3f}{income(r, c):>9.4f}")
```

```
    c      λ*    λ*-c   u rate  surplus   wages   rents   income
  0.0   7.096   7.096    2.13%   46.708  37.844   8.864   0.7577
  0.2   7.206   7.006    1.65%   46.586  37.987   8.600   0.7575
  0.5   7.371   6.871    1.21%   46.351  38.167   8.184   0.7601
  1.0   7.661   6.661    0.73%   46.134  38.464   7.671   0.7625
  2.0   8.262   6.262    0.24%   45.325  38.434   6.892   0.7684
```

Surplus, wages and rents are flows per market, and income is a flow per worker. To compare what workers gain with what the economy loses, put both in present values per worker, dividing flows per worker by $1 - \beta$.

```
β = model.β
r_0 = results[0.0][1]
pv = lambda flow: flow/(1 - β)
surplus_pw = lambda r: r['surplus']/r['workforce']
print(f"{'c':>5}{'workers gain':>14}{'surplus lost':>14}{'ratio':>7}")
for c, (_, r) in results.items():
    gain = pv(income(r, c) - income(r_0, 0.0))
    loss = pv(surplus_pw(r_0) - surplus_pw(r))
    ratio = f"{loss/gain:7.1f}" if gain > 0 else f"{'':>7}"
    print(f"{c:>5}{gain:>14.4f}{loss:>14.4f}{ratio}")

r_2 = results[2.0][1]
print(f"\nc = 2: unemployment falls {100*(1 - r_2['unemployment']/r_0['unemployment
↪']):.0f}%, "
      f"the wage bill rises {100*(r_2['wage_bill']/r_0['wage_bill'] - 1):.1f}%, "
      f"rents fall {100*(1 - rents(r_2)/rents(r_0)):.0f}%")
print(f"moving costs paid, a present value per worker: "
      f"{pv(2.0*r_2['unemployment']/r_2['workforce']):.4f}")
```

```
    c  workers gain  surplus lost  ratio
  0.0        0.0000        0.0000
  0.2       -0.0020        0.0214
  0.5        0.0239        0.0473    2.0
  1.0        0.0480        0.1181    2.5
  2.0        0.1068        0.2344    2.2

c = 2: unemployment falls 89%, the wage bill rises 1.6%, rents fall 22%
moving costs paid, a present value per worker: 0.0472
```

For part 1, Lucas and Prescott say that the cost shifts the demand curve of their Figure 4 down and lowers λ, but here it does the opposite.

At the laissez-faire λ^*, the cost raises workforce demand by about half. It raises the employment threshold $\bar{n}(s)$ in

every state where anyone works, by a lot, since a worker who would leave now gives up c as well, while it lowers the arrival thresholds a little.

That is the paper's own first step, "raise the curve $y = \bar{n}(s, \lambda)$", and with λ on the vertical axis of Figure 4 it shifts the demand curve up, not down.

With more workers wanted than the economy has, λ^* must rise, and it does. What falls is $\lambda^* - c$, the value of the option to leave net of its cost, which is what a worker deciding whether to stay compares with staying, and the paper's statement holds for that number, not for λ^* itself.

For part 2, a cost of two cuts measured unemployment by close to nine tenths. Measured by their income net of moving costs, workers gain clearly from $c = 0.5$ on.

For smaller costs what they pay to move nearly offsets the extra wages, so the gain is close to zero, and on this grid it is slightly negative at $c = 0.2$.

The economy loses more than workers gain: at $c = 2$ surplus falls by about two to two and a half times as much as workers' income rises. These are comparisons of steady states, which leave out the transition from one to the other.

So lower unemployment is not a welfare index, but the lesson arrives in a different form from the paper's: Lucas and Prescott's workers are worse off because λ falls, while ours are better off and the economy as a whole is worse off.

The unemployment that the cost eliminated was *productive*. Those workers were not idle in any useful sense; they were in transit from markets where their marginal product had fallen to markets where it was high, and the cost keeps them where they are.

For part 3, the wage bill rises a little, while rents, surplus minus the wage bill, fall by about a fifth.

Surplus is the area under R, so rents are the profits of firms plus, when product demand slopes down, the consumer surplus of the buyers of the market's good, and it is they who pay.

How the account closes depends on what c is. If it is a real resource, the moving costs printed above are used up as well, on top of the lost surplus, and workers bear them.

If it is a tax rebated lump sum to workers, nothing is used up beyond the lost surplus, and the rebate returns those same moving costs to workers each period without changing anyone's decisions, so workers gain more.

The two cases differ in what the lost surplus means, too. Exercise 119.11.6 shows that with a resource cost the equilibrium is the planner's allocation for the costlier technology of moving, so the lower surplus is the price of a worse technology, not an inefficiency; with a rebated tax the technology is unchanged and the equilibrium is no longer the planner's allocation for it, so the lower surplus is an efficiency loss.

For part 4, recall the note in *Three regions, one transition law*. Separations stop exactly when there is a λ at which a market holding μ workers never moves, with no state's arrival threshold above μ and no state's employment threshold below it.

A cost raises the employment thresholds, so we look for the smallest cost at which such a λ exists.

Once separations stop every market holds μ workers for ever, so a worker in demand state s holds v_s, with $v = (I - \beta P)^{-1} R(\cdot, \mu)$, and nobody leaves or arrives when $\beta(Pv)_s \leq \lambda \leq v_s + c$ for every s.

That gives a formula to set beside the computation, $c_{\min} \approx \beta \max_s (Pv)_s - \min_s v_s$, which ignores the integer grid.

```
def at_rest_values(model, μ):
    "The value of a position when every market holds μ workers for ever."
    return np.linalg.solve(np.eye(len(model.s)) - model.β*model.P, model.R[:, μ])

def min_cost(model, μ, lo=1.0, hi=20.0, c_hi=20.0):
    "The smallest c at which some λ leaves a market holding μ workers at rest."
    def at_rest(c):
        ends = lambda λ: thresholds(model, worker_value(model, λ, c)[0], λ, c)
        λ_a = bisect(lambda λ: ends(λ)[1].max() <= μ, lo, hi, tol=1e-3)  # nobody␣
↪fills past μ
        n_bar, y_bar = ends(λ_a)
        return y_bar.max() <= μ <= n_bar.min()
    return bisect(at_rest, 0.0, c_hi, tol=1e-2)

print(f"{'states':>7}{'c_min/wage':>12}{'formula':>9}{'log s ranges over':>20}")
for n_s in (7, 15, 25):
    m = create_model(n_s=n_s)
    v_rest = at_rest_values(m, μ)
    wage = qe.MarkovChain(m.P).stationary_distributions[0] @ m.R[:, μ]
    formula = m.β*(m.P @ v_rest).max() - v_rest.min()
    print(f"{n_s:>7}{min_cost(m, μ)/wage:>12.2f}{formula/wage:>9.2f}"
          f"{np.log(m.s).min():>11.2f} to {np.log(m.s).max():.2f}")
```

```
 states  c_min/wage  formula   log s ranges over
      7        4.91     4.99      -0.64 to 0.64
     15        8.30     8.39      -0.97 to 0.97
     25       11.67    11.77      -1.27 to 1.27
```

The wage used as the unit is the average wage when every market holds μ workers, which is what the economy looks like once separations stop; it is within half a percent of the laissez-faire average wage.

The cost that stops all separations grows with the number of states, and the formula says why. It is set by the gap between the best and the worst demand state a market can be in, and Rouwenhorst's chain places its extreme states at $\pm 0.26\sqrt{n_s - 1}$ in $\log s$, so they move apart as states are added.

$\log s$ itself is an AR(1) with unbounded support, so for the model with continuous demand no finite cost stops all separations: the number computed here measures the support of the discretized demand process.

For the symmetric two-state chain of Exercise 119.11.3, in which demand stays put with probability ρ and $R(s, n) = s\, g(n)$, the formula has a closed form,

$$\frac{c_{\min}}{\bar{w}} = -1 + \frac{s_{\text{high}} - s_{\text{low}}}{s_{\text{high}} + s_{\text{low}}} \cdot \frac{1 + \beta(2\rho - 1)}{1 - \beta(2\rho - 1)},$$

about 1.05 periods' wages there, which depends on the demand process and β but not on the shape of g: in this model the diagnostic measures the spread and persistence of demand, not the curvature of R.

The calibration does not say how long a period is; with $\beta = 0.9$ it is naturally read as a year, which would make every spell of unemployment a year long. For comparison, in the Ljungqvist–Sargent matching model that Baley *et al.* [2023] use as their benchmark, layoff taxes of 163 to 184 percent of a year's output per worker shut down all endogenous separations, at a model period of half a quarter.

Baley, Ljungqvist and Sargent's point is that this number has to be *large* to be credible, because extensive reallocation is observed in economies whose layoff costs differ enormously.

Exercise 119.11.3

The numerical examples in the appendix of Lucas and Prescott [1974] use just two demand states, with

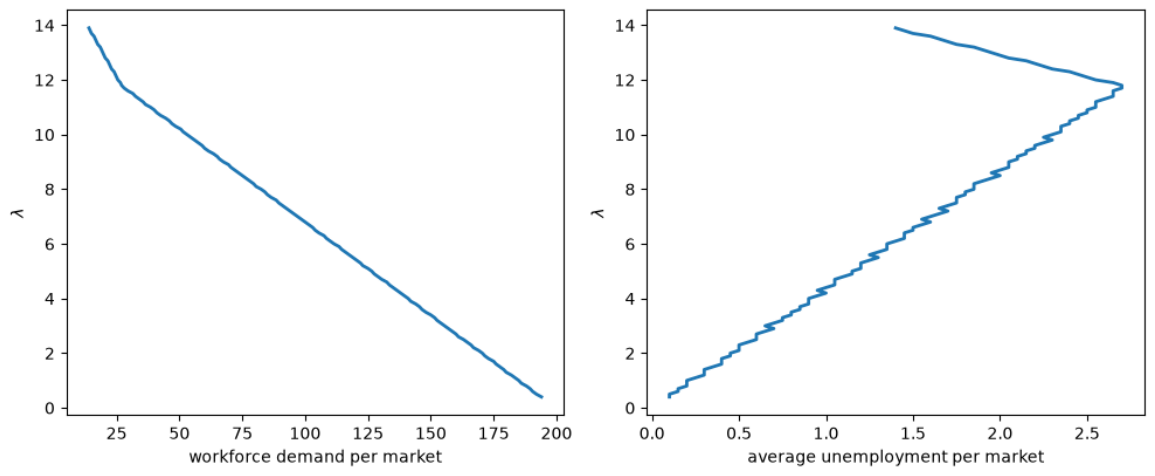
$$P = \begin{bmatrix} \rho & 1-\rho \\ 1-\rho & \rho \end{bmatrix}, \qquad \rho = 0.9, \qquad s \in \{1, 2\}, \qquad \beta = 0.9.$$

Here ρ is the probability that demand stays where it is, so the autocorrelation of s is $2\rho - 1 = 0.8$; in the seven-state chain ρ is the autocorrelation itself.

Build that economy, keeping $R(s, n) = s\,(1 - n/N)^+$ with $N = 200$, and $\mu = 50$ wherever an equilibrium is needed.

1. For λ on a grid, plot workforce demand and average unemployment against λ, as in the middle and bottom panels of the paper's Figure 5.
2. At $\lambda = 6$, show that the invariant distribution puts all of its mass on *two* values of the workforce, and say which two.
3. Use that fact to derive a formula for average unemployment per market in terms of $\bar{n}$, $\bar{y}$ and ρ, check it against the computed value at every λ on the grid, and use it to explain the shape of the plot in part 1.
4. Show that the unemployment *rate* depends only on ρ and on $r = \bar{y}(s_{\text{high}})/\bar{n}(s_{\text{low}})$, and that it can never exceed $1 - \rho$.
5. Now replace R by the marginal product of a decreasing returns technology: output $s\,n^\alpha$ with $0 < \alpha < 1$, so that $R(s, n) = s\,\alpha\,n^{\alpha-1}$. Solve for $\alpha \in \{0.4, 0.6, 0.75\}$, and for an economy like Alvarez and Veracierto's, with $\alpha = \theta_n/(1 - \theta_k)$ and $s_{\text{high}} = 2.12^{1/(1-\theta_k)}$ at their $\theta_k = 0.19$ and $\theta_n = 0.58$, which is their technology once capital, rented each period, has been chosen optimally. Report the ratio of mean employment across the two demand states, its frictionless counterpart (119.11), and the unemployment rate. Show that the ratio of mean employment is $\rho r + 1 - \rho$, write the unemployment rate in terms of it, and say what happens to unemployment as the returns to labor mobility rise.

Solution



The two-state chain needs only its own P and s.

```
def two_state_model(ρ=0.9, s_high=2.0, β=0.9, y_max=260, R=linear_R, **R_args):
    "The paper's two-state demand process: demand stays put with probability ρ."
    P = np.array([[ρ, 1 - ρ], [1 - ρ, ρ]])
    return make_model(P, np.array([1.0, s_high]), β, y_max, R, **R_args)

two = two_state_model()
grid2 = np.arange(0.4, 14.0, 0.1)
res2 = [market_outcomes(two, λ) for λ in grid2]
Ey2 = np.array([r['workforce'] for r in res2])
Eu2 = np.array([r['unemployment'] for r in res2])
```

The paper puts λ on the vertical axis.

```
fig, axes = plt.subplots(1, 2, figsize=(10, 4.2))
axes[0].plot(Ey2, grid2, lw=2)
axes[0].set_xlabel('workforce demand per market')
axes[1].plot(Eu2, grid2, lw=2)
axes[1].set_xlabel('average unemployment per market')
for ax in axes:
    ax.set_ylabel(r'$\lambda$')
plt.tight_layout()
plt.show()
```

The right panel has the shape of the bottom panels of the paper's Figure 5: average unemployment is largest at intermediate values of λ.

For part 2, look at the support of the invariant distribution at $\lambda = 6$.

```
r_six = market_outcomes(two, 6.0)
support = np.where(r_six['ψ'].sum(axis=0) > 1e-12)[0]
print("workforce values with positive probability:", support)
print("n̄(s) =", r_six['n_bar'], "   ȳ(s) =", r_six['y_bar'])
```

```
workforce values with positive probability: [ 98 125]
n̄(s) = [ 98 140]    ȳ(s) = [ 78 125]
```

The two values are $\bar{n}(s_{\text{low}})$ and $\bar{y}(s_{\text{high}})$. To see why, follow (119.6).

In the low state the workforce is clipped into $[\bar{y}(s_{\text{low}}), \bar{n}(s_{\text{low}})]$ and in the high state into $[\bar{y}(s_{\text{high}}), \bar{n}(s_{\text{high}})]$, and at this λ the second interval lies entirely above the first.

So one period in the low state carries any workforce to $\bar{n}(s_{\text{low}})$, one period in the high state carries it to $\bar{y}(s_{\text{high}})$, and the market shuttles between the two. The same is true at every λ at which $\bar{n}(s_{\text{low}}) < \bar{y}(s_{\text{high}})$, which includes the whole grid.

For part 3, unemployment is positive only in the first period of a downturn: the market enters with $\bar{y}(s_{\text{high}})$ workers, demand has just fallen, and employment is $\bar{n}(s_{\text{low}})$.

That event is "the state was high last period and is low now", which has stationary probability $\frac{1}{2}(1-\rho)$, so

$$E[u] = \tfrac{1}{2}(1-\rho)\,[\bar{y}(s_{\text{high}}) - \bar{n}(s_{\text{low}})].$$

We check the formula at every point of the grid, reading ρ from the transition matrix.

```
ρ_2 = two.P[0, 0]
gap2 = np.array([r['y_bar'][1] - r['n_bar'][0] for r in res2])
print(f"largest difference between formula and computation: "
      f"{np.abs(0.5*(1 - ρ_2)*gap2 - Eu2).max():.1e}")

n_lo = np.array([r['n_bar'][0] for r in res2])
print(f"unemployment per market peaks at λ = {grid2[Eu2.argmax()]:.1f}; "
      f"the low-demand market is closed for λ ≥ {grid2[n_lo == 0].min():.1f}")
```

```
largest difference between formula and computation: 4.4e-16
unemployment per market peaks at λ = 11.7; the low-demand market is closed for␣
↪λ ≥ 11.8
```

The formula also explains the hump: average unemployment is the gap between two thresholds, multiplied by the chance of crossing it.

At high λ the low-demand market is closed, $\bar{n}(s_{\text{low}}) = 0$, and the gap is just $\bar{y}(s_{\text{high}})$, which rises as λ falls.

Once λ is low enough for the low-demand market to keep some workers, $\bar{n}(s_{\text{low}})$ rises faster than $\bar{y}(s_{\text{high}})$ as λ falls, and the gap narrows. So unemployment per market peaks where the low-demand market stops closing, as the second line of the print shows.

For part 4, the workforce is $\bar{n}(s_{\text{low}})$ in half the periods and $\bar{y}(s_{\text{high}})$ in the other half, so $E[y] = \frac{1}{2}[\bar{n}(s_{\text{low}}) + \bar{y}(s_{\text{high}})]$ and the unemployment rate is

$$\frac{E[u]}{E[y]} = (1-\rho)\,\frac{\bar{y}(s_{\text{high}}) - \bar{n}(s_{\text{low}})}{\bar{y}(s_{\text{high}}) + \bar{n}(s_{\text{low}})} = (1-\rho)\,\frac{r-1}{r+1}, \qquad r = \frac{\bar{y}(s_{\text{high}})}{\bar{n}(s_{\text{low}})}.$$

It rises with r toward $1-\rho$, which it reaches when the low-demand market closes.

For part 5, mean employment in the low state is $\bar{n}(s_{\text{low}})$, and in the high state it is $\bar{y}(s_{\text{high}})$ with probability ρ and $\bar{n}(s_{\text{low}})$ with probability $1-\rho$, the first period of an upturn, so the ratio of mean employment is

$$\mathcal{E} = \frac{E[n \mid s_{\text{high}}]}{E[n \mid s_{\text{low}}]} = \rho\, r + 1 - \rho.$$

Substituting $r = (\mathcal{E} - 1 + \rho)/\rho$ into the unemployment rate of part 4 gives

$$\frac{E[u]}{E[y]} = (1-\rho)\,\frac{\mathcal{E}-1}{\mathcal{E}-1+2\rho},$$

which rises with $\mathcal{E}$.

Only the construction of `R` changes: on the integer grid the first worker's marginal product $s\,\alpha$ is finite, and an empty market pays nothing. Workers are now cheap at the margin far out, so we use a larger grid, and we bracket λ^* around the value of search at which a market holding μ workers would just stop attracting arrivals, $\beta \max_s (Pv)_s$ in the notation of Exercise 119.11.2.

```
def power_R(s, y, α):

```

The identity $\mathcal{E} = \rho r + 1 - \rho$ and the formula for the unemployment rate hold in every economy, as the columns show.

The frictionless column is (119.11) with $\theta_k = 0$ and $\theta_n = \alpha$: equating marginal products $s\,\alpha\,n^{\alpha-1}$ across the two states gives $n_{\text{high}}/n_{\text{low}} = (s_{\text{high}}/s_{\text{low}})^{1/(1-\alpha)}$.

The economy like Alvarez and Veracierto's has the same frictionless ratio, about 26, as their technology with capital, because optimizing out capital turns $z\,k^{\theta_k}n^{\theta_n}$ into a multiple of $z^{1/(1-\theta_k)}n^{\theta_n/(1-\theta_k)}$. That labor-only form is the right comparison here, since in this model the friction falls on labor alone.

For the linear schedule the frictionless benchmark is a corner, and only just. Equating $2(1-n_{\text{high}}/N) = 1-n_{\text{low}}/N$ with $n_{\text{high}} + n_{\text{low}} = 2\mu$ gives $n_{\text{low}} = (4\mu - N)/3$, so the low-demand market closes for every $\mu \le N/4$, which is exactly the lecture's $\mu = 50$.

```
N = 200                                    # the capacity of the two-state economy
for μ_f in (50, 55, 60):
    n_low = max((4*μ_f - N)/3, 0.0)
    ratio = (2*μ_f - n_low)/n_low if n_low > 0 else np.inf
    print(f"μ = {μ_f}: frictionless n_low = {n_low:.1f}, ratio {ratio:.1f}")
```

```
μ = 50: frictionless n_low = 0.0, ratio inf
μ = 55: frictionless n_low = 6.7, ratio 15.5
μ = 60: frictionless n_low = 13.3, ratio 8.0
```

So the frictionless ratio is infinite at $\mu = 50$ and still large just above it, against about 2.5 in the model.

In every economy the model responds far less than its frictionless benchmark, as a one-period moving friction should. A frictionless economy would move workers until marginal products were equal across markets; here workers move only until arriving is worth λ, arrivals stop at $\bar{y}(s_{\text{high}})$ because demand may fall back, and an upturn takes a period to be met at all.

The comparison of like with like is the last row: the technology and the shock that give Alvarez and Veracierto's establishments an employment ratio of about 26 give about 5.6 under the one-period move of this model, although the persistence of the shock still differs from theirs.

Across the rows with $s_{\text{high}} = 2$ the employment response rises with α, holding the friction fixed, and the unemployment rate rises with it. That is not a coincidence, and it is this lecture's finding rather than Baley, Ljungqvist and Sargent's.

Unemployment in this model is the time workers spend moving, and the more there is to gain by moving, the more of them move: holding the friction fixed, an economy with higher returns to labor mobility shows more reallocation and records the unemployment that goes with it.

Exercise 119.11.4

This exercise asks what the model's directed search is doing.

Alvarez and Veracierto [1999] replace it with **undirected** search: a searcher cannot choose where to go, and every market receives the same inflow U, which is the economy's unemployment per market.

1. Show that under undirected search the min disappears from (119.2), and say which economic condition it was enforcing.
2. Write down the transition law for a market's workforce, and show that at any stationary distribution the inflow U equals the average outflow. Does the same identity hold under directed search?
3. Under directed search, (119.8) pins down λ. Under undirected search, what condition must λ satisfy instead? Count the unknowns and the conditions of an equilibrium with a fixed workforce μ per market.
4. Compute the undirected equilibrium of the lecture's economy, $\mu/N = 1/4$. An integer inflow into markets of capacity $N = 200$ is too coarse, so count workers in tenths: use $N = 2000$ and a grid up to 2600, which is the lecture's economy on a ten times finer workforce grid. For inflows $U = 1, 3, 5, 7, 9$ and 10, find the values of λ that satisfy the consistency condition of part 3 and the mean workforce that each serves, and plot the mean workforce against U. How many equilibria does an economy with a given μ have? Compare λ and the unemployment rate at $\mu/N = 1/4$ with directed search on the same grid.
5. Explain why undirected search lowers the value of search here, and why it also lowers unemployment.

Solution

For part 1, the min in (119.2) is the restriction, imposed by competition among searchers, that the continuation value in a market cannot exceed λ. Take away their ability to choose where to go and nothing enforces it.

A worker who stays simply collects the wage and the continuation value his own market happens to deliver,

$$v(s,y) = \max\left\{\lambda,\ R(s,y) + \beta \int v(s', y+U) f(s', s)\, ds'\right\},$$

and the continuation can be worth more or less than λ, because nobody can act on the difference.

For part 2, employment is still $n(s,y) = \min\{\bar{n}(s), y\}$, those not employed leave, and the inflow is the same everywhere, so

$$y' = n(s,y) + U.$$

At a stationary distribution $E[y'] = E[y]$, so averaging across markets gives

$$U = E[y] - E[n(s,y)] = E[\,y - n(s,y)\,]:$$

the inflow equals the average outflow.

That is an accounting identity, and it holds under directed search too: at the stationary distribution of (119.6), the workers arriving in markets that fill up equal the workers leaving markets that shed, at every value of λ and not only at λ^*.

```
print(f"{'λ':>8}{'E[y]':>9}{'outflow':>10}{'inflow':>9}")
y = model.y[None, :]
for λ in (4.0, 7.1, 10.0):
    r = market_outcomes(model, λ)
    y_next = np.clip(y, r['y_bar'][:, None], r['n_bar'][:, None])
    print(f"{λ:>8.3f}{r['workforce']:>9.2f}"
          f"{(r['ψ']*np.maximum(y - y_next, 0)).sum():>10.4f}"
          f"{(r['ψ']*np.maximum(y_next - y, 0)).sum():>9.4f}")
```

```
       λ     E[y]   outflow   inflow
   4.000   114.97    0.6512   0.6512
   7.100    49.92    1.0647   1.0647
  10.000     8.71    0.4841   0.4841
```

So the identity cannot be what distinguishes the two models; what does is how λ is determined.

For part 3, a searcher under undirected search lands in a market drawn at random from the invariant distribution, so the value of search must satisfy

$$\lambda = \beta \sum_{s,y} \psi(s,y)\, v(s,y),$$

the discounted value of landing in a randomly drawn market, a market-weighted average.

An equilibrium with a fixed population therefore has two unknowns, λ and U, and two conditions, $\mu = \sum_{s,y} \psi(s,y)\, y$ and the condition above.

Under directed search the min makes every market that receives workers worth exactly λ, so λ needs no separate consistency condition, and μ pins it down alone through a schedule that slopes down. Here λ needs a condition of its own, and nothing makes that condition monotone in λ.

For part 4, a market's employment threshold is the largest workforce at which staying is still worth λ, given that next period's workforce will be $n(s,y) + U$.

The invariant distribution is unique, because a market that passes through the worst demand state ends up holding $\bar{n}(s_1) + U$ workers from anywhere, so we find it by iterating on it.

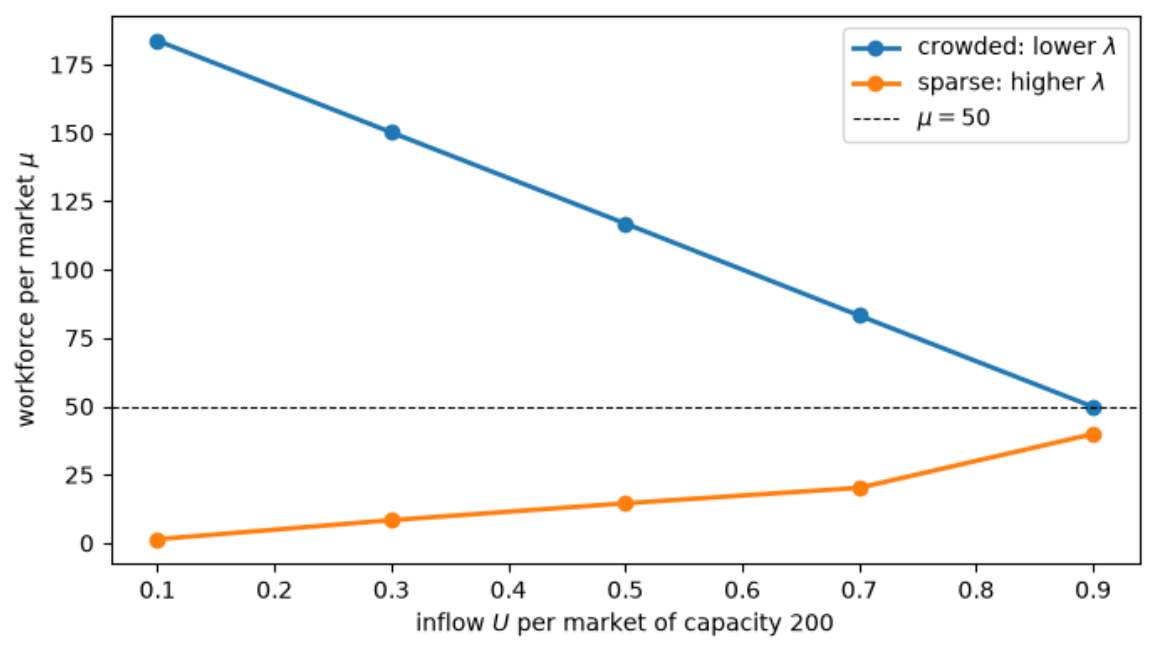
```
def undirected_market(model, λ, U, tol=1e-10, max_iter=100_000):
    """A market that receives U searchers every period, whether it wants them or␣
↪not.
    Returns the implied value of search, the mean workforce, and n̄(s)."""
    P, R, β, y = model.P, model.R, model.β, model.y
    n_s, n_y = R.shape
    up = np.minimum(y + U, y[-1])                    # next workforce if nobody␣
↪leaves
    v = np.full(R.shape, λ)
    for _ in range(max_iter):
        v_new = np.maximum(λ, R + β*(P @ v)[:, up])
        if np.max(np.abs(v_new - v)) < tol:
            break
        v = v_new
    else:
        raise RuntimeError(f"the value function did not converge at λ = {λ}")
    n_bar = last_at_least(R + β*(P @ v_new)[:, up], λ)
    if n_bar.max() + U > y[-1]:
        raise GridTooSmall(f"n̄ + U passes the top of the grid at λ = {λ}")
    # iterate on the distribution of (s, y) under y' = min(y, n̄(s)) + U
    to = (np.arange(n_s)[:, None]*n_y + np.minimum(y[None, :], n_bar[:, None]) +␣
↪U).ravel()
    ψ = np.full(n_s*n_y, 1/(n_s*n_y))
    for _ in range(max_iter):
        ψ_new = (P.T @ np.bincount(to, weights=ψ, minlength=n_s*n_y).reshape(n_s,␣
↪n_y)).ravel()
        if np.abs(ψ_new - ψ).sum() < tol:
            break
        ψ = ψ_new
    else:
        raise RuntimeError(f"the distribution did not converge at λ = {λ}")
```

```
    ψ = ψ_new.reshape(n_s, n_y)
    return β*(ψ*v_new).sum(), (ψ*y).sum(), n_bar
```

The gap between the implied value of search and λ turns out to be positive between two roots and negative outside them, so for each inflow we look for one root on each side of a value where it is positive.

On this grid the directed-search λ^* is such a value at every inflow that has roots, and `brentq` from SciPy stops with an error if a bracket fails.

```
def consistent_λs(model, U, λ_mid, lo=0.1, hi=12.0):
    "The roots of λ = β Σ ψ v below and above λ_mid, with the mean workforce of␣
 ↪each."
    gap = lambda λ: undirected_market(model, λ, U)[0] - λ
    roots = (brentq(gap, lo, λ_mid, xtol=2e-3), brentq(gap, λ_mid, hi, xtol=2e-3))
    return [(λ, undirected_market(model, λ, U)[1]) for λ in roots]



N_fine = 2000                              # the lecture's economy, in tenths of a␣
 ↪worker
m_fine = create_model(N=N_fine, y_max=13*N_fine//10)
λ_dir = equilibrium_λ(m_fine, N_fine//4)
r_dir = market_outcomes(m_fine, λ_dir)

locus = {U: consistent_λs(m_fine, U, λ_dir) for U in (1, 3, 5, 7, 9)}
gaps_10 = [undirected_market(m_fine, λ, 10)[0] - λ for λ in np.arange(6.0, 8.6, 0.
 ↪5)]
print(f"at U = 10 the largest gap on a grid of λ is {max(gaps_10):.4f}")
```

```
at U = 10 the largest gap on a grid of λ is -0.0418
```

Each of these inflows has two solutions, and each serves its own population; at $U = 10$ there are none.

```
Us = np.array(list(locus))
scale = 200/N_fine                         # back to the lecture's units
fig, ax = plt.subplots(figsize=(7, 4))
for k, label in ((0, r'crowded: lower $\lambda$'), (1, r'sparse: higher $\lambda$
 ↪')):
    ax.plot(scale*Us, [scale*locus[U][k][1] for U in Us], 'o-', lw=2, label=label)
ax.axhline(50, color='k', lw=0.8, ls='--', label=r'$\mu = 50$')
ax.set_xlabel('inflow $U$ per market of capacity 200')
ax.set_ylabel(r'workforce per market $\mu$')
ax.legend()
plt.tight_layout()
plt.show()
```

At a given inflow the two solutions belong to *different* populations, a crowded economy with a low value of search and a sparse one with a high value. Along each branch the population moves monotonically with the inflow, the two branches meet in a fold between $U = 9$ and $U = 10$, and their ranges of μ do not overlap.

So in this calibration each population has exactly one undirected equilibrium (λ, U), and the inflow it needs rises with μ up to the fold and falls beyond it.

The fold also explains why $N = 200$ will not do: the largest equilibrium inflow is a little below one worker per market of capacity 200, so even $U = 1$ on that grid is past it. The lecture's economy is the point nearest $\mu = 50$.

```
U_eq, k_eq = min(((U, k) for U in locus for k in (0, 1)),
                 key=lambda Uk: abs(locus[Uk[0]][Uk[1]][1] - N_fine//4))
λ_und, y_und = locus[U_eq][k_eq]
print(f"undirected: U = {U_eq}, λ = {λ_und:.3f}, workforce {scale*y_und:.2f}, "
      f"unemployment rate {100*U_eq/y_und:.2f}%")
print(f"directed:   λ* = {λ_dir:.3f}, workforce {scale*r_dir['workforce']:.2f}, "
      f"unemployment rate {100*r_dir['unemployment']/r_dir['workforce']:.2f}%")
```

```
undirected: U = 9, λ = 6.906, workforce 49.80, unemployment rate 1.81%
directed:   λ* = 7.126, workforce 50.00, unemployment rate 2.13%
```

It lies on the crowded branch, close to the fold, and undirected search gives it a lower value of search and a lower unemployment rate than directed search does.

For part 5, compare the employment thresholds.

```
n_bar_und = undirected_market(m_fine, λ_und, U_eq)[2]
n_bar_low, _ = thresholds(m_fine, worker_value(m_fine, λ_und)[0], λ_und)
print("n̄(s), undirected:                      ", n_bar_und)
print("n̄(s), directed, at its own λ*:         ", r_dir['n_bar'])
print("n̄(s), directed, at the undirected λ:   ", n_bar_low)
```

```
n̄(s), undirected:                      [  77  297  518  732  933 1113 1269]
n̄(s), directed, at its own λ*:         [   0  161  449  694  905 1087 1246]
n̄(s), directed, at the undirected λ:   [   0  218  496  734  939 1116 1269]
```

Undirected search lowers the value of search because searchers can no longer avoid markets that do not want them: under directed search every searcher goes where arriving is worth λ, while here many land in markets that are shedding workers or soon will.

With a lower value of search, workers whose market's demand has fallen are slower to leave: the employment thresholds are higher in every demand state, and outside the lowest demand states most of the difference is what directed search itself would give at the same lower λ, as the last line shows. So markets keep more of their workers, and the economy holds its population with a smaller flow of searchers, which is its unemployment.

Note that for a given inflow, the map from a perceived λ to the implied value $\beta \sum \psi v$ is a genuine map from a perceived to an actual value of search, unlike the tâtonnement of *Learning the value of search*.

Exercise 119.11.5

The model has no aggregate shocks, but Lucas and Prescott open their concluding remarks by arguing that its mechanism "is consistent with the now familiar account of the observed Phillips curve in terms of expectations":

> *an unanticipated change in aggregate demand (a change in $E(s'|s)$) will move unemployment and wage changes in opposite directions.*

Check this at the equilibrium of the lecture, starting from the invariant distribution at λ^*, which describes the economy last period.

This period, a share of markets chosen at random draws a demand state one notch lower than the law of motion that everyone knows would give it, and the rest draw as usual; the share is chosen so that mean log s falls by Δ.

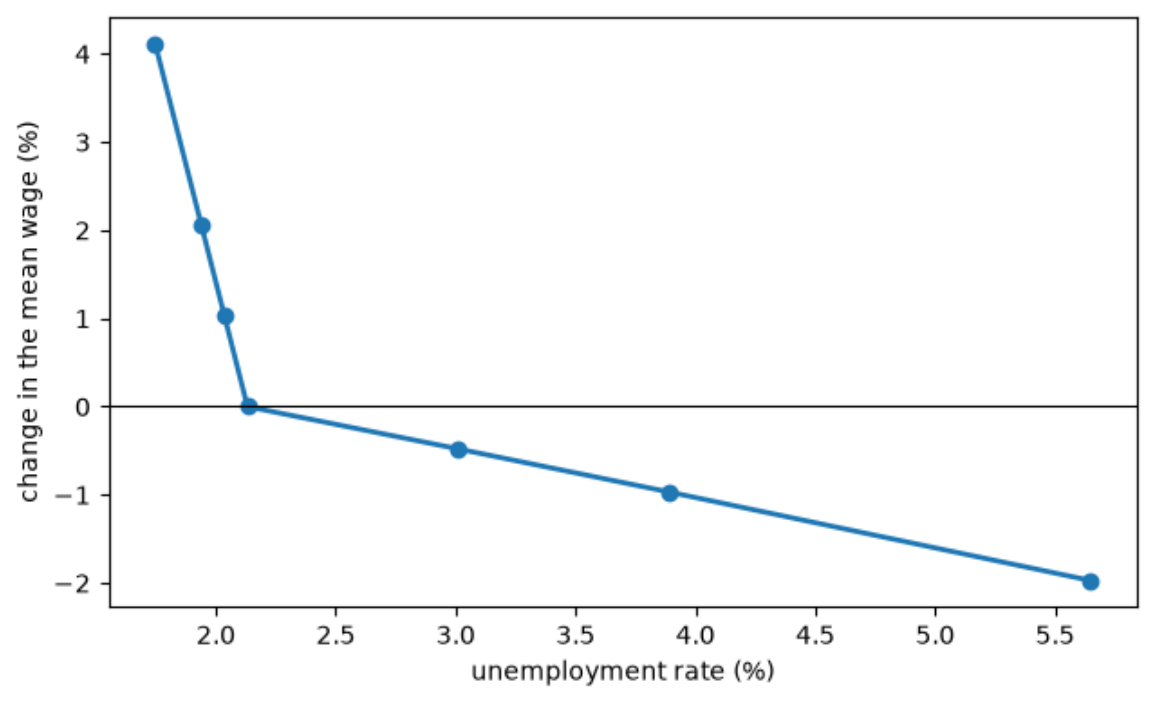
Nobody anticipated it, so the thresholds $\bar{n}(s)$ and $\bar{y}(s)$ stay as they were, and λ stays at λ^*.

1. Compute this period's unemployment rate and mean wage for $\Delta = 0.01, 0.02, 0.04$, and for rises in mean log s of the same sizes.
2. Plot the unemployment rate against the percentage change in the mean wage. Explain the shape.
3. Lucas and Prescott add that if such changes "were a recurrent event, as they are in reality, this fact would become incorporated into the maximum problem facing workers". What would change in the calculation?

Solution

The surprise changes only the transition matrix that applies this period, so we carry last period's markets forward with the thresholds they already have and draw this period's demand from the altered matrix.

```
def demand_surprise(model, r, Δ):
    """This period's unemployment rate and mean wage when mean log demand moves by␣
 ↪Δ:
    a share |Δ|/notch of markets draws a state one notch away from the usual draw."
 ↪""
    n_s, y = len(model.s), model.y
    notch = np.log(model.s[1]/model.s[0])
    step = int(np.sign(Δ))
    move = np.zeros((n_s, n_s))                          # shift a state, within the␣
 ↪grid
    move[np.arange(n_s), np.clip(np.arange(n_s) + step, 0, n_s - 1)] = 1
    P_now = (1 - abs(Δ)/notch)*model.P + abs(Δ)/notch*(model.P @ move)
    y_carried = np.clip(y[None, :], r['y_bar'][:, None], r['n_bar'][:, None])
    ψ_now = sum(np.outer(P_now[i], np.bincount(y_carried[i], weights=r['ψ'][i],
                                               minlength=len(y)))
                for i in range(n_s))
```



```
    n, w = r['n'], r['w']
    rate = (ψ_now*(y[None, :] - n)).sum()/(ψ_now*y[None, :]).sum()
    return rate, (ψ_now*n*w).sum()/(ψ_now*n).sum()

r_star = market_outcomes(model, equilibrium_λ(model, μ))
base_rate, base_wage = demand_surprise(model, r_star, 0.0)
print(f"no surprise: unemployment rate {100*base_rate:.2f}%, mean wage {base_wage:.
↪4f}")
print(f"{'Δ':>7}{'u rate':>9}{'wage change':>13}{'per unit of Δ':>15}")
points = [(100*base_rate, 0.0)]
for Δ in (-0.04, -0.02, -0.01, 0.01, 0.02, 0.04):
    rate, mean_wage = demand_surprise(model, r_star, Δ)
    change = 100*(mean_wage/base_wage - 1)
    points.append((100*rate, change))
    print(f"{Δ:>7}{100*rate:>8.2f}%{change:>12.2f}%{change/(100*Δ):>15.2f}")
```

```
no surprise: unemployment rate 2.13%, mean wage 0.7742
      Δ   u rate  wage change  per unit of Δ
  -0.04    5.65%       -1.97%           0.49
  -0.02    3.89%       -0.97%           0.48
  -0.01    3.01%       -0.48%           0.48
   0.01    2.04%        1.03%           1.03
   0.02    1.94%        2.06%           1.03
   0.04    1.75%        4.11%           1.03
```

The no-surprise line reproduces the equilibrium, as it should.

```
u_pts, w_pts = np.array(sorted(points)).T
fig, ax = plt.subplots(figsize=(6.5, 4))
ax.plot(u_pts, w_pts, 'o-', lw=2)
ax.axhline(0, color='k', lw=0.8)
ax.set_xlabel('unemployment rate (%)')
ax.set_ylabel('change in the mean wage (%)')
plt.tight_layout()
plt.show()
```

Unemployment and wages move in opposite directions, as Lucas and Prescott say, and the points trace out a downward-sloping curve with a kink at the equilibrium: a Phillips curve.

A surprise fall in demand pushes some markets below their employment thresholds, and they shed workers, so unemployment rises a lot. Wages fall, but by less than demand, because the markets that shed cut employment, which raises the marginal product of those who stay.

A surprise rise in demand can lower unemployment only by preventing separations that would have happened anyway, and there are few of those, while every market's wage rises with its demand, about one for one, and no new workers can arrive within the period to hold it down.

So the curve is steep where unemployment is low and flat where it is high.

The signs and the kink do not depend on the grid, but the size of the unemployment response does: a notch is about a fifth in $\log s$ on the seven-state chain, so a given fall in mean log demand is concentrated on few markets, each hit hard, and with finer chains the same fall raises unemployment by less.

For part 3, the calculation holds the thresholds and λ fixed because nobody expected the shift. If such shifts recurred, workers would build them into the transition law they use, the Bellman equation would change, and so would $\bar{n}$, $\bar{y}$ and λ^*; Lucas and Prescott leave that "nontrivial development for future research".

The Rise and Fall of U.S. Inflation follows the expectational account of the Phillips curve, and the natural-rate hypothesis behind it, into the data.

Exercise 119.11.6

Efficiency proves that the equilibrium solves the planner's problem (119.10). Check it numerically, and see what it does and does not imply.

1. Solve (119.10) at λ^* by value function iteration, choosing y' on the whole grid, and verify that $W(s, y) - W(s, y-1) = v(s, y)$ and that the planner's choice of y' is (119.6).

2. Now let moving use up resources: each worker who leaves costs $c = 2$. Show that the equilibrium of Exercise 119.11.2 is the allocation of a planner who faces that cost, credited $\lambda - c$ for each worker released and charged λ for each worker brought in. What does that imply about the lower surplus in Exercise 119.11.2?

3. Compare steady-state surplus per worker at the equilibrium with two alternatives that keep $\mu = 50$: a small subsidy to moving, $c = -0.1$ and $c = -0.2$, and the thresholds that a more patient planner would choose, with $\beta' = 0.95$ and 0.99 and λ chosen to keep μ workers per market. Does the equilibrium maximize steady-state surplus? Reconcile the answer with *Efficiency*.

Solution

For part 1, `planner_value` solves (119.10), with the release credit lowered to $\lambda - c$ for part 2. The flow term does not depend on W, so we compute it once.

```
def planner_value(model, λ, c=0.0, tol=1e-10, max_iter=10_000):
    """W(s, y) = max over y' of Φ(s, min(y, y')) + credit for releases - charge for
    arrivals + β E W(s', y'), with releases credited at λ - c and arrivals charged␣
↪λ."""
    P, R, β, y = model.P, model.R, model.β, model.y
    Φ = np.cumsum(R, axis=1)
    moved = y[:, None] - y[None, :]                    # workers released, for each␣
↪(y, y')
    flow = (Φ[:, np.minimum(y[:, None], y[None, :])]
            + np.where(moved > 0, (λ - c)*moved, λ*moved))
    W = np.zeros(R.shape)
    for _ in range(max_iter):
        value = flow + β*(P @ W)[:, None, :]
        W_new = value.max(axis=2)
        if np.max(np.abs(W_new - W)) < tol:
            return W_new, y[value.argmax(axis=2)]
        W = W_new
    raise RuntimeError(f"no convergence in {max_iter} iterations at λ = {λ}")

def check_planner(model, λ, c=0.0):
    "Compare the planner's marginal values and policy with the equilibrium."
    r = market_outcomes(model, λ, c)
    W, y_choice = planner_value(model, λ, c)
    law = np.clip(model.y[None, :], r['y_bar'][:, None], r['n_bar'][:, None])
    print(f"c = {c}, λ = {λ:.3f}: largest |ΔW - v| = "
          f"{np.abs(np.diff(W, axis=1) - r['v'][:, 1:]).max():.1e}, "
          f"policy equals the transition law: {np.array_equal(y_choice, law)}")

λ_0 = equilibrium_λ(model, μ)
check_planner(model, λ_0)
```

```
c = 0.0, λ = 7.096: largest |ΔW - v| = 3.8e-11, policy equals the transition␣
↪law: True
```

For part 2, the same check with the resource cost.

```
λ_2 = equilibrium_λ(model, μ, 2.0, lo=λ_0)
check_planner(model, λ_2, 2.0)
```

```
c = 2.0, λ = 8.262: largest |ΔW - v| = 6.9e-11, policy equals the transition␣
↪law: True
```

With a resource cost, the equilibrium is the planner's allocation for the costlier technology of moving: the argument

of *Efficiency* goes through with the release credit $\lambda - c$, and the resource cost enters surplus.

So the lower surplus that Exercise 119.11.2 finds with a resource cost is the price of a worse technology, and the equilibrium makes the best of it. A rebated tax changes decisions in exactly the same way but uses up nothing, so the technology is the laissez-faire one, whose planner chooses the laissez-faire allocation, and the taxed equilibrium is distorted: its lower surplus is an efficiency loss.

For part 3, a subsidy is a negative c, and a more patient planner's thresholds come from the worker's problem with β' in place of β.

```
def steady_state(model, policy, λ):
    """Steady-state surplus, unemployment and workforce per market of model when␣
 ↪its
    markets follow the thresholds that the worker's problem in policy gives at λ.""
 ↪"
    n_bar, y_bar = thresholds(policy, worker_value(policy, λ)[0], λ)
    ψ = stationary_distribution(model, n_bar, y_bar)
    y = model.y[None, :]
    n = np.minimum(y, n_bar[:, None])
    return ((ψ*np.take_along_axis(np.cumsum(model.R, axis=1), n, axis=1)).sum(),
            (ψ*(y - n)).sum(), (ψ*y).sum())

r_0 = market_outcomes(model, λ_0)
print(f"{'':>24}{'surplus per worker':>20}{'u rate':>9}{'workforce':>11}")

 ↪")
for c in (-0.1, -0.2):
    r = market_outcomes(model, equilibrium_λ(model, μ, c, lo=2.0, hi=λ_0), c)
    print(f"{f'subsidy {-c}':>24}{r['surplus']/r['workforce']:>20.5f}"
          f"{100*r['unemployment']/r['workforce']:>8.2f}%{r['workforce']:>11.2f}")
for β_p in (0.95, 0.99):
    patient = model._replace(β=β_p)
    λ_p = bisect(lambda λ: steady_state(model, patient, λ)[2] <= μ, 0.01, 2000.0)
    s_p, u_p, y_p = steady_state(model, patient, λ_p)
    print(f"{f'patient planner, β = {β_p}':>24}{s_p/y_p:>20.5f}"
          f"{100*u_p/y_p:>8.2f}%{y_p:>11.2f}")
```

```
                         surplus per worker   u rate  workforce
            equilibrium             0.93521    2.13%      49.94
            subsidy 0.1             0.93549    2.37%      49.99
            subsidy 0.2             0.93571    2.60%      49.94
patient planner, β = 0.95            0.93561    2.35%      49.97
patient planner, β = 0.99            0.93565    2.42%      50.00
```

Both alternatives raise steady-state surplus per worker above its equilibrium level, and both do it with more reallocation and more unemployment. So the equilibrium does not maximize steady-state surplus, and *Efficiency* never said it did.

The theorem compares present values starting from the equilibrium's own distribution, and a move to one of these steady states would cost surplus along the way: more workers in transit means a period of their output lost now, for gains that come later and are discounted.

A planner who discounted at $\beta' > \beta$ would value those later gains more, which is why its thresholds move more workers; in the limit of no discounting it would maximize steady-state surplus, the analogue of the golden rule, and the equilibrium is the analogue of the modified golden rule.

The steady-state comparison in Exercise 119.11.2 points the same way as the theorem for a large cost, but that is not something the theorem implies: a small subsidy, which also moves the economy away from the planner's allocation, raises steady-state surplus.

120.1 Overview

This lecture studies two papers.

The first is Brock and Mirman [1972], a classic analysis of optimal one-sector growth when the production function is hit by random shocks.

The second is Sargent [1980], which adds one small ingredient – **irreversible investment** – and uses the result to think about James Tobin's q theory of investment.

The lecture *Investment Under Uncertainty* studied a competitive industry whose equilibrium is the solution of a planning problem, and whose equilibrium is a Markov process with an invariant distribution.

Brock and Mirman ask the same questions about a one-sector growth model:

- does the planning problem have a well-behaved solution, with continuous and monotone policy functions?
- the optimal policy makes capital a Markov process; does that process have an *invariant distribution*?
- does the distribution of capital converge to it from *any* initial condition?
- do *time averages* computed from a single realization converge to population moments?

The last two questions are the reason both papers matter for econometrics.

A model that answers them affirmatively delivers a stationary, ergodic stochastic process for observable time series.

Sample moments computed from one long realization then estimate population moments, which is exactly what the rational expectations econometrics of Hansen and Sargent [1980] requires.

Sargent [1980] puts the Brock-Mirman apparatus to work on a question in macroeconomics: when, and in what sense, is there an investment demand schedule relating investment to Tobin's q?

Along the way, this lecture pauses over a technical issue that turns out to be central:

- the derivative of the planner's value function with respect to capital *is* the competitive price of used capital, i.e. it is essentially Tobin's q
- so the analysis stands or falls on whether that derivative exists
- irreversible investment creates a **corner**, and at a corner the standard argument for differentiability breaks down

We'll describe the difficulty, note a gap in the published argument, and give a corrected proof.

Let's start with some imports:

```
import numpy as np
import matplotlib.pyplot as plt
from collections import namedtuple
```

120.2 The Brock-Mirman planning problem

A planner chooses consumption to maximize

$$\mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t u(c_t), \qquad 0 < \beta < 1, \tag{120.1}$$

subject to

$$c_t + i_t \leq f(k_t, r_t), \qquad c_t \geq 0, \quad i_t \geq 0,$$

where k_t is capital per worker, i_t is investment, and $\{r_t\}$ is a sequence of independent and identically distributed shocks to production.

Brock and Mirman assume that for each realization of the shock, $f(\cdot, r)$ is increasing, strictly concave, and satisfies the Inada conditions

$$f(0, r) = 0, \qquad f'(0, r) = +\infty, \qquad f'(\infty, r) = 0,$$

and that f is increasing in r, so that a higher shock means more output.

The period utility function u is increasing, strictly concave, and differentiable.

In their formulation capital depreciates fully in one period, so that $k_{t+1} = i_t$ and current resources are $s_t = f(k_{t-1}, r_{t-1})$.

The Bellman equation is

$$v(s) = \max_{0 \leq c \leq s} \left\{ u(c) + \beta \int v(f(s-c, r))\, \nu(dr) \right\}, \tag{120.2}$$

where ν is the distribution of the shock.

Standard arguments – a contraction mapping, plus preservation of monotonicity and concavity – give a unique bounded solution v, attained by a unique consumption policy $c = g(s)$ and investment policy $x = h(s) = s - g(s)$.

Proposition 120.2.1

The optimal policies g and h are increasing and continuous, with $g(0) = h(0) = 0$.

Brock and Mirman prove monotonicity from the first-order condition

$$u'(g(s)) = \beta \int u'(g(f(s - g(s), r))) \, f'(s - g(s), r) \, \nu(dr), \tag{120.3}$$

which is the stochastic analogue of the Euler equation.

If g did not increase with s, the left side of (120.3) would stay constant while the right side would fall, because f increases and u' and f' decrease.

120.3 Long-run behavior

The optimal policy makes capital a Markov process,

$$k_{t+1} = h(f(k_t, r_t)), \tag{120.4}$$

and Brock and Mirman devote most of their paper to the long-run behavior of this process.

The strategy resembles the one used in *Investment Under Uncertainty*.

Consider the deterministic difference equations obtained by fixing the shock at its lowest possible value $\underline{r}$ and at its highest possible value $\bar{r}$:

$$k_{t+1} = h(f(k_t, \underline{r})), \qquad k_{t+1} = h(f(k_t, \bar{r})).$$

Let $\underline{k}$ be a positive fixed point of the first and $\bar{k}$ a positive fixed point of the second.

Because f is increasing in the shock and h is increasing, $\underline{k} \leq \bar{k}$.

Brock and Mirman say that the model has a **stable configuration of fixed points** when $\underline{k}$ and $\bar{k}$ are positive and $\underline{k} < \bar{k}$.

They then show that

- the sets of capital stocks below $\underline{k}$ and above $\bar{k}$ are **transient**: the process leaves them and does not return
- the interval $[\underline{k}, \bar{k}]$ is where the process eventually lives

Theorem 120.3.1

There is a distribution function F such that the distribution F_t of k_t converges to F uniformly, and F does not depend on the initial capital stock.

Theorem 120.3.1 is the counterpart of the invariant-distribution theorem of *Investment Under Uncertainty*.

An important part of the proof is an argument about the **inverse optimal process**, which runs the Markov process backwards in time; Brock and Mirman use it to show that a stationary distribution exists and is unique without appealing to heavier machinery from probability theory.

Convergence of distributions is not by itself enough for econometrics.

What an econometrician needs in addition is a **mean-ergodic theorem**: a guarantee that averages computed along a single realization converge to moments of F,

$$\frac{1}{T} \sum_{t=1}^{T} \phi(k_t) \to \int \phi \, dF \qquad \text{with probability one.} \tag{120.5}$$

For Markov processes with a unique invariant distribution and a stable configuration of fixed points, such laws of large numbers are available; Sargent [1980] invokes the version in Doob's book to justify computing population moments of his model and comparing them with sample moments.

This is the bridge from Brock and Mirman's theory to the rational expectations econometrics developed in the late 1970s and early 1980s.

Without *Theorem 120.3.1* and (120.5), a likelihood function computed from a single time series would have no firm justification.

Note

Brock and Mirman [1972] study the case in which the shocks are independent and identically distributed.

The lecture *Investment Under Uncertainty* describes a parallel set of results for a model in which the shock is serially correlated.

In both cases the economics is the same: the state must eventually wander inside a compact set on which the process is well behaved, and the boundaries of that set are the stationary points associated with the most and least favorable shocks.

120.4 Irreversible investment and Tobin's q

Sargent [1980] modifies the model in one respect: capital, once installed, cannot be eaten.

Output can be consumed or added to the capital stock, but the conversion does not run backwards,

$$K_{t+1} = (1-\delta)K_t + I_t, \qquad I_t \geq 0, \tag{120.6}$$

where $0 < \delta < 1$ is the depreciation rate.

Production is $y_t = f(K_t)\theta_t$, and the one-period utility function $u(c_t, e_t)$ is hit by a preference shock e_t.

The shocks (θ_t, e_t) are independent and identically distributed over time.

Why does this small change matter?

In the model with reversible investment, the price of a unit of installed capital always equals the price of a unit of newly produced output, so Tobin's q is identically one and firms have no investment demand schedule at all.

The irreversibility constraint is a **friction** that lets the price of installed capital fall below the price of new capital.

Sargent describes a competitive economy in which households own capital, rent it to firms, and trade claims to installed capital at a relative price p_{Kt}, which is Tobin's q.

Following Lucas and Prescott [1971] – exactly the strategy of *Investment Under Uncertainty* – he studies the competitive equilibrium indirectly, through the planning problem that generates it.

The planner solves

$$v(K,\theta,e) = \max_{K' \geq (1-\delta)K} \left\{ u(f(K)\theta + (1-\delta)K - K', e) + \beta \mathbb{E}\left[v(K', \theta', e') \right] \right\}. \tag{120.7}$$

Let $\lambda \geq 0$ be the multiplier on the irreversibility constraint.

The first-order condition is

$$u_c(c,e) = \beta \mathbb{E}\left[v_K(K', \theta', e') \right] + \lambda, \qquad \lambda \geq 0, \quad \lambda I = 0, \tag{120.8}$$

and the price of installed capital is

$$q = \frac{\beta \mathbb{E}\left[v_K(K', \theta', e') \right]}{u_c(c,e)} = 1 - \frac{\lambda}{u_c(c,e)}. \tag{120.9}$$

So this model implies

- $q \leq 1$ always
- $q = 1$ exactly when investment is positive
- $q < 1$ exactly when the irreversibility constraint binds, which is when investment is zero

Notice what (120.9) says: *Tobin's q is the derivative of the planner's value function*, normalized by marginal utility.

Everything therefore depends on whether v_K exists.

120.5 Differentiability of the value function

Here is the difficulty.

The standard tool for differentiability of a value function is the theorem of Benveniste and Scheinkman [1979].

Theorem 120.5.1 (Benveniste-Scheinkman)

Let v be concave on an open set D and let $K_0 \in D$.

Suppose W is concave, differentiable at K_0, and satisfies $W(K) \leq v(K)$ on a neighborhood of K_0, with $W(K_0) = v(K_0)$.

Then v is differentiable at K_0 and $v'(K_0) = W'(K_0)$.

The usual way to build such a W is to take the optimal plan at K_0, *freeze* next period's capital at its optimal value K_0', and let consumption absorb the change in K:

$$W_1(K) = u(f(K)\theta + (1-\delta)K - K_0', e) + \beta \mathbb{E}\big[v(K_0', \theta', e')\big]. \tag{120.10}$$

This is a feasible plan, so $W_1 \leq v$, with equality at K_0, and it is differentiable.

But feasibility requires $K_0' \geq (1-\delta)K$, that is $K \leq K_0'/(1-\delta)$.

When investment is positive, $K_0' > (1-\delta)K_0$ and the plan is feasible on a full neighborhood of K_0.

When investment is *zero*, $K_0' = (1-\delta)K_0$ exactly, and the plan is infeasible for every $K > K_0$.

At a corner, the standard support function is available only from the left.

This is precisely where the published argument becomes delicate, and in our reading it has gaps.

Note

Two specific difficulties.

First, Sargent [1980] states the derivative of the value function in the form

$$v_K(K, \theta, e) = u_c(c, e)\big[f'(K)\theta + (1-\delta)\big],$$

which is obtained by substituting the first-order condition (120.8) *with equality* into the envelope condition.

That substitution is legitimate only where investment is positive.

Where investment is zero, $\lambda > 0$ and the formula overstates v_K; the paper's own subsequent inequality records this, so the two statements are not consistent with each other.

Second, the argument establishes differentiability of the value function by induction along the iterates $v^j = T^j v^0$, and then passes to the limit.

That route requires knowing how the set of capital stocks at which the constraint just binds is structured.

The published proof handles three configurations, drawn in its Figures 3-5, and appeals to an appendix that assumes the iterates are twice differentiable almost everywhere.

The appendix in turn justifies this by differentiating the first-order condition and observing that "since the right-hand side exists almost everywhere, so does the left," which does not follow as stated, and it asserts without proof that the set of binding points has Lebesgue measure zero.

Fortunately the conclusion is true, and there is a route to it that avoids the induction on iterates entirely.

The key observation is that at a corner a *different* feasible plan supplies the needed support function: investing nothing is feasible at *every* capital stock, so it works on both sides.

Proposition 120.5.1

Assume u and f are increasing, strictly concave and continuously differentiable, with $u_c(0, e) = \infty$ and $f'(0) = \infty$.

Then for each (θ, e) the value function $v(\cdot, \theta, e)$ defined by (120.7) is continuously differentiable on $(0, \infty)$, and

$$v_K(K, \theta, e) = u_c(c, e) f'(K)\theta + \beta(1-\delta)\mathbb{E}[v_K(K', \theta', e')], \tag{120.11}$$

where c and K' are optimal at (K, θ, e).

Where investment is positive, (120.11) reduces to $v_K = u_c(c, e)[f'(K)\theta + (1-\delta)]$.

Where investment is zero, $v_K < u_c(c, e)[f'(K)\theta + (1-\delta)]$.

Proof. **Step 0.** The operator associated with (120.7) maps bounded continuous concave functions into bounded continuous strictly concave functions, so $v(\cdot, \theta, e)$ is concave and continuous, and the optimal policy is single valued and continuous.

Step 1 (investment positive). Suppose $I(K_0, \theta, e) > 0$, and let K_0' be the optimal choice.

Then $K_0' > (1-\delta)K_0$, so by continuity the plan that freezes next period's capital at K_0' is feasible for all K in a neighborhood of K_0.

The function W_1 of (120.10) is therefore concave, continuously differentiable, dominated by v, and equal to v at K_0.

Theorem 120.5.1 gives differentiability at K_0 with

$$v_K(K_0, \theta, e) = u_c(c, e)[f'(K_0)\theta + (1-\delta)].$$

Because the first-order condition holds with equality here, $\beta\mathbb{E}[v_K(K_0', \cdot)] = u_c(c, e)$, and substituting gives (120.11).

Step 2 (investment zero, conditional on a smaller capital stock). Suppose $I(K_0, \theta, e) = 0$, so that $K_0' = (1-\delta)K_0$ and investing nothing is optimal at K_0.

Consider instead the plan that invests nothing this period and behaves optimally thereafter:

$$W_2(K) = u(f(K)\theta, e) + \beta\mathbb{E}[v((1-\delta)K, \theta', e')].$$

Investing nothing is feasible at *every* capital stock, so $W_2 \leq v$ everywhere, with $W_2(K_0) = v(K_0)$, and W_2 is concave.

Suppose that $v(\cdot, \theta', e')$ is differentiable at $(1-\delta)K_0$ for every (θ', e').

Then W_2 is differentiable at K_0; differentiation under the expectation is legitimate because the functions $v(\cdot, \theta', e')$ are concave, hence locally Lipschitz with a common bound on a compact neighborhood.

Theorem 120.5.1 then gives differentiability of v at K_0, with

$$v_K(K_0, \theta, e) = u_c(c, e) f'(K_0)\theta + \beta(1-\delta)\mathbb{E}\big[v_K((1-\delta)K_0, \theta', e')\big],$$

which is (120.11).

Step 3 (a region where the corner cannot bind). Because $f'(0) = \infty$, there is an $\eta > 0$ such that $I(K, \theta, e) > 0$ for every $K \le \eta$ and every (θ, e).

The intuition is that the marginal product of capital becomes arbitrarily large as capital approaches zero, so that giving up a little consumption today buys a great deal of consumption tomorrow.

Making this precise requires comparing the rates at which the two sides of (120.8) diverge as $K \downarrow 0$, since with, say, logarithmic utility both sides become unbounded.

Sargent [1980] proves the statement in his Appendix A (his Proposition A2), under an explicit restriction on u and f that he imposes for this purpose.

That result is the one ingredient of his appendix that the argument below borrows, and it is independent of the differentiability question at issue here.

By Step 1, $v(\cdot, \theta, e)$ is therefore differentiable on $(0, \eta]$ for every (θ, e).

Step 4 (bootstrap). Let

$$D = \{K > 0 : v(\cdot, \theta, e) \text{ is differentiable at } K \text{ for every } (\theta, e)\}.$$

We claim that if $(0, A) \subseteq D$ then $(0, A/(1-\delta)) \subseteq D$.

Take $K < A/(1-\delta)$ and any (θ, e).

If $I(K, \theta, e) > 0$, Step 1 applies directly.

If $I(K, \theta, e) = 0$, then $(1-\delta)K < A$, so $v(\cdot, \theta', e')$ is differentiable at $(1-\delta)K$ for every (θ', e'), and Step 2 applies.

By Step 3 we may start the induction at $A = \eta$.

Since $1/(1-\delta) > 1$, iterating the claim gives $(0, \eta(1-\delta)^{-n}) \subseteq D$ for every n, and therefore $D = (0, \infty)$.

Step 5 (continuity). A concave function that is differentiable on an open interval has a continuous derivative there, so $v(\cdot, \theta, e)$ is continuously differentiable.

Finally, where investment is zero the first-order condition holds with $\lambda > 0$, so $\beta\mathbb{E}[v_K(K', \cdot)] < u_c$, and (120.11) gives $v_K < u_c[f'(K)\theta + (1-\delta)]$.

The corrected formula has a natural reading.

Iterating (120.11) forward gives

$$v_K(K_t, \theta_t, e_t) = \mathbb{E}_t \sum_{j=0}^{\infty} \beta^j (1-\delta)^j \, u_c(c_{t+j}, e_{t+j}) \, f'(K_{t+j})\theta_{t+j}. \tag{120.12}$$

A marginal unit of capital installed today yields marginal products for as long as it survives, and each is valued at the marginal utility of consumption on the date it arrives.

When investment is positive, the market prices that whole stream at the cost of a unit of new output, and (120.12) collapses to $u_c[f'(K)\theta + (1-\delta)]$.

When investment is zero, it does not, and the difference is exactly what pushes q below one.

120.6 Computing the model

We now solve the model of (120.7) with

$$u(c, e) = e \ln c, \qquad f(K) = K^a.$$

The shocks θ and e each take two values with equal probability and are independent of each other and over time.

One numerical detail matters a great deal.

The irreversibility constraint says $K' \geq (1-\delta)K$, so we want $(1-\delta)K$ to be a point of the capital grid whenever K is.

Following Sargent [1980], we use a *geometric* grid with ratio $(1-\delta)^{1/z}$ for an integer z, so that $(1-\delta)K_i = K_{i-z}$ exactly.

```
Model = namedtuple("Model", "β δ a z K θ e W nθ ne")

def create_model(β=0.95, δ=0.05, a=0.25, z=10, n_K=500, K_hi=20.0,
                 θ_vals=(0.85, 1.15), e_vals=(0.6, 1.4)):
    "Geometric capital grid so that (1-δ)K is itself a grid point."
    ratio = (1 - δ)**(1/z)
    K = K_hi * ratio**np.arange(n_K - 1, -1, -1)
    θ, e = np.array(θ_vals), np.array(e_vals)
    W = np.outer(np.ones(len(θ))/len(θ), np.ones(len(e))/len(e))
    return Model(β, δ, a, z, K, θ, e, W, len(θ), len(e))

f  = lambda m, K: K**m.a
f_prime = lambda m, K: m.a * K**(m.a - 1)
```

The planner chooses next period's capital from the grid, subject to positive consumption and to irreversibility.

```
def solve_model(m, irreversible=True, tol=1e-10, maxit=5000, howard=50):
    "Value function iteration with Howard policy improvement steps."
    nK = len(m.K)
    C = f(m, m.K)[:, None] * m.θ[None, :]                          # output (K, θ)
    C = C[:, None, :] + (1 - m.δ)*m.K[:, None, None] - m.K[None, :, None]
    ok = C > 1e-12                                                 # (K, K', θ)

    if irreversible:                                               # K' ≥ (1-δ)K
        irr = np.zeros((nK, nK), bool)
        for i in range(nK):
            irr[i, max(i - m.z, 0):] = True
        ok = ok & irr[:, :, None]

    U = np.where(ok[:, :, :, None],
                 m.e[None, None, None, :] * np.log(np.where(ok, C, 1.0))[:, :, :,␣
↪None],
                 -1e12)

    v = np.zeros((nK, m.nθ, m.ne))
    for it in range(maxit):
        EV = np.tensordot(v, m.W, axes=([1, 2], [0, 1]))           # E v(K') over (θ', e
↪')
        obj = U + m.β * EV[None, :, None, None]
        idx = obj.argmax(axis=1)
        v_new = np.take_along_axis(obj, idx[:, None, :, :], axis=1)[:, 0, :, :]

        for _ in range(howard):
```

(continues on next page)

(continued from previous page)

```
            EV = np.tensordot(v_new, m.W, axes=([1, 2], [0, 1]))
            v_new = (np.take_along_axis(U, idx[:, None, :, :], axis=1)[:, 0, :, :]
                     + m.β * EV[idx])

        if np.max(np.abs(v_new - v)) < tol:
            v = v_new
            break
        v = v_new

    K_next = m.K[idx]
    I = K_next - (1 - m.δ) * m.K[:, None, None]
    C_pol = (f(m, m.K)[:, None, None] * m.θ[None, :, None]
             + (1 - m.δ) * m.K[:, None, None] - K_next)
    return v, idx, K_next, I, C_pol
```

To compute q we need v_K, and *Proposition 120.5.1* tells us how to get it: equation (120.11) is a linear fixed point problem in v_K given the optimal policy, and it is a contraction with modulus $\beta(1-\delta)$.

```
def marginal_value(m, idx, C_pol, tol=1e-13, maxit=50_000):
    "Solve the envelope equation v_K = u_c f'(K)θ + β(1-δ) E v_K(K')."
    vK = np.zeros_like(C_pol)
    direct = (m.e[None, None, :]/C_pol) * f_prime(m, m.K)[:, None, None] * m.θ[None,␣
↪:, None]
    for _ in range(maxit):
        EvK = np.tensordot(vK, m.W, axes=([1, 2], [0, 1]))
        new = direct + m.β * (1 - m.δ) * EvK[idx]
        if np.max(np.abs(new - vK)) < tol:
            return new
        vK = new
    return vK

m = create_model()
v, idx, K_next, I, C_pol = solve_model(m)
vK = marginal_value(m, idx, C_pol)

u_c = m.e[None, None, :] / C_pol
E_vK = np.tensordot(vK, m.W, axes=([1, 2], [0, 1]))
q = m.β * E_vK[idx] / u_c
corner = I <= 1e-12

print(f"share of states with zero investment: {corner.mean():.3f}")
```

```
share of states with zero investment: 0.567
```

Let's check *Proposition 120.5.1* numerically, by comparing the envelope formula with a finite-difference derivative of the computed value function.

```
vK_fd = np.gradient(v, m.K, axis=0)
naive = u_c * (f_prime(m, m.K)[:, None, None] * m.θ[None, :, None] + (1 - m.δ))
mid = ((m.K > 2.2) & (m.K < 7.0))[:, None, None] & np.ones_like(corner)

rel = lambda x: np.median((np.abs(x - vK_fd)/np.abs(vK_fd))[mid & sel])

sel = ~corner
print(f"investment positive: envelope error {rel(vK):.4f}, "
      f"naive formula error {rel(naive):.4f}")
```

(continues on next page)

(continued from previous page)

```
sel = corner
print(f"investment zero:     envelope error {rel(vK):.4f}, "
      f"naive formula error {rel(naive):.4f}")
```

```
investment positive: envelope error 0.0005, naive formula error 0.0066
investment zero:     envelope error 0.0001, naive formula error 0.3856
```

Where investment is positive, both formulas agree with the numerical derivative.

Where investment is zero, the envelope formula (120.11) remains accurate while the formula $u_c[f'(K)\theta + (1-\delta)]$ is off by tens of percent.

This is the practical content of the correction: at corners the two expressions are genuinely different objects, and it is the envelope formula that gives the price of installed capital.

We can also verify Step 3 of the proof, which asserts a region of small capital stocks where the corner never binds.

```
m_wide = create_model(n_K=700)        # a grid reaching lower capital stocks
_, idx_w, _, I_w, _ = solve_model(m_wide)
frac_corner = (I_w <= 1e-12).reshape(len(m_wide.K), -1).mean(axis=1)
first = np.argmax(frac_corner > 0)
print(f"grid runs from K = {m_wide.K.min():.3f}")
print(f"investment is positive for every shock when K < {m_wide.K[first]:.3f}")
```

```
grid runs from K = 0.555
investment is positive for every shock when K < 1.058
```

120.6.1 Policies and the price of installed capital

```
fig, axes = plt.subplots(1, 2, figsize=(12, 4.5))
show = (m.K > 1.5) & (m.K < 9)

for j in range(m.nθ):
    for l in range(m.ne):
        lab = rf'$\theta={m.θ[j]}, e={m.e[l]}$'
        axes[0].plot(m.K[show], K_next[show, j, l], label=lab)
        axes[1].plot(m.K[show], q[show, j, l], label=lab)

axes[0].plot(m.K[show], m.K[show], 'k--', lw=1, label='45 degree line')
axes[0].plot(m.K[show], (1-m.δ)*m.K[show], 'k:', lw=1, label=r'$(1-\delta)K$')
axes[0].set_xlabel('$K$'); axes[0].set_ylabel("$K'$"); axes[0].set_title('law of␣
↪motion')
axes[1].axhline(1.0, color='k', ls='--', lw=1)
axes[1].set_xlabel('$K$'); axes[1].set_ylabel('$q$'); axes[1].set_title("Tobin's $q$")
axes[0].legend(fontsize=8); axes[1].legend(fontsize=8)
plt.tight_layout()
plt.show()
```

The law of motion runs along the lower dotted line $(1-\delta)K$ whenever the irreversibility constraint binds.

Exactly on that region, q falls below one.

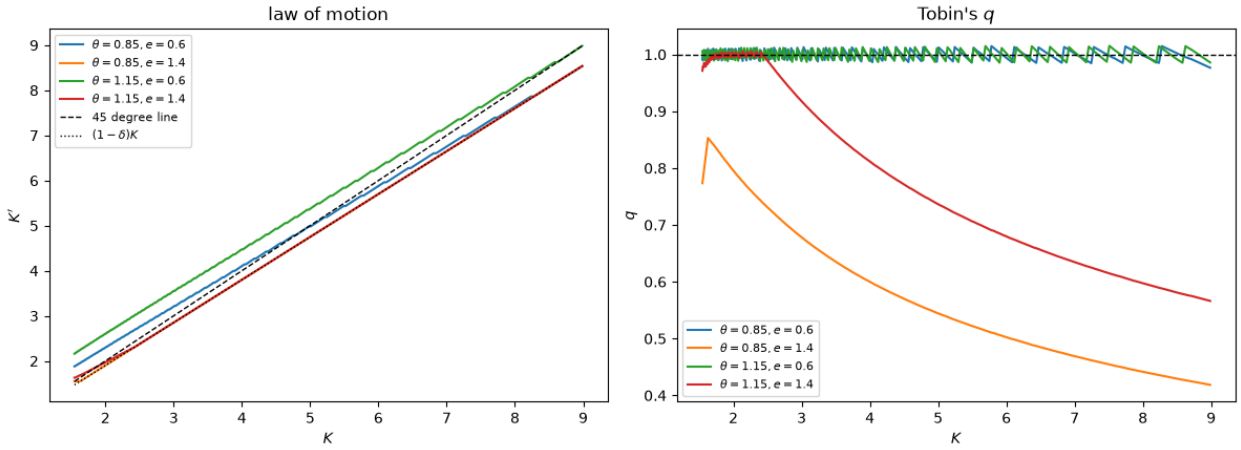

Fig. 120.1: Law of motion and Tobin's q

120.6.2 The invariant distribution

As in *Investment Under Uncertainty*, we check that the long-run distribution does not depend on where the economy starts.

```
def simulate(m, idx, K0, T=50_000, seed=0, burn=500):
    "Simulate the equilibrium Markov process."

plt.tight_layout()
plt.show()
```

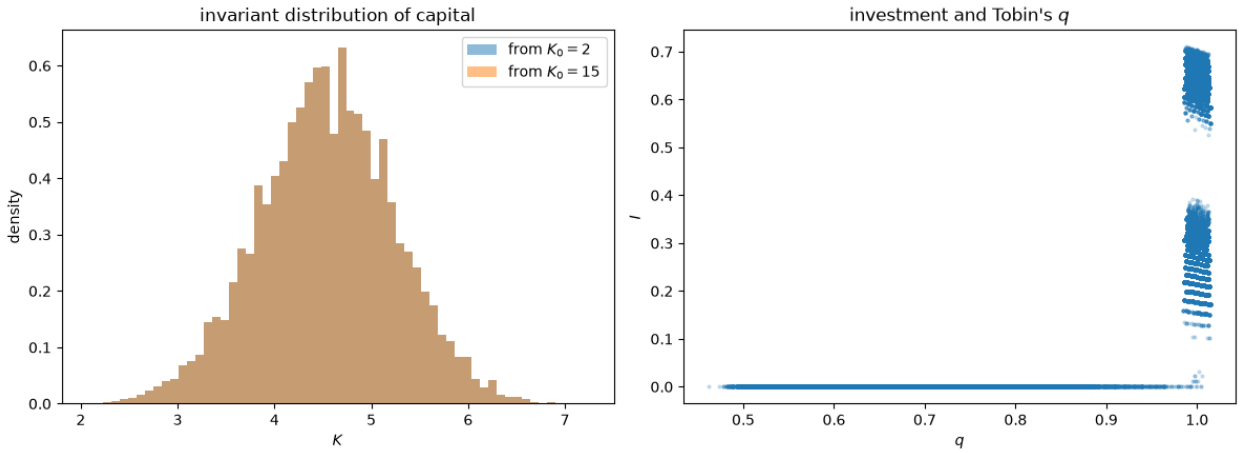

Fig. 120.2: Invariant distribution and investment against q

The two histograms coincide, as *Theorem 120.3.1* leads us to expect.

The scatter plot on the right reproduces the central picture of Sargent [1980].

Investment is positive only when q equals one; when q is below one, investment is exactly zero.

```
print(f"q when I > 0: [{q_sim[I_sim > 1e-12].min():.4f}, {q_sim[I_sim > 1e-12].max():.
↪4f}]")
print(f"q when I = 0: [{q_sim[I_sim <= 1e-12].min():.4f}, {q_sim[I_sim <= 1e-12].
↪max():.4f}]")
```

```
q when I > 0: [0.9851, 1.0148]
q when I = 0: [0.4619, 1.0040]
```

The small departures from exactly one reflect the discreteness of the capital grid.

Sargent's point is now visible.

There *is* a positive relationship between investment and q in these data, and an econometrician could certainly run that regression.

But the relationship is not an investment demand schedule.

It is a **mongrel relation** that mixes together preferences, technology and the distribution of the shocks, and it will shift whenever any of them changes.

Exercise 120.7.3 asks you to demonstrate this.

120.7 Exercises

Exercise 120.7.1

Brock and Mirman [1972] is famous partly for a special case that can be solved by hand.

Let $u(c) = \ln c$, let $f(k, r) = rk^\alpha$ with $0 < \alpha < 1$, and let capital depreciate fully each period, so that $k_{t+1} = f(k_t, r_t) - c_t$.

1. Verify that the optimal policy is $k_{t+1} = \alpha\beta\, r_t k_t^\alpha$.
2. Show that $\ln k_t$ follows an AR(1) process, and derive the mean and variance of its invariant distribution when $\ln r_t \sim N(\mu, \sigma^2)$.
3. Simulate the model and check both the invariant distribution and the mean-ergodic property (120.5).

Solution

Guess that a constant fraction of resources is saved, $k_{t+1} = s\, r_t k_t^\alpha$.

The Euler equation for this problem is

$$\frac{1}{c_t} = \beta \mathbb{E}_t \left[\frac{1}{c_{t+1}} \alpha r_{t+1} k_{t+1}^{\alpha-1} \right].$$

With $c_t = (1-s) r_t k_t^\alpha$ and $k_{t+1} = s r_t k_t^\alpha$, the right side becomes

$$\beta \mathbb{E}_t \left[\frac{\alpha r_{t+1} k_{t+1}^{\alpha-1}}{(1-s) r_{t+1} k_{t+1}^\alpha} \right] = \frac{\beta\alpha}{(1-s) k_{t+1}} = \frac{\beta\alpha}{(1-s) s r_t k_t^\alpha},$$

while the left side is $1/[(1-s) r_t k_t^\alpha]$.

Equating the two gives $s = \alpha\beta$.

Taking logs of the policy,

$$\ln k_{t+1} = \ln(\alpha\beta) + \alpha \ln k_t + \ln r_t,$$

an AR(1) with coefficient α.

With $\ln r_t \sim N(\mu, \sigma^2)$, the invariant distribution of $\ln k$ is normal with

$$\text{mean} = \frac{\ln(\alpha\beta) + \mu}{1-\alpha}, \qquad \text{variance} = \frac{\sigma^2}{1-\alpha^2}.$$

```
α, β_d, μ, σ = 0.4, 0.95, 0.0, 0.1
T = 200_000
rng = np.random.default_rng(0)
ln_r = μ + σ * rng.normal(size=T)

k = np.empty(T + 1)
k[0] = 1.0
for t in range(T):
    k[t+1] = α * β_d * np.exp(ln_r[t]) * k[t]**α

ln_k = np.log(k[1000:])
print(f"mean of ln k: simulated {ln_k.mean():.4f}, "
      f"theory {(np.log(α*β_d) + μ)/(1-α):.4f}")
print(f"var  of ln k: simulated {ln_k.var():.4f}, "
      f"theory {σ**2/(1-α**2):.4f}")
```

```
mean of ln k: simulated -1.6126, theory -1.6126
var  of ln k: simulated 0.0119, theory 0.0119
```

The time averages match the population moments of the invariant distribution, which is the mean-ergodic property (120.5) in action.

Exercise 120.7.2

This exercise examines the difference between the two candidate formulas for v_K discussed above.

For the baseline model, compute at every state

- the envelope formula (120.11)
- the formula $u_c(c,e)[f'(K)\theta + (1-\delta)]$
- a finite-difference derivative of the value function

Then

1. Confirm that all three agree where investment is positive.
2. Confirm that the second disagrees with the other two where investment is zero, and report by how much.
3. Explain, using (120.8), why the second formula is an upper bound for v_K.
4. What would go wrong with the computed q if you used the second formula everywhere?

Solution

The second formula is what you get by substituting the first-order condition (120.8) into the envelope condition *as though* $\lambda = 0$.

Since $\lambda \geq 0$, dropping it can only raise the expression, so

$$v_K = u_c f'(K)\theta + (1-\delta)\big[u_c - \lambda\big] \leq u_c\big[f'(K)\theta + (1-\delta)\big],$$

with equality exactly when $\lambda = 0$, that is, when investment is positive.

```
gap = np.abs(naive - vK_fd)/np.abs(vK_fd)
env = np.abs(vK - vK_fd)/np.abs(vK_fd)

for name, sel in (("investment positive", ~corner), ("investment zero", corner)):
    s = mid & sel
    print(f"{name:20}: envelope {np.median(env[s]):.4f}   "
          f"naive {np.median(gap[s]):.4f}   max naive {gap[s].max():.4f}")

q_naive = m.β * np.tensordot(naive, m.W, axes=([1, 2], [0, 1]))[idx] / u_c
print(f"\nusing the naive formula, max q = {q_naive.max():.3f} "
      f"(theory says q ≤ 1)")
print(f"fraction of states with q > 1: {(q_naive > 1 + 1e-8).mean():.3f}")
```

```
investment positive : envelope 0.0005   naive 0.0066   max naive 0.0134
investment zero     : envelope 0.0001   naive 0.3856   max naive 1.0175

using the naive formula, max q = 1.863 (theory says q ≤ 1)
fraction of states with q > 1: 0.578
```

Using the second formula everywhere produces values of q that exceed one, which the theory rules out.

The reason is economic, not numerical: at a corner the market does not price installed capital at the cost of new capital, precisely because the household would like to sell capital and cannot.

Exercise 120.7.3

Show that the regression of investment on q is not structural.

Solve and simulate the model for several economies that differ in

- the amount of preference risk (the spread of e)
- the amount of technology risk (the spread of θ)
- the depreciation rate δ

For each economy, report the slope and R^2 of a regression of I on q, together with the frequency with which investment is zero.

Comment on what this implies for an econometrician who estimates an "investment demand schedule" relating investment to q.

Solution

Here is one solution.

```
def q_regression(**kwargs):
    "Solve an economy, simulate it, and regress I on q."
    mm = create_model(**kwargs)
    vv, ii, _, II, CC = solve_model(mm)
    vvK = marginal_value(mm, ii, CC)
    uu_c = mm.e[None, None, :]/CC
    qq = mm.β * np.tensordot(vvK, mm.W, axes=([1, 2], [0, 1]))[ii] / uu_c
    p, j, l = simulate(mm, ii, K0=3.5)
    q_s, I_s = qq[p, j, l], II[p, j, l]
    slope = np.polyfit(q_s, I_s, 1)[0]
    corr = np.corrcoef(I_s, q_s)[0, 1]
    return slope, corr**2, (I_s <= 1e-12).mean()

cases = [("baseline",              {}),
         ("less preference risk",  dict(e_vals=(0.8, 1.2))),
         ("more preference risk",  dict(e_vals=(0.4, 1.6))),
         ("less technology risk",  dict(θ_vals=(0.95, 1.05))),
         ("more technology risk",  dict(θ_vals=(0.7, 1.3))),
         ("faster depreciation",   dict(δ=0.10))]

print(f"{'economy':24}{'slope':>9}{'R^2':>8}{'zero I':>9}")
for name, kw in cases:
    slope, r2, zero = q_regression(**kw)
    print(f"{name:24}{slope:9.3f}{r2:8.3f}{zero:9.3f}")
```

```
economy                  slope     R^2   zero I
baseline                 1.127   0.594    0.500
less preference risk     1.094   0.283    0.279
more preference risk     1.131   0.780    0.501
less technology risk     1.308   0.904    0.501
more technology risk     0.780   0.234    0.529
faster depreciation      1.271   0.436    0.456
```

The slope and the fit both move around substantially across economies that share the same preferences and technology parameters but differ in the distribution of shocks or in the depreciation rate.

Nothing in the regression is invariant, so it cannot be used to predict what investment would do under a policy that changed any of these features.

This is the message of Sargent [1980], and it is a concrete instance of the Lucas critique: the very friction that makes q interesting – the occasionally binding irreversibility constraint – also makes the relationship between I and q a reduced-form artifact rather than a decision rule.

In addition to what's in Anaconda, this lecture deploys the following libraries:

```
!pip install quantecon
```

```
import matplotlib.pyplot as plt
import numpy as np
import quantecon as qe
from sympy import init_printing, symbols, Matrix
init_printing()
```

121.1 Overview

This lecture studies stability in the context of an elementary rational expectations model.

We study a rational expectations version of Philip Cagan's model [Cagan, 1956] linking the price level to the money supply.

Cagan did not use a rational expectations version of his model, but Sargent [Sargent, 1977] did.

We study a rational expectations version of this model because it is intrinsically interesting and because it has a mathematical structure that appears in virtually all linear rational expectations model, namely, that a key endogenous variable equals a mathematical expectation of a geometric sum of future values of another variable.

The model determines the price level or rate of inflation as a function of the money supply or the rate of change in the money supply.

In this lecture, we'll encounter:

- a convenient formula for the expectation of geometric sum of future values of a variable
- a way of solving an expectational difference equation by mapping it into a vector first-order difference equation and appropriately manipulating an eigen decomposition of the transition matrix in order to impose stability
- a way to use a Big K, little k argument to allow apparent feedback from endogenous to exogenous variables within a rational expectations equilibrium
- a use of eigenvector decompositions of matrices that allowed Blanchard and Khan (1981) [Blanchard and Kahn, 1980] and Whiteman (1983) [Whiteman, 1983] to solve a class of linear rational expectations models
- how to use **SymPy** to get analytical formulas for some key objects comprising a rational expectations equilibrium

Matrix decompositions employed here are described in more depth in this lecture *Lagrangian formulations*.

We formulate a version of Cagan's model under rational expectations as an **expectational difference equation** whose solution is a rational expectations equilibrium.

We'll start this lecture with a quick review of deterministic (i.e., non-random) first-order and second-order linear difference equations.

121.2 Linear Difference Equations

We'll use the **backward shift** or **lag** operator L.

The lag operator L maps a sequence $\{x_t\}_{t=0}^{\infty}$ into the sequence $\{x_{t-1}\}_{t=0}^{\infty}$

We'll deploy L by using the equality $Lx_t \equiv x_{t-1}$ in algebraic expressions.

Further, the inverse L^{-1} of the lag operator is the **forward shift** operator.

We'll often use the equality $L^{-1}x_t \equiv x_{t+1}$ below.

The algebra of lag and forward shift operators can simplify representing and solving linear difference equations.

121.2.1 First Order

We want to solve a linear first-order scalar difference equation.

Let $|\lambda| < 1$ and let $\{u_t\}_{t=-\infty}^{\infty}$ be a bounded sequence of scalar real numbers.

Let L be the lag operator defined by $Lx_t \equiv x_{t-1}$ and let L^{-1} be the forward shift operator defined by $L^{-1}x_t \equiv x_{t+1}$.

Then

$$(1 - \lambda L)y_t = u_t, \forall t \tag{121.1}$$

has solutions

$$y_t = (1 - \lambda L)^{-1}u_t + k\lambda^t \tag{121.2}$$

or

$$y_t = \sum_{j=0}^{\infty} \lambda^j u_{t-j} + k\lambda^t$$

for any real number k.

You can verify this fact by applying $(1 - \lambda L)$ to both sides of equation (121.2) and noting that $(1 - \lambda L)\lambda^t = 0$.

To pin down k we need one condition imposed from outside (e.g., an initial or terminal condition) on the path of y.

Now let $|\lambda| > 1$.

Rewrite equation (121.1) as

$$y_{t-1} = \lambda^{-1} y_t - \lambda^{-1} u_t, \forall t \tag{121.3}$$

or

$$(1 - \lambda^{-1} L^{-1}) y_t = -\lambda^{-1} u_{t+1}. \tag{121.4}$$

A solution is

$$y_t = -\lambda^{-1} \left(\frac{1}{1 - \lambda^{-1} L^{-1}} \right) u_{t+1} + k\lambda^t \tag{121.5}$$

for any k.

To verify that this is a solution, check the consequences of operating on both sides of equation (121.5) by $(1 - \lambda L)$ and compare to equation (121.1).

For any bounded $\{u_t\}$ sequence, solution (121.2) exists for $|\lambda| < 1$ because the **distributed lag** in u converges.

Solution (121.5) exists when $|\lambda| > 1$ because the **distributed lead** in u converges.

When $|\lambda| > 1$, the distributed lag in u in (121.2) may diverge, in which case a solution of this form does not exist.

The distributed lead in u in (121.5) need not converge when $|\lambda| < 1$.

121.2.2 Second Order

Now consider the second order difference equation

$$(1 - \lambda_1 L)(1 - \lambda_2 L) y_{t+1} = u_t \tag{121.6}$$

where $\{u_t\}$ is a bounded sequence, y_0 is an initial condition, $|\lambda_1| < 1$ and $|\lambda_2| > 1$.

We seek a bounded sequence $\{y_t\}_{t=0}^{\infty}$ that satisfies (121.6). Using insights from our analysis of the first-order equation, operate on both sides of (121.6) by the forward inverse of $(1 - \lambda_2 L)$ to rewrite equation (121.6) as

$$(1 - \lambda_1 L) y_{t+1} = -\frac{\lambda_2^{-1}}{1 - \lambda_2^{-1} L^{-1}} u_{t+1}$$

or

$$y_{t+1} = \lambda_1 y_t - \lambda_2^{-1} \sum_{j=0}^{\infty} \lambda_2^{-j} u_{t+j+1}. \tag{121.7}$$

Thus, we obtained equation (121.7) by solving a stable root (in this case λ_1) **backward**, and an unstable root (in this case λ_2) **forward**.

Equation (121.7) has a form that we shall encounter often.

- $\lambda_1 y_t$ is called the **feedback part**
- $-\frac{\lambda_2^{-1}}{1 - \lambda_2^{-1} L^{-1}} u_{t+1}$ is called the **feedforward part**

121.3 Illustration: Cagan's Model

Now let's use linear difference equations to represent and solve Sargent's [Sargent, 1977] rational expectations version of Cagan's model [Cagan, 1956] that connects the price level to the public's anticipations of future money supplies.

Cagan did not use a rational expectations version of his model, but Sargent [Sargent, 1977]

Let

- m_t^d be the log of the demand for money
- m_t be the log of the supply of money
- p_t be the log of the price level

It follows that $p_{t+1} - p_t$ is the rate of inflation.

The logarithm of the demand for real money balances $m_t^d - p_t$ is an inverse function of the expected rate of inflation $p_{t+1} - p_t$ for $t \geq 0$:

$$m_t^d - p_t = -\beta(p_{t+1} - p_t), \quad \beta > 0$$

Equate the demand for log money m_t^d to the supply of log money m_t in the above equation and rearrange to deduce that the logarithm of the price level p_t is related to the logarithm of the money supply m_t by

$$p_t = (1 - \lambda)m_t + \lambda p_{t+1} \tag{121.8}$$

where $\lambda \equiv \frac{\beta}{1+\beta} \in (0, 1)$.

(We note that the characteristic polynomial if $1 - \lambda^{-1}z^{-1} = 0$ so that the zero of the characteristic polynomial in this case is $\lambda \in (0, 1)$ which here is **inside** the unit circle.)

Solving the first order difference equation (121.8) forward gives

$$p_t = (1 - \lambda) \sum_{j=0}^{\infty} \lambda^j m_{t+j}, \tag{121.9}$$

which is the unique **stable** solution of difference equation (121.8) among a class of more general solutions

$$p_t = (1 - \lambda) \sum_{j=0}^{\infty} \lambda^j m_{t+j} + c\lambda^{-t} \tag{121.10}$$

that is indexed by the real number $c \in \mathbf{R}$.

Because we want to focus on stable solutions, we set $c = 0$.

Equation (121.10) attributes **perfect foresight** about the money supply sequence to the holders of real balances.

We begin by assuming that the log of the money supply is **exogenous** in the sense that it is an autonomous process that does not feed back on the log of the price level.

In particular, we assume that the log of the money supply is described by the linear state space system

$$\begin{aligned} m_t &= Gx_t \\ x_{t+1} &= Ax_t \end{aligned} \tag{121.11}$$

where x_t is an $n \times 1$ vector that does not include p_t or lags of p_t, A is an $n \times n$ matrix with eigenvalues that are less than λ^{-1} in absolute values, and G is a $1 \times n$ selector matrix.

Variables appearing in the vector x_t contain information that might help predict future values of the money supply.

We'll start with an example in which x_t includes only m_t, possibly lagged values of m, and a constant.

An example of such an $\{m_t\}$ process that fits info state space system (121.11) is one that satisfies the second order linear difference equation

$$m_{t+1} = \alpha + \rho_1 m_t + \rho_2 m_{t-1}$$

where the zeros of the characteristic polynomial $(1 - \rho_1 z - \rho_2 z^2)$ are strictly greater than 1 in modulus.

(Please see *this* QuantEcon lecture for more about characteristic polynomials and their role in solving linear difference equations.)

We seek a stable or non-explosive solution of the difference equation (121.8) that obeys the system comprised of (121.8)-(121.11).

By stable or non-explosive, we mean that neither m_t nor p_t diverges as $t \to +\infty$.

This requires that we shut down the term $c\lambda^{-t}$ in equation (121.10) above by setting $c = 0$

The solution we are after is

$$p_t = F x_t \tag{121.12}$$

where

$$F = (1 - \lambda) G (I - \lambda A)^{-1} \tag{121.13}$$

Note

As mentioned above, an **explosive solution** of difference equation (121.8) can be constructed by adding to the right hand of (121.12) a sequence $c\lambda^{-t}$ where c is an arbitrary positive constant.

121.4 Some Python Code

We'll construct examples that illustrate (121.11).

Our first example takes as the law of motion for the log money supply the second order difference equation

$$m_{t+1} = \alpha + \rho_1 m_t + \rho_2 m_{t-1} \tag{121.14}$$

that is parameterized by ρ_1, ρ_2, α

To capture this parameterization with system (121.9) we set

$$x_t = \begin{bmatrix} 1 \\ m_t \\ m_{t-1} \end{bmatrix}, \quad A = \begin{bmatrix} 1 & 0 & 0 \\ \alpha & \rho_1 & \rho_2 \\ 0 & 1 & 0 \end{bmatrix}, \quad G = \begin{bmatrix} 0 & 1 & 0 \end{bmatrix}$$

Here is Python code

```
λ = .9

α = 0
ρ1 = .9
ρ2 = .05

A = np.array([[1,  0,  0],
              [α, ρ1, ρ2],
              [0,  1,  0]])
G = np.array([[0, 1, 0]])
```

The matrix A has one eigenvalue equal to unity.

It is associated with the A_{11} component that captures a constant component of the state x_t.

We can verify that the two eigenvalues of A not associated with the constant in the state x_t are strictly less than unity in modulus.

```
eigvals = np.linalg.eigvals(A)
print(eigvals)
```

```
[-0.05249378  0.95249378  1.        ]
```

```
(abs(eigvals) <= 1).all()
```

```
np.True_
```

Now let's compute F in formulas (121.12) and (121.13).

```
# compute the solution, i.e. forumula (3)
F = (1 - λ) * G @ np.linalg.inv(np.eye(A.shape[0]) - λ * A)
print("F= ",F)
```

```
F=  [[0.         0.66889632 0.03010033]]
```

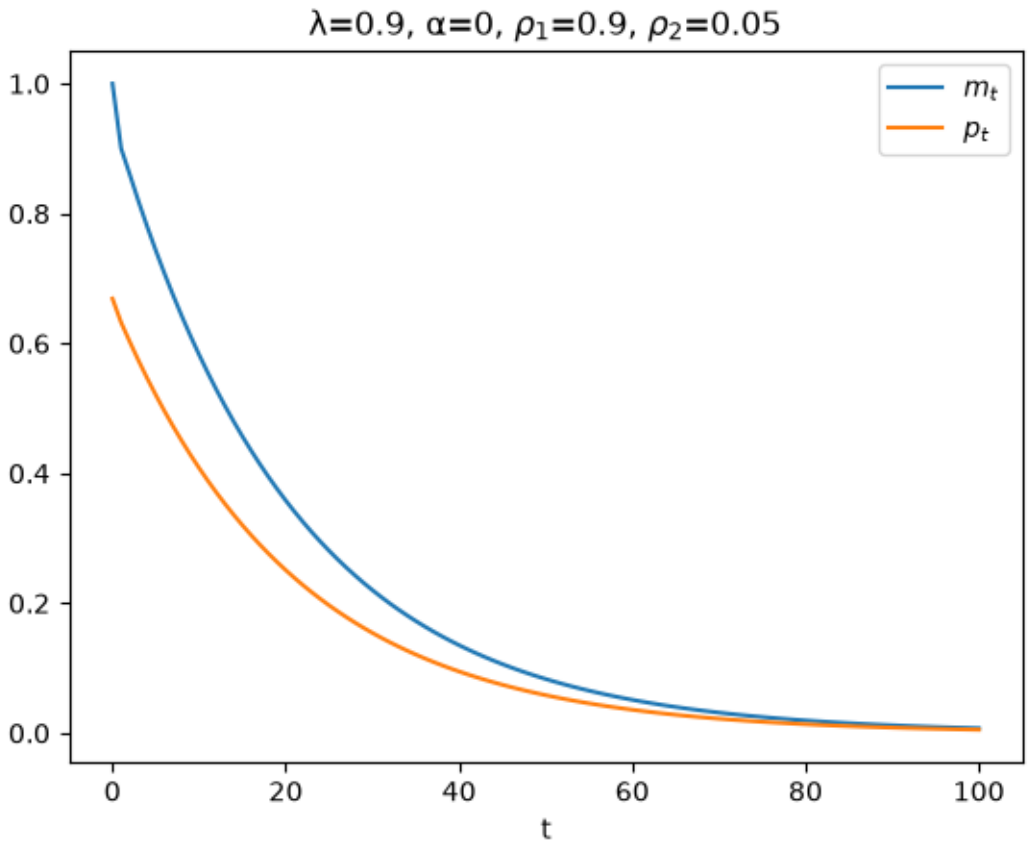
Now let's simulate paths of m_t and p_t starting from an initial value x_0.

```
# set the initial state
x0 = np.array([1, 1, 0])

T = 100 # length of simulation

m_seq = np.empty(T+1)
p_seq = np.empty(T+1)

[m_seq[0]] = G @ x0
[p_seq[0]] = F @ x0



# simulate for T periods
x_old = x0
for t in range(T):

    x = A @ x_old

    [m_seq[t+1]] = G @ x
    [p_seq[t+1]] = F @ x

    x_old = x
```

```
plt.figure()
plt.plot(range(T+1), m_seq, label=r'$m_t$')
plt.plot(range(T+1), p_seq, label=r'$p_t$')
plt.xlabel('t')
plt.title(rf'λ={λ}, α={α}, $ρ_1$={ρ1}, $ρ_2$={ρ2}')
plt.legend()
plt.show()
```

In the above graph, why is the log of the price level always less than the log of the money supply?

Because

- according to equation (121.9), p_t is a geometric weighted average of current and future values of m_t, and
- it happens that in this example future m's are always less than the current m

121.5 Alternative Code

We could also have run the simulation using the quantecon **LinearStateSpace** code.

The following code block performs the calculation with that code.

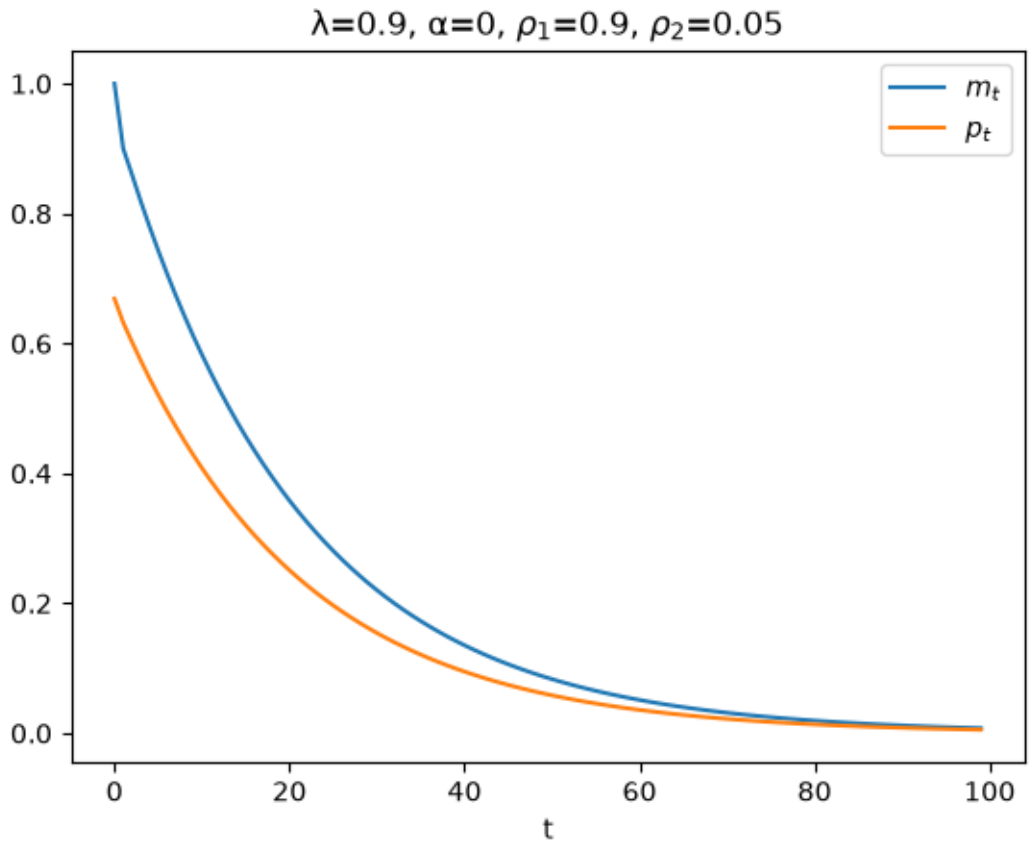
```
# construct a LinearStateSpace instance

# stack G and F
G_ext = np.vstack([G, F])

C = np.zeros((A.shape[0], 1))

ss = qe.LinearStateSpace(A, C, G_ext, mu_0=x0)
```

```
T = 100



# simulate using LinearStateSpace
```

(continues on next page)

(continued from previous page)

```
x, y = ss.simulate(ts_length=T)

# plot
plt.figure()
plt.plot(range(T), y[0,:], label='$m_t$')
plt.plot(range(T), y[1,:], label='$p_t$')
plt.xlabel('t')
plt.title(f'λ={λ}, α={α}, $ρ_1$={ρ1}, $ρ_2$={ρ2}')
plt.legend()
plt.show()
```

121.5.1 Special Case

To simplify our presentation in ways that will let focus on an important idea, in the above second-order difference equation (121.14) that governs m_t, we now set $\alpha = 0$, $\rho_1 = \rho \in (-1, 1)$, and $\rho_2 = 0$ so that the law of motion for m_t becomes

$$m_{t+1} = \rho m_t \tag{121.15}$$

and the state x_t becomes

$$x_t = m_t.$$

Consequently, we can set $G = 1, A = \rho$ making our formula (121.13) for F become

$$F = (1 - \lambda)(1 - \lambda\rho)^{-1}.$$

so that the log the log price level satisfies

$$p_t = Fm_t.$$

Please keep these formulas in mind as we investigate an alternative route to and interpretation of our formula for F.

121.6 Another Perspective

Above, we imposed stability or non-explosiveness on the solution of the key difference equation (121.8) in Cagan's model by solving the unstable root of the characteristic polynomial forward.

To shed light on the mechanics involved in imposing stability on a solution of a potentially unstable system of linear difference equations and to prepare the way for generalizations of our model in which the money supply is allowed to feed back on the price level itself, we stack equations (121.8) and (121.15) to form the system

$$\begin{bmatrix} m_{t+1} \\ p_{t+1} \end{bmatrix} = \begin{bmatrix} \rho & 0 \\ -(1-\lambda)/\lambda & \lambda^{-1} \end{bmatrix} \begin{bmatrix} m_t \\ p_t \end{bmatrix} \tag{121.16}$$

or

$$y_{t+1} = Hy_t, \quad t \geq 0 \tag{121.17}$$

where

$$H = \begin{bmatrix} \rho & 0 \\ -(1-\lambda)/\lambda & \lambda^{-1} \end{bmatrix}. \tag{121.18}$$

Transition matrix H has eigenvalues $\rho \in (0,1)$ and $\lambda^{-1} > 1$.

Because an eigenvalue of H exceeds unity, if we iterate on equation (121.17) starting from an arbitrary initial vector $y_0 = \begin{bmatrix} m_0 \\ p_0 \end{bmatrix}$ with $m_0 > 0, p_0 > 0$, we discover that in general absolute values of both components of y_t diverge toward $+\infty$ as $t \to +\infty$.

To substantiate this claim, we can use the eigenvector matrix decomposition of H that is available to us because the eigenvalues of H are distinct

$$H = Q\Lambda Q^{-1}.$$

Here Λ is a diagonal matrix of eigenvalues of H and Q is a matrix whose columns are eigenvectors associated with the corresponding eigenvalues.

Note that

$$H^t = Q\Lambda^t Q^{-1}$$

so that

$$y_t = Q\Lambda^t Q^{-1} y_0$$

For almost all initial vectors y_0, the presence of the eigenvalue $\lambda^{-1} > 1$ causes both components of y_t to diverge in absolute value to $+\infty$.

To explore this outcome in more detail, we can use the following transformation

$$y_t^* = Q^{-1} y_t$$

that allows us to represent the dynamics in a way that isolates the source of the propensity of paths to diverge:

$$y^*_{t+1} = \Lambda^t y^*_t$$

Staring at this equation indicates that unless

$$y^*_0 = \begin{bmatrix} y^*_{1,0} \\ 0 \end{bmatrix} \tag{121.19}$$

the path of y^*_t and therefore the paths of both components of $y_t = Q y^*_t$ will diverge in absolute value as $t \to +\infty$. (We say that the paths *explode*)

Equation (121.19) also leads us to conclude that there is a unique setting for the initial vector y_0 for which both components of y_t do not diverge.

The required setting of y_0 must evidently have the property that

$$Q y_0 = y^*_0 = \begin{bmatrix} y^*_{1,0} \\ 0 \end{bmatrix}.$$

But note that since $y_0 = \begin{bmatrix} m_0 \\ p_0 \end{bmatrix}$ and m_0 is given to us an initial condition, p_0 has to do all the adjusting to satisfy this equation.

Sometimes this situation is described by saying that while m_0 is truly a **state** variable, p_0 is a **jump** variable that must adjust at $t = 0$ in order to satisfy the equation.

Thus, in a nutshell the unique value of the vector y_0 for which the paths of y_t do not diverge must have second component p_0 that verifies equality (121.19) by setting the second component of y^*_0 equal to zero.

The component p_0 of the initial vector $y_0 = \begin{bmatrix} m_0 \\ p_0 \end{bmatrix}$ must evidently satisfy

$$Q^{\{2\}} y_0 = 0$$

where $Q^{\{2\}}$ denotes the second row of Q^{-1}, a restriction that is equivalent to

$$Q^{21} m_0 + Q^{22} p_0 = 0 \tag{121.20}$$

where Q^{ij} denotes the (i, j) component of Q^{-1}.

Solving this equation for p_0, we find

$$p_0 = -(Q^{22})^{-1} Q^{21} m_0. \tag{121.21}$$

This is the unique **stabilizing value** of p_0 expressed as a function of m_0.

121.6.1 Refining the Formula

We can get an even more convenient formula for p_0 that is cast in terms of components of Q instead of components of Q^{-1}.

To get this formula, first note that because $(Q^{21} \; Q^{22})$ is the second row of the inverse of Q and because $Q^{-1}Q = I$, it follows that

$$\begin{bmatrix} Q^{21} & Q^{22} \end{bmatrix} \begin{bmatrix} Q_{11} \\ Q_{21} \end{bmatrix} = 0$$

which implies that

$$Q^{21}Q_{11} + Q^{22}Q_{21} = 0.$$

Therefore,

$$-(Q^{22})^{-1}Q^{21} = Q_{21}Q_{11}^{-1}.$$

So we can write

$$p_0 = Q_{21}Q_{11}^{-1}m_0. \tag{121.22}$$

It can be verified that this formula replicates itself over time in the sense that

$$p_t = Q_{21}Q_{11}^{-1}m_t. \tag{121.23}$$

To implement formula (121.23), we want to compute Q_1 the eigenvector of Q associated with the stable eigenvalue ρ of Q.

By hand it can be verified that the eigenvector associated with the stable eigenvalue ρ is proportional to

$$Q_1 = \begin{bmatrix} 1 - \lambda\rho \\ 1 - \lambda \end{bmatrix}.$$

Notice that if we set $A = \rho$ and $G = 1$ in our earlier formula for p_t we get

$$p_t = G(I - \lambda A)^{-1}m_t = (1 - \lambda)(1 - \lambda\rho)^{-1}m_t,$$

a formula that is equivalent with

$$p_t = Q_{21}Q_{11}^{-1}m_t,$$

where

$$Q_1 = \begin{bmatrix} Q_{11} \\ Q_{21} \end{bmatrix}.$$

121.6.2 Remarks about Feedback

We have expressed (121.16) in what superficially appears to be a form in which y_{t+1} feeds back on y_t, even though what we actually want to represent is that the component p_t feeds **forward** on p_{t+1}, and through it, on future m_{t+j}, $j = 0, 1, 2, ...$

A tell-tale sign that we should look beyond its superficial "feedback" form is that $\lambda^{-1} > 1$ so that the matrix H in (121.16) is **unstable**

- it has one eigenvalue ρ that is less than one in modulus that does not imperil stability, but ...
- it has a second eigenvalue λ^{-1} that exceeds one in modulus and that makes H an unstable matrix

We'll keep these observations in mind as we turn now to a case in which the log money supply actually does feed back on the log of the price level.

121.7 Log money Supply Feeds Back on Log Price Level

An arrangement of eigenvalues that split around unity, with one being below unity and another being greater than unity, sometimes prevails when there is *feedback* from the log price level to the log money supply.

Let the feedback rule be

$$m_{t+1} = \rho m_t + \delta p_t \tag{121.24}$$

where $\rho \in (0, 1)$ and where we shall now allow $\delta \neq 0$.

Warning: If things are to fit together as we wish to deliver a stable system for some initial value p_0 that we want to determine uniquely, δ cannot be too large.

The forward-looking equation (121.8) continues to describe equality between the demand and supply of money.

We assume that equations (121.8) and (121.24) govern $y_t \equiv \begin{bmatrix} m_t \\ p_t \end{bmatrix}$ for $t \geq 0$.

The transition matrix H in the law of motion

$$y_{t+1} = H y_t$$

now becomes

$$H = \begin{bmatrix} \rho & \delta \\ -(1-\lambda)/\lambda & \lambda^{-1} \end{bmatrix}.$$

We take m_0 as a given initial condition and as before seek an initial value p_0 that stabilizes the system in the sense that y_t converges as $t \to +\infty$.

Our approach is identical with the one followed above and is based on an eigenvalue decomposition in which, cross our fingers, one eigenvalue exceeds unity and the other is less than unity in absolute value.

When $\delta \neq 0$ as we now assume, the eigenvalues of H will no longer be $\rho \in (0, 1)$ and $\lambda^{-1} > 1$

We'll just calculate them and apply the same algorithm that we used above.

That algorithm remains valid so long as the eigenvalues split around unity as before.

Again we assume that m_0 is an initial condition, but that p_0 is not given but to be solved for.

Let's write and execute some Python code that will let us explore how outcomes depend on δ.

```
def construct_H(ρ, λ, δ):
    "contruct matrix H given parameters."

    H = np.empty((2, 2))
    H[0, :] = ρ,δ
    H[1, :] = - (1 - λ) / λ, 1 / λ

    return H

def H_eigvals(ρ=.9, λ=.5, δ=0):
    "compute the eigenvalues of matrix H given parameters."

    # construct H matrix
    H = construct_H(ρ, λ, δ)

    # compute eigenvalues
    eigvals = np.linalg.eigvals(H)

    return eigvals
```

```
H_eigvals()
```

```
array([2. , 0.9])
```

Notice that a negative δ will not imperil the stability of the matrix H, even if it has a big absolute value.

```
# small negative δ
H_eigvals(δ=-0.05)
```

```
array([0.8562829, 2.0437171])
```

```
# large negative δ
H_eigvals(δ=-1.5)
```

```
array([0.10742784, 2.79257216])
```

A sufficiently small positive δ also causes no problem.

```
# sufficiently small positive δ
H_eigvals(δ=0.05)
```

```
array([0.94750622, 1.95249378])
```

But a large enough positive δ makes both eigenvalues of H strictly greater than unity in modulus.

For example,

```
H_eigvals(δ=0.2)
```

```
array([1.12984379, 1.77015621])
```

We want to study systems in which one eigenvalue exceeds unity in modulus while the other is less than unity in modulus, so we avoid values of δ that are too.

That is, we want to avoid too much positive feedback from p_t to m_{t+1}.

```
def magic_p0(m0, ρ=.9, λ=.5, δ=0):
    """
    Use the magic formula (8) to compute the level of p0
    that makes the system stable.
    """

    H = construct_H(ρ, λ, δ)
    eigvals, Q = np.linalg.eig(H)

    # find the index of the smaller eigenvalue
    ind = 0 if eigvals[0] < eigvals[1] else 1

    # verify that the eigenvalue is less than unity
    if eigvals[ind] > 1:

        print("both eigenvalues exceed unity in modulus")

        return None
```

(continues on next page)

(continued from previous page)

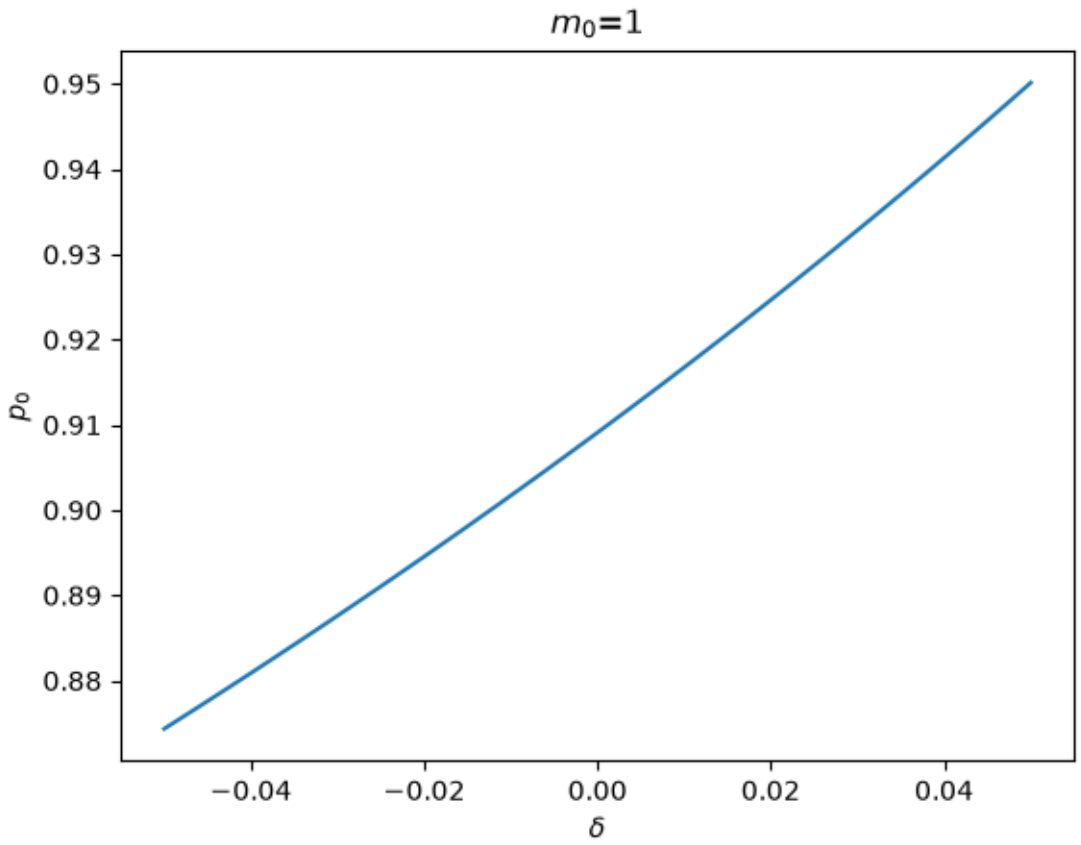
```
    p0 = Q[1, ind] / Q[0, ind] * m0

    return p0
```

Let's plot how the solution p_0 changes as m_0 changes for different settings of δ.

```
m_range = np.arange(0.1, 2., 0.1)

for δ in [-0.05, 0, 0.05]:
    plt.plot(m_range, [magic_p0(m0, δ=δ) for m0 in m_range], label=f"δ={δ}")
plt.legend()



plt.xlabel(r"$m_0$")
plt.ylabel(r"$p_0$")
plt.show()
```

To look at things from a different angle, we can fix the initial value m_0 and see how p_0 changes as δ changes.

```
m0 = 1

δ_range = np.linspace(-0.05, 0.05, 100)
plt.plot(δ_range, [magic_p0(m0, δ=δ) for δ in δ_range])
plt.xlabel(r'$\delta$')
plt.ylabel(r'$p_0$')
plt.title(rf'$m_0$={m0}')
plt.show()
```

Notice that when δ is large enough, both eigenvalues exceed unity in modulus, causing a stabilizing value of p_0 not to exist.

```
magic_p0(1, δ=0.2)
```

```
both eigenvalues exceed unity in modulus
```

121.8 Big P, Little p Interpretation

It is helpful to view our solutions of difference equations having feedback from the price level or inflation to money or the rate of money creation in terms of the Big K, little k idea discussed in *Rational Expectations Models*.

This will help us sort out what is taken as given by the decision makers who use the difference equation (121.9) to determine p_t as a function of their forecasts of future values of m_t.

Let's write the stabilizing solution that we have computed using the eigenvector decomposition of H as $P_t = F^* m_t$, where

$$F^* = Q_{21} Q_{11}^{-1}.$$

Then from $P_{t+1} = F^* m_{t+1}$ and $m_{t+1} = \rho m_t + \delta P_t$ we can deduce the recursion $P_{t+1} = F^* \rho m_t + F^* \delta P_t$ and create the stacked system

$$\begin{bmatrix} m_{t+1} \\ P_{t+1} \end{bmatrix} = \begin{bmatrix} \rho & \delta \\ F^* \rho & F^* \delta \end{bmatrix} \begin{bmatrix} m_t \\ P_t \end{bmatrix}$$

or

$$x_{t+1} = Ax_t$$

where $x_t = \begin{bmatrix} m_t \\ P_t \end{bmatrix}$.

Apply formula (121.13) for F to deduce that

$$p_t = F \begin{bmatrix} m_t \\ P_t \end{bmatrix} = F \begin{bmatrix} m_t \\ F^* m_t \end{bmatrix}$$

which implies that

$$p_t = \begin{bmatrix} F_1 & F_2 \end{bmatrix} \begin{bmatrix} m_t \\ F^* m_t \end{bmatrix} = F_1 m_t + F_2 F^* m_t$$

so that we can anticipate that

$$F^* = F_1 + F_2 F^*$$

We shall verify this equality in the next block of Python code that implements the following computations.

1. For the system with $\delta \neq 0$ so that there is feedback, we compute the stabilizing solution for p_t in the form $p_t = F^* m_t$ where $F^* = Q_{21} Q_{11}^{-1}$ as above.
2. Recalling the system (121.11), (121.12), and (121.13) above, we define $x_t = \begin{bmatrix} m_t \\ P_t \end{bmatrix}$ and notice that it is Big P_t and not little p_t here. Then we form A and G as $A = \begin{bmatrix} \rho & \delta \\ F^* \rho & F^* \delta \end{bmatrix}$ and $G = \begin{bmatrix} 1 & 0 \end{bmatrix}$ and we compute $\begin{bmatrix} F_1 & F_2 \end{bmatrix} \equiv F$ from equation (121.13) above.
3. We compute $F_1 + F_2 F^*$ and compare it with F^* and check for the anticipated equality.

```
# set parameters
ρ = .9
λ = .5
δ = .05
```

```
# solve for F_star
H = construct_H(ρ, λ, δ)
eigvals, Q = np.linalg.eig(H)

ind = 0 if eigvals[0] < eigvals[1] else 1
F_star = Q[1, ind] / Q[0, ind]
F_star
```

```
0.950124378879 11
```

```
# solve for F_check
A = np.empty((2, 2))
A[0, :] = ρ, δ
A[1, :] = F_star * A[0, :]

G = np.array([1, 0])

F_check= (1 - λ) * G @ np.linalg.inv(np.eye(2) - λ * A)
F_check
```

```
array([0.92755597, 0.02375311])
```

Compare F^* with $F_1 + F_2 F^*$

```
F_check[0] + F_check[1] * F_star, F_star
```

$$(0.950124378879\,11,\ 0.950124378879\,11)$$

121.9 Fun with SymPy

This section is a gift for readers who have made it this far.

It puts SymPy to work on our model.

Thus, we use Sympy to compute some key objects comprising the eigenvector decomposition of H.

We start by generating an H with nonzero δ.

```
λ, δ, ρ = symbols('λ, δ, ρ')
```

```
H1 = Matrix([[ρ,δ], [- (1 - λ) / λ, λ ** -1]])
```

```
H1
```

$$\begin{bmatrix} \rho & \delta \\ \frac{\lambda-1}{\lambda} & \frac{1}{\lambda} \end{bmatrix}$$

```
H1.eigenvals()
```

$$\left\{(\lambda\rho+1)/2\lambda - \sqrt{4\delta\lambda^2 - 4\delta\lambda + \lambda^2\rho^2 - 2\lambda\rho + 1}/2\lambda : 1,\ (\lambda\rho+1)/2\lambda + \sqrt{4\delta\lambda^2 - 4\delta\lambda + \lambda^2\rho^2 - 2\lambda\rho + 1}/2\lambda : 1\right\}$$

```
H1.eigenvects()
```

$$\left[\left(\frac{\lambda\rho+1}{2\lambda} - \frac{\sqrt{4\delta\lambda^2 - 4\delta\lambda + \lambda^2\rho^2 - 2\lambda\rho + 1}}{2\lambda},\ 1,\ \left[\begin{bmatrix} \frac{\lambda\left(\frac{\lambda\rho+1}{2\lambda} - \frac{\sqrt{4\delta\lambda^2-4\delta\lambda+\lambda^2\rho^2-2\lambda\rho+1}}{2\lambda}\right)}{\lambda-1} - \frac{1}{\lambda-1} \\ 1 \end{bmatrix}\right]\right),\ \left(\frac{\lambda\rho+1}{2\lambda} + \frac{\sqrt{4\delta\lambda^2 - 4\delta\lambda}\right.$$

Now let's compute H when δ is zero.

```
H2 = Matrix([[ρ,0], [- (1 - λ) / λ, λ ** -1]])
```

```
H2
```

$$\begin{bmatrix} \rho & 0 \\ \frac{\lambda-1}{\lambda} & \frac{1}{\lambda} \end{bmatrix}$$

```
H2.eigenvals()
```

$$\{1/\lambda : 1,\ \rho : 1\}$$

```
H2.eigenvects()
```

$$\left[\left(\frac{1}{\lambda},\ 1,\ \left[\begin{bmatrix}0\\1\end{bmatrix}\right]\right),\ \left(\rho,\ 1,\ \left[\begin{bmatrix}\frac{\lambda\rho-1}{\lambda-1}\\1\end{bmatrix}\right]\right)\right]$$

Below we do induce SymPy to do the following fun things for us analytically:

1. We compute the matrix Q whose first column is the eigenvector associated with ρ. and whose second column is the eigenvector associated with λ^{-1}.
2. We use SymPy to compute the inverse Q^{-1} of Q (both in symbols).
3. We use SymPy to compute $Q_{21}Q_{11}^{-1}$ (in symbols).
4. Where Q^{ij} denotes the (i,j) component of Q^{-1}, we use SymPy to compute $-(Q^{22})^{-1}Q^{21}$ (again in symbols)

```
# construct Q
vec = []
for i, (eigval, _, eigvec) in enumerate(H2.eigenvects()):

    vec.append(eigvec[0])

    if eigval == ρ:
        ind = i

Q = vec[ind].col_insert(1, vec[1-ind])
```

```
Q
```

$$\begin{bmatrix}\frac{\lambda\rho-1}{\lambda-1} & 0\\ 1 & 1\end{bmatrix}$$

Q^{-1}

```
Q_inv = Q ** (-1)
Q_inv
```

$$\begin{bmatrix}\frac{\lambda-1}{\lambda\rho-1} & 0\\ \frac{1-\lambda}{\lambda\rho-1} & 1\end{bmatrix}$$

$Q_{21}Q_{11}^{-1}$

```
Q[1, 0] / Q[0, 0]
```

$$\frac{\lambda-1}{\lambda\rho-1}$$

$-(Q^{22})^{-1}Q^{21}$

```
- Q_inv[1, 0] / Q_inv[1, 1]
```

$$-\frac{1-\lambda}{\lambda\rho-1}$$

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

122.1 Overview

This lecture describes the concept of Markov perfect equilibrium.

Markov perfect equilibrium is a key notion for analyzing economic problems involving dynamic strategic interaction, and a cornerstone of applied game theory.

In this lecture, we teach Markov perfect equilibrium by example.

We will focus on settings with

- two players
- quadratic payoff functions
- linear transition rules for the state

Other references include chapter 7 of [Ljungqvist and Sargent, 2018].

Let's start with some standard imports:

```
import matplotlib.pyplot as plt
import numpy as np
import quantecon as qe
```

122.2 Background

Markov perfect equilibrium is a refinement of the concept of Nash equilibrium.

It is used to study settings where multiple decision-makers interact non-cooperatively over time, each pursuing its own objective.

The agents in the model face a common state vector, the time path of which is influenced by – and influences – their decisions.

In particular, the transition law for the state that confronts each agent is affected by decision rules of other agents.

Individual payoff maximization requires that each agent solve a dynamic programming problem that includes this transition law.

Markov perfect equilibrium prevails when no agent wishes to revise its policy, taking as given the policies of all other agents.

Well known examples include

- Choice of price, output, location or capacity for firms in an industry (e.g., [Ericson and Pakes, 1995], [Ryan, 2012], [Doraszelski and Satterthwaite, 2010]).
- Rate of extraction from a shared natural resource, such as a fishery (e.g., [Levhari and Mirman, 1980], [Van Long, 2011]).

Let's examine a model of the first type.

122.2.1 Example: A Duopoly Model

Two firms are the only producers of a good, the demand for which is governed by a linear inverse demand function

$$p = a_0 - a_1(q_1 + q_2) \tag{122.1}$$

Here $p = p_t$ is the price of the good, $q_i = q_{it}$ is the output of firm $i = 1, 2$ at time t and $a_0 > 0, a_1 > 0$.

In (122.1) and what follows,

- the time subscript is suppressed when possible to simplify notation
- $\hat{x}$ denotes a next period value of variable x

Each firm recognizes that its output affects total output and therefore the market price.

The one-period payoff function of firm i is price times quantity minus adjustment costs:

$$\pi_i = pq_i - \gamma(\hat{q}_i - q_i)^2, \quad \gamma > 0, \tag{122.2}$$

Substituting the inverse demand curve (122.1) into (122.2) lets us express the one-period payoff as

$$\pi_i(q_i, q_{-i}, \hat{q}_i) = a_0 q_i - a_1 q_i^2 - a_1 q_i q_{-i} - \gamma(\hat{q}_i - q_i)^2, \tag{122.3}$$

where q_{-i} denotes the output of the firm other than i.

The objective of the firm is to maximize $\sum_{t=0}^{\infty} \beta^t \pi_{it}$.

Firm i chooses a decision rule that sets next period quantity $\hat{q}_i$ as a function f_i of the current state (q_i, q_{-i}).

An essential aspect of a Markov perfect equilibrium is that each firm takes the decision rule of the other firm as known and given.

Given f_{-i}, the Bellman equation of firm i is

$$v_i(q_i, q_{-i}) = \max_{\hat{q}_i} \{\pi_i(q_i, q_{-i}, \hat{q}_i) + \beta v_i(\hat{q}_i, f_{-i}(q_{-i}, q_i))\} \tag{122.4}$$

Definition 122.2.1 (Markov Perfect Equilibrium)

A **Markov perfect equilibrium** of the duopoly model is a pair of value functions (v_1, v_2) and a pair of policy functions (f_1, f_2) such that, for each $i \in \{1, 2\}$ and each possible state,

- The value function v_i satisfies Bellman equation (122.4).
- The maximizer on the right side of (122.4) equals $f_i(q_i, q_{-i})$.

The adjective "Markov" denotes that the equilibrium decision rules depend only on the current values of the state variables, not other parts of their histories.

"Perfect" means complete, in the sense that the equilibrium is constructed by backward induction and hence builds in optimizing behavior for each firm at all possible future states.

- These include many states that will not be reached when we iterate forward on the pair of equilibrium strategies f_i starting from a given initial state.

122.2.2 Computation

One strategy for computing a Markov perfect equilibrium is iterating to convergence on pairs of Bellman equations and decision rules.

In particular, let v_i^j, f_i^j be the value function and policy function for firm i at the j-th iteration.

Imagine constructing the iterates

$$v_i^{j+1}(q_i, q_{-i}) = \max_{\hat{q}_i} \left\{\pi_i(q_i, q_{-i}, \hat{q}_i) + \beta v_i^j(\hat{q}_i, f_{-i}(q_{-i}, q_i))\right\} \tag{122.5}$$

These iterations can be challenging to implement computationally.

However, they simplify for the case in which one-period payoff functions are quadratic and transition laws are linear — which takes us to our next topic.

122.3 Linear Markov Perfect Equilibria

As we saw in the duopoly example, the study of Markov perfect equilibria in games with two players leads us to an interrelated pair of Bellman equations.

In linear-quadratic dynamic games, these "stacked Bellman equations" become "stacked Riccati equations" with a tractable mathematical structure.

We'll lay out that structure in a general setup and then apply it to some simple problems.

122.3.1 Coupled Linear Regulator Problems

We consider a general linear-quadratic regulator game with two players.

For convenience, we'll start with a finite horizon formulation, where t_0 is the initial date and t_1 is the common terminal date.

Player i takes $\{u_{-it}\}$ as given and minimizes

$$\sum_{t=t_0}^{t_1-1} \beta^{t-t_0} \{x_t' R_i x_t + u_{it}' Q_i u_{it} + u_{-it}' S_i u_{-it} + 2x_t' W_i u_{it} + 2u_{-it}' M_i u_{it}\} \tag{122.6}$$

while the state evolves according to

$$x_{t+1} = Ax_t + B_1 u_{1t} + B_2 u_{2t} \tag{122.7}$$

Here

- x_t is an $n \times 1$ state vector and u_{it} is a $k_i \times 1$ vector of controls for player i
- R_i is $n \times n$
- S_i is $k_{-i} \times k_{-i}$
- Q_i is $k_i \times k_i$
- W_i is $n \times k_i$
- M_i is $k_{-i} \times k_i$
- A is $n \times n$
- B_i is $n \times k_i$

122.3.2 Computing Equilibrium

We formulate a linear Markov perfect equilibrium as follows.

Player i employs linear decision rules $u_{it} = -F_{it} x_t$, where F_{it} is a $k_i \times n$ matrix.

A Markov perfect equilibrium is a pair of sequences $\{F_{1t}, F_{2t}\}$ over $t = t_0, \ldots, t_1 - 1$ such that

- $\{F_{1t}\}$ solves player 1's problem, taking $\{F_{2t}\}$ as given, and
- $\{F_{2t}\}$ solves player 2's problem, taking $\{F_{1t}\}$ as given

If we take $u_{2t} = -F_{2t} x_t$ and substitute it into (122.6) and (122.7), then player 1's problem becomes minimization of

$$\sum_{t=t_0}^{t_1-1} \beta^{t-t_0} \{x_t' \Pi_{1t} x_t + u_{1t}' Q_1 u_{1t} + 2u_{1t}' \Gamma_{1t} x_t\} \tag{122.8}$$

subject to

$$x_{t+1} = \Lambda_{1t} x_t + B_1 u_{1t}, \tag{122.9}$$

where

- $\Lambda_{it} := A - B_{-i} F_{-it}$
- $\Pi_{it} := R_i + F_{-it}' S_i F_{-it}$
- $\Gamma_{it} := W_i' - M_i' F_{-it}$

This is an LQ dynamic programming problem that can be solved by working backwards.

Decision rules that solve this problem are

$$F_{1t} = (Q_1 + \beta B_1' P_{1t+1} B_1)^{-1} (\beta B_1' P_{1t+1} \Lambda_{1t} + \Gamma_{1t}) \tag{122.10}$$

where P_{1t} solves the matrix Riccati difference equation

$$P_{1t} = \Pi_{1t} - (\beta B_1' P_{1t+1} \Lambda_{1t} + \Gamma_{1t})' (Q_1 + \beta B_1' P_{1t+1} B_1)^{-1} (\beta B_1' P_{1t+1} \Lambda_{1t} + \Gamma_{1t}) + \beta \Lambda_{1t}' P_{1t+1} \Lambda_{1t} \tag{122.11}$$

Similarly, decision rules that solve player 2's problem are

$$F_{2t} = (Q_2 + \beta B_2' P_{2t+1} B_2)^{-1} (\beta B_2' P_{2t+1} \Lambda_{2t} + \Gamma_{2t}) \tag{122.12}$$

where P_{2t} solves

$$P_{2t} = \Pi_{2t} - (\beta B_2' P_{2t+1} \Lambda_{2t} + \Gamma_{2t})' (Q_2 + \beta B_2' P_{2t+1} B_2)^{-1} (\beta B_2' P_{2t+1} \Lambda_{2t} + \Gamma_{2t}) + \beta \Lambda_{2t}' P_{2t+1} \Lambda_{2t} \tag{122.13}$$

Here, in all cases $t = t_0, \ldots, t_1 - 1$ and the terminal conditions are $P_{it_1} = 0$.

The solution procedure is to use equations (122.10), (122.11), (122.12), and (122.13), and "work backwards" from time $t_1 - 1$.

Since we're working backward, P_{1t+1} and P_{2t+1} are taken as given at each stage.

Moreover, since

- some terms on the right-hand side of (122.10) contain F_{2t}
- some terms on the right-hand side of (122.12) contain F_{1t}

we need to solve these $k_1 + k_2$ equations simultaneously.

Key Insight

A key insight is that equations (122.10) and (122.12) are linear in F_{1t} and F_{2t}.

After these equations have been solved, we can take F_{it} and solve for P_{it} in (122.11) and (122.13).

Infinite Horizon

We often want to compute the solutions of such games for infinite horizons, in the hope that the decision rules F_{it} settle down to be time-invariant as $t_1 \to +\infty$.

In practice, we usually fix t_1 and compute the equilibrium of an infinite horizon game by driving $t_0 \to -\infty$.

This is the approach we adopt in the next section.

122.3.3 Implementation

We use the function nnash from QuantEcon.py that computes a Markov perfect equilibrium of the infinite horizon linear-quadratic dynamic game in the manner described above.

122.4 Application

Let's use these procedures to treat some applications, starting with the duopoly model.

122.4.1 A Duopoly Model

To map the duopoly model into coupled linear-quadratic dynamic programming problems, define the state and controls as

$$x_t := \begin{bmatrix} 1 \\ q_{1t} \\ q_{2t} \end{bmatrix} \quad \text{and} \quad u_{it} := q_{i,t+1} - q_{it}, \quad i = 1, 2$$

If we write

$$x_t' R_i x_t + u_{it}' Q_i u_{it}$$

where $Q_1 = Q_2 = \gamma$,

$$R_1 := \begin{bmatrix} 0 & -\frac{a_0}{2} & 0 \\ -\frac{a_0}{2} & a_1 & \frac{a_1}{2} \\ 0 & \frac{a_1}{2} & 0 \end{bmatrix} \quad \text{and} \quad R_2 := \begin{bmatrix} 0 & 0 & -\frac{a_0}{2} \\ 0 & 0 & \frac{a_1}{2} \\ -\frac{a_0}{2} & \frac{a_1}{2} & a_1 \end{bmatrix}$$

then we recover the one-period payoffs in expression (122.3).

The law of motion for the state x_t is $x_{t+1} = Ax_t + B_1 u_{1t} + B_2 u_{2t}$ where

$$A := \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad B_1 := \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}, \quad B_2 := \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix}$$

The optimal decision rule of firm i will take the form $u_{it} = -F_i x_t$, inducing the following closed-loop system for the evolution of x in the Markov perfect equilibrium:

$$x_{t+1} = (A - B_1 F_1 - B_1 F_2) x_t \tag{122.14}$$

122.4.2 Parameters and Solution

Consider the previously presented duopoly model with parameter values of:

- $a_0 = 10$
- $a_1 = 2$
- $\beta = 0.96$
- $\gamma = 12$

From these, we compute the infinite horizon MPE using the preceding code

```
import numpy as np
import quantecon as qe

# Parameters
a0 = 10.0
a1 = 2.0
```

(continues on next page)

(continued from previous page)

```
β = 0.96
γ = 12.0

# In LQ form
A = np.eye(3)
B1 = np.array([[0.], [1.], [0.]])
B2 = np.array([[0.], [0.], [1.]])

R1 = [[      0.,     -a0 / 2,           0.],
      [-a0 / 2.,           a1,     a1 / 2.],
      [       0,     a1 / 2.,           0.]]

R2 = [[     0.,           0.,      -a0 / 2],
      [     0.,           0.,      a1 / 2.],
      [-a0 / 2,      a1 / 2.,           a1]]

Q1 = Q2 = γ
S1 = S2 = W1 = W2 = M1 = M2 = 0.0

# Solve using QE's nnash function
F1, F2, P1, P2 = qe.nnash(A, B1, B2, R1, R2, Q1,
                          Q2, S1, S2, W1, W2, M1,
                          M2, beta=β)

# Display policies
print("Computed policies for firm 1 and firm 2:\n")
print(f"F1 = {F1}")
print(f"F2 = {F2}")
print("\n")
```

```
Computed policies for firm 1 and firm 2:

F1 = [[-0.66846615  0.29512482  0.07584666]]
F2 = [[-0.66846615  0.07584666  0.29512482]]
```

Running the code produces the following output.

One way to see that F_i is indeed optimal for firm i taking F_2 as given is to use QuantEcon.py's LQ class.

In particular, let's take F2 as computed above, plug it into (122.8) and (122.9) to get firm 1's problem and solve it using LQ.

We hope that the resulting policy will agree with F1 as computed above

```
beta = 0.96
Λ1 = A - B2 @ F2
lq1 = qe.LQ(Q1, R1, Λ1, B1, beta=beta)
P1_ih, F1_ih, d = lq1.stationary_values()
F1_ih
```

```
array([[-0.66846613,  0.29512482,  0.07584666]])
```

This is close enough for rock and roll, as they say in the trade.

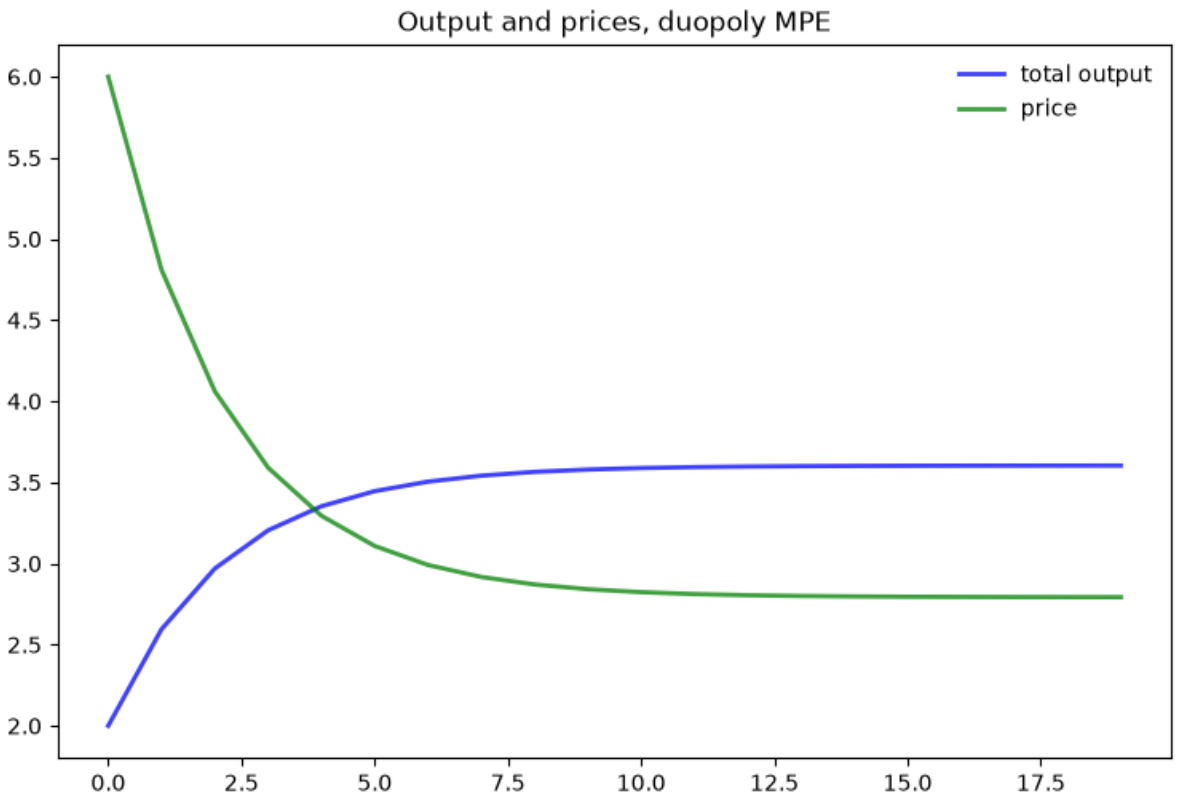
Indeed, np.allclose agrees with our assessment

```
np.allclose(F1, F1_ih)
```

```
True
```

122.4.3 Dynamics

Let's now investigate the dynamics of price and output in this simple duopoly model under the MPE policies.



Given our optimal policies $F1$ and $F2$, the state evolves according to (122.14).

The following program

- imports $F1$ and $F2$ from the previous program along with all parameters.
- computes the evolution of x_t using (122.14).
- extracts and plots industry output $q_t = q_{1t} + q_{2t}$ and price $p_t = a_0 - a_1 q_t$.

```
AF = A - B1 @ F1 - B2 @ F2
n = 20
x = np.empty((3, n))
x[:, 0] = 1, 1, 1
for t in range(n-1):
    x[:, t+1] = AF @ x[:, t]
q1 = x[1, :]
q2 = x[2, :]
q = q1 + q2        # Total output, MPE
p = a0 - a1 * q    # Price, MPE

fig, ax = plt.subplots(figsize=(9, 5.8))
ax.plot(q, 'b-', lw=2, alpha=0.75, label='total output')
ax.plot(p, 'g-', lw=2, alpha=0.75, label='price')
ax.set_title('Output and prices, duopoly MPE')
ax.legend(frameon=False)
plt.show()
```

Note that the initial condition has been set to $q_{10} = q_{20} = 1.0$.

To gain some perspective we can compare this to what happens in the monopoly case.

The first panel in the next figure compares output of the monopolist and industry output under the MPE, as a function of time.

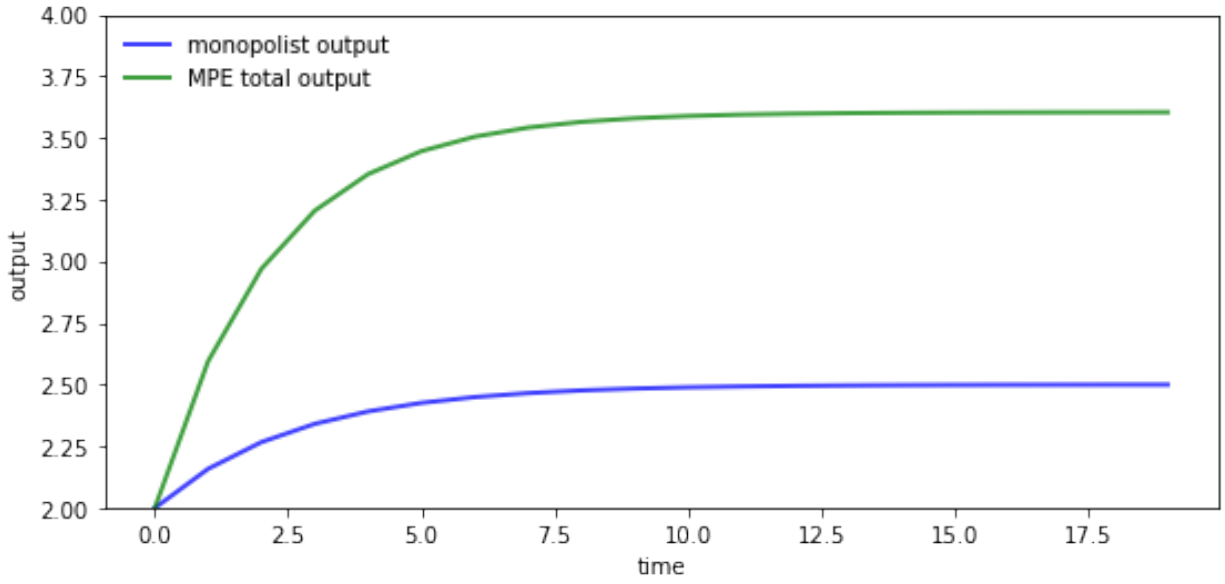
The second panel shows analogous curves for price.

Here parameters are the same as above for both the MPE and monopoly solutions.

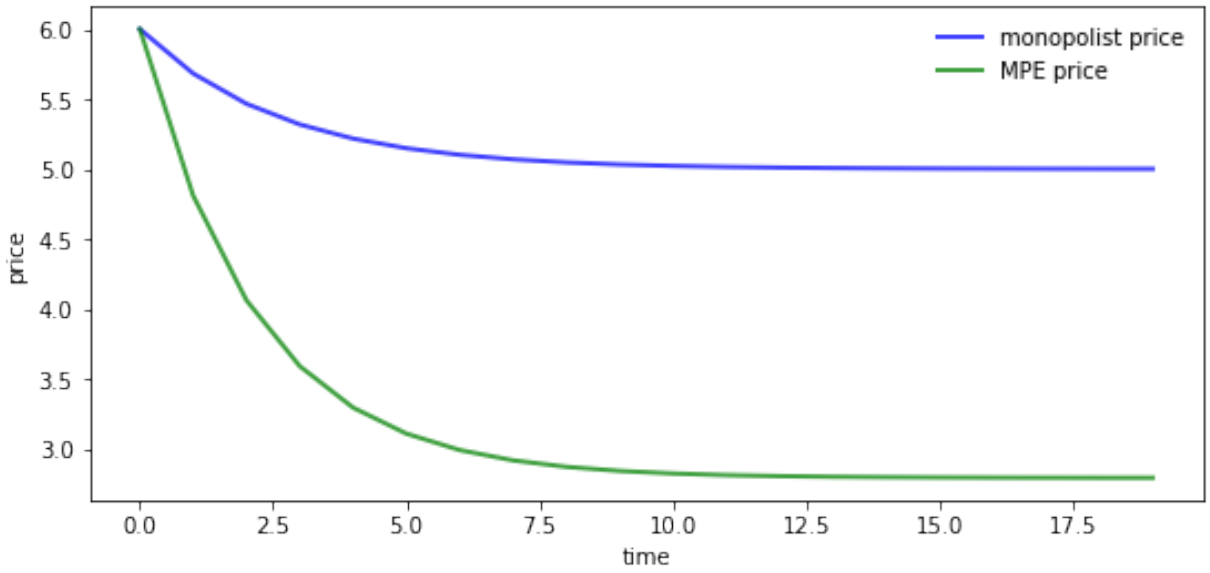
The monopolist initial condition is $q_0 = 2.0$ to mimic the industry initial condition $q_{10} = q_{20} = 1.0$ in the MPE case.

As expected, output is higher and prices are lower under duopoly than monopoly.

122.5 Exercises



Exercise 122.5.1



Replicate the *pair of figures* showing the comparison of output and prices for the monopolist and duopoly under MPE.

Parameters are as in duopoly_mpe.py and you can use that code to compute MPE policies under duopoly.

The optimal policy in the monopolist case can be computed using QuantEcon.py's LQ class.

Solution

monopolist output
MPE total output
output
time
4.00
3.75
3.50
3.25
3.00
2.75
2.50
2.25
2.00
0.0
2.5
5.0
7.5
10.0
12.5
15.0
17.5

monopolist price
MPE price
price
time
6.0
5.5
5.0
4.5
4.0
3.5
3.0
0.0
2.5
5.0
7.5
10.0
12.5
15.0
17.5

First, let's compute the duopoly MPE under the stated parameters

```
# == Parameters == #
a0 = 10.0
a1 = 2.0
β = 0.96
γ = 12.0

# == In LQ form == #
A  = np.eye(3)
B1 = np.array([[0.], [1.], [0.]])
B2 = np.array([[0.], [0.], [1.]])
R1 = [[      0.,      -a0/2,          0.],
      [-a0 / 2.,         a1,     a1 / 2.],
      [       0,    a1 / 2.,          0.]]

R2 = [[     0.,          0.,     -a0 / 2],
      [     0.,          0.,     a1 / 2.],
      [-a0 / 2,     a1 / 2.,          a1]]

Q1 = Q2 = γ
S1 = S2 = W1 = W2 = M1 = M2 = 0.0

# == Solve using QE's nnash function == #
F1, F2, P1, P2 = qe.nnash(A, B1, B2, R1, R2, Q1,
                          Q2, S1, S2, W1, W2, M1,
                          M2, beta=β)
```

Now we evaluate the time path of industry output and prices given initial condition $q_{10} = q_{20} = 1$.

```
AF = A - B1 @ F1 - B2 @ F2
n = 20
x = np.empty((3, n))
x[:, 0] = 1, 1, 1
for t in range(n-1):
    x[:, t+1] = AF @ x[:, t]
q1 = x[1, :]
q2 = x[2, :]
q = q1 + q2        # Total output, MPE
p = a0 - a1 * q    # Price, MPE
```

Next, let's have a look at the monopoly solution.

For the state and control, we take

$$x_t = q_t - \bar{q} \quad \text{and} \quad u_t = q_{t+1} - q_t$$

To convert to an LQ problem we set

$$R = a_1 \quad \text{and} \quad Q = \gamma$$

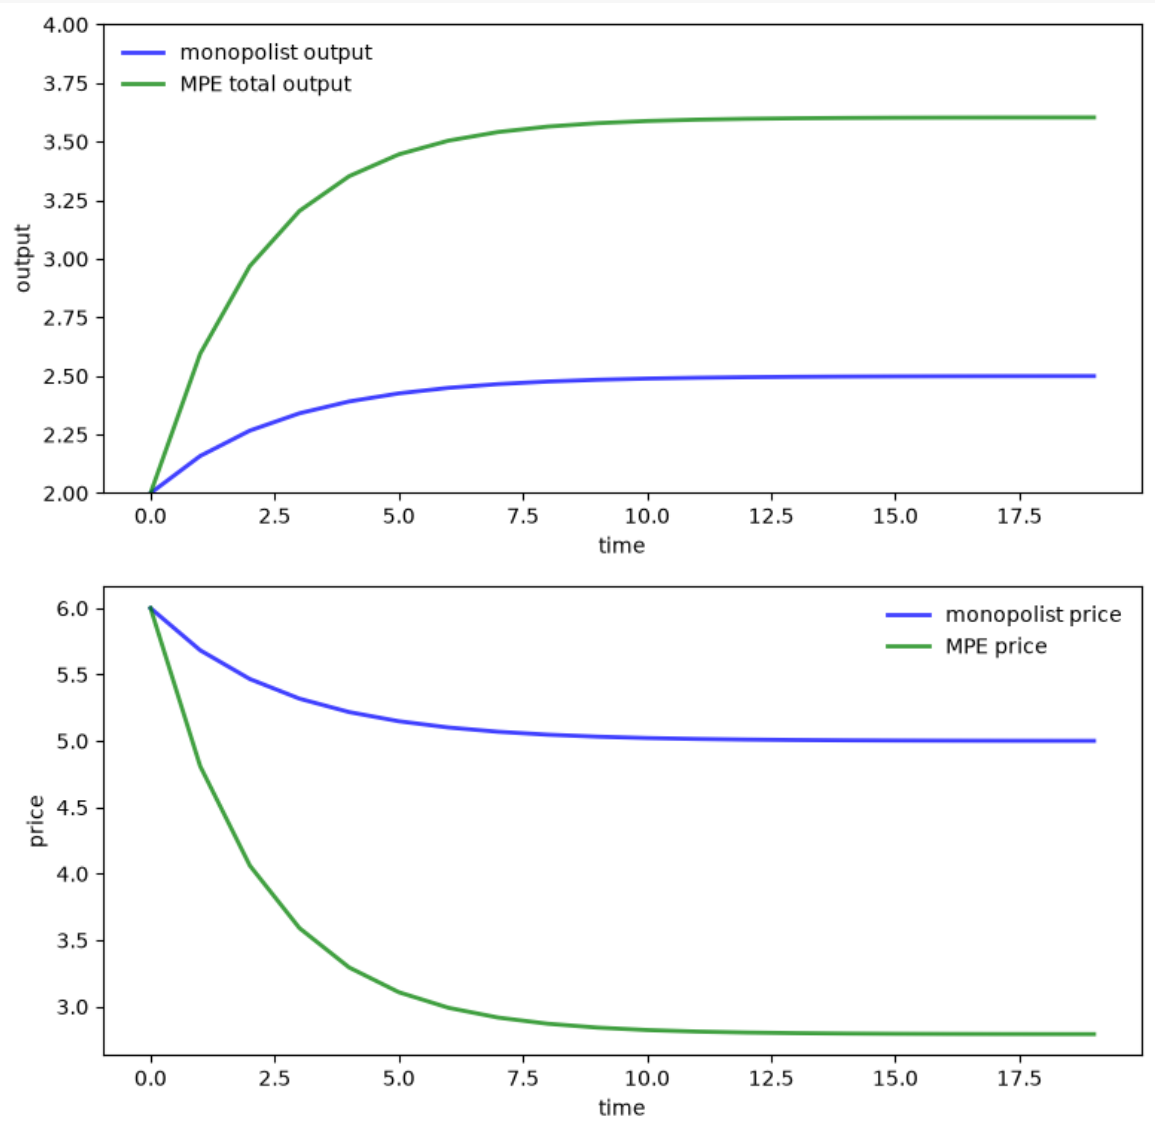
in the payoff function $x_t' R x_t + u_t' Q u_t$ and

$$A = B = 1$$

in the law of motion $x_{t+1} = A x_t + B u_t$.

We solve for the optimal policy $u_t = -F x_t$ and track the resulting dynamics of $\{q_t\}$, starting at $q_0 = 2.0$.

```
R = a1
Q = γ
```



```
A = B = 1
lq_alt = qe.LQ(Q, R, A, B, beta=β)
P, F, d = lq_alt.stationary_values()
q_bar = a0 / (2.0 * a1)
qm = np.empty(n)
qm[0] = 2
x0 = qm[0] - q_bar
x = x0
for i in range(1, n):
    x = A * x - B * F * x
    qm[i] = float(x.item()) + q_bar
pm = a0 - a1 * qm
```

Let's have a look at the different time paths

```
fig, axes = plt.subplots(2, 1, figsize=(9, 9))

ax = axes[0]
ax.plot(qm, 'b-', lw=2, alpha=0.75, label='monopolist output')
ax.plot(q, 'g-', lw=2, alpha=0.75, label='MPE total output')
ax.set(ylabel="output", xlabel="time", ylim=(2, 4))
ax.legend(loc='upper left', frameon=0)

ax = axes[1]
ax.plot(pm, 'b-', lw=2, alpha=0.75, label='monopolist price')
ax.plot(p, 'g-', lw=2, alpha=0.75, label='MPE price')
ax.set(ylabel="price", xlabel="time")
ax.legend(loc='upper right', frameon=0)
plt.show()
```

Exercise 122.5.2

In this exercise, we consider a slightly more sophisticated duopoly problem.

It takes the form of infinite horizon linear-quadratic game proposed by Judd [Judd, 1990].

Two firms set prices and quantities of two goods interrelated through their demand curves.

Relevant variables are defined as follows:

- I_{it} = inventories of firm i at beginning of t
- q_{it} = production of firm i during period t
- p_{it} = price charged by firm i during period t
- S_{it} = sales made by firm i during period t
- E_{it} = costs of production of firm i during period t

- C_{it} = costs of carrying inventories for firm i during t

The firms' cost functions are

- $C_{it} = c_{i1} + c_{i2} I_{it} + 0.5 c_{i3} I_{it}^2$
- $E_{it} = e_{i1} + e_{i2} q_{it} + 0.5 e_{i3} q_{it}^2$ where e_{ij}, c_{ij} are positive scalars

Inventories obey the laws of motion

$$I_{i,t+1} = (1 - \delta) I_{it} + q_{it} - S_{it}$$

Demand is governed by the linear schedule

$$S_t = D p_{it} + b$$

where

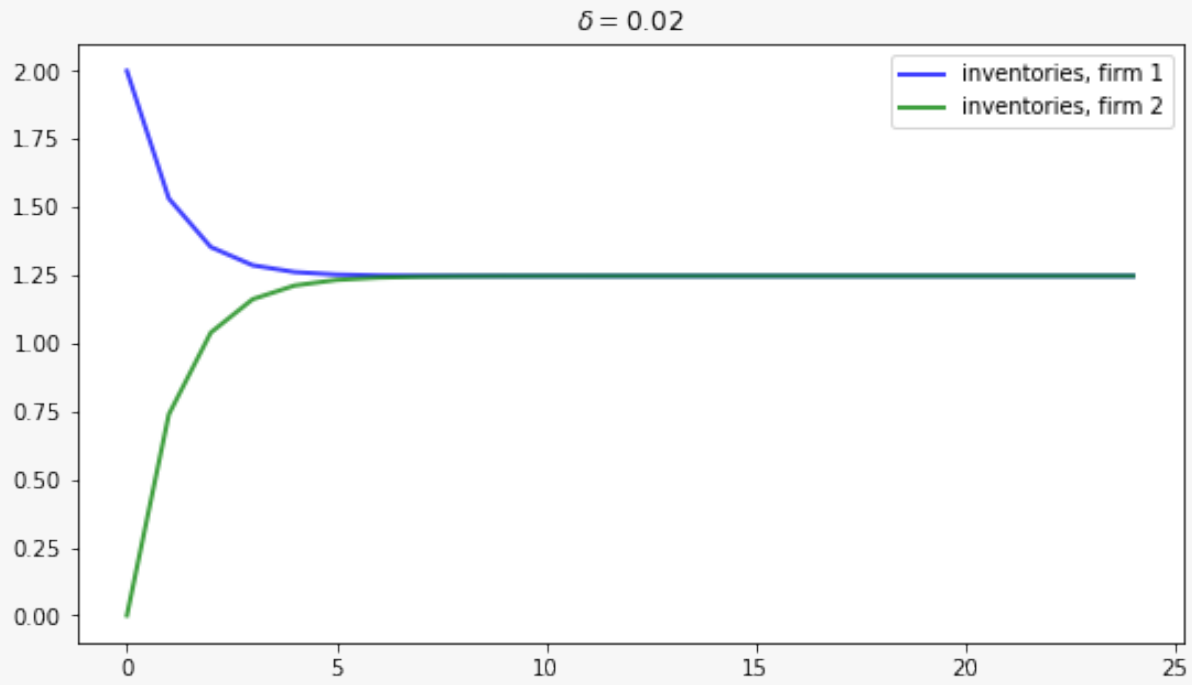
- $S_t = \begin{bmatrix} S_{1t} & S_{2t} \end{bmatrix}'$
- D is a 2×2 negative definite matrix and
- b is a vector of constants

Firm i maximizes the undiscounted sum

$$\lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T} (p_{it} S_{it} - E_{it} - C_{it})$$

We can convert this to a linear-quadratic problem by taking

$$u_{it} = \begin{bmatrix} p_{it} \\ q_{it} \end{bmatrix} \quad \text{and} \quad x_t = \begin{bmatrix} I_{1t} \\ I_{2t} \\ 1 \end{bmatrix}$$

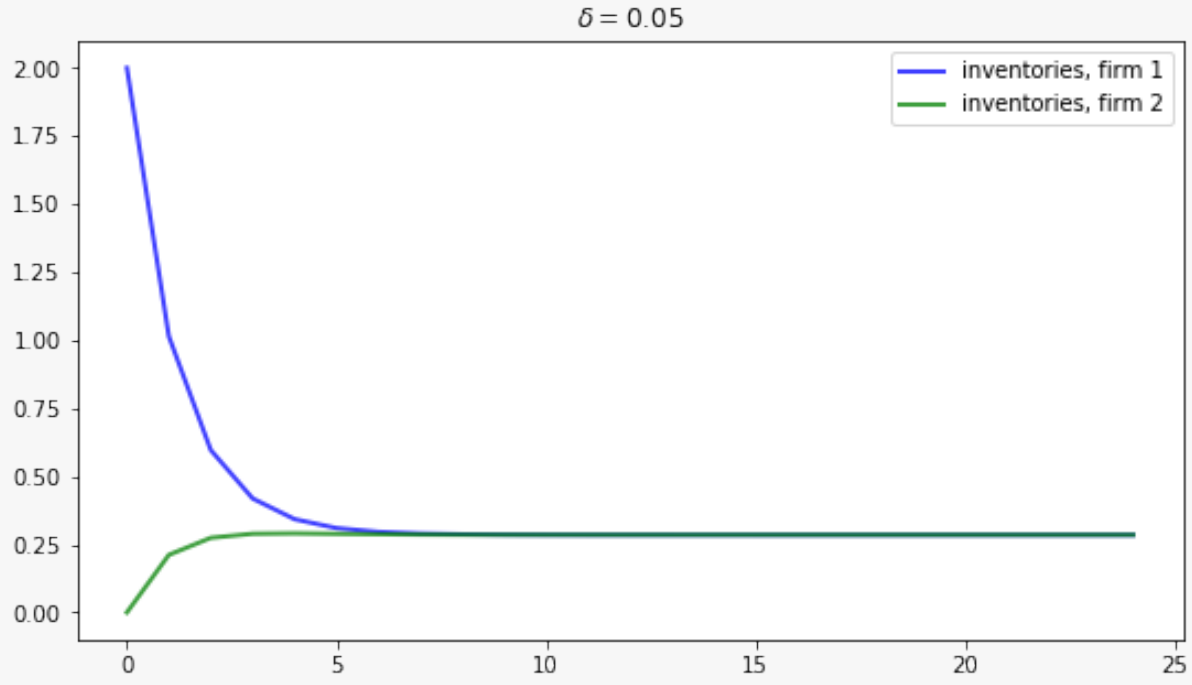


Decision rules for price and quantity take the form $u_{it} = -F_i x_t$.

The Markov perfect equilibrium of Judd's model can be computed by filling in the matrices appropriately.

The exercise is to calculate these matrices and compute the following figures.

The first figure shows the dynamics of inventories for each firm when the parameters are



```
δ = 0.02
D = np.array([[-1, 0.5], [0.5, -1]])
b = np.array([25, 25])
c1 = c2 = np.array([1, -2, 1])
e1 = e2 = np.array([10, 10, 3])
```

Inventories trend to a common steady state.

If we increase the depreciation rate to $\delta = 0.05$, then we expect steady state inventories to fall.

This is indeed the case, as the next figure shows

In this exercise, reproduce the figure when $\delta = 0.02$.

Solution

We treat the case $\delta = 0.02$

```
δ = 0.02
D = np.array([[-1, 0.5], [0.5, -1]])
b = np.array([25, 25])
c1 = c2 = np.array([1, -2, 1])
e1 = e2 = np.array([10, 10, 3])

δ_1 = 1 - δ
```

Recalling that the control and state are

$$u_{it} = \begin{bmatrix} p_{it} \\ q_{it} \end{bmatrix} \quad \text{and} \quad x_t = \begin{bmatrix} I_{1t} \\ I_{2t} \\ 1 \end{bmatrix}$$

we set up the matrices as follows:

```
# ==  Create matrices needed to compute the Nash feedback equilibrium == #

A = np.array([[δ_1,      0,     -δ_1 * b[0]],
              [  0,    δ_1,     -δ_1 * b[1]],
              [  0,      0,               1]])

B1 = δ_1 * np.array([[1, -D[0, 0]],
                     [0, -D[1, 0]],
                     [0,       0]])
B2 = δ_1 * np.array([[0, -D[0, 1]],
                     [1, -D[1, 1]],
                     [0,       0]])

R1 = -np.array([[0.5 * c1[2],      0,     0.5 * c1[1]],
                [          0,      0,               0],
                [0.5 * c1[1],      0,         c1[0]]])
R2 = -np.array([[0,                0,               0],
                [0,      0.5 * c2[2],     0.5 * c2[1]],
                [0,      0.5 * c2[1],         c2[0]]])

Q1 = np.array([[-0.5 * e1[2], 0], [0, D[0, 0]]])
Q2 = np.array([[-0.5 * e2[2], 0], [0, D[1, 1]]])

S1 = np.zeros((2, 2))
S2 = np.copy(S1)

W1 = np.array([[           0,             0],
               [           0,             0],
               [-0.5 * e1[1],    b[0] / 2.]])
W2 = np.array([[           0,             0],
               [           0,             0],
               [-0.5 * e2[1],    b[1] / 2.]])

M1 = np.array([[0, 0], [0, D[0, 1] / 2.]])
M2 = np.copy(M1)
```

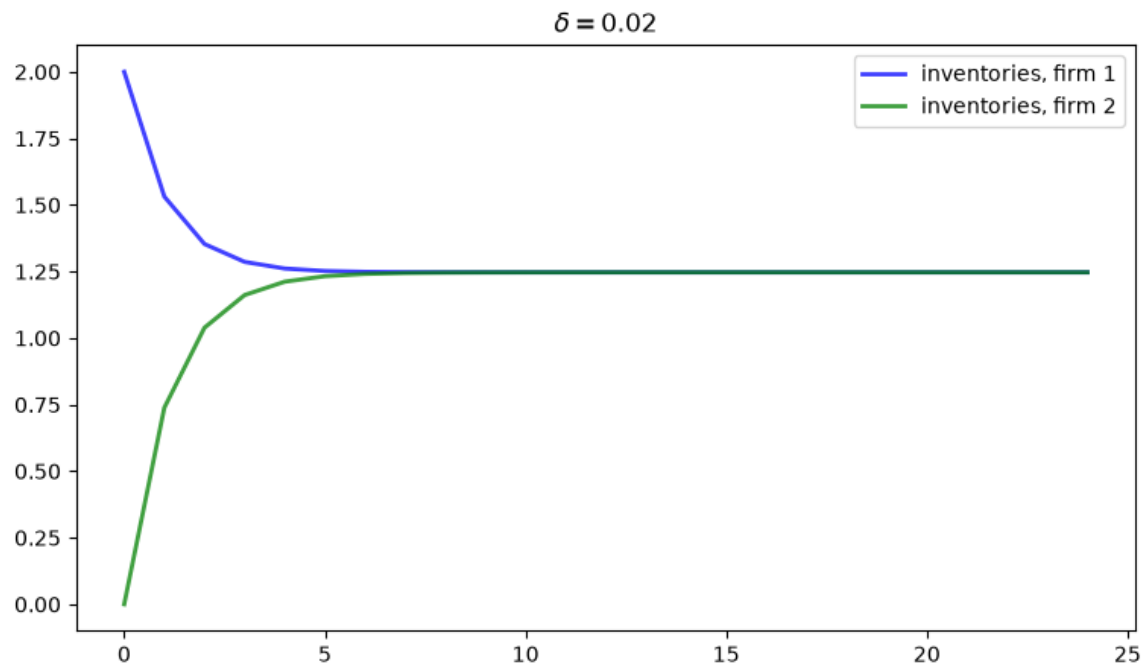
We can now compute the equilibrium using `qe.nnash`

```
F1, F2, P1, P2 = qe.nnash(A, B1, B2, R1,
                          R2, Q1, Q2, S1,
                          S2, W1, W2, M1, M2)

print("\nFirm 1's feedback rule:\n")
print(F1)

print("\nFirm 2's feedback rule:\n")
print(F2)
```

```
Firm 1's feedback rule:



[[ 2.43666582e-01  2.72360627e-02 -6.82788293e+00]
 [ 3.92370734e-01  1.39696451e-01 -3.77341073e+01]]

Firm 2's feedback rule:

[[ 2.72360627e-02  2.43666582e-01 -6.82788293e+00]
 [ 1.39696451e-01  3.92370734e-01 -3.77341073e+01]]
```

Now let's look at the dynamics of inventories, and reproduce the graph corresponding to $\delta = 0.02$

```
AF = A - B1 @ F1 - B2 @ F2
n = 25
x = np.empty((3, n))
x[:, 0] = 2, 0, 1
for t in range(n-1):
    x[:, t+1] = AF @ x[:, t]
I1 = x[0, :]
I2 = x[1, :]
fig, ax = plt.subplots(figsize=(9, 5))
ax.plot(I1, 'b-', lw=2, alpha=0.75, label='inventories, firm 1')
ax.plot(I2, 'g-', lw=2, alpha=0.75, label='inventories, firm 2')
ax.set_title(rf'$\delta = {δ}$')
ax.legend()
plt.show()
```

$\delta = 0.02$
inventories, firm 1
inventories, firm 2

  - *Results*
  - *Exercises*

123.1 Overview

In this lecture, we study a simplified version of an uncertainty traps model of Fajgelbaum, Schaal and Taschereau-Dumouchel [Fajgelbaum *et al.*, 2015].

The model features self-reinforcing uncertainty that has big impacts on economic activity.

In the model,

- Fundamentals vary stochastically and are not fully observable.
- At any moment there are both active and inactive entrepreneurs; only active entrepreneurs produce.
- Agents – active and inactive entrepreneurs – have beliefs about the fundamentals expressed as probability distributions.
- Greater uncertainty means greater dispersions of these distributions.
- Entrepreneurs are risk-averse and hence less inclined to be active when uncertainty is high.
- The output of active entrepreneurs is observable, supplying a noisy signal that helps everyone inside the model infer fundamentals.
- Entrepreneurs update their beliefs about fundamentals using Bayes' Law, implemented via *Kalman filtering*.

Uncertainty traps emerge because:

- High uncertainty discourages entrepreneurs from becoming active.
- A low level of participation – i.e., a smaller number of active entrepreneurs – diminishes the flow of information about fundamentals.

- Less information translates to higher uncertainty, further discouraging entrepreneurs from choosing to be active, and so on.

Uncertainty traps stem from a positive externality: high aggregate economic activity levels generates valuable information.

Let's start with some standard imports:

```
import matplotlib.pyplot as plt
import numpy as np
```

123.2 The Model

The original model described in [Fajgelbaum *et al.*, 2015] has many interesting moving parts.

Here we examine a simplified version that nonetheless captures many of the key ideas.

123.2.1 Fundamentals

The evolution of the fundamental process $\{\theta_t\}$ is given by

$$\theta_{t+1} = \rho\theta_t + \sigma_\theta w_{t+1}$$

where

- $\sigma_\theta > 0$ and $0 < \rho < 1$
- $\{w_t\}$ is IID and standard normal

The random variable θ_t is not observable at any time.

123.2.2 Output

There is a total $\bar{M}$ of risk-averse entrepreneurs.

Output of the m-th entrepreneur, conditional on being active in the market at time t, is equal to

$$x_m = \theta + \epsilon_m \quad \text{where} \quad \epsilon_m \sim N\left(0, \gamma_x^{-1}\right) \tag{123.1}$$

Here the time subscript has been dropped to simplify notation.

The inverse of the shock variance, γ_x, is called the shock's **precision**.

The higher is the precision, the more informative x_m is about the fundamental.

Output shocks are independent across time and firms.

123.2.3 Information and Beliefs

All entrepreneurs start with identical beliefs about θ_0.

Signals are publicly observable and hence all agents have identical beliefs always.

Dropping time subscripts, beliefs for current θ are represented by the normal distribution $N(\mu, \gamma^{-1})$.

Here γ is the precision of beliefs; its inverse is the degree of uncertainty.

These parameters are updated by Kalman filtering.

Let

- $\mathbb{M} \subset \{1, \ldots, \bar{M}\}$ denote the set of currently active firms.
- $M := |\mathbb{M}|$ denote the number of currently active firms.
- X be the average output $\frac{1}{M}\sum_{m \in \mathbb{M}} x_m$ of the active firms.

With this notation and primes for next period values, we can write the updating of the mean and precision via

$$\mu' = \rho \frac{\gamma\mu + M\gamma_x X}{\gamma + M\gamma_x} \tag{123.2}$$

$$\gamma' = \left(\frac{\rho^2}{\gamma + M\gamma_x} + \sigma_\theta^2 \right)^{-1} \tag{123.3}$$

These are standard Kalman filtering results applied to the current setting.

Exercise 1 provides more details on how (123.2) and (123.3) are derived and then asks you to fill in remaining steps.

The next figure plots the law of motion for the precision in (123.3) as a 45 degree diagram, with one curve for each $M \in \{0, \ldots, 6\}$.

The other parameter values are $\rho = 0.99, \gamma_x = 0.5, \sigma_\theta = 0.5$

Points where the curves hit the 45 degree lines are long-run steady states for precision for different values of M.

Thus, if one of these values for M remains fixed, a corresponding steady state is the equilibrium level of precision

- high values of M correspond to greater information about the fundamental, and hence more precision in steady state
- low values of M correspond to less information and more uncertainty in steady state

In practice, as we'll see, the number of active firms fluctuates stochastically.

123.2.4 Participation

Omitting time subscripts once more, entrepreneurs enter the market in the current period if

$$\mathbb{E}[u(x_m - F_m)] > c \tag{123.4}$$

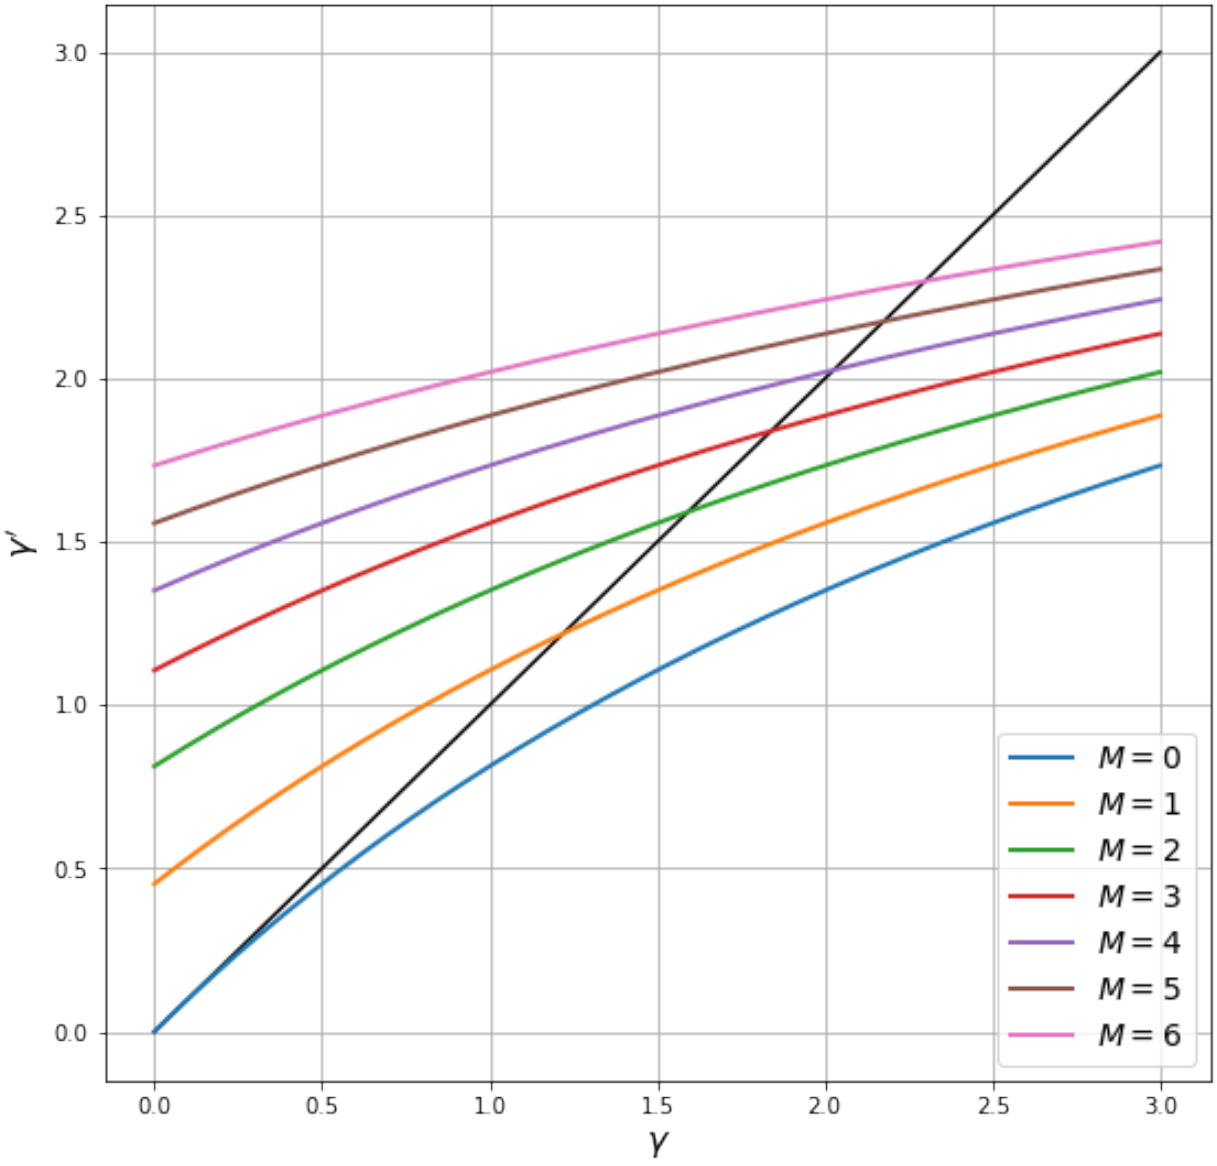
Here

- the mathematical expectation of x_m is based on (123.1) and beliefs $N(\mu, \gamma^{-1})$ for θ
- F_m is a stochastic but pre-visible fixed cost, independent across time and firms
- c is a constant reflecting opportunity costs

The statement that F_m is pre-visible means that it is realized at the start of the period and treated as a constant in (123.4).

The utility function has the constant absolute risk aversion form

$$u(x) = \frac{1}{a}\left(1 - \exp(-ax)\right) \tag{123.5}$$



where a is a positive parameter.

Combining (123.4) and (123.5), entrepreneur m participates in the market (or is said to be active) when

$$\frac{1}{a}\left\{1 - \mathbb{E}[\exp\left(-a(\theta + \epsilon_m - F_m)\right)]\right\} > c$$

Using standard formulas for expectations of lognormal random variables, this is equivalent to the condition

$$\psi(\mu, \gamma, F_m) := \frac{1}{a}\left(1 - \exp\left(-a\mu + aF_m + \frac{a^2\left(\frac{1}{\gamma} + \frac{1}{\gamma_x}\right)}{2}\right)\right) - c > 0 \tag{123.6}$$

123.3 Implementation

We want to simulate this economy.

As a first step, let's put together a class that bundles

- the parameters, the current value of θ and the current values of the two belief parameters μ and γ
- methods to update θ, μ and γ, as well as to determine the number of active firms and their outputs

The updating methods follow the laws of motion for θ, μ and γ given above.

The method to evaluate the number of active firms generates $F_1, \ldots, F_{\bar{M}}$ and tests condition (123.6) for each firm.

The **init** method encodes as default values the parameters we'll use in the simulations below

```
class UncertaintyTrapEcon:

    def __init__(self,
                 a=1.5,           # Risk aversion
                 γ_x=0.5,         # Production shock precision
                 ρ=0.99,          # Correlation coefficient for θ
                 σ_θ=0.5,         # Standard dev of θ shock
                 num_firms=100,   # Number of firms
                 σ_F=1.5,         # Standard dev of fixed costs
                 c=-420,          # External opportunity cost
                 μ_init=0,        # Initial value for μ
                 γ_init=4,        # Initial value for γ
                 θ_init=0):       # Initial value for θ

        # == Record values == #
        self.a, self.γ_x, self.ρ, self.σ_θ = a, γ_x, ρ, σ_θ
        self.num_firms, self.σ_F, self.c, = num_firms, σ_F, c
        self.σ_x = np.sqrt(1/γ_x)

        # == Initialize states == #
        self.γ, self.μ, self.θ = γ_init, μ_init, θ_init

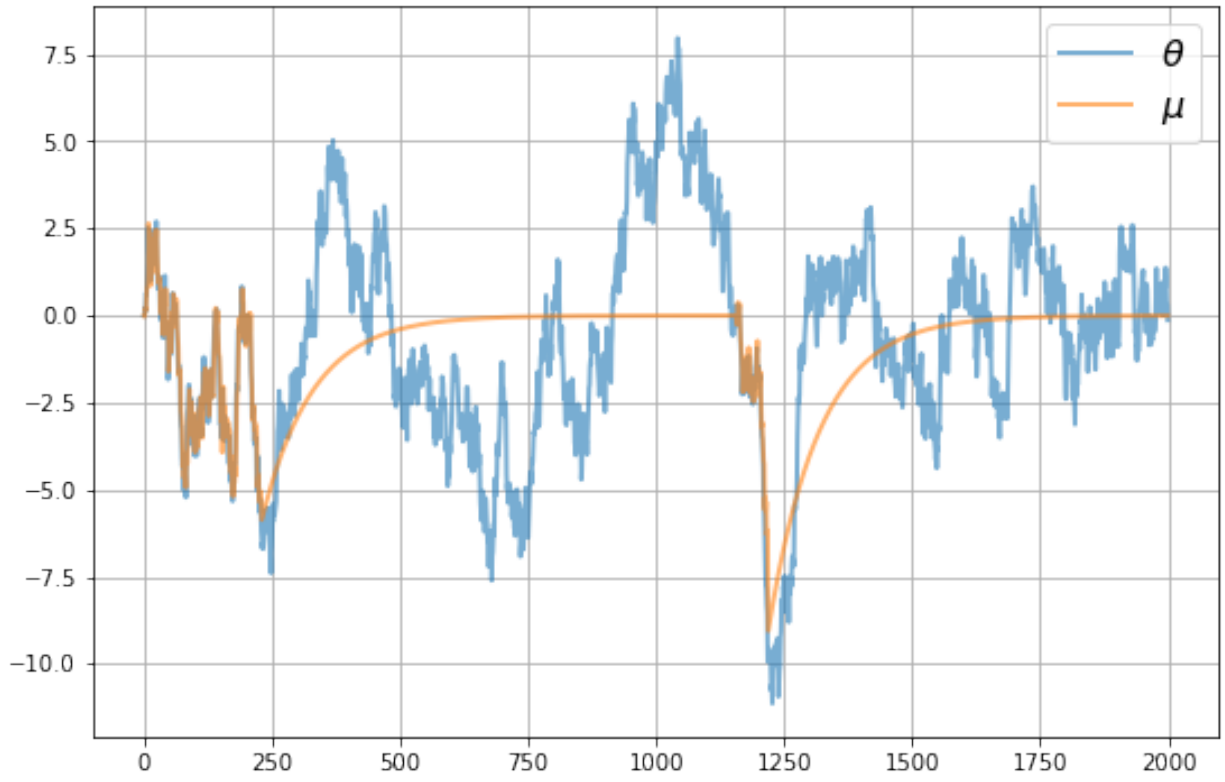
    def ψ(self, F):
        temp1 = -self.a * (self.μ - F)
        temp2 = self.a**2 * (1/self.γ + 1/self.γ_x) / 2
        return (1 / self.a) * (1 - np.exp(temp1 + temp2)) - self.c

    def update_beliefs(self, X, M):
        """
        Update beliefs (μ, γ) based on aggregates X and M.
        """
        # Simplify names
        γ_x, ρ, σ_θ = self.γ_x, self.ρ, self.σ_θ
        # Update μ
        temp1 = ρ * (self.γ * self.μ + M * γ_x * X)
        temp2 = self.γ + M * γ_x
        self.μ = temp1 / temp2
        # Update γ
        self.γ = 1 / (ρ**2 / (self.γ + M * γ_x) + σ_θ**2)

    def update_θ(self, w):
        """
        Update the fundamental state θ given shock w.
```

(continues on next page)

(continued from previous page)



```
        """
        self.θ = self.ρ * self.θ + self.σ_θ * w

    def gen_aggregates(self, rng):
        """
        Generate aggregates based on current beliefs (μ, γ). This
        is a simulation step that depends on the draws for F.
        """
        F_vals = self.σ_F * rng.standard_normal(self.num_firms)
        M = np.sum(self.ψ(F_vals) > 0)  # Counts number of active firms
        if M > 0:
            x_vals = self.θ + self.σ_x * rng.standard_normal(M)
            X = x_vals.mean()
        else:
            X = 0
        return X, M
```

In the results below we use this code to simulate time series for the major variables.

123.4 Results

Let's look first at the dynamics of μ, which the agents use to track θ

We see that μ tracks θ well when there are sufficient firms in the market.

However, there are times when μ tracks θ poorly due to insufficient information.

These are episodes where the uncertainty traps take hold.

During these episodes

- precision is low and uncertainty is high
- few firms are in the market

To get a clearer idea of the dynamics, let's look at all the main time series at once, for a given set of shocks

Notice how the traps only take hold after a sequence of bad draws for the fundamental.

Thus, the model gives us a **propagation mechanism** that maps bad random draws into long downturns in economic activity.

123.5 Exercises

Exercise 123.5.1

Fill in the details behind (123.2) and (123.3) based on the following standard result (see, e.g., p. 24 of [Young and Smith, 2005]).

Fact Let $\mathbf{x} = (x_1, \ldots, x_M)$ be a vector of IID draws from common distribution $N(\theta, 1/\gamma_x)$ and let $\bar{x}$ be the sample mean. If γ_x is known and the prior for θ is $N(\mu, 1/\gamma)$, then the posterior distribution of θ given $\mathbf{x}$ is

$$\pi(\theta \,|\, \mathbf{x}) = N(\mu_0, 1/\gamma_0)$$

where

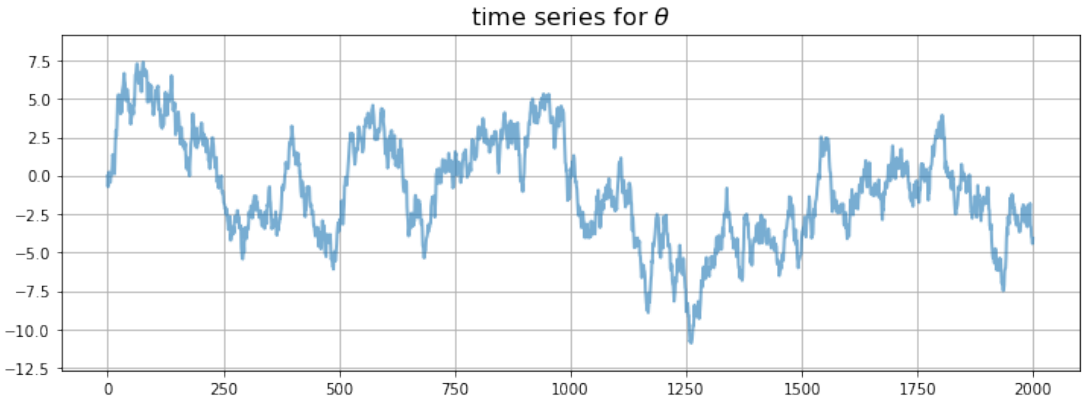
$$\mu_0 = \frac{\mu\gamma + M\bar{x}\gamma_x}{\gamma + M\gamma_x} \quad \text{and} \quad \gamma_0 = \gamma + M\gamma_x$$

Solution

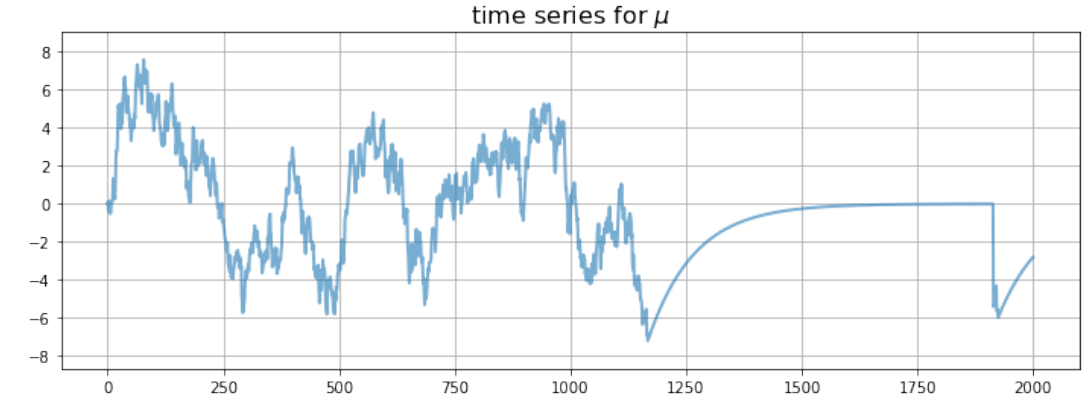
This exercise asked you to validate the laws of motion for γ and μ given in the lecture, based on the stated result about Bayesian updating in a scalar Gaussian setting. The stated result tells us that after observing average output X of the M firms, our posterior beliefs will be

$$N(\mu_0, 1/\gamma_0)$$

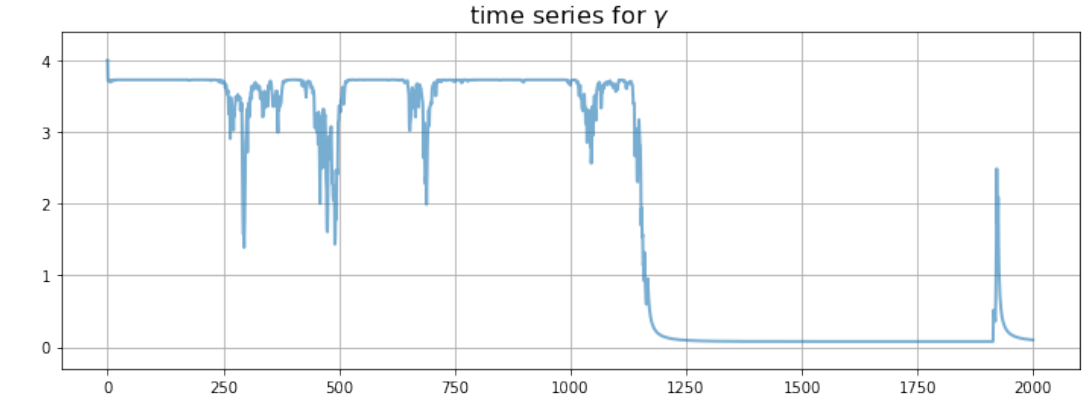
where



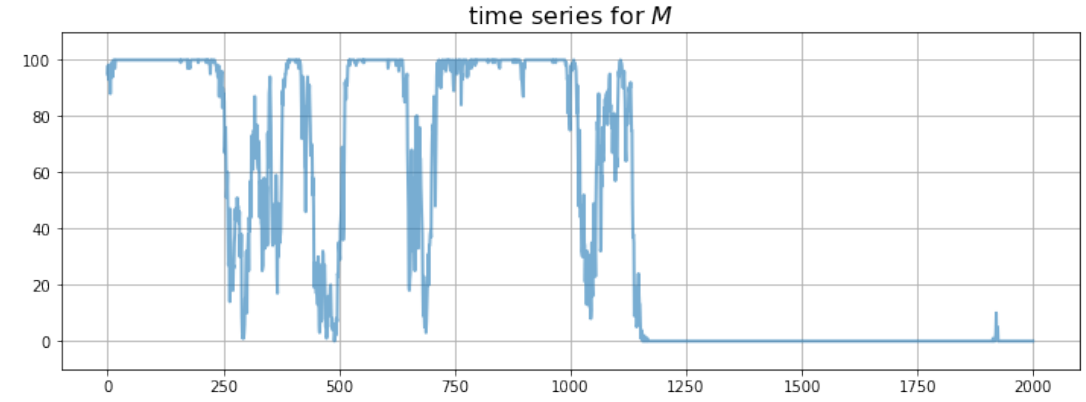
$$\mu_0 = \frac{\mu\gamma + MX\gamma_x}{\gamma + M\gamma_x} \quad \text{and} \quad \gamma_0 = \gamma + M\gamma_x$$



If we take a random variable θ with this distribution and then evaluate the distribution of $\rho\theta + \sigma_\theta w$ where w is independent and standard normal, we get the expressions for μ' and γ' given in the lecture.



Exercise 123.5.2



Modulo randomness, replicate the simulation figures shown above.

- Use the parameter values listed as defaults in the **init** method of the UncertaintyTrapEcon class.

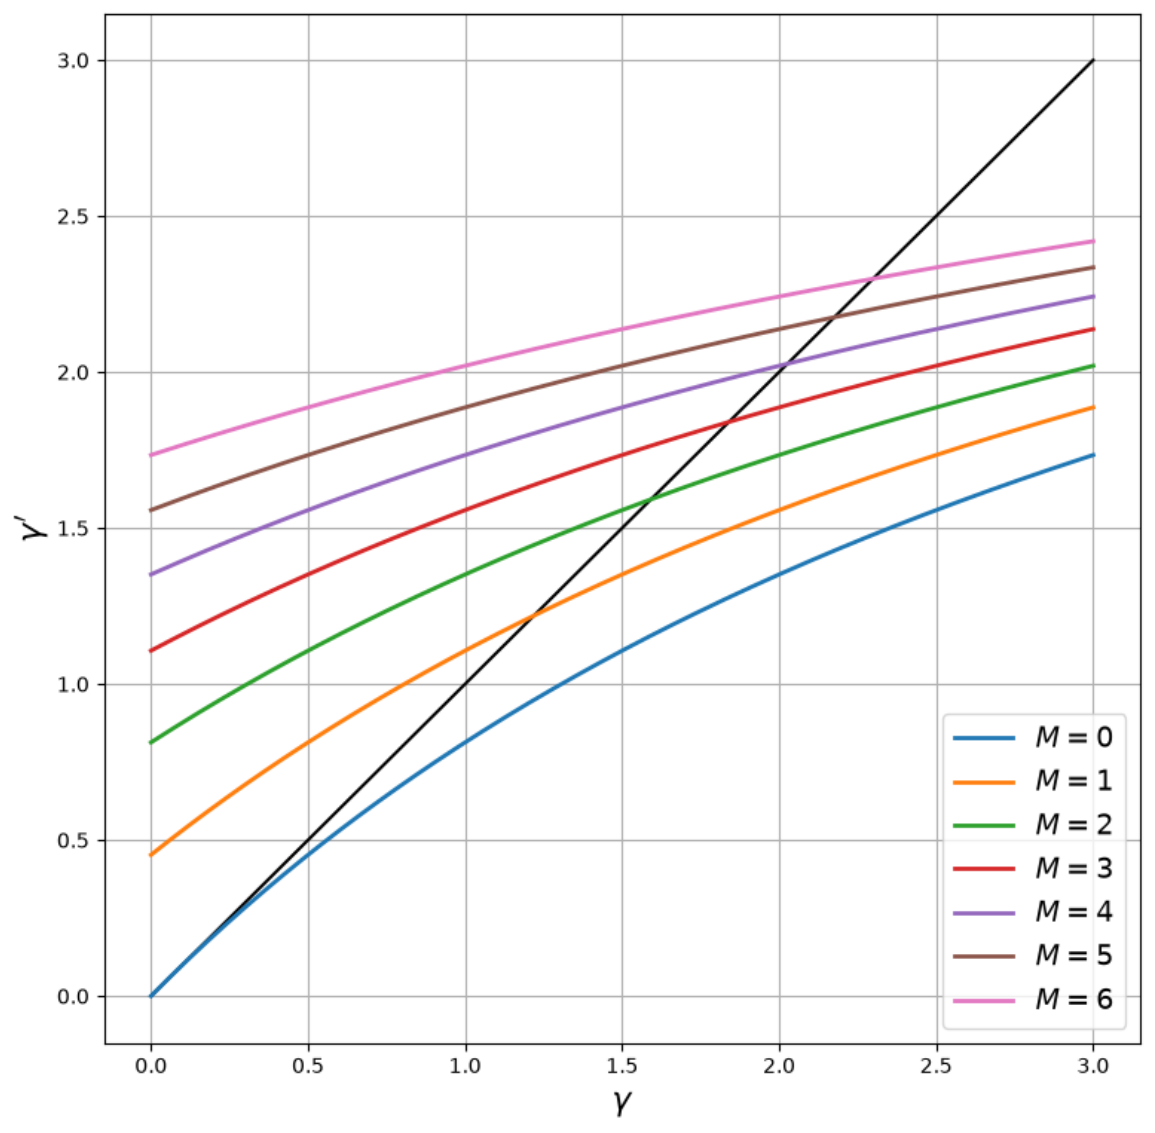
Solution



First, let's replicate the plot that illustrates the law of motion for precision, which is

$$\gamma_{t+1} = \left(\frac{\rho^2}{\gamma_t + M\gamma_x} + \sigma_\theta^2 \right)^{-1}$$

Here M is the number of active firms. The next figure plots γ_{t+1} against γ_t on a 45 degree diagram for different values of M

```
econ = UncertaintyTrapEcon()
ρ, σ_θ, γ_x = econ.ρ, econ.σ_θ, econ.γ_x    # Simplify names
γ = np.linspace(1e-10, 3, 200)              # γ grid
fig, ax = plt.subplots(figsize=(9, 9))
ax.plot(γ, γ, 'k-')                         # 45 degree line

for M in range(7):
    γ_next = 1 / (ρ**2 / (γ + M * γ_x) + σ_θ**2)
    label_string = f"$M = {M}$"
    ax.plot(γ, γ_next, lw=2, label=label_string)
ax.legend(loc='lower right', fontsize=14)
ax.set_xlabel(r'$\gamma$', fontsize=16)
ax.set_ylabel(r"$\gamma'$", fontsize=16)
ax.grid()
plt.show()
```

The points where the curves hit the 45 degree lines are the long-run steady states corresponding to each M, if that value of M was to remain fixed. As the number of firms falls, so does the long-run steady state of precision.

Next let's generate time series for beliefs and the aggregates – that is, the number of active firms and average output

```
sim_length=2000

μ_vec = np.empty(sim_length)
θ_vec = np.empty(sim_length)
γ_vec = np.empty(sim_length)
X_vec = np.empty(sim_length)
M_vec = np.empty(sim_length)

μ_vec[0] = econ.μ
γ_vec[0] = econ.γ
θ_vec[0] = 0

rng = np.random.default_rng()
w_shocks = rng.standard_normal(sim_length)

for t in range(sim_length-1):
    X, M = econ.gen_aggregates(rng)
    X_vec[t] = X
    M_vec[t] = M

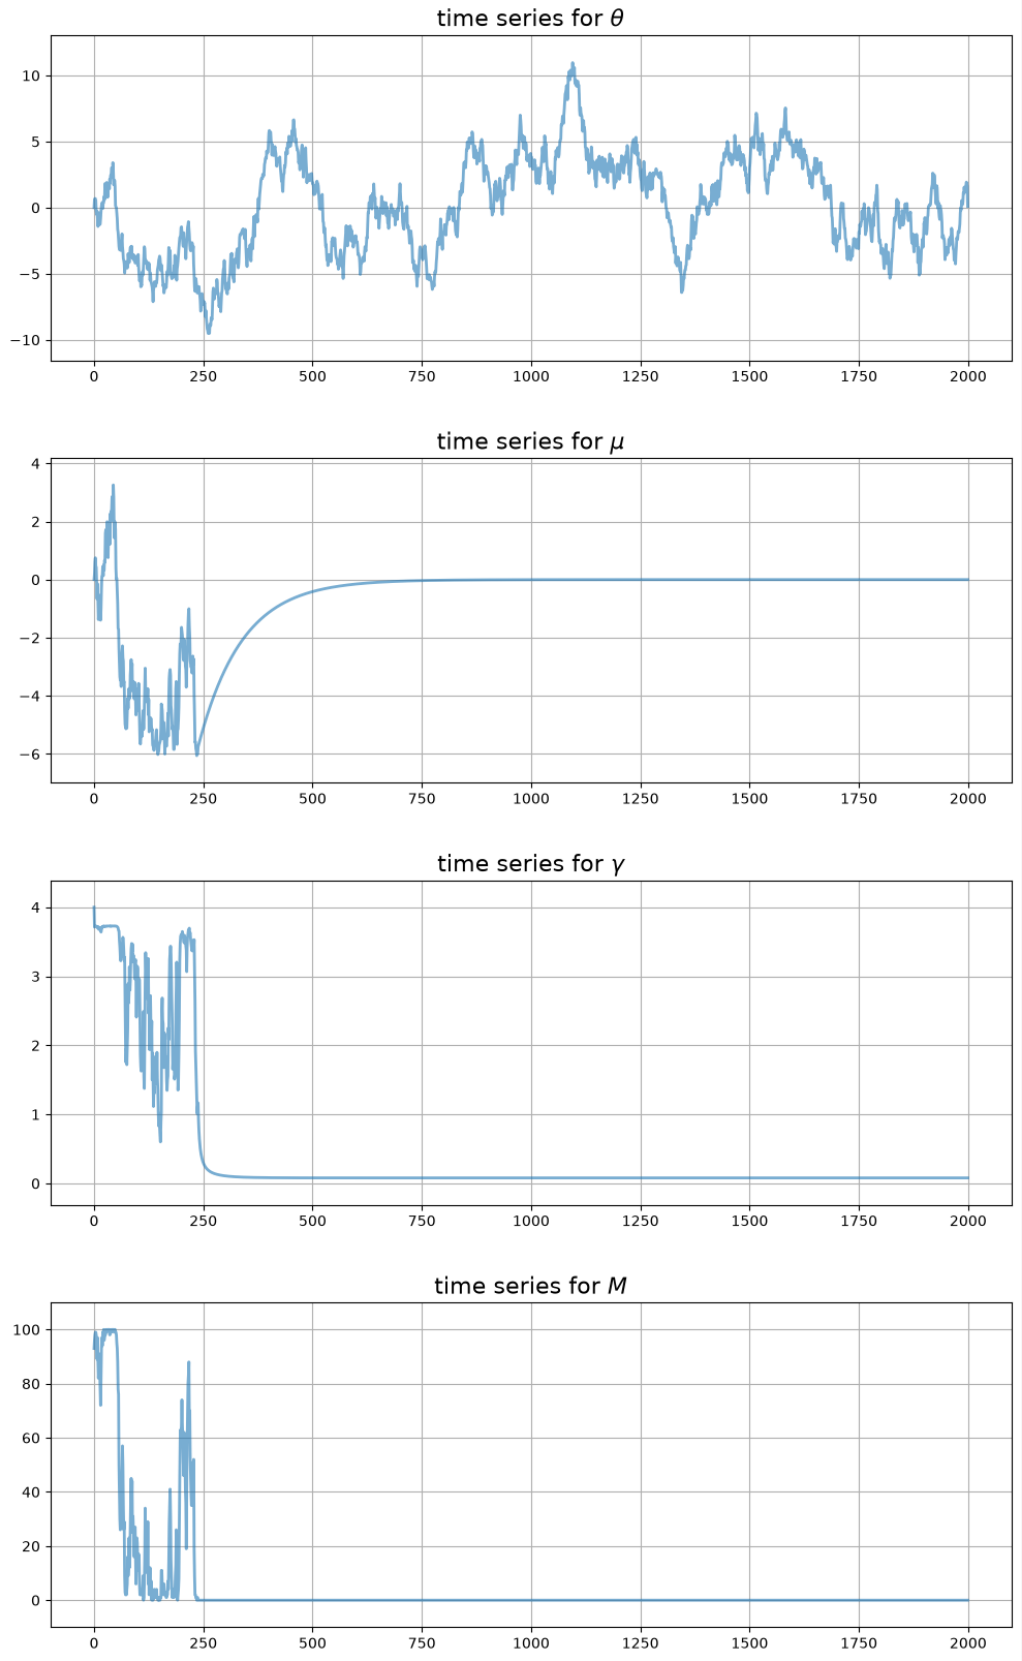
    econ.update_beliefs(X, M)
    econ.update_θ(w_shocks[t])

    μ_vec[t+1] = econ.μ
    γ_vec[t+1] = econ.γ
    θ_vec[t+1] = econ.θ

# Record final values of aggregates
X, M = econ.gen_aggregates(rng)
X_vec[-1] = X
M_vec[-1] = M
```

First, let's see how well μ tracks θ in these simulations

```
fig, ax = plt.subplots(figsize=(9, 6))
ax.plot(range(sim_length), θ_vec, alpha=0.6, lw=2, label=r"$\theta$")
ax.plot(range(sim_length), μ_vec, alpha=0.6, lw=2, label=r"$\mu$")
ax.legend(fontsize=16)
ax.grid()
plt.show()
```



Now let's plot the whole thing together

```
fig, axes = plt.subplots(4, 1, figsize=(12, 20))
# Add some spacing
fig.subplots_adjust(hspace=0.3)

series = (θ_vec, μ_vec, γ_vec, M_vec)
names = r'$\theta$', r'$\mu$', r'$\gamma$', r'$M$'

for ax, vals, name in zip(axes, series, names):
    # Determine suitable y limits
    s_max, s_min = max(vals), min(vals)
    s_range = s_max - s_min
    y_max = s_max + s_range * 0.1
    y_min = s_min - s_range * 0.1
    ax.set_ylim(y_min, y_max)
    # Plot series
    ax.plot(range(sim_length), vals, alpha=0.6, lw=2)
    ax.set_title(f"time series for {name}", fontsize=16)
    ax.grid()

plt.show()
```

If you run the code above you'll get different plots, of course.

Try experimenting with different parameters to see the effects on the time series.

(It would also be interesting to experiment with non-Gaussian distributions for the shocks, but this is a big exercise since it takes us outside the world of the standard Kalman filter)

CHAPTER

FOUR

THE AIYAGARI MODEL

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

Contents

- *The Aiyagari Model*
  - *Overview*
  - *The Economy*
  - *Implementation*
  - *Exercises*

In addition to what's included in base Anaconda, we need to install JAX

```
!pip install quantecon jax
```

124.1 Overview

In this lecture, we describe the structure of a class of models that build on work by Truman Bewley [Bewley, 1977].

We begin by discussing an example of a Bewley model due to Rao Aiyagari [Aiyagari, 1994].

The model features

- heterogeneous agents
- a single exogenous vehicle for borrowing and lending
- limits on amounts individual agents may borrow

The Aiyagari model has been used to investigate many topics, including

- precautionary savings and the effect of liquidity constraints [Aiyagari, 1994]
- risk sharing and asset pricing [Heaton and Lucas, 1996]
- the shape of the wealth distribution [Benhabib *et al.*, 2015]
- etc., etc., etc.

124.1.1 Preliminaries

We use the following imports:

```
import quantecon as qe
import matplotlib.pyplot as plt
import jax
import jax.numpy as jnp
from typing import NamedTuple
from scipy.optimize import bisect
```

We will use 64-bit floats with JAX in order to increase precision.

```
jax.config.update("jax_enable_x64", True)
```

We will use the following function to compute stationary distributions of stochastic matrices (for a reference to the algorithm, see p. 88 of Economic Dynamics).

```
@jax.jit
def compute_stationary(P):
    n = P.shape[0]
    I = jnp.identity(n)
    O = jnp.ones((n, n))
    A = I - jnp.transpose(P) + O
    return jnp.linalg.solve(A, jnp.ones(n))
```

124.1.2 References

The primary reference for this lecture is [Aiyagari, 1994].

A textbook treatment is available in chapter 18 of [Ljungqvist and Sargent, 2018].

A continuous time version of the model by SeHyoun Ahn and Benjamin Moll can be found here.

124.2 The Economy

124.2.1 Households

Infinitely lived households / consumers face idiosyncratic income shocks.

A unit interval of *ex-ante* identical households face a common borrowing constraint.

The savings problem faced by a typical household is

$$\max \mathbb{E} \sum_{t=0}^{\infty} \beta^t u(c_t)$$

subject to

$$a_{t+1} + c_t \leq wz_t + (1+r)a_t \quad c_t \geq 0, \quad \text{and} \quad a_t \geq -B$$

where

- c_t is current consumption
- a_t is assets
- z_t is an exogenous component of labor income capturing stochastic unemployment risk, etc.
- w is a wage rate
- r is a net interest rate
- B is the maximum amount that the agent is allowed to borrow

The exogenous process $\{z_t\}$ follows a finite state Markov chain with given stochastic matrix P.

The wage and interest rate are fixed over time.

In this simple version of the model, households supply labor inelastically because they do not value leisure.

124.2.2 Firms

Firms produce output by hiring capital and labor.

Firms act competitively and face constant returns to scale.

Since returns to scale are constant, the number of firms does not matter.

Hence we can consider a single (but nonetheless competitive) representative firm.

The firm's output is

$$Y = AK^\alpha N^{1-\alpha}$$

where

- A and α are parameters with $A > 0$ and $\alpha \in (0, 1)$
- K is aggregate capital
- N is total labor supply (which is constant in this simple version of the model)

The firm's problem is

$$\max_{K,N} \left\{ AK^\alpha N^{1-\alpha} - (r+\delta)K - wN \right\}$$

The parameter δ is the depreciation rate.

These parameters are stored in the following namedtuple:

```
class Firm(NamedTuple):
    A: float = 1.0    # Total factor productivity
    N: float = 1.0    # Total labor supply
    α: float = 0.33   # Capital share
    δ: float = 0.05   # Depreciation rate
```

From the first-order condition with respect to capital, the firm's inverse demand for capital is

$$r = A\alpha \left(\frac{N}{K} \right)^{1-\alpha} - \delta \tag{124.1}$$

```
def r_given_k(K, firm):
    """
    Inverse demand curve for capital. The interest rate associated with a
    given demand for capital K.
    """
    A, N, α, δ = firm
    return A * α * (N / K)**(1 - α) - δ
```

Using this expression and the firm's first-order condition for labor, we can pin down the equilibrium wage rate as a function of r as

$$w(r) = A(1-\alpha)(A\alpha/(r+\delta))^{\alpha/(1-\alpha)} \tag{124.2}$$

```
def r_to_w(r, firm):
    """
    Equilibrium wages associated with a given interest rate r.
    """
    A, N, α, δ = firm
    return A * (1 - α) * (A * α / (r + δ))**(α / (1 - α))
```

124.2.3 Equilibrium

We construct a **stationary rational expectations equilibrium (SREE)**.

In such an equilibrium

- prices induce behavior that generates aggregate quantities consistent with the prices
- aggregate quantities and prices are constant over time

In more detail, an SREE lists a set of prices, savings and production policies such that

- households want to choose the specified savings policies taking the prices as given
- firms maximize profits taking the same prices as given
- the resulting aggregate quantities are consistent with the prices; in particular, the demand for capital equals the supply
- aggregate quantities (defined as cross-sectional averages) are constant

124.3 Implementation

Let's look at how we might compute such an equilibrium in practice.

Below we provide code to solve the household problem, taking r and w as fixed.

124.3.1 Primitives and operators

We will solve the household problem using value function iteration.

First we set up a `NamedTuple` to store the parameters that define a household asset accumulation problem, as well as the grids used to solve it

```
class Household(NamedTuple):
    β: float            # Discount factor
    a_grid: jnp.ndarray # Asset grid
    z_grid: jnp.ndarray # Exogenous states
    Π: jnp.ndarray      # Transition matrix

def create_household(β=0.96,                       # Discount factor
                     Π=[[0.9, 0.1], [0.1, 0.9]],  # Markov chain
                     z_grid=[0.1, 1.0],           # Exogenous states
                     a_min=1e-10, a_max=12.5,     # Asset grid
                     a_size=100):
    """
    Create a Household namedtuple with custom grids.
    """
    a_grid = jnp.linspace(a_min, a_max, a_size)
    z_grid, Π = map(jnp.array, (z_grid, Π))
    return Household(β=β, a_grid=a_grid, z_grid=z_grid, Π=Π)
```

For now we assume that $u(c) = \log(c)$

```
u = jnp.log
```

Here's a namedtuple that stores the wage rate and interest rate with default values

```
class Prices(NamedTuple):
    r: float = 0.01  # Interest rate
    w: float = 1.0   # Wages
```

Now we set up a vectorized version of the right-hand side of the Bellman equation (before maximization), which is a 3D array representing

$$B(a, z, a') = u(wz + (1 + r)a - a') + \beta \sum_{z'} v(a', z')\Pi(z, z')$$

for all (a, z, a').

```
def B(v, household, prices):
    # Unpack
    β, a_grid, z_grid, Π = household
    a_size, z_size = len(a_grid), len(z_grid)
    r, w = prices

    # Compute current consumption as array c[i, j, ip]
    a  = jnp.reshape(a_grid, (a_size, 1, 1))    # a[i]   ->  a[i, j, ip]
    z  = jnp.reshape(z_grid, (1, z_size, 1))    # z[j]   ->  z[i, j, ip]
    ap = jnp.reshape(a_grid, (1, 1, a_size))    # ap[ip] -> ap[i, j, ip]
    c = w * z + (1 + r) * a - ap

    # Calculate continuation rewards at all combinations of (a, z, ap)
    v = jnp.reshape(v, (1, 1, a_size, z_size)) # v[ip, jp] -> v[i, j, ip, jp]
    Π = jnp.reshape(Π, (1, z_size, 1, z_size)) # Π[j, jp]  -> Π[i, j, ip, jp]
```

(continues on next page)

(continued from previous page)

```
    EV = jnp.sum(v * Π, axis=-1)               # sum over last index jp

    # Compute the right-hand side of the Bellman equation
    return jnp.where(c > 0, u(c) + β * EV, -jnp.inf)
```

The next function computes greedy policies

```
def get_greedy(v, household, prices):
    """
    Computes a v-greedy policy σ, returned as a set of indices. If
    σ[i, j] equals ip, then a_grid[ip] is the maximizer at i, j.
    """
    # argmax over ap
    return jnp.argmax(B(v, household, prices), axis=-1)
```

We define the Bellman operator T, which takes a value function v and returns Tv as given in the Bellman equation

```
def T(v, household, prices):
    """
    The Bellman operator. Takes a value function v and returns Tv.
    """
    return jnp.max(B(v, household, prices), axis=-1)
```

Here's value function iteration, which repeatedly applies the Bellman operator until convergence

```
@jax.jit
def value_function_iteration(household, prices, tol=1e-4, max_iter=10_000):
    """
    Implements value function iteration using a compiled JAX loop.
    """
    β, a_grid, z_grid, Π = household
    a_size, z_size = len(a_grid), len(z_grid)

    def condition_function(loop_state):
        i, v, error = loop_state
        return jnp.logical_and(error > tol, i < max_iter)

    def update(loop_state):
        i, v, error = loop_state
        v_new = T(v, household, prices)
        error = jnp.max(jnp.abs(v_new - v))
        return i + 1, v_new, error

    # Initial loop state
    v_init = jnp.zeros((a_size, z_size))
    loop_state_init = (0, v_init, tol + 1)

    # Run the fixed point iteration
    i, v, error = jax.lax.while_loop(condition_function, update, loop_state_init)

    return get_greedy(v, household, prices)
```

As a first example of what we can do, let's compute and plot an optimal accumulation policy at fixed prices

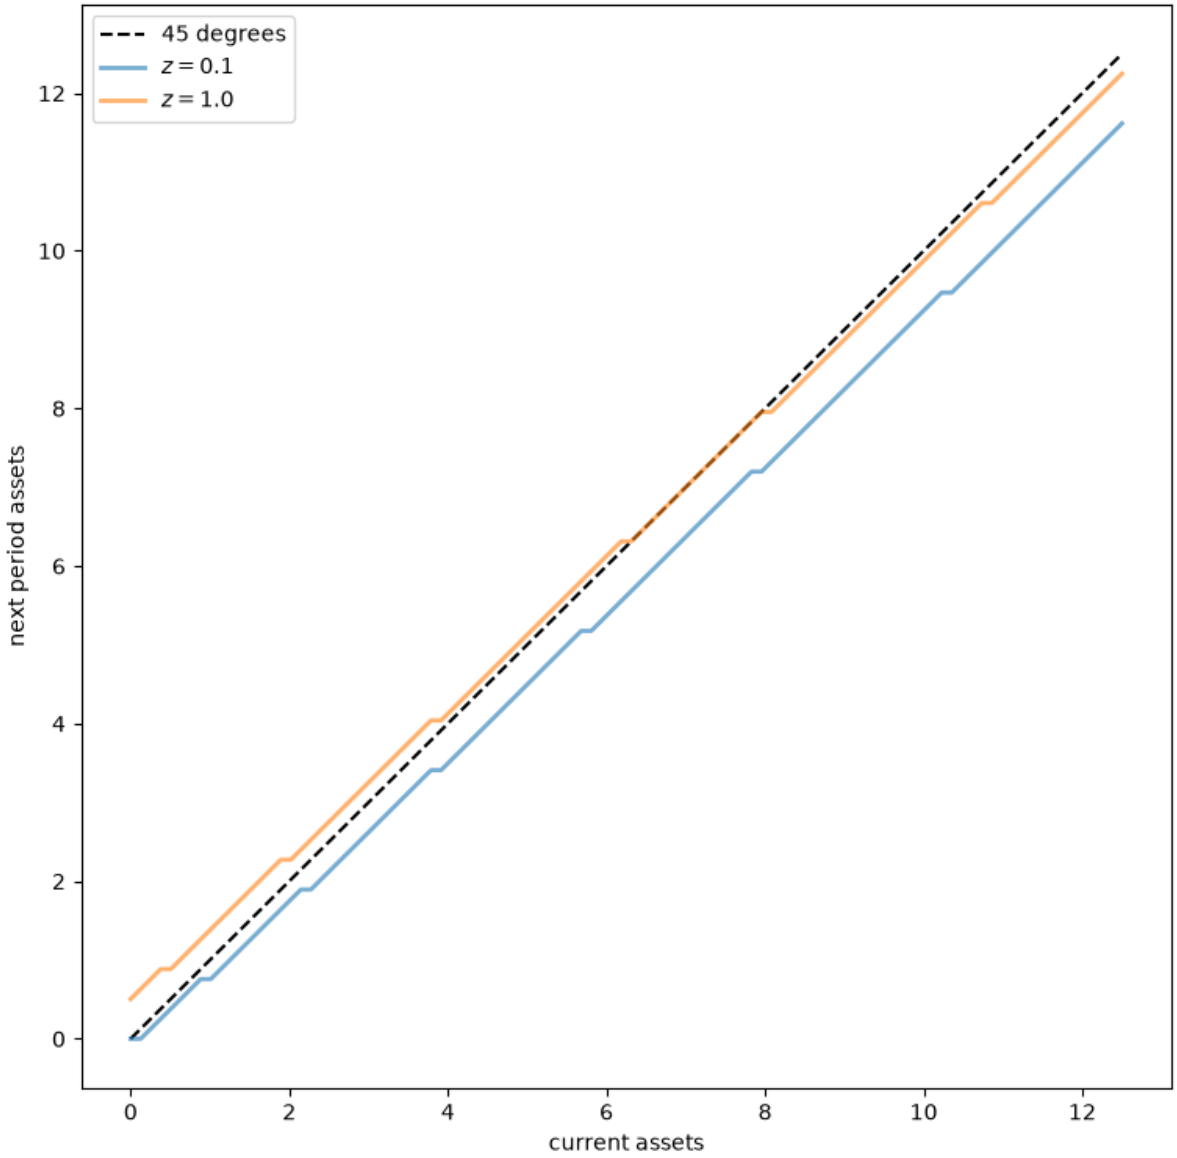
```
# Create an instance of Household
household = create_household()
prices = Prices()
```

(continues on next page)

(continued from previous page)

```
r, w = prices
print(f"Interest rate: {r}, Wage: {w}")
```

```
Interest rate: 0.01, Wage: 1.0
```



```
with qe.Timer():
    σ_star = value_function_iteration(household, prices).block_until_ready()
```

```
0.2355 seconds elapsed
```

The next plot shows asset accumulation policies at different values of the exogenous state

```
β, a_grid, z_grid, Π = household

fig, ax = plt.subplots(figsize=(9, 9))
ax.plot(a_grid, a_grid, 'k--', label="45 degrees")
for j, z in enumerate(z_grid):
    lb = f'$z = {z:.2}$'
    policy_vals = a_grid[σ_star[:, j]]
    ax.plot(a_grid, policy_vals, lw=2, alpha=0.6, label=lb)
    ax.set_xlabel('current assets')
    ax.set_ylabel('next period assets')
ax.legend(loc='upper left')
plt.show()
```

The plot shows asset accumulation policies at different values of the exogenous state.

124.3.2 Capital supply

To start thinking about equilibrium, we need to know how much capital households supply at a given interest rate r.

This quantity can be calculated by taking the stationary distribution of assets under the optimal policy and computing the mean.

The next function computes the stationary distribution for a given policy σ via the following steps:

- Compute the stationary distribution $\psi = (\psi(a, z))$ of P_σ, which defines the Markov chain of the state (a_t, z_t) under policy σ.
- Sum out z_t to get the marginal distribution for a_t.

```
@jax.jit
def compute_asset_stationary(σ, household):
    # Unpack
    β, a_grid, z_grid, Π = household
    a_size, z_size = len(a_grid), len(z_grid)

    # Construct P_σ as an array of the form P_σ[i, j, ip, jp]
    ap_idx = jnp.arange(a_size)
    ap_idx = jnp.reshape(ap_idx, (1, 1, a_size, 1))
    σ = jnp.reshape(σ, (a_size, z_size, 1, 1))
    A = jnp.where(σ == ap_idx, 1, 0)
    Π = jnp.reshape(Π, (1, z_size, 1, z_size))
    P_σ = A * Π

    # Reshape P_σ into a matrix
    n = a_size * z_size
    P_σ = jnp.reshape(P_σ, (n, n))

    # Get stationary distribution and reshape back onto [i, j] grid
    ψ = compute_stationary(P_σ)
    ψ = jnp.reshape(ψ, (a_size, z_size))

    # Sum along the rows to get the marginal distribution of assets
    ψ_a = jnp.sum(ψ, axis=1)
    return ψ_a
```

Let's give this a test run.

```
ψ_a = compute_asset_stationary(σ_star, household)

fig, ax = plt.subplots()
ax.bar(household.a_grid, ψ_a)
ax.set_xlabel("asset level")
ax.set_ylabel("probability mass")
plt.show()
```

The distribution should sum to one:

```
ψ_a.sum()
```

```
Array(1., dtype=float64)
```

The next function computes aggregate capital supply by households under policy σ, given wages and interest rates

```
def capital_supply(σ, household):
    """
    Induced level of capital stock under the policy, taking r and w as given.
    """
    β, a_grid, z_grid, Π = household
    ψ_a = compute_asset_stationary(σ, household)
    return float(jnp.sum(ψ_a * a_grid))
```

124.3.3 Equilibrium

We compute a SREE as follows:

1. Set $n = 0$ and start with an initial guess K_0 for aggregate capital.
2. Determine prices r, w from the firm decision problem, given K_n.
3. Compute the optimal savings policy of households given these prices.
4. Compute aggregate capital K_{n+1} as the mean of steady-state capital given this savings policy.
5. If $K_{n+1} \approx K_n$, stop; otherwise, go to step 2.

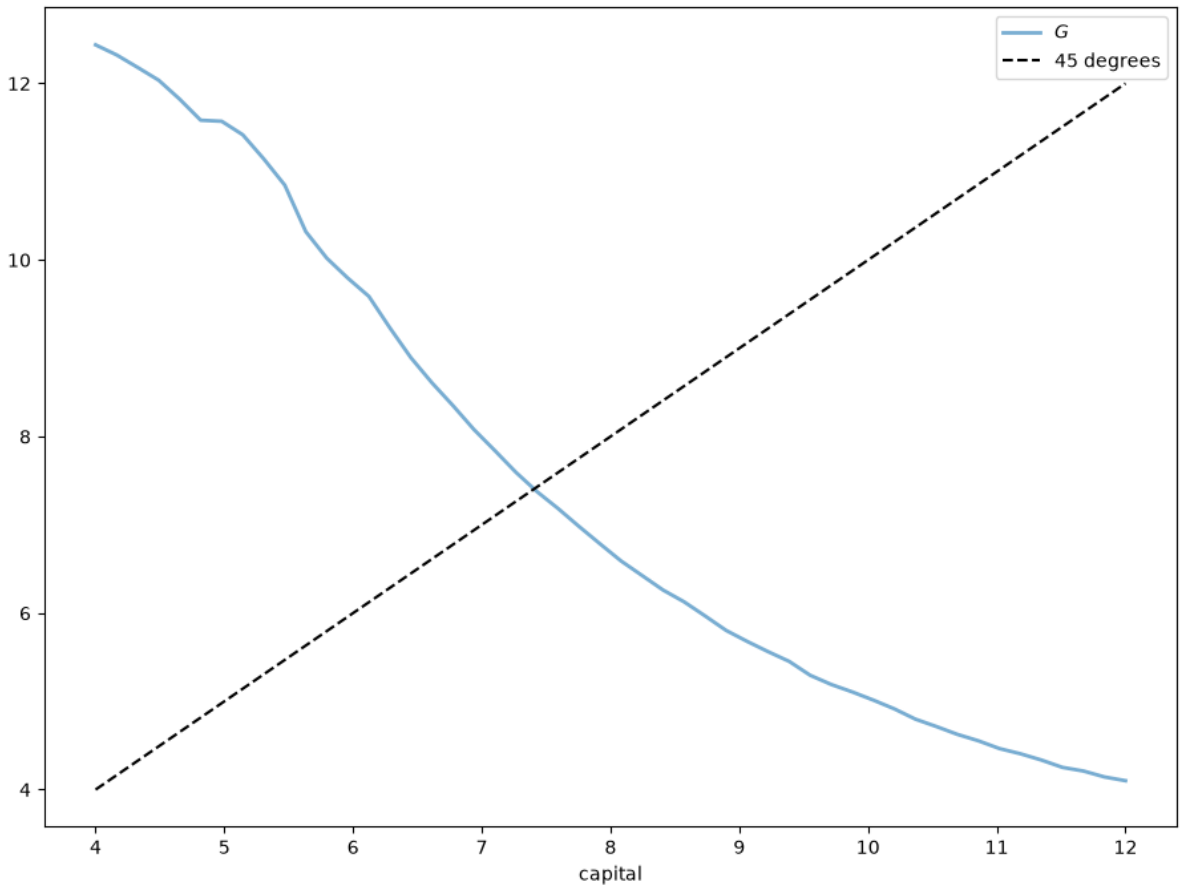
We can write the sequence of operations in steps 2-4 as

$$K_{n+1} = G(K_n)$$

If K_{n+1} agrees with K_n then we have a SREE.

In other words, our problem is to find the fixed point of the one-dimensional map G.

Here's G expressed as a Python function



```
def G(K, firm, household):
    # Get prices r, w associated with K
    r = r_given_k(K, firm)
    w = r_to_w(r, firm)

    # Generate a household object with these prices, compute
    # aggregate capital.
    prices = Prices(r=r, w=w)
    σ_star = value_function_iteration(household, prices)
    return capital_supply(σ_star, household)
```

Let's inspect visually as a first pass

```
num_points = 50
firm = Firm()
household = create_household()
k_vals = jnp.linspace(4, 12, num_points)
out = [G(k, firm, household) for k in k_vals]

fig, ax = plt.subplots(figsize=(11, 8))
ax.plot(k_vals, out, lw=2, alpha=0.6, label='$G$')
ax.plot(k_vals, k_vals, 'k--', label="45 degrees")
ax.set_xlabel('capital')
ax.legend()
plt.show()
```

Now let's compute the equilibrium.

Looking at the figure above, we see that a simple iteration scheme $K_{n+1} = G(K_n)$ will cycle from high to low values, leading to slow convergence.

As a result, we use a damped iteration scheme of the form

$$K_{n+1} = \alpha K_n + (1 - \alpha) G(K_n)$$

```
def compute_equilibrium(firm, household,
                        K0=6, α=0.99, max_iter=1_000, tol=1e-4,
                        print_skip=10, verbose=False):
    n = 0
    K = K0
    error = tol + 1
    while error > tol and n < max_iter:
        new_K = α * K + (1 - α) * G(K, firm, household)
        error = abs(new_K - K)
        K = new_K
        n += 1
        if verbose and n % print_skip == 0:
            print(f"At iteration {n} with error {error}")
    return K, n
```

```
firm = Firm()
household = create_household()
```

(continues on next page)

(continued from previous page)

```
print("\nComputing equilibrium capital stock")
with qe.Timer():
    K_star, n = compute_equilibrium(firm, household, K0=6.0)
print(f"Computed equilibrium {K_star:.5} in {n} iterations")
```

```
Computing equilibrium capital stock
2.3125 seconds elapsed
Computed equilibrium 7.4095 in 259 iterations
```

This convergence is not very fast, given how quickly we can solve the household problem.

You can try varying α, but usually this parameter is hard to set a priori.

In the exercises below you will be asked to use bisection instead, which generally performs better.

124.3.4 Supply and demand curves

We can visualize the equilibrium using supply and demand curves.

The following code draws the aggregate supply and demand curves.

The intersection gives the equilibrium interest rate and capital

```
def prices_to_capital_stock(household, r, firm):
    """
    Map prices to the induced level of capital stock.
    """
    w = r_to_w(r, firm)
    prices = Prices(r=r, w=w)

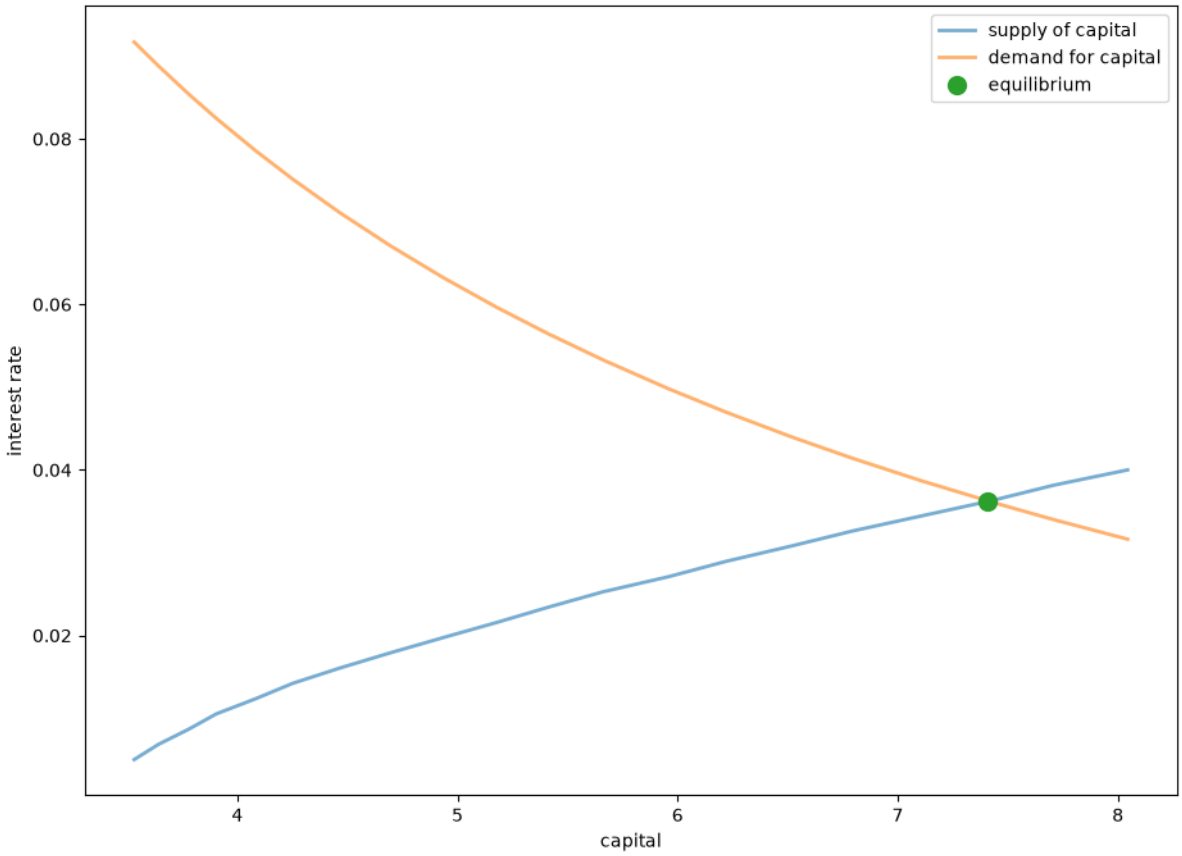
    # Compute the optimal policy
    σ_star = value_function_iteration(household, prices)

    # Compute capital supply
    return capital_supply(σ_star, household)

# Create a grid of r values to compute demand and supply of capital
num_points = 20
r_vals = jnp.linspace(0.005, 0.04, num_points)

# Compute supply of capital
k_vals = []
for r in r_vals:
    k_vals.append(prices_to_capital_stock(household, r, firm))

# Plot against demand for capital by firms
fig, ax = plt.subplots(figsize=(11, 8))
ax.plot(k_vals, r_vals, lw=2, alpha=0.6,
        label='supply of capital')
ax.plot(k_vals, r_given_k(
        jnp.array(k_vals), firm), lw=2, alpha=0.6,
        label='demand for capital')



# Add marker at equilibrium
r_star = r_given_k(K_star, firm)
ax.plot(K_star, r_star, 'o', markersize=10, label='equilibrium')
```

(continues on next page)

(continued from previous page)

```
ax.set_xlabel('capital')
ax.set_ylabel('interest rate')
ax.legend(loc='upper right')

plt.show()
```

124.4 Exercises

Exercise 124.4.1

Write a new version of `compute_equilibrium` that uses `bisect` from `scipy.optimize` instead of damped iteration.

See if you can make it faster than the previous version.

In `bisect`,

- you should set `xtol=1e-4` to have the same error tolerance as the previous version.
- for the lower and upper bounds of the bisection routine try `a = 1.0` and `b = 20.0`.

Solution

We use bisection to find the zero of the function $h(k) = k - G(k)$

```
def compute_equilibrium_bisect(firm, household, a=1.0, b=20.0):
    K = bisect(lambda k: k - G(k, firm, household), a, b, xtol=1e-4)
    return K

firm = Firm()
household = create_household()
print("\nComputing equilibrium capital stock using bisection")
with qe.Timer():
    K_star = compute_equilibrium_bisect(firm, household)
print(f"Computed equilibrium capital stock {K_star:.5}")
```

```
Computing equilibrium capital stock using bisection
0.1819 seconds elapsed
Computed equilibrium capital stock 7.4178
```

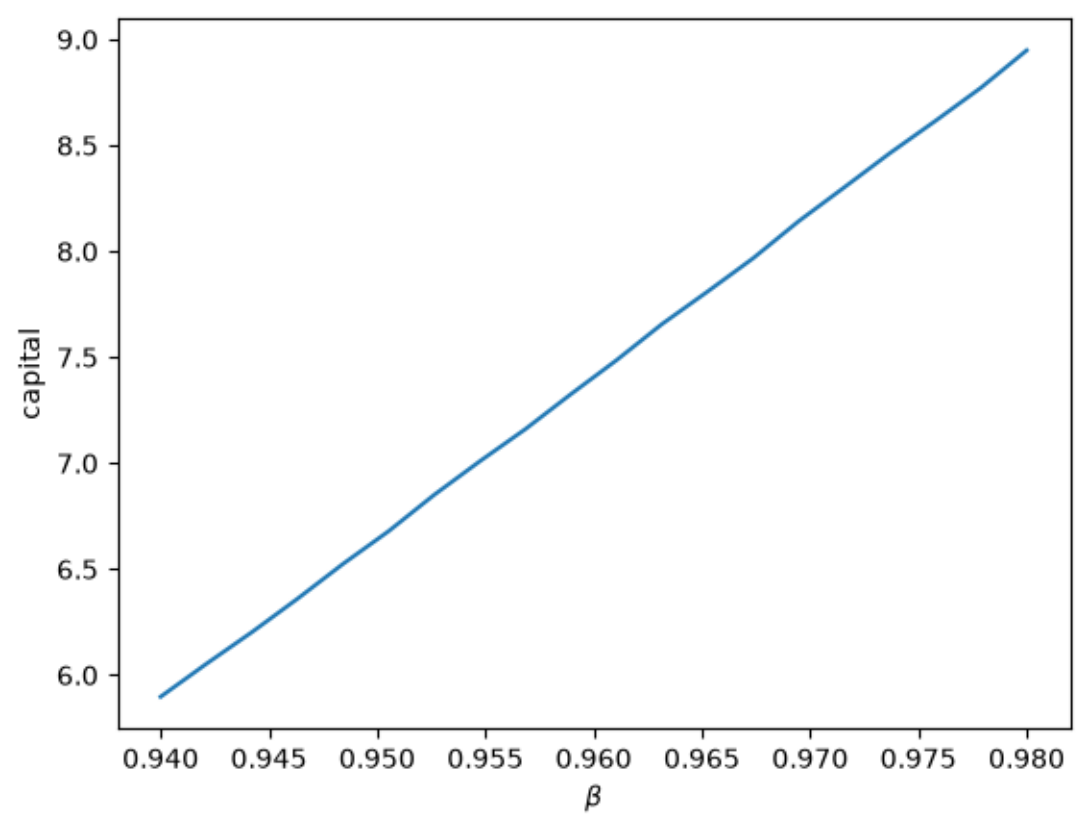
The bisection method is faster than the damped iteration scheme.

Exercise 124.4.2

Show how equilibrium capital stock changes with β.

Use the following values of β and plot the relationship you find.

```
β_vals = jnp.linspace(0.94, 0.98, 20)
```



Solution

```
K_vals = []
K = 6.0  # initial guess

for β in β_vals:
    household = create_household(β=β)
    K = compute_equilibrium_bisect(firm, household, 0.5 * K, 1.5 * K)
    print(f"Computed equilibrium {K:.4} at β = {β}")
    K_vals.append(K)

fig, ax = plt.subplots()
ax.plot(β_vals, K_vals, ms=2)
ax.set_xlabel(r'$\beta$')
ax.set_ylabel('capital')
plt.show()
```

```
Computed equilibrium 5.897 at β = 0.94
Computed equilibrium 6.052 at β = 0.9421052631578948
Computed equilibrium 6.202 at β = 0.9442105263157894
Computed equilibrium 6.36 at β = 0.9463157894736841
Computed equilibrium 6.524 at β = 0.9484210526315789
Computed equilibrium 6.679 at β = 0.9505263157894737
Computed equilibrium 6.85 at β = 0.9526315789473683
Computed equilibrium 7.008 at β = 0.9547368421052631
Computed equilibrium 7.16 at β = 0.9568421052631579
Computed equilibrium 7.325 at β = 0.9589473684210527
Computed equilibrium 7.486 at β = 0.9610526315789474
Computed equilibrium 7.657 at β = 0.963157894736842
Computed equilibrium 7.81 at β = 0.9652631578947368
Computed equilibrium 7.967 at β = 0.9673684210526317
Computed equilibrium 8.142 at β = 0.9694736842105263
Computed equilibrium 8.302 at β = 0.971578947368421
Computed equilibrium 8.463 at β = 0.9736842105263158
Computed equilibrium 8.616 at β = 0.9757894736842105
Computed equilibrium 8.773 at β = 0.9778947368421053
Computed equilibrium 8.948 at β = 0.98
```

Exercise 124.4.3

In this lecture, we used value function iteration to solve the household problem.

An alternative is Howard policy iteration (HPI), which is discussed in detail in Dynamic Programming.

HPI can be faster than VFI for some problems because it uses fewer but more computationally intensive iterations.

Your task is to implement Howard policy iteration and compare the results with value function iteration.

Key concepts you'll need:

Howard policy iteration requires computing the value v_σ of a policy σ, defined as:

$$v_\sigma = (I - \beta P_\sigma)^{-1} r_\sigma$$

where r_σ is the reward vector under policy σ, and P_σ is the transition matrix induced by σ.

To solve this, you'll need to:

1. Compute current rewards $r_\sigma(a, z) = u((1 + r)a + wz - \sigma(a, z))$
2. Set up the linear operator R_σ where $(R_\sigma v)(a, z) = v(a, z) - \beta \sum_{z'} v(\sigma(a, z), z')\Pi(z, z')$
3. Solve $v_\sigma = R_\sigma^{-1} r_\sigma$ using `jax.scipy.sparse.linalg.bicgstab`

You can use the `get_greedy` function that's already defined in this lecture.

Implement the following Howard policy iteration routine:

```
def howard_policy_iteration(household, prices,
                            tol=1e-4, max_iter=10_000, verbose=False):
    """
    Howard policy iteration routine.
    """
    # Your code here
    pass
```

Once implemented, compute the equilibrium capital stock using HPI and verify that it produces approximately the same result as VFI at the default parameter values.

Solution

First, we need to implement the helper functions for Howard policy iteration.

The following function computes the array r_σ which gives current rewards given policy σ:

```
def compute_r_σ(σ, household, prices):
    """
    Compute current rewards at each i, j under policy σ. In particular,

        r_σ[i, j] = u((1 + r)a[i] + wz[j] - a'[ip])

    when ip = σ[i, j].
    """
    # Unpack
    β, a_grid, z_grid, Π = household
    a_size, z_size = len(a_grid), len(z_grid)
    r, w = prices

    # Compute r_σ[i, j]
    a = jnp.reshape(a_grid, (a_size, 1))
    z = jnp.reshape(z_grid, (1, z_size))
    ap = a_grid[σ]
    c = (1 + r) * a + w * z - ap
    r_σ = u(c)

    return r_σ
```

The linear operator R_σ is defined as:

```
def R_σ(v, σ, household):
    # Unpack
    β, a_grid, z_grid, Π = household
    a_size, z_size = len(a_grid), len(z_grid)

    # Set up the array v[σ[i, j], jp]
    zp_idx = jnp.arange(z_size)
    zp_idx = jnp.reshape(zp_idx, (1, 1, z_size))
    σ = jnp.reshape(σ, (a_size, z_size, 1))
    V = v[σ, zp_idx]

    # Expand Π[j, jp] to Π[i, j, jp]
    Π = jnp.reshape(Π, (1, z_size, z_size))

    # Compute and return v[i, j] - β Σ_jp v[σ[i, j], jp] * Π[j, jp]
    return v - β * jnp.sum(V * Π, axis=-1)
```

The next function computes the lifetime value of a given policy:

```
def get_value(σ, household, prices):
    """
    Get the lifetime value of policy σ by computing

        v_σ = R_σ^{-1} r_σ
    """
    r_σ = compute_r_σ(σ, household, prices)

    # Reduce R_σ to a function in v
    _R_σ = lambda v: R_σ(v, σ, household)

    # Compute v_σ = R_σ^{-1} r_σ using an iterative routine.
    return jax.scipy.sparse.linalg.bicgstab(_R_σ, r_σ)[0]
```

Now we can implement Howard policy iteration:

```
@jax.jit
def howard_policy_iteration(household, prices, tol=1e-4, max_iter=10_000):
    """
    Howard policy iteration routine using a compiled JAX loop.
    """
    β, a_grid, z_grid, Π = household
    a_size, z_size = len(a_grid), len(z_grid)

    def condition_function(loop_state):
        i, σ, v_σ, error = loop_state
        return jnp.logical_and(error > tol, i < max_iter)

    def update(loop_state):
        i, σ, v_σ, error = loop_state
        σ_new = get_greedy(v_σ, household, prices)
        v_σ_new = get_value(σ_new, household, prices)
        error = jnp.max(jnp.abs(v_σ_new - v_σ))
        return i + 1, σ_new, v_σ_new, error

    # Initial loop state
    σ_init = jnp.zeros((a_size, z_size), dtype=int)
    v_σ_init = get_value(σ_init, household, prices)
    loop_state_init = (0, σ_init, v_σ_init, tol + 1)
```

```
    # Run the fixed point iteration
    i, σ, v_σ, error = jax.lax.while_loop(condition_function, update, loop_state_
↪init)

    return σ
```

Now let's create a modified version of the G function that uses HPI:

```
def G_hpi(K, firm, household):
    # Get prices r, w associated with K
    r = r_given_k(K, firm)
    w = r_to_w(r, firm)

    # Generate prices and compute aggregate capital using HPI.
    prices = Prices(r=r, w=w)
    σ_star = howard_policy_iteration(household, prices)
    return capital_supply(σ_star, household)
```

And compute the equilibrium using HPI:

```
def compute_equilibrium_bisect_hpi(firm, household, a=1.0, b=20.0):
    K = bisect(lambda k: k - G_hpi(k, firm, household), a, b, xtol=1e-4)
    return K

firm = Firm()
household = create_household()
print("\nComputing equilibrium capital stock using HPI")
with qe.Timer():
    K_star_hpi = compute_equilibrium_bisect_hpi(firm, household)
print(f"Computed equilibrium capital stock with HPI: {K_star_hpi:.5}")
print(f"Previous equilibrium capital stock with VFI: {K_star:.5}")
print(f"Difference: {abs(K_star_hpi - K_star):.6}")
```

```
Computing equilibrium capital stock using HPI
0.9478 seconds elapsed
Computed equilibrium capital stock with HPI: 7.4172
Previous equilibrium capital stock with VFI: 7.4178
Difference: 0.000579834
```

The results show that both methods produce approximately the same equilibrium, confirming that HPI is a valid alternative to VFI.

  - *Exercises*

In addition to what's included in base Anaconda, we need to install QuantEcon's Python library and JAX.

```
!pip install quantecon jax
```

125.1 Overview

This lecture combines two important computational methods in macroeconomics:

1. The **Aiyagari model** [Aiyagari, 1994] – a heterogeneous agent model with incomplete markets
2. The **endogenous grid method** (EGM) [Carroll, 2006] – an efficient algorithm for solving dynamic programming problems

In the *standard Aiyagari lecture*, we solved the household problem using discretization and value function iteration.

We then computed aggregate capital at a given set of prices using the stationary distribution of the finite Markov chain.

In this lecture, we take a different approach:

1. We use the **endogenous grid method** to solve the household problem via the Euler equation and linear interpolation.
2. We compute aggregate capital by **simulation** rather than an algebraic technique (which only works for the finite case).

These modifications make the solution method faster and more flexible, especially when dealing with more complex models.

We use JAX throughout, so that the EGM operator, the solver and the simulation are all JIT-compiled and vectorized.

125.1.1 References

The primary references for this lecture are:

- our *previous Aiyagari lecture* for the key ideas
- [Aiyagari, 1994] for the economic model
- [Carroll, 2006] for the endogenous grid method
- Chapter 18 of [Ljungqvist and Sargent, 2018] for textbook treatment

125.1.2 Preliminaries

We use the following imports:

```
import quantecon as qe
import matplotlib.pyplot as plt
import jax
import jax.numpy as jnp
import numpy as np
from typing import NamedTuple
from functools import partial
from scipy.optimize import bisect
```

We will use 64-bit floats with JAX in order to increase precision.

```
jax.config.update("jax_enable_x64", True)
```

125.2 The Economy

The economy consists of households and a representative firm.

125.2.1 Households

Infinitely lived households face idiosyncratic income shocks and a borrowing constraint.

The savings problem faced by a typical household is

$$\max \mathbb{E} \sum_{t=0}^{\infty} \beta^t u(c_t)$$

subject to

$$a_{t+1} + c_t \leq w z_t + (1+r) a_t \quad c_t \geq 0, \quad \text{and} \quad a_t \geq -B$$

where

- c_t is current consumption

- a_t is assets
- z_t is an exogenous component of labor income (stochastic employment status)
- w is the wage rate
- r is the interest rate
- B is the maximum amount that the agent is allowed to borrow

The exogenous process $\{z_t\}$ follows a finite state Markov chain with stochastic matrix Π.

Optimal interior consumption choices satisfy the Euler equation

$$u'(c) = \beta \mathbb{E}_z[(1+r)u'(c')]$$

(We use $'$ symbols for both derivatives and future values, which is not ideal but convenient and common.)

In terms of assets, this is

$$u'(wz + (1+r)a - a') = \beta(1+r)\sum_{z'} u'(wz' + (1+r)a' - s(a', z'))\Pi(z, z')$$

where s is the optimal savings policy function.

125.2.2 Firms

Firms produce output by hiring capital and labor under constant returns to scale.

The representative firm's output is

$$Y = AK^\alpha N^{1-\alpha}$$

where

- A and α are parameters with $A > 0$ and $\alpha \in (0, 1)$
- K is aggregate capital
- N is total labor supply (normalized to 1)

These parameters are stored in the following namedtuple:

```
class Firm(NamedTuple):
    A: float = 1.0    # Total factor productivity
    N: float = 1.0    # Total labor supply
    α: float = 0.33   # Capital share
    δ: float = 0.05   # Depreciation rate
```

From the firm's first-order condition, the inverse demand for capital is

$$r = A\alpha \left(\frac{N}{K}\right)^{1-\alpha} - \delta \tag{125.1}$$

```
def r_given_k(K, firm):
    """
    Inverse demand curve for capital.
    """
    A, N, α, δ = firm
    return A * α * (N / K)**(1 - α) - δ
```

The equilibrium wage rate as a function of r is

$$w(r) = A(1-\alpha)(A\alpha/(r+\delta))^{\alpha/(1-\alpha)} \tag{125.2}$$

```
def r_to_w(r, firm):
    """
    Equilibrium wages associated with a given interest rate r.
    """
    A, N, α, δ = firm
    return A * (1 - α) * (A * α / (r + δ))**(α / (1 - α))
```

125.2.3 Equilibrium

A **stationary rational expectations equilibrium (SREE)** consists of prices and policies such that:

- Households optimize given prices
- Firms maximize profits given prices
- Markets clear: aggregate capital supply equals aggregate capital demand
- Aggregate quantities are constant over time

125.3 Implementation with EGM

125.3.1 Household primitives

First we set up the household parameters and grids:

```
class Household(NamedTuple):
    β: float            # Discount factor
    a_grid: jnp.ndarray # Asset grid
    z_grid: jnp.ndarray # Exogenous states
    Π: jnp.ndarray      # Transition matrix

def create_household(β=0.96,                      # Discount factor
                     Π=[[0.9, 0.1], [0.1, 0.9]],  # Markov chain
                     z_grid=[0.1, 1.0],           # Exogenous states
                     a_min=1e-10, a_max=50.0,     # Asset grid
                     a_size=200):
    """
    Create a Household namedtuple with custom grids.
    """
    a_grid = jnp.linspace(a_min, a_max, a_size)
    z_grid, Π = map(jnp.array, (z_grid, Π))
    return Household(β=β, a_grid=a_grid, z_grid=z_grid, Π=Π)
```

For utility, we assume $u(c) = \log(c)$, which gives us $u'(c) = 1/c$ and $(u')^{-1}(x) = 1/x$.

```
@jax.jit
def u_prime(c):
    return 1 / c

@jax.jit
```

(continues on next page)

(continued from previous page)

```
def u_prime_inv(x):
    return 1 / x
```

Here's a namedtuple for prices:

```
class Prices(NamedTuple):
    r: float = 0.01  # Interest rate
    w: float = 1.0   # Wages
```

125.3.2 The EGM operator

The key insight of EGM is to avoid root-finding by choosing the asset grid exogenously and computing the consumption values directly from the Euler equation.

The Coleman-Reffett operator using EGM works as follows:

1. Start with a consumption policy σ represented on an exogenous grid of (next-period) assets $\{a_i\}$.
2. For each asset level a_i and current employment state z_j:
   - Compute the right-hand side of the Euler equation: \$RHS $= \beta(1+r)\sum_{z'} \Pi(z_j, z')\, u'(\sigma(a_i, z'))$\$
   - Use the inverse marginal utility to get current consumption: \$$c_{ij} = (u')^{-1}$(RHS)\$
   - Recover the implied current asset level from the budget constraint: \$$a_{ij} = \frac{c_{ij}+a_i-wz_j}{1+r}$\$
3. Reconstruct the new policy $K\sigma$ on the original asset grid by interpolating (a_{ij}, c_{ij}), handling the borrowing constraint where it binds.

The whole operation vectorizes cleanly, so we write it as a single JIT-compiled function and use `vmap` over the employment states:

```
@jax.jit
def K_egm(σ, household, prices):
    """
    The Coleman-Reffett operator using EGM for the Aiyagari model.

    Here σ[i, j] is consumption when next-period assets are a_grid[i]
    and the current employment state is z_grid[j].
    """
    β, a_grid, z_grid, Π = household
    r, w = prices
    z_size = len(z_grid)

    # Expectation E[u'(c(a', z')) | z] over the next-period shock
    Eu_prime = (Π @ u_prime(σ).T).T                          # (a_size, z_size)

    # Euler equation -> consumption on the endogenous grid
    c_endo = u_prime_inv(β * (1 + r) * Eu_prime)             # (a_size, z_size)

    # Implied current assets: a = (c + a' - w z) / (1 + r)
    a_endo = (c_endo + a_grid[:, None] - w * z_grid[None, :]) / (1 + r)

    # Interpolate back onto the exogenous grid for each employment state
    def interp_policy(j):
        # Where today's assets fall below the endogenous grid the borrowing
        # constraint binds, so the household saves a_grid[0] and consumes
```

(continues on next page)

(continued from previous page)

```
        # the rest of current income.
        return jnp.where(
            a_grid < a_endo[0, j],
            w * z_grid[j] + (1 + r) * a_grid - a_grid[0],
            jnp.interp(a_grid, a_endo[:, j], c_endo[:, j])
        )

    σ_new = jax.vmap(interp_policy)(jnp.arange(z_size))     # (z_size, a_size)
    return σ_new.T                                          # (a_size, z_size)
```

125.3.3 Solving the household problem

We solve for the optimal policy by iterating the EGM operator to convergence.

The solver is fully JIT-compiled and uses `jax.lax.while_loop` for the iteration:

```
@jax.jit
def solve_household(household, prices, tol=1e-6, max_iter=10_000):
    """
    Solve the household problem by iterating the EGM operator.

    Returns the optimal consumption policy σ[i, j], where i indexes
    next-period assets and j indexes employment states.
    """
    β, a_grid, z_grid, Π = household
    r, w = prices

    # Initial guess: consume half of current income
    income = w * z_grid[None, :] + (1 + r) * a_grid[:, None]
    σ_init = 0.5 * income

    def condition(state):
        i, σ, error = state
        return (error > tol) & (i < max_iter)

    def body(state):
        i, σ, error = state
        σ_new = K_egm(σ, household, prices)
        error = jnp.max(jnp.abs(σ_new - σ))
        return i + 1, σ_new, error

    i, σ, error = jax.lax.while_loop(condition, body, (0, σ_init, tol + 1))
    return σ
```

Let's test this on an example:

```
household = create_household()
prices = Prices(r=0.01, w=1.0)

with qe.Timer():
    σ_star = solve_household(household, prices)
    jax.block_until_ready(σ_star)
```

```
0.5206 seconds elapsed
```

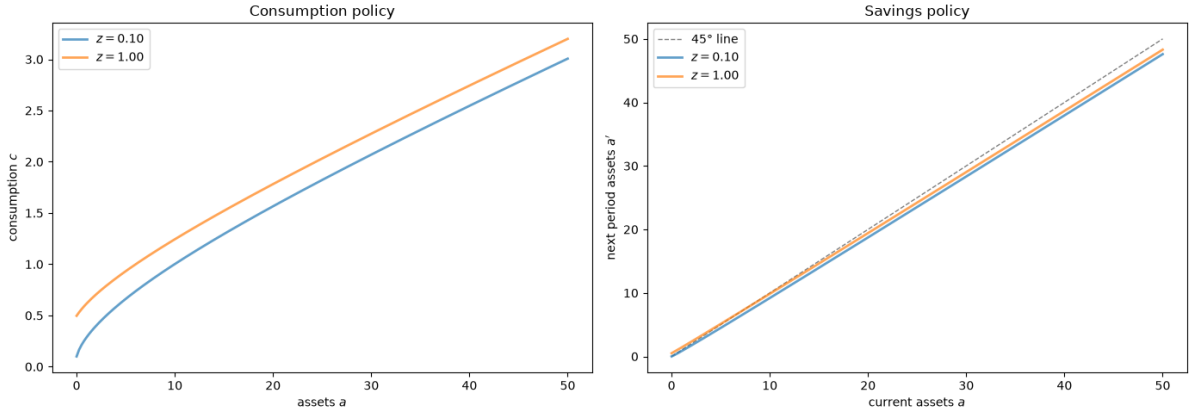
We can check that the policy is a fixed point of the EGM operator by measuring the residual:

```
residual = jnp.max(jnp.abs(K_egm(σ_star, household, prices) - σ_star))
print(f"Final Euler residual: {residual:.2e}")
```

```
Final Euler residual: 8.34e-07
```

Let's plot the resulting policy functions:

```
β, a_grid, z_grid, Π = household
r, w = prices



# Convert consumption policy to savings policy
income = w * z_grid[None, :] + (1 + r) * a_grid[:, None]
savings = income - σ_star

fig, axes = plt.subplots(1, 2, figsize=(14, 5))

# Plot consumption policy
ax = axes[0]
for j, z in enumerate(z_grid):
    ax.plot(a_grid, σ_star[:, j], label=f'$z={z:.2f}$', lw=2, alpha=0.7)
ax.set_xlabel('assets $a$')
ax.set_ylabel('consumption $c$')
ax.set_title('Consumption policy')
ax.legend()

# Plot savings policy
ax = axes[1]
ax.plot(a_grid, a_grid, 'k--', lw=1, alpha=0.5, label='45° line')
for j, z in enumerate(z_grid):
    ax.plot(a_grid, savings[:, j], label=f'$z={z:.2f}$', lw=2, alpha=0.7)
ax.set_xlabel('current assets $a$')
ax.set_ylabel("next period assets $a'$")
ax.set_title('Savings policy')
ax.legend()

plt.tight_layout()
plt.show()
```

125.4 Computing Aggregate Capital by Simulation

Instead of computing the stationary distribution of the Markov chain analytically, we compute aggregate capital by simulating a large cross-section of households.

This approach:

- is more flexible (works with continuous shocks, non-linear policies, etc.)
- avoids storing and manipulating large transition matrices
- is conceptually simpler

The simulation is fully vectorized: we advance all households simultaneously with `jax.lax.fori_loop`, drawing the employment transitions by inverse-CDF sampling and looking up consumption with a `vmap`-ed interpolation.

```
@partial(jax.jit, static_argnames=('num_households', 'num_periods'))
def simulate_cross_section(σ, household, prices, key,
                           num_households=50_000, num_periods=1_000):
    """
    Simulate a panel of households forward and return the terminal
    cross-section of assets and employment states.
    """
    β, a_grid, z_grid, Π = household
    r, w = prices

    # CDF of each row of Π, used for inverse-CDF sampling of transitions
    Π_cdf = jnp.cumsum(Π, axis=1)

    # Vectorized consumption lookup: interpolate σ along assets for each z
    @jax.vmap
    def consume(a, j):
        return jnp.interp(a, a_grid, σ[:, j])

    # Initial conditions: everyone at the middle of the grid, in state 0
    assets = jnp.full(num_households, a_grid[len(a_grid) // 2])
    z_idx = jnp.zeros(num_households, dtype=jnp.int32)

    def step(t, state):
        assets, z_idx, key = state
        key, subkey = jax.random.split(key)
        unif = jax.random.uniform(subkey, (num_households,))
        # Markov transition via inverse CDF
        z_idx = (unif[:, None] > Π_cdf[z_idx]).sum(axis=1).astype(jnp.int32)
        # Budget constraint: consume, then carry assets to next period
        income = w * z_grid[z_idx] + (1 + r) * assets
        assets = income - consume(assets, z_idx)
        # Enforce the asset grid bounds
        assets = jnp.clip(assets, a_grid[0], a_grid[-1])
        return assets, z_idx, key

    assets, z_idx, key = jax.lax.fori_loop(
        0, num_periods, step, (assets, z_idx, key)
    )
    return assets, z_idx
```

Now we can compute capital supply for given prices by solving the household problem and averaging assets across the simulated cross-section:

```
def capital_supply(household, prices, key,
                   num_households=50_000, num_periods=1_000):
    """
    Compute aggregate capital supply by simulation.
    """
    σ = solve_household(household, prices)
    assets, _ = simulate_cross_section(
        σ, household, prices, key,
        num_households=num_households, num_periods=num_periods
    )
    return float(jnp.mean(assets))
```

Let's test it:

```
household = create_household()
prices = Prices(r=0.01, w=1.0)
key = jax.random.key(42)

with qe.Timer():
    K_supply = capital_supply(household, prices, key)

print(f"Capital supply: {K_supply:.4f}")
```

```
0.9411 seconds elapsed
Capital supply: 2.5863
```

125.5 Computing Equilibrium

Now we can compute the equilibrium by finding the capital stock at which capital supply equals capital demand.

Given K, the equilibrium mapping G computes:

1. prices (r, w) from the firm's first-order conditions,
2. the household's optimal policy given those prices,
3. aggregate capital supply via simulation.

```
def G(K, firm, household, key,
      num_households=50_000, num_periods=1_000):
    """
    The equilibrium mapping K -> capital supply.
    """
    r = r_given_k(K, firm)
    w = r_to_w(r, firm)
    prices = Prices(r=r, w=w)
    return capital_supply(household, prices, key,
                          num_households=num_households,
                          num_periods=num_periods)
```

We compute the equilibrium by applying bisection to the excess demand $K - G(K)$.

We pass a fixed random key to every evaluation so that the excess demand function is deterministic, as required by the root finder.

```
def compute_equilibrium(firm, household, key,
                        K_min=4.0, K_max=12.0,
                        num_households=50_000, num_periods=1_000,
                        xtol=1e-2):
    """
    Compute the equilibrium capital stock using bisection.
    """
    def excess_demand(K):
        return K - G(K, firm, household, key,
                     num_households=num_households,
                     num_periods=num_periods)

    return bisect(excess_demand, K_min, K_max, xtol=xtol)
```

Let's compute the equilibrium:

```
firm = Firm()
household = create_household()
key = jax.random.key(42)

with qe.Timer():
    K_star = compute_equilibrium(firm, household, key)

r_star = r_given_k(K_star, firm)
w_star = r_to_w(r_star, firm)

print(f"\nEquilibrium capital:       {K_star:.4f}")
print(f"Equilibrium interest rate: {r_star:.4f}")
print(f"Equilibrium wage:          {w_star:.4f}")
```

```
1.9711 seconds elapsed

Equilibrium capital:       8.1484
Equilibrium interest rate: 0.0309
Equilibrium wage:          1.3388
```

125.5.1 Visualizing equilibrium

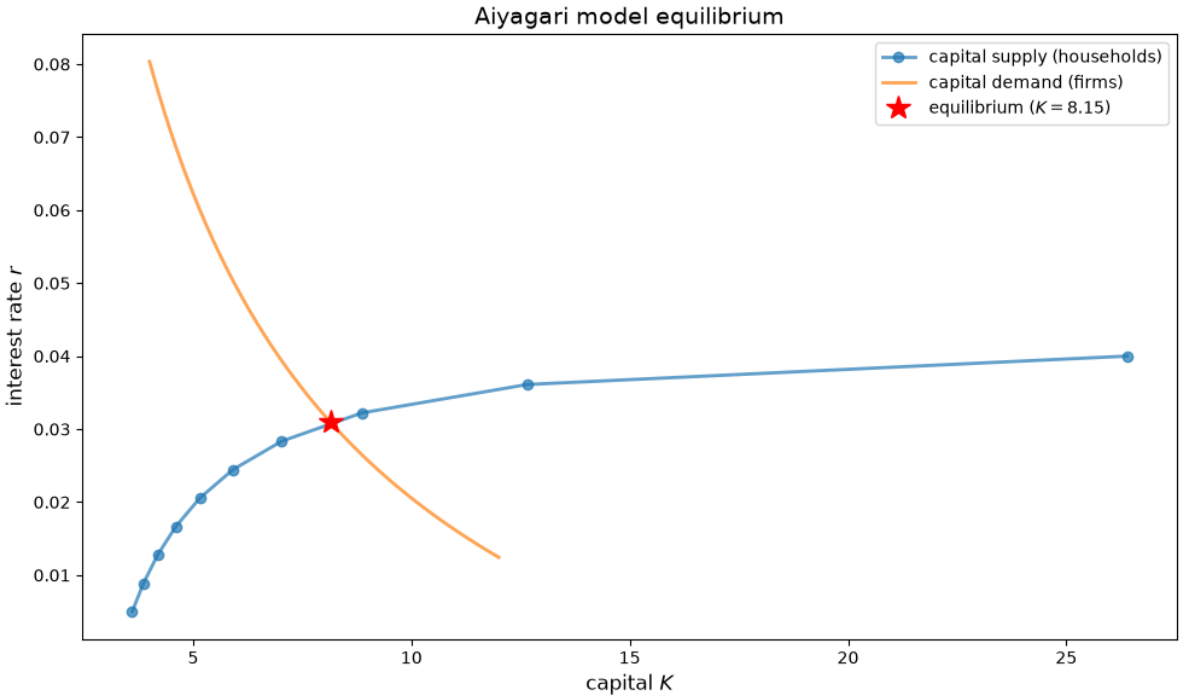
Let's plot the supply and demand curves:

```
# Supply curve: capital supplied by households as a function of r
r_vals = np.linspace(0.005, 0.04, 10)
K_supply_vals = []

for r in r_vals:
    w = r_to_w(r, firm)
    prices = Prices(r=r, w=w)
    K_supply_vals.append(capital_supply(household, prices, key))

# Demand curve: capital demanded by firms as a function of r
K_vals = np.linspace(4, 12, 50)
r_demand_vals = r_given_k(K_vals, firm)

fig, ax = plt.subplots(figsize=(10, 6))
```



(continues on next page)

(continued from previous page)

```
ax.plot(K_supply_vals, r_vals, 'o-', lw=2, alpha=0.7,
        label='capital supply (households)', markersize=6)
ax.plot(K_vals, r_demand_vals, lw=2, alpha=0.7,
        label='capital demand (firms)')
ax.plot(K_star, r_star, 'r*', markersize=15, zorder=5,
        label=f'equilibrium ($K={K_star:.2f}$)')

ax.set_xlabel('capital $K$', fontsize=12)
ax.set_ylabel('interest rate $r$', fontsize=12)
ax.set_title('Aiyagari model equilibrium', fontsize=14)
ax.legend(fontsize=10)

plt.tight_layout()
plt.show()
```

125.6 Wealth Distribution

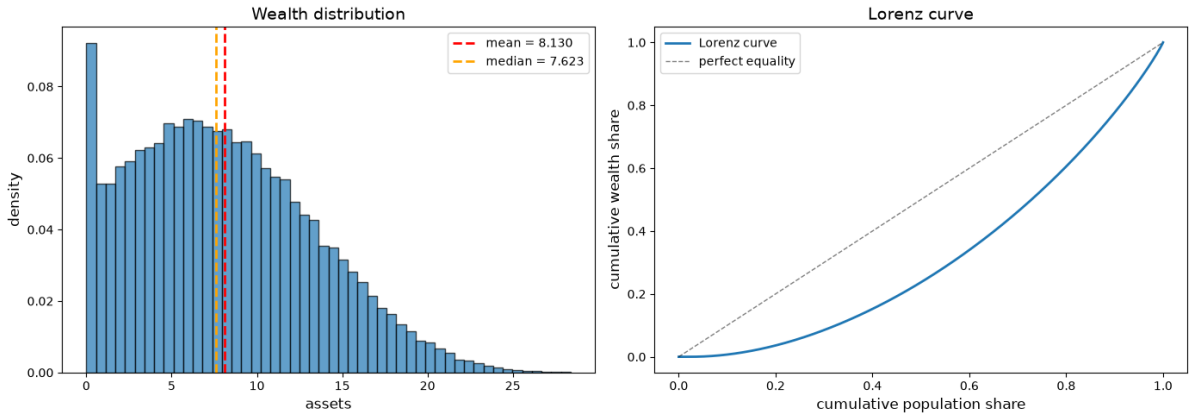
One advantage of the simulation approach is that we can easily examine the wealth distribution.

We reuse the cross-section simulated at equilibrium prices:

```
prices_star = Prices(r=r_star, w=w_star)
σ_star = solve_household(household, prices_star)
assets_dist, z_dist = simulate_cross_section(σ_star, household, prices_star, key)

assets_dist = np.asarray(assets_dist)
```

We use QuantEcon's `lorenz_curve` and `gini_coefficient` to summarize inequality:



```
fig, axes = plt.subplots(1, 2, figsize=(14, 5))

# Histogram
ax = axes[0]
ax.hist(assets_dist, bins=50, density=True, alpha=0.7, edgecolor='black')
ax.axvline(np.mean(assets_dist), color='red', linestyle='--', linewidth=2,
           label=f'mean = {np.mean(assets_dist):.3f}')
ax.axvline(np.median(assets_dist), color='orange', linestyle='--', linewidth=2,
           label=f'median = {np.median(assets_dist):.3f}')
ax.set_xlabel('assets', fontsize=12)
ax.set_ylabel('density', fontsize=12)
ax.set_title('Wealth distribution', fontsize=14)
ax.legend()

# Lorenz curve
ax = axes[1]
cum_pop, cum_wealth = qe.lorenz_curve(assets_dist)
ax.plot(cum_pop, cum_wealth, lw=2, label='Lorenz curve')
ax.plot([0, 1], [0, 1], 'k--', lw=1, alpha=0.5, label='perfect equality')
ax.set_xlabel('cumulative population share', fontsize=12)
ax.set_ylabel('cumulative wealth share', fontsize=12)
ax.set_title('Lorenz curve', fontsize=14)
ax.legend()

plt.tight_layout()
plt.show()

gini = qe.gini_coefficient(assets_dist)
print(f"\nGini coefficient: {gini:.4f}")
```

```
Gini coefficient: 0.3645
```

125.7 Summary and Comparison

This lecture demonstrated how to solve the Aiyagari model using:

1. **Endogenous Grid Method (EGM)** for the household problem
    - avoids costly root-finding by working backwards from the Euler equation
    - directly computes consumption from marginal utility
    - more efficient than value function iteration
2. **Simulation** for computing aggregate capital
    - simulates a large cross-section of households
    - more flexible than analytical stationary distributions
    - allows easy computation of wealth inequality measures

125.7.1 Comparison with standard approach

Compared to the *standard Aiyagari lecture*:

Advantages:

- EGM avoids the root-finding required by value function iteration
- simulation is more flexible (works with continuous shocks, non-linear policies)
- it is easy to compute distributional statistics (Gini, percentiles, etc.)
- the approach is simpler to extend to more complex models

Disadvantages:

- simulation requires a large number of households for accuracy
- equilibrium computation is subject to Monte Carlo noise
- it is less precise than the analytical stationary distribution

125.7.2 Extensions

This framework can be easily extended to:

- continuous income shocks (e.g., lognormal)
- more complex preference specifications
- aggregate shocks and heterogeneous agent New Keynesian (HANK) models
- life-cycle models with age-dependent policies

125.8 Exercises

Exercise 125.8.1

Compare the speed and accuracy of EGM against the value function iteration approach used in the *standard Aiyagari lecture*.

1. Solve the household problem with both methods at the same prices.
2. Time both methods and compare the resulting policies.
3. Which method is faster? Are the policies close?

Exercise 125.8.2

Study how the wealth distribution changes with the discount factor β.

1. Compute equilibria for $\beta \in \{0.94, 0.95, 0.96, 0.97\}$.
2. For each β, compute and plot the wealth distribution.
3. How does the Gini coefficient change with β?
4. Explain the economic intuition.

Exercise 125.8.3

The simulation method introduced in this lecture uses a fixed number of periods. Investigate the impact of this choice:

1. Vary `num_periods` from 200 to 2000.
2. For each value, compute the mean assets multiple times with different random keys.
3. Plot the standard deviation of the capital estimate as a function of `num_periods`.
4. What is the trade-off between accuracy and computational cost?

Exercise 125.8.4

Extend the model to include a third employment state (e.g., unemployed, part-time, full-time):

1. Set up a 3-state Markov chain with appropriate transition probabilities.
2. Define income levels for each state.
3. Re-compute the equilibrium.
4. How does the additional heterogeneity affect the wealth distribution?

CHAPTER

SIX

TRANSITIONS IN AN OVERLAPPING GENERATIONS MODEL

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install --upgrade quantecon
```

126.1 Overview

This lecture presents a life-cycle model consisting of overlapping generations of two-period lived people proposed by Peter Diamond [Diamond, 1965].

We'll present the version that was analyzed in chapter 2 of Auerbach and Kotlikoff (1987) [Auerbach and Kotlikoff, 1987].

Auerbach and Kotlikoff (1987) used their two period model as a warm-up for their analysis of overlapping generation models of long-lived people that is the main topic of their book.

Their model of two-period lived overlapping generations is a useful starting point because

- it sets forth the structure of interactions between generations of different agents who are alive at a given date
- it activates forces and tradeoffs confronting the government and successive generations of people
- it is a good laboratory for studying connections between government tax and subsidy programs and for policies for issuing and servicing government debt
- some interesting experiments involving transitions from one steady state to another can be computed by hand
- it is a good setting for illustrating a **shooting method** for solving a system of non-linear difference equations with initial and terminal condition

Note

Auerbach and Kotlikoff use computer code to calculate transition paths for their models with long-lived people.

We take the liberty of extending Auerbach and Kotlikoff's chapter 2 model to study some arrangements for redistributing resources across generations

- these take the form of a sequence of age-specific lump sum taxes and transfers

We study how these arrangements affect capital accumulation and government debt

126.2 Setting

Time is discrete and is indexed by $t = 0, 1, 2, ...$

The economy lives forever, but the people inside it do not.

At each time $t \geq 0$ a representative old person and a representative young person are alive.

At time t a representative old person coexists with a representative young person who will become an old person at time $t + 1$.

We assume that the population size is constant over time.

A young person works, saves, and consumes.

An old person dissaves and consumes, but does not work.

A government lives forever, i.e., at $t = 0, 1, 2, ...$

Each period $t \geq 0$, the government taxes, spends, transfers, and borrows.

Initial conditions set outside the model at time $t = 0$ are

- K_0 – initial capital stock brought into time $t = 0$ by a representative initial old person
- D_0 – government debt falling due at $t = 0$ and owned by a representative old person at time $t = 0$

K_0 and D_0 are both measured in units of time 0 goods.

A government **policy** consists of five sequences $\{G_t, D_t, \tau_t, \delta_{ot}, \delta_{yt}\}_{t=0}^{\infty}$ whose components are

- τ_t – flat rate tax at time t on wages and earnings from capital and government bonds
- D_t – one-period government bond principal due at time t, per capita
- G_t – government purchases of goods at time t, per capita
- δ_{yt} – a lump sum tax on each young person at time t
- δ_{ot} – a lump sum tax on each old person at time t

An **allocation** is a collection of sequences $\{C_{yt}, C_{ot}, K_{t+1}, L_t, Y_t, G_t\}_{t=0}^{\infty}$; constituents of the sequences include

- K_t – physical capital per capita
- L_t – labor per capita
- Y_t – output per capita

and also

- C_{yt} – consumption of young person at time $t \geq 0$
- C_{ot} – consumption of old person at time $t \geq 0$
- $K_{t+1} - K_t \equiv I_t$ – investment in physical capital at time $t \geq 0$
- G_t – government purchases

National income and product accounts consist of a sequence of equalities

- $Y_t = C_{yt} + C_{ot} + (K_{t+1} - K_t) + G_t, \quad t \geq 0$

A **price system** is a pair of sequences $\{W_t, r_t\}_{t=0}^{\infty}$; constituents of a price sequence include rental rates for the factors of production

- W_t – rental rate for labor at time $t \geq 0$
- r_t – rental rate for capital at time $t \geq 0$

126.3 Production

There are two factors of production, physical capital K_t and labor L_t.

Capital does not depreciate, so r_t below is a net rate of return.

Because each young person supplies one unit of labor inelastically and the population is constant, labor supply satisfies $L_t = 1$ for all t.

We use that fact to simplify formulas below.

The initial capital stock K_0 is owned by the representative initial old person, who rents it to the firm at time 0.

Net investment rate I_t at time t is

$$I_t = K_{t+1} - K_t$$

The capital stock at time t emerges from cumulating past rates of investment:

$$K_t = K_0 + \sum_{s=0}^{t-1} I_s$$

A Cobb-Douglas technology converts physical capital K_t and labor services L_t into output Y_t

$$Y_t = K_t^\alpha L_t^{1-\alpha}, \quad \alpha \in (0,1) \tag{126.1}$$

126.4 Government

At time $t-1$, the government issues one-period risk-free debt that promises to pay D_t time t goods per capita at time t.

Young people at time t purchase government debt D_{t+1} that matures at time $t+1$.

Government debt issued at t bears a before-tax net rate of interest r_{t+1} that is paid at time $t+1$.

The government budget constraint at time $t \geq 0$ is

$$D_{t+1} - D_t = r_t D_t + G_t - T_t$$

or

$$D_{t+1} = (1 + r_t) D_t + G_t - T_t. \tag{126.2}$$

Total tax collections net of transfers equal T_t and satisfy

$$T_t = \tau_t W_t L_t + \tau_t r_t (D_t + K_t) + \delta_{yt} + \delta_{ot}$$

Because one young person and one old person are alive at each date, the two lump sum taxes enter T_t with unit weights.

126.5 Activities in factor markets

Old people: At each $t \geq 0$, a representative old person

- brings K_t and D_t into the period,
- rents capital to a representative firm for $r_t K_t$,

- pays taxes $\tau_t r_t (K_t + D_t)$ on its rental and interest earnings,
- pays a lump sum tax δ_{ot} to the government,
- sells K_t to a young person.

Young people: At each $t \geq 0$, a representative young person

- sells one unit of labor services to a representative firm for W_t in wages,
- pays taxes $\tau_t W_t$ on its labor earnings
- pays a lump sum tax δ_{yt} to the government,
- spends C_{yt} on consumption,
- acquires non-negative assets A_{t+1} consisting of a sum of physical capital K_{t+1} and one-period government bonds D_{t+1} that mature at $t+1$.

Note

If a lump-sum tax is negative, it means that the government pays the person a subsidy.

126.6 Representative firm's problem

The representative firm hires labor services from young people at competitive wage rate W_t and hires capital from old people at competitive rental rate r_t.

The rental rate on capital r_t equals the interest rate on government one-period bonds.

Units of the rental rates are:

- for W_t, output at time t per unit of labor at time t
- for r_t, output at time t per unit of capital at time t

We take output at time t as **numeraire**, so the price of output at time t is one.

The firm's profits at time t are

$$K_t^\alpha L_t^{1-\alpha} - r_t K_t - W_t L_t.$$

To maximize profits a firm equates marginal products to rental rates:

$$\begin{aligned} W_t &= (1-\alpha) K_t^\alpha L_t^{-\alpha} \\ r_t &= \alpha K_t^{\alpha-1} L_t^{1-\alpha} \end{aligned} \tag{126.3}$$

Output can be consumed either by old people or young people; or sold to young people who use it to augment the capital stock; or sold to the government for uses that do not generate utility for the people in the model (i.e., "it is thrown into the ocean").

The firm thus sells output to old people, young people, and the government.

126.7 Individuals' problems

126.7.1 Initial old person

At time $t = 0$, a representative initial old person is endowed with $(1+r_0(1-\tau_0))A_0$ in initial assets, where $A_0 = K_0+D_0$.

It must pay a lump sum tax to (if positive) or receive a subsidy from (if negative) δ_{o0} the government.

An old person's budget constraint is

$$C_{o0} = (1 + r_0(1 - \tau_0))A_0 - \delta_{o0}. \tag{126.4}$$

An initial old person's utility function is C_{o0}, so the person's optimal consumption plan is provided by equation (126.4).

126.7.2 Young person

At each $t \geq 0$, a young person inelastically supplies one unit of labor and in return receives pre-tax labor earnings of W_t units of output.

A young person's post-tax-and-transfer earnings are $W_t(1 - \tau_t) - \delta_{yt}$.

At each $t \geq 0$, a young person chooses a consumption plan C_{yt}, C_{ot+1} to maximize the Cobb-Douglas utility function

$$U_t = C_{yt}^{\beta} C_{o,t+1}^{1-\beta}, \quad \beta \in (0, 1) \tag{126.5}$$

subject to the following budget constraints at times t and $t + 1$:

$$\begin{aligned} C_{yt} + A_{t+1} &= W_t(1 - \tau_t) - \delta_{yt} \\ C_{ot+1} &= (1 + r_{t+1}(1 - \tau_{t+1}))A_{t+1} - \delta_{o,t+1} \end{aligned} \tag{126.6}$$

Solving the second equation of (126.6) for savings A_{t+1} and substituting it into the first equation implies the present value budget constraint

$$C_{yt} + \frac{C_{ot+1}}{1 + r_{t+1}(1 - \tau_{t+1})} = W_t(1 - \tau_t) - \delta_{yt} - \frac{\delta_{o,t+1}}{1 + r_{t+1}(1 - \tau_{t+1})} \tag{126.7}$$

To solve the young person's choice problem, form a Lagrangian

$$\begin{aligned} \mathcal{L} &= C_{yt}^{\beta} C_{o,t+1}^{1-\beta} \\ &\quad + \lambda\Big[W_t(1 - \tau_t) - \delta_{yt} - \frac{\delta_{o,t+1}}{1 + r_{t+1}(1 - \tau_{t+1})} - C_{yt} - \frac{C_{ot+1}}{1 + r_{t+1}(1 - \tau_{t+1})}\Big], \end{aligned} \tag{126.8}$$

where $\lambda \geq 0$ is a Lagrange multiplier on the intertemporal budget constraint (126.7).

After several lines of algebra, the intertemporal budget constraint (126.7) and the first-order conditions for maximizing $\mathcal{L}$ with respect to C_{yt}, C_{ot+1} imply that an optimal consumption plan satisfies

$$\begin{aligned} C_{yt} &= \beta\Big[W_t(1 - \tau_t) - \delta_{yt} - \frac{\delta_{o,t+1}}{1 + r_{t+1}(1 - \tau_{t+1})}\Big] \\ \frac{C_{o,t+1}}{1 + r_{t+1}(1 - \tau_{t+1})} &= (1 - \beta)\Big[W_t(1 - \tau_t) - \delta_{yt} - \frac{\delta_{o,t+1}}{1 + r_{t+1}(1 - \tau_{t+1})}\Big] \end{aligned} \tag{126.9}$$

The first-order condition for the Lagrangian (126.8) with respect to the Lagrange multiplier λ recovers the budget constraint (126.7), which, using (126.9) gives the optimal savings plan

$$A_{t+1} = (1 - \beta)[(1 - \tau_t)W_t - \delta_{yt}] + \beta\frac{\delta_{o,t+1}}{1 + r_{t+1}(1 - \tau_{t+1})} \tag{126.10}$$

126.8 Equilibrium

Definition: An equilibrium is an allocation, a government policy, and a price system with the properties that

- given the price system and the government policy, the allocation solves
  - representative firms' problems for $t \geq 0$
  - individual persons' problems for $t \geq 0$
- given the price system and the allocation, the government budget constraint is satisfied for all $t \geq 0$.

126.9 Next steps

To begin our analysis of equilibrium outcomes, we'll study the special case of the model with which Auerbach and Kotlikoff (1987) [Auerbach and Kotlikoff, 1987] began their analysis in chapter 2.

It can be solved by hand.

We shall do that next.

After we derive a closed form solution, we'll pretend that we don't know and will compute equilibrium outcome paths.

We'll do that by first formulating an equilibrium as a fixed point of a mapping from sequences of factor prices and tax rates to sequences of factor prices and tax rates.

We'll compute an equilibrium by iterating to convergence on that mapping.

126.10 Closed form solution

To get the special chapter 2 case of Auerbach and Kotlikoff (1987) [Auerbach and Kotlikoff, 1987], we set both δ_{ot} and δ_{yt} to zero.

As our special case of (126.9), we compute the following consumption-savings plan for a representative young person:

$$
\begin{aligned}
C_{yt} &= \beta(1-\tau_t)W_t \\
A_{t+1} &= (1-\beta)(1-\tau_t)W_t
\end{aligned}
$$

Using (126.3) and $A_t = K_t + D_t$, we obtain the following closed form transition law for capital:

$$
K_{t+1} = K_t^{\alpha}\left(1-\tau_t\right)\left(1-\alpha\right)\left(1-\beta\right) - D_{t+1} \tag{126.11}
$$

The debt term is dated $t+1$ because the assets A_{t+1} that a young person carries into time $t+1$ consist of physical capital K_{t+1} *and* the government bonds D_{t+1} that mature at $t+1$.

126.10.1 Steady states

From (126.11) and the government budget constraint (126.2), we compute **time-invariant** or **steady state values** $\hat{K}, \hat{D}, \hat{T}$:

$$
\begin{aligned}
\hat{K} &= \hat{K}\left(1-\hat{\tau}\right)\left(1-\alpha\right)\left(1-\beta\right) - \hat{D} \\
\hat{D} &= (1+\hat{r})\hat{D} + \hat{G} - \hat{T} \\
\hat{T} &= \hat{\tau}\hat{Y} + \hat{\tau}\hat{r}\hat{D}.
\end{aligned} \tag{126.12}
$$

These imply

$$\hat{\tau} = \frac{\hat{G} + \hat{r}\hat{D}}{\hat{Y} + \hat{r}\hat{D}}$$

When $\hat{D} = 0$, the first equation of (126.12) can be solved in closed form for

$$\hat{K} = \left[(1 - \hat{\tau})(1 - \alpha)(1 - \beta)\right]^{\frac{1}{1-\alpha}}$$

When $\hat{D} \neq 0$, that equation must be solved numerically, a task that Exercise 126.12.1 takes up.

Let's take an example in which

1. there is no initial government debt, $D_t = 0$,
2. government consumption G_t equals 15% of output Y_t

Our formulas for steady-state values tell us that

$$\begin{aligned}\hat{D} &= 0 \\ \hat{G} &= 0.15\hat{Y} \\ \hat{\tau} &= 0.15\end{aligned}$$

126.10.2 Implementation

```
import numpy as np
import matplotlib.pyplot as plt
from numba import jit
from quantecon.optimize import brent_max
```

For parameters $\alpha = 0.3$ and $\beta = 0.5$, let's compute $\hat{K}$:

```
# parameters
α = 0.3
β = 0.5

# steady states of τ and D
τ_hat = 0.15
D_hat = 0.

# solve for steady state of K
K_hat = ((1 - τ_hat) * (1 - α) * (1 - β)) ** (1 / (1 - α))
K_hat
```

```
0.17694509514972878
```

Knowing $\hat{K}$, we can calculate other equilibrium objects.

Let's first define some Python helper functions.

```
@jit
def K_to_Y(K, α):

    return K ** α

@jit
```

(continues on next page)

(continued from previous page)

```
def K_to_r(K, α):

    return α * K ** (α - 1)

@jit
def K_to_W(K, α):

    return (1 - α) * K ** α

@jit
def K_to_C(K, D, τ, r, α, β):

    # optimal consumption for the old when δ=0
    A = K + D
    Co = A * (1 + r * (1 - τ))

    # optimal consumption for the young when δ=0
    W = K_to_W(K, α)
    Cy = β * W * (1 - τ)

    return Cy, Co
```

We can use these helper functions to obtain steady state values $\hat{Y}$, $\hat{r}$, and $\hat{W}$ associated with steady state values $\hat{K}$ and $\hat{r}$.

```
Y_hat, r_hat, W_hat = K_to_Y(K_hat, α), K_to_r(K_hat, α), K_to_W(K_hat, α)
Y_hat, r_hat, W_hat
```

```
(0.5947734290747186, 1.0084033613445376, 0.41634140035230305)
```

The steady state net rate of return $\hat{r}$ is close to one, i.e., about 100 percent.

That is not a mistake: a period in this model is half of a lifetime, so $\hat{r}$ cumulates returns over a generation.

Since steady state government debt $\hat{D}$ is 0, all taxes are used to pay for government expenditures

```
G_hat = τ_hat * Y_hat
G_hat
```

```
0.0892160143612078
```

We use the optimal consumption plans to find steady state consumptions for young and old

```
Cy_hat, Co_hat = K_to_C(K_hat, D_hat, τ_hat, r_hat, α, β)
Cy_hat, Co_hat
```

```
(0.17694509514972878, 0.32861231956378195)
```

Let's store the steady state quantities and prices using an array called `init_ss`

```
init_ss = np.array([K_hat, Y_hat, Cy_hat, Co_hat,      # quantities
                    W_hat, r_hat,                      # prices
                    τ_hat, D_hat, G_hat                # policies
                    ])
```

126.10.3 Transitions

We have computed a steady state in which the government policy sequences are each constant over time.

We'll use this steady state as an initial condition at time $t = 0$ for another economy in which government policy sequences are with time-varying sequences.

To make sense of our calculation, we'll treat $t = 0$ as time when a huge unanticipated shock occurs in the form of

- a time-varying government policy sequences that disrupts an original steady state
- new government policy sequences are eventually time-invariant in the sense that after some date $T > 0$, each sequence is constant over time.
- sudden revelation of a new government policy in the form of sequences starting at time $t = 0$

We assume that everyone, including old people at time $t = 0$, knows the new government policy sequence and chooses accordingly.

As the capital stock and other aggregates adjust to the fiscal policy change over time, the economy will approach a new steady state.

We can find a transition path from an old steady state to a new steady state by employing a fixed-point algorithm in a space of sequences.

But in our special case with its closed form solution, we have available a simpler and faster approach.

Here we define a Python class `ClosedFormTrans` that computes length T transition path in response to a particular fiscal policy change.

We choose T large enough so that we have gotten very close to a new steady state after T periods.

The class takes three keyword arguments, `τ_pol`, `D_pol`, and `G_pol`.

These are sequences of tax rate, government debt level, and government purchases, respectively.

In each policy experiment below, we will pass two out of three as inputs required to depict a fiscal policy.

We'll then compute the single remaining undetermined policy variable from the government budget constraint.

When we simulate transition paths, it is useful to distinguish **state variables** at time t such as K_t, Y_t, D_t, W_t, r_t from **control variables** that include $C_{yt}, C_{ot}, \tau_t, G_t$.

```
class ClosedFormTrans:
    """
    This class simulates length T transitional path of a economy
    in response to a fiscal policy change given its initial steady
    state. The simulation is based on the closed form solution when
    the lump sum taxations are absent.

    """

    def __init__(self, α, β):

        self.α, self.β = α, β

    def simulate(self,
                 T,           # length of transitional path to simulate
                 init_ss,     # initial steady state
                 τ_pol=None,  # sequence of tax rates
                 D_pol=None,  # sequence of government debt levels
                 G_pol=None): # sequence of government purchases
```

(continues on next page)

(continued from previous page)

```
        α, β = self.α, self.β

        # unpack the steady state variables
        K_hat, Y_hat, Cy_hat, Co_hat = init_ss[:4]
        W_hat, r_hat = init_ss[4:6]
        τ_hat, D_hat, G_hat = init_ss[6:9]

```

We can create an instance `closed` for model parameters $\{\alpha, \beta\}$ and use it for various fiscal policy experiments.

```
closed = ClosedFormTrans(α, β)
```

126.10.4 Experiment 1: a tax cut

To illustrate the power of `ClosedFormTrans`, let's first experiment with the following fiscal policy change:

1. at $t = 0$, the government unexpectedly announces a one-period tax cut, $\tau_0 = (1 - \frac{1}{3})\hat{\tau}$, by issuing government debt $\bar{D}$
2. from $t = 1$, the government will keep $D_t = \bar{D}$ and adjust τ_t to collect taxation to pay for the government consumption and interest payments on the debt
3. government consumption G_t will be fixed at $0.15\hat{Y}$

The following equations completely characterize the equilibrium transition path originating from the initial steady state

$$
\begin{aligned}
K_{t+1} &= K_t^{\alpha}\left(1-\tau_t\right)\left(1-\alpha\right)\left(1-\beta\right) - \bar{D} \\
\tau_0 &= (1 - \frac{1}{3})\hat{\tau} \\
\bar{D} &= \hat{G} - \tau_0 \hat{Y} \\
\tau_t &= \frac{\hat{G} + r_t \bar{D}}{\hat{Y} + r_t \bar{D}}
\end{aligned}
$$

We can simulate the transition for 20 periods, after which the economy will be close to a new steady state.

The first step is to prepare sequences of policy variables that describe fiscal policy.

We must define sequences of government expenditure $\{G_t\}_{t=0}^{T}$ and debt level $\{D_t\}_{t=0}^{T+1}$ in advance, then pass them to the solver.

```
T = 20

# tax cut
τ0 = τ_hat * (1 - 1/3)

# sequence of government purchase
G_seq = τ_hat * Y_hat * np.ones(T+1)

# sequence of government debt
D_bar = G_hat - τ0 * Y_hat
D_seq = np.ones(T+2) * D_bar
D_seq[0] = D_hat
```

Let's use the `simulate` method of `closed` to compute dynamic transitions.

Note that we leave `τ_pol` as `None`, since the tax rates need to be determined to satisfy the government budget constraint.

```
quant_seq1, price_seq1, policy_seq1 = closed.simulate(T, init_ss,
                                                      D_pol=D_seq,
                                                      G_pol=G_seq)
closed.plot()
```

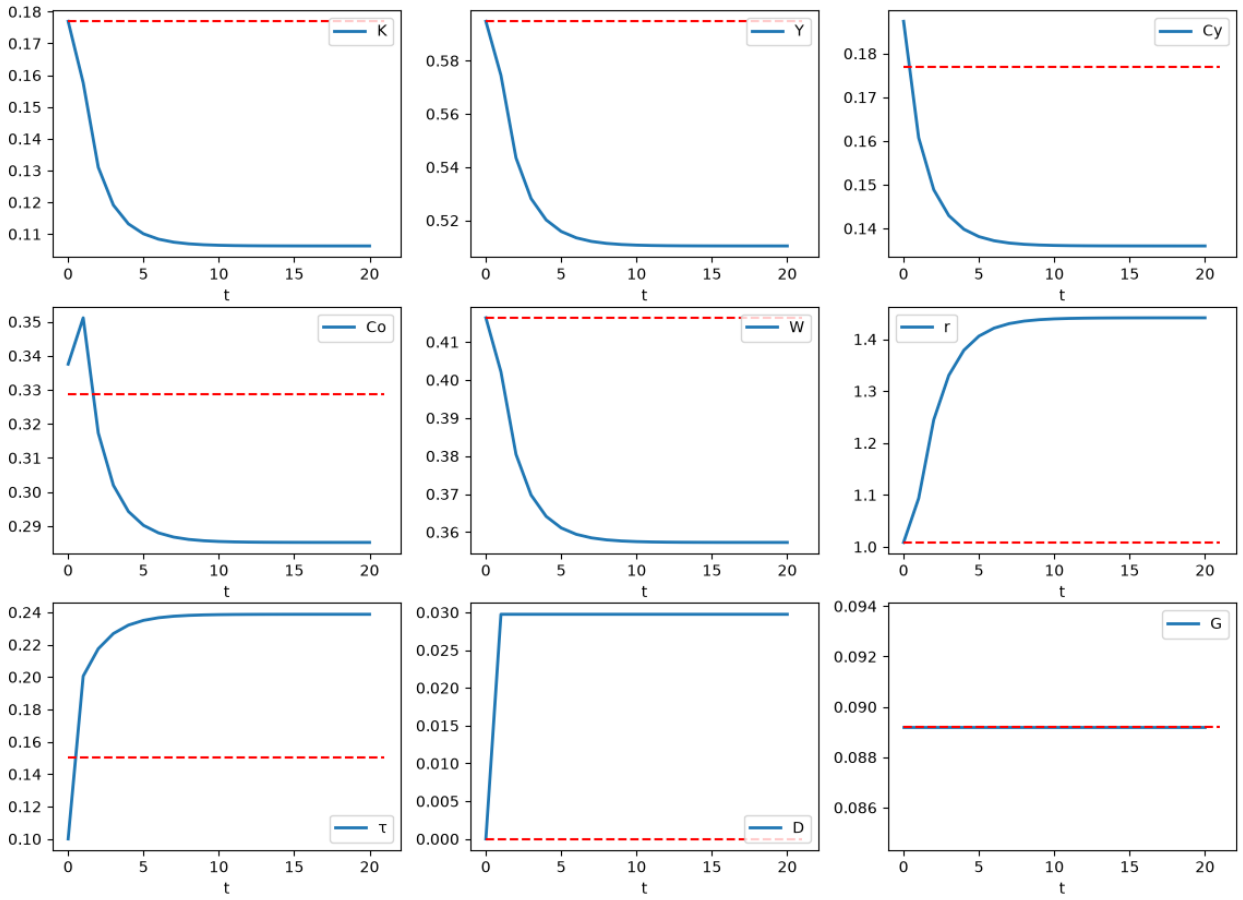

Fig. 126.1: Transition after a tax cut

We can also experiment with a lower tax cut rate, such as 0.2.

```
# lower tax cut rate
τ0 = 0.15 * (1 - 0.2)

# the corresponding debt sequence
D_bar = G_hat - τ0 * Y_hat
D_seq = np.ones(T+2) * D_bar
D_seq[0] = D_hat

quant_seq2, price_seq2, policy_seq2 = closed.simulate(T, init_ss,
                                                      D_pol=D_seq,
                                                      G_pol=G_seq)
```

```
fig, axs = plt.subplots(3, 3, figsize=(14, 10))
```

(continues on next page)

(continued from previous page)

```
# quantities
for i, name in enumerate(['K', 'Y', 'Cy', 'Co']):
    ax = axs[i//3, i%3]
    ax.plot(range(T+1), quant_seq1[:T+1, i], label=f'{name}, 1/3', lw=2)
    ax.plot(range(T+1), quant_seq2[:T+1, i], label=f'{name}, 0.2', lw=2)
    ax.hlines(init_ss[i], 0, T+1, color='r', linestyle='--')
    ax.legend()
    ax.set_xlabel('t')

# prices
for i, name in enumerate(['W', 'r']):
    ax = axs[(i+4)//3, (i+4)%3]
    ax.plot(range(T+1), price_seq1[:T+1, i], label=f'{name}, 1/3', lw=2)
    ax.plot(range(T+1), price_seq2[:T+1, i], label=f'{name}, 0.2', lw=2)
    ax.hlines(init_ss[i+4], 0, T+1, color='r', linestyle='--')
    ax.legend()
    ax.set_xlabel('t')

# policies
for i, name in enumerate(['τ', 'D', 'G']):

    ax.plot(range(T+1), policy_seq2[:T+1, i], label=f'{name}, 0.2', lw=2)
    ax.hlines(init_ss[i+6], 0, T+1, color='r', linestyle='--')
    ax.legend()
    ax.set_xlabel('t')
```

The economy with lower tax cut rate at $t = 0$ has the same transitional pattern, but is less distorted, and it converges to a new steady state with higher physical capital stock.

126.10.5 Experiment 2: government asset accumulation

Assume that the economy is initially in the same steady state.

Now the government promises to cut its spending on services and goods by half $\forall t \geq 0$.

The government targets the same tax rate $\tau_t = \hat{\tau}$ and to accumulate assets $-D_t$ over time.

To conduct this experiment, we pass `τ_seq` and `G_seq` as inputs and let `D_pol` be determined along the path by satisfying the government budget constraint.

```
# government expenditure cut by a half
G_seq = τ_hat * 0.5 * Y_hat * np.ones(T+1)

# targeted tax rate
τ_seq = τ_hat * np.ones(T+1)

closed.simulate(T, init_ss, τ_pol=τ_seq, G_pol=G_seq);
closed.plot()
```

As the government accumulates assets, it supplies funds that would otherwise have been supplied by private savers, so the capital stock rises and the rental rate on capital falls.

As a result, the ratio $-\frac{D_t}{K_t}$ of the government asset to physical capital used in production will increase over time

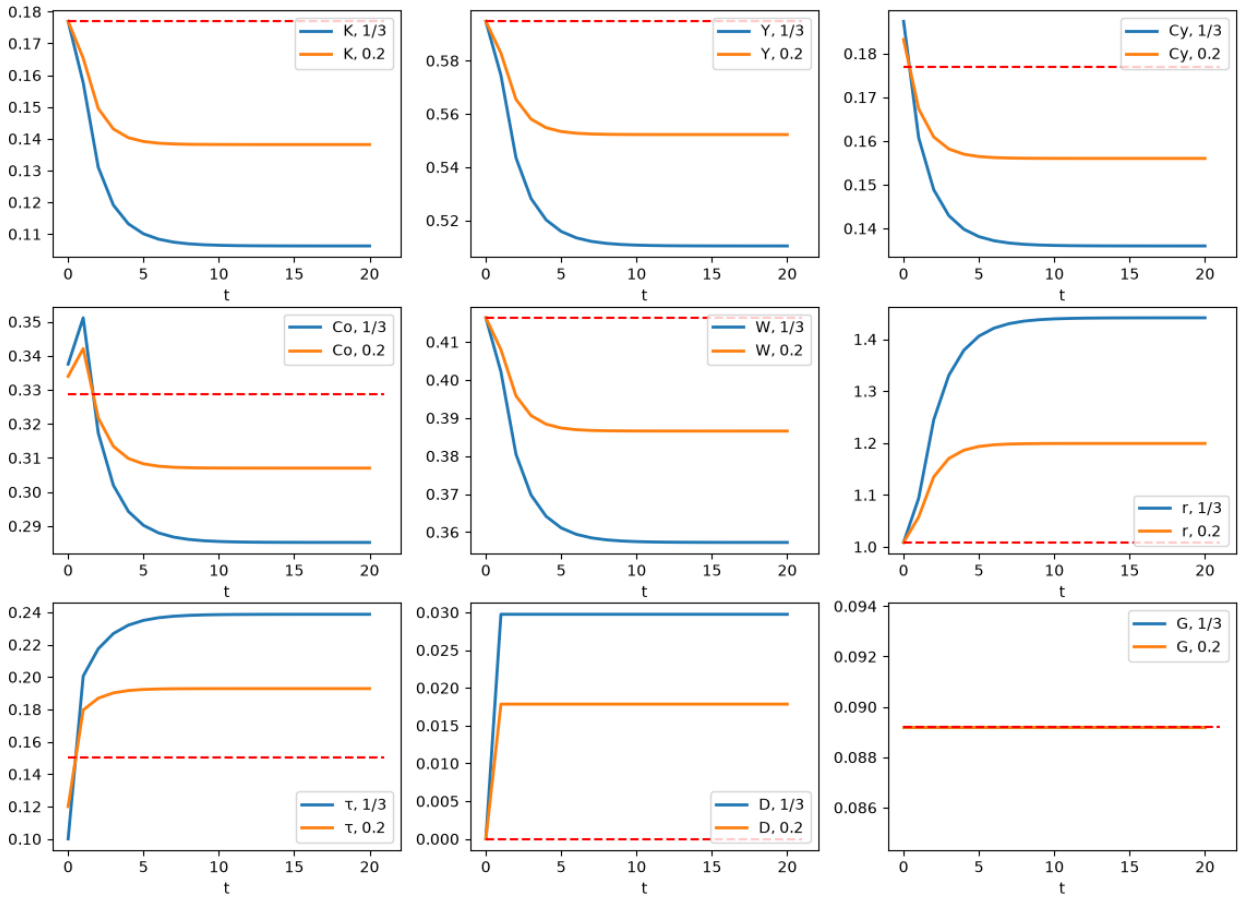

Fig. 126.2: Tax cut transitions for two tax rates

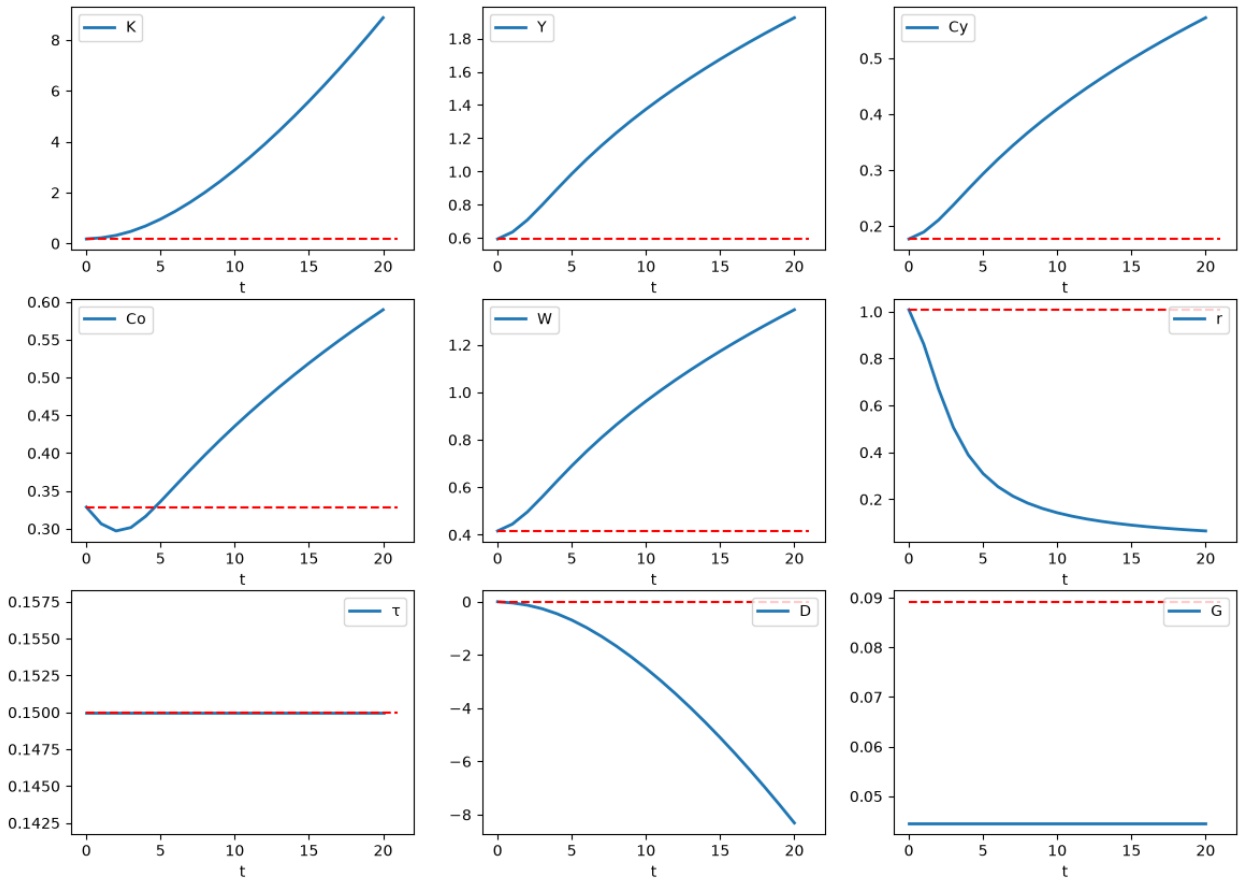

Fig. 126.3: Transition after a permanent expenditure cut

```
plt.plot(range(T+1), -closed.policy_seq[:-1, 1] / closed.quant_seq[:, 0], lw=2)
plt.xlabel('t')
plt.ylabel('-D/K')
plt.show()
```

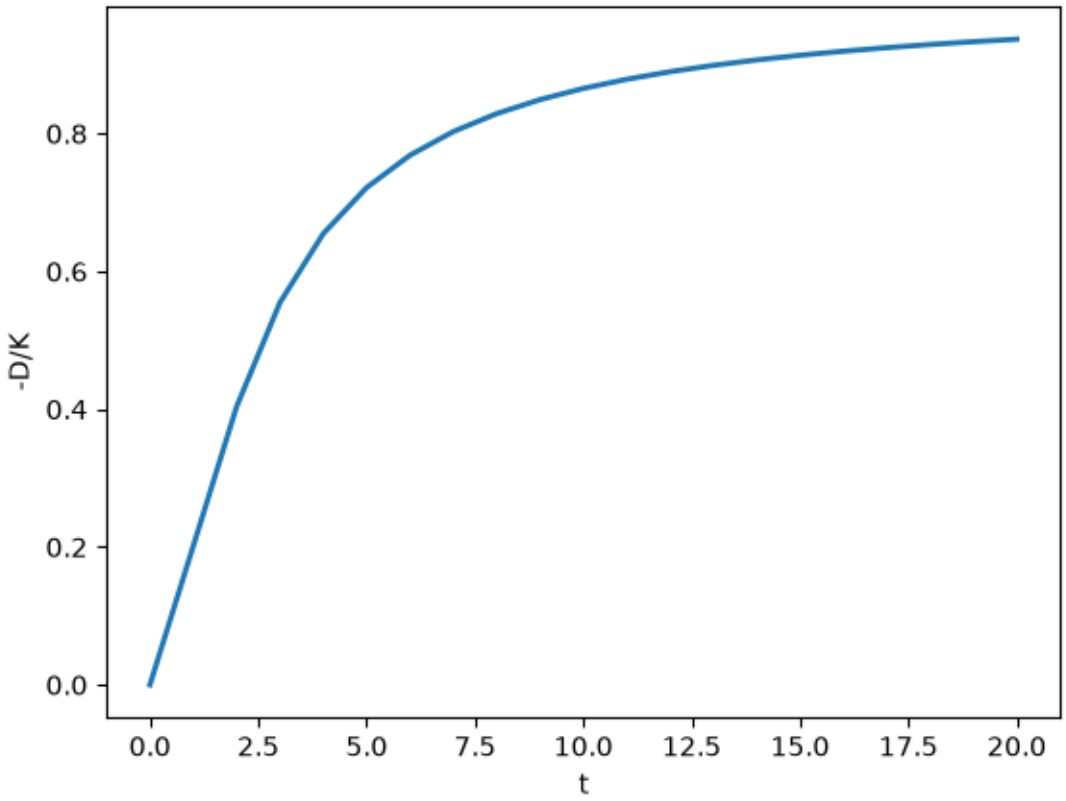

Fig. 126.4: Ratio of government assets to capital

We want to know how this policy experiment affects individuals.

In the long run, future cohorts will enjoy higher consumption throughout their lives because they will earn higher labor income when they work.

In the short run, early cohorts lose.

The representative old person at $t = 0$ is unaffected, because K_0, r_0, and τ_0 are all unchanged at $t = 0$.

But the cohorts that are young at $t = 0$ and $t = 1$ save at wages that the policy has not yet raised, and they collect their returns at the much lower interest rates that the larger capital stock brings.

Exercise 126.12.2 computes these gains and losses cohort by cohort.

Such distinct long run and short run effects motivate us to study transition paths.

Note

Although the consumptions in the new steady state are strictly higher, it is at a cost of fewer public services and goods.

126.10.6 Experiment 3: temporary expenditure cut

Let's now investigate a scenario in which the government again accumulates assets by cutting its spending.

But now the cut lasts for one period only: the government sets $G_0 = 0$ and returns its purchases to $\hat{G}$ from $t = 1$ onwards.

From $t \geq 1$, government expenditures return to $\hat{G}$ and τ_t adjusts to maintain the asset level $-D_t = -D_1$.

```
# sequence of government purchase
G_seq = τ_hat * Y_hat * np.ones(T+1)
G_seq[0] = 0

# sequence of government debt
D_bar = G_seq[0] - τ_hat * Y_hat
D_seq = D_bar * np.ones(T+2)
D_seq[0] = D_hat

closed.simulate(T, init_ss, D_pol=D_seq, G_pol=G_seq);
closed.plot()
```

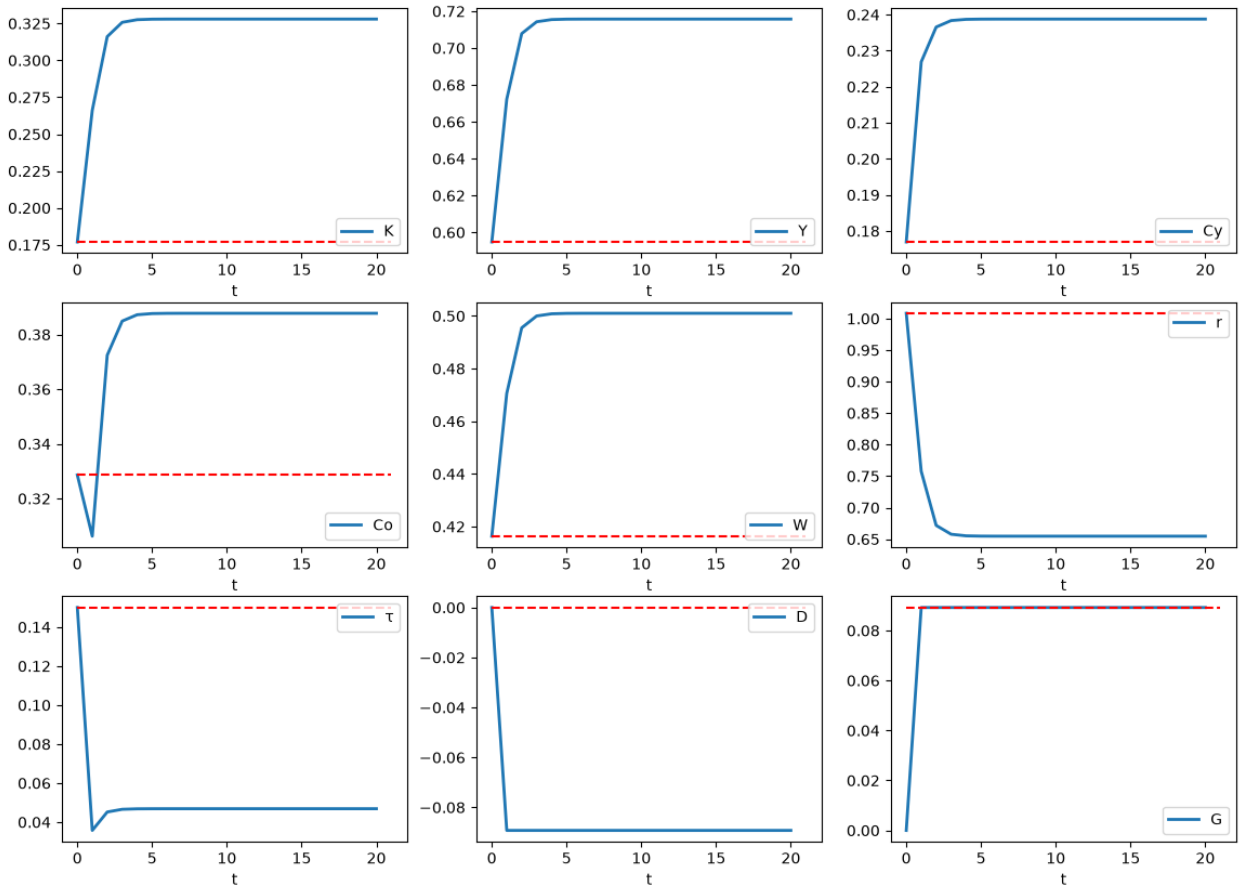

Fig. 126.5: Transition after a temporary expenditure cut

The economy quickly converges to a new steady state with higher physical capital stock, lower interest rate, higher wage rate, and higher consumptions for both the young and the old.

Even though government expenditure G_t returns to its high initial level from $t \geq 1$, the government can balance the budget at a lower tax rate because it gathers additional revenue $-r_t D_t$ from the asset accumulated during the temporary cut in the spendings.

As in *Experiment 2: government asset accumulation*, the cohorts that are young early in the transition lose from this policy shock, because they save before wages rise and earn the lower interest rates that follow.

126.11 A computational strategy

With the preceding calculations, we studied dynamic transitions instigated by alternative fiscal policies.

In all these experiments, we maintained the assumption that lump sum taxes were absent so that $\delta_{yt} = 0, \delta_{ot} = 0$.

In this section, we investigate the transition dynamics when the lump sum taxes are present.

The government will use lump sum taxes and transfers to redistribute resources across successive generations.

Including lump sum taxes disrupts closed form solution because of how they make optimal consumption and saving plans depend on future prices and tax rates.

Therefore, we compute equilibrium transitional paths by finding a fixed point of a mapping from sequences to sequences.

- that fixed point pins down an equilibrium

To set the stage for the entry of the mapping whose fixed point we seek, we return to concepts introduced in section *Equilibrium*.

Definition: Given parameters $\{\alpha, \beta\}$, a competitive equilibrium consists of

- sequences of optimal consumptions $\{C_{yt}, C_{ot}\}$
- sequences of prices $\{W_t, r_t\}$
- sequences of capital stock and output $\{K_t, Y_t\}$
- sequences of tax rates, government assets (debt), government purchases, and lump sum taxes $\{\tau_t, D_t, G_t, \delta_{yt}, \delta_{ot}\}$

with the properties that

- given the price system and government fiscal policy, consumption plans are optimal
- the government budget constraints are satisfied for all t

An equilibrium transition path can be computed by "guessing and verifying" some endogenous sequences.

In our *Experiment 1: a tax cut* example, sequences $\{D_t\}_{t=0}^T$ and $\{G_t\}_{t=0}^T$ are exogenous.

In addition, we assume that the lump sum taxes $\{\delta_{yt}, \delta_{ot}\}_{t=0}^T$ are given and known to everybody inside the model.

We can solve for sequences of other equilibrium sequences following the steps below

1. guess prices $\{W_t, r_t\}_{t=0}^T$ and tax rates $\{\tau_t\}_{t=0}^T$
2. solve for optimal consumption and saving plans $\{C_{yt}, C_{ot}\}_{t=0}^T$, treating the guesses of future prices and taxes as true
3. solve for transition of the capital stock $\{K_t\}_{t=0}^T$
4. update the guesses for prices and tax rates with the values implied by the equilibrium conditions
5. iterate until convergence

Let's implement this "guess and verify" approach

We start by defining the Cobb-Douglas utility function

```
@jit
def U(Cy, Co, β):

    return (Cy ** β) * (Co ** (1-β))
```

We use `Cy_val` to compute the lifetime value of an arbitrary consumption plan, C_y, given the intertemporal budget constraint.

Note that it requires knowing future prices r_{t+1} and tax rate τ_{t+1}.

```
@jit
def Cy_val(Cy, W, r_next, τ, τ_next, δy, δo_next, β):

    # Co given by the budget constraint
    Co = (W * (1 - τ) - δy - Cy) * (1 + r_next * (1 - τ_next)) - δo_next

    return U(Cy, Co, β)
```

An optimal consumption plan C_y^* can be found by maximizing `Cy_val`.

Here is an example that computes optimal consumption $C_y^* = \hat{C}_y$ in the steady state with $\delta_{yt} = \delta_{ot} = 0$, like one that we studied earlier

```
W, r_next, τ, τ_next = W_hat, r_hat, τ_hat, τ_hat
δy, δo_next = 0, 0

Cy_opt, U_opt, _ = brent_max(Cy_val,             # maximand
                             1e-6,               # lower bound
                             W*(1-τ)-δy-1e-6,    # upper bound
                             args=(W, r_next, τ, τ_next, δy, δo_next, β))

Cy_opt, U_opt
```

```
(0.17694509514972878, 0.241135518231111)
```

Let's define a Python class `AK2` that computes the transition paths with the fixed-point algorithm.

It can handle nonzero lump sum taxes

```
class AK2():
    """
    This class simulates length T transitional path of a economy
    in response to a fiscal policy change given its initial steady
    state. The transitional path is found by employing a fixed point
    algorithm to satisfy the equilibrium conditions.

    """

    def __init__(self, α, β):

        self.α, self.β = α, β

    def simulate(self,
                 T,           # length of transitional path to simulate
                 init_ss,     # initial steady state
                 δy_seq,      # sequence of lump sum tax for the young
                 δo_seq,      # sequence of lump sum tax for the old
```

(continues on next page)

(continued from previous page)

```
            τ_pol=None,  # sequence of tax rates
            D_pol=None,  # sequence of government debt levels
            G_pol=None,  # sequence of government purchases
            verbose=False,
            max_iter=500,
            tol=1e-5):

        α, β = self.α, self.β

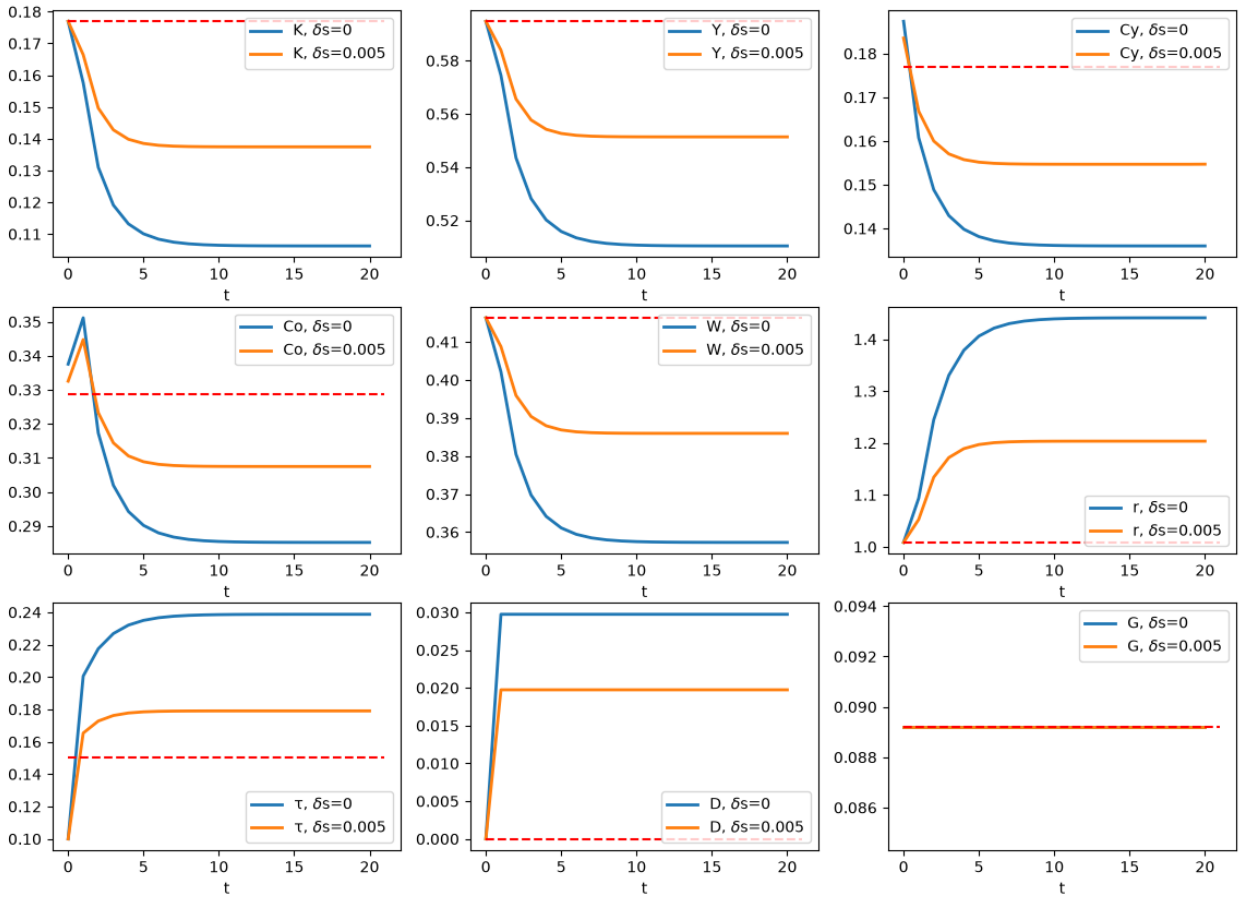

Fig. 126.8: Transitions with and without lump sum taxes

Comparing to *Experiment 1: a tax cut*, the government raises lump-sum taxes to finance the increasing debt interest payment, which is less distortionary comparing to raising the capital income tax rate.

126.11.1 Experiment 4: an unfunded social security system

In this experiment, lump-sum taxes are of equal magnitudes for old and the young, but of opposite signs.

A negative lump-sum tax is a subsidy.

Thus, in this experiment we tax the young and subsidize the old.

We start the economy at the same initial steady state that we assumed in several earlier experiments.

The government sets the lump sum taxes $\delta_{y,t} = -\delta_{o,t} = 10\%\hat{C}_y$ starting from $t = 0$.

It keeps debt levels and expenditures at their steady state levels $\hat{D}$ and $\hat{G}$.

In effect, this experiment amounts to launching an unfunded social security system.

We can use our code to compute the transition ignited by launching this system.

Let's compare the results to the *Experiment 1: a tax cut*.

```
δy_seq = np.ones(T+2) * Cy_hat * 0.1
δo_seq = np.ones(T+2) * -Cy_hat * 0.1

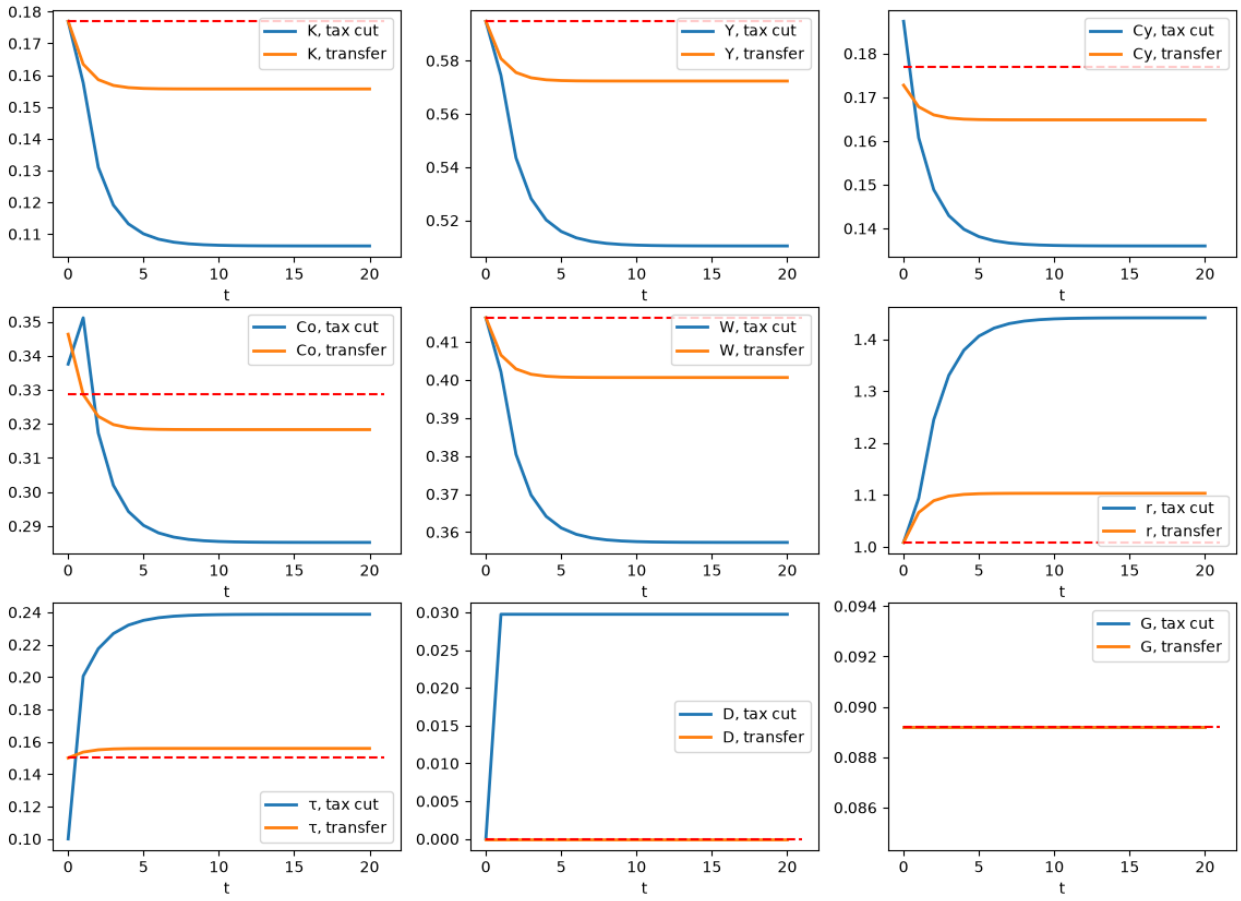

Fig. 126.9: Tax cut versus social security transfer

An initial old person benefits especially when the social security system is launched because they receive a transfer but pay nothing for it.

But in the long run, consumption of both young and old people decreases because the social security system reduces incentives to save.

That lowers the stock of physical capital and consequently lowers output.

The government must then raise tax rate in order to pay for its expenditures.

The higher rate on capital income further distorts incentives to save.

126.12 Exercises

Exercise 126.12.1

This exercise studies how government debt affects the steady state capital stock.

1. Explain why the law of motion (126.11) contains D_{t+1} rather than D_t.
2. Show that a steady state with a constant debt level $\hat{D}$ satisfies

$$\hat{K} = c\,\hat{K}^{\alpha} - \hat{D}, \qquad c \equiv (1-\hat{\tau})\,(1-\alpha)\,(1-\beta)$$

3. Holding $\hat{\tau} = 0.15$, compute $\hat{K}$ for $\hat{D} \in \{0, 0.02, 0.05, 0.07\}$.
4. Find the largest $\hat{D}$ for which a steady state exists, and count the number of steady states when $0 < \hat{D} < \hat{D}_{\max}$.

Solution

Part 1. A young person at t saves $A_{t+1} = (1-\beta)(1-\tau_t)W_t$.

Those savings are held as physical capital K_{t+1} plus the government bonds D_{t+1} that mature at $t+1$, so $K_{t+1} = A_{t+1} - D_{t+1}$.

Part 2. Set $K_{t+1} = K_t = \hat{K}$, $\tau_t = \hat{\tau}$, and $D_{t+1} = \hat{D}$ in (126.11), and use $W_t = (1-\alpha)\hat{K}^{\alpha}$.

Parts 3 and 4. The function $cK^{\alpha} - K$ is strictly concave in K, equals zero at $K = 0$, and attains its maximum at $K^{\star} = (\alpha c)^{1/(1-\alpha)}$.

So the steady state equation $cK^{\alpha} - K = \hat{D}$ has two solutions when $0 < \hat{D} < \hat{D}_{\max} \equiv c(K^{\star})^{\alpha} - K^{\star}$, one solution when $\hat{D} = \hat{D}_{\max}$, and none when $\hat{D} > \hat{D}_{\max}$.

```
from scipy.optimize import brentq

c = (1 - τ_hat) * (1 - α) * (1 - β)
K_star = (α * c) ** (1 / (1 - α))
D_max = c * K_star ** α - K_star

def K_ss(D, high=True):
    "Steady state K solving c K^α - D - K = 0."
    f = lambda K: c * K ** α - D - K
    return brentq(f, K_star, 10) if high else brentq(f, 1e-12, K_star)

print(f"D_max = {D_max:.5f} at K = {K_star:.5f}\n")
print(f"{'D':>6}  {'K (high)':>9}  {'K (low)':>9}  {'r (high)':>9}")
for D in [0.0, 0.02, 0.05, 0.07]:
    K_high = K_ss(D)
    K_low = K_ss(D, high=False) if D > 0 else 0.0
    print(f"{D:>6.2f}  {K_high:>9.5f}  {K_low:>9.5f}  {K_to_r(K_high, α):>9.4f}")
```

```
D_max = 0.07393 at K = 0.03169

     D   K (high)    K (low)   r (high)
  0.00    0.17695    0.00000     1.0084
  0.02    0.14756    0.00013     1.1451
  0.05    0.09837    0.00323     1.5210
  0.07    0.05380    0.01593     2.3204
```

Government debt crowds out capital: at $\hat{D} = 0.05$ the high-capital steady state holds only a little more than half of the capital that it holds when $\hat{D} = 0$.

Beyond $\hat{D}_{\max} \approx 0.074$, the young simply cannot save enough to absorb the debt, and no steady state exists.

The debt level $\bar{D}$ created by the tax cut in *Experiment 1: a tax cut* is well inside this limit.

Exercise 126.12.2

In *Experiment 2: government asset accumulation*, the government permanently halves its purchases and accumulates assets while holding $\tau_t = \hat{\tau}$.

Compute the consumption of the representative old person at $t = 0$ and the lifetime utility

$$U_t = C_{yt}^{\beta} C_{o,t+1}^{1-\beta}$$

of the cohorts that are young at $t = 0, 1, \ldots, 7$, each measured relative to its initial steady state value.

Which generations gain, which lose, and why?

Solution

```
G_seq_ex = τ_hat * 0.5 * Y_hat * np.ones(T+1)
τ_seq_ex = τ_hat * np.ones(T+1)
quant_ex, price_ex, policy_ex = closed.simulate(T, init_ss,
                                                τ_pol=τ_seq_ex,
                                                G_pol=G_seq_ex)

U = lambda Cy, Co: Cy ** β * Co ** (1 - β)
U_hat = U(Cy_hat, Co_hat)

print(f"initial old: Co_0 = {quant_ex[0, 3]:.5f}, "
      f"steady state Co_hat = {Co_hat:.5f}\n")
print(f"{'cohort young at t':>18}  {'Cy':>7}  {'Co next':>8}  {'r next':>7}  {'U/U_
↪hat - 1':>12}")
for t in range(8):
    gain = U(quant_ex[t, 2], quant_ex[t+1, 3]) / U_hat - 1
    print(f"{t:>18}  {quant_ex[t, 2]:>7.4f}  {quant_ex[t+1, 3]:>8.4f}"
          f"  {price_ex[t+1, 1]:>7.4f}  {gain:>11.2%}")
```

```
initial old: Co_0 = 0.32861, steady state Co_hat = 0.32861

 cohort young at t       Cy   Co next   r next   U/U_hat - 1
                 0   0.1769    0.3065   0.8616       -3.42%
                 1   0.1893    0.2971   0.6699       -1.66%
                 2   0.2108    0.3016   0.5062        4.57%
                 3   0.2377    0.3164   0.3894       13.75%
                 4   0.2660    0.3360   0.3096       23.99%
                 5   0.2935    0.3569   0.2540       34.22%
                 6   0.3195    0.3776   0.2139       44.04%
                 7   0.3439    0.3977   0.1839       53.37%
```

The representative old person at $t = 0$ is unaffected to the last digit.

That person's consumption is $(1 + r_0(1 - \tau_0))(K_0 + D_0)$, and the policy changes none of K_0, r_0, τ_0, or D_0.

The cohorts that are young at $t = 0$ and $t = 1$ lose about 3.4 and 1.7 percent of lifetime utility.

They save out of wages that the policy has barely raised, and they earn the much lower interest rates that the rising capital stock produces, with r falling from 1.01 to 0.86 and then to 0.67.

From $t = 2$ onwards every cohort gains, by 4.6 percent and then by steadily more, because by then the wage increases dominate the interest rate declines.

This is the sense in which the policy redistributes from early to later generations.

Exercise 126.12.3

This exercise uses the lump sum taxes to study an unfunded social security system in the **steady state**, complementing the transition computed in *Experiment 4: an unfunded social security system*.

Set $\delta_{yt} = -\delta_{ot} = d$ for all t, with $D_t = 0$ and $G_t = \hat{G}$.

1. Use (126.10) to show that

$$A_{t+1} = (1-\beta)\left[(1-\tau_t)W_t - d\right] - \beta\frac{d}{1 + r_{t+1}(1-\tau_{t+1})}$$

2. Use the class `AK2` to compute the new steady state for $d \in \{0,\ 0.05\hat{C}_y,\ 0.1\hat{C}_y,\ 0.2\hat{C}_y\}$, reporting K, r, τ, C_y, and C_o at the end of the transition.
3. The transfer scheme is balanced period by period. Why does it nevertheless lower both consumptions in the steady state?

Solution

Part 1. Substitute $\delta_{yt} = d$ and $\delta_{o,t+1} = -d$ into (126.10).

Part 2.

```
D_pol_ex = np.zeros(T+2)
G_pol_ex = np.ones(T+2) * G_hat

print(f"{'d / Cy_hat':>10}  {'K':>8}  {'r':>7}  {'τ':>7}  {'Cy':>7}  {'Co':>7}")
for frac in [0.0, 0.05, 0.1, 0.2]:
    d = frac * Cy_hat
    δy_ex, δo_ex = np.ones(T+2) * d, -np.ones(T+2) * d
    q_ex, p_ex, pol_ex = ak2.simulate(T, init_ss, δy_ex, δo_ex,
                                      D_pol=D_pol_ex, G_pol=G_pol_ex)
    print(f"{frac:>10.2f}  {q_ex[T, 0]:>8.5f}  {p_ex[T, 1]:>7.4f}"
          f"  {pol_ex[T, 0]:>7.5f}  {q_ex[T, 2]:>7.4f}  {q_ex[T, 3]:>7.4f}")
```

```
d / Cy_hat         K        r        τ       Cy       Co
      0.00   0.17695   1.0084  0.15000   0.1769   0.3286
      0.05   0.16637   1.0529  0.15280   0.1710   0.3236
      0.10   0.15567   1.1030  0.15588   0.1648   0.3183
      0.20   0.13376   1.2266  0.16313   0.1512   0.3064
```

Part 3. The system pays the old out of taxes on the young, so it promises old-age income that a young person does not have to save to obtain.

Both terms in the savings rule of part 1 fall with d: the young have less after-tax income, and the prospect of a transfer when old reduces the saving that they want to do with what remains.

Lower savings mean a lower capital stock, which lowers the wage and raises the interest rate.

Lower output then requires a higher flat rate tax τ to pay for the unchanged purchases $\hat{G}$, which depresses saving further.

CHAPTER

SEVEN

A LONG-LIVED, HETEROGENEOUS AGENTS, OVERLAPPING GENERATIONS MODEL

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

In addition to what's in Anaconda, this lecture will need the following library

```
!pip install jax
```

127.1 Overview

This lecture describes an overlapping generations model with these features:

- A competitive equilibrium with incomplete markets determines prices and quantities
- Agents live many periods as in [Auerbach and Kotlikoff, 1987]
- Agents receive idiosyncratic labor productivity shocks that cannot be fully insured as in [Aiyagari, 1994]
- Government fiscal policy instruments include tax rates, debt, and transfers as in chapter 2 of [Auerbach and Kotlikoff, 1987] and *Transitions in an Overlapping Generations Model*
- Among other equilibrium objects, a competitive equilibrium determines a sequence of cross-section densities of heterogeneous agents' consumptions, labor incomes, and savings

We use the model to study:

- How fiscal policies affect different generations
- How market incompleteness promotes precautionary savings
- How life-cycle savings and buffer-stock savings motives interact
- How fiscal policies redistribute resources across and within generations

As prerequisites for this lecture, we recommend two quantecon lectures:

1. Discrete State Dynamic Programming
2. *Transitions in an Overlapping Generations Model*

as well as the optional reading *The Aiyagari Model*

As usual, let's start by importing some Python modules

```
from collections import namedtuple
import numpy as np
import matplotlib.pyplot as plt
import jax.numpy as jnp
import jax.scipy as jsp
import jax
```

127.2 Environment

We start by introducing the economic environment we are operating in.

127.2.1 Demographics and time

We work in discrete time indexed by $t = 0, 1, 2, ...$

Each agent lives for $J = 50$ periods and faces no mortality risk.

We index age by $j = 0, 1, ..., 49$.

Each cohort has mass $1/J$ and total population is one, so a cross-section average equals $\frac{1}{J}\sum_j$ of cohort averages.

Throughout, we normalize each cohort's density $\mu_{j,t}$ to integrate to one, so that population weights $1/J$ appear explicitly in aggregates.

127.2.2 Individuals' state variables

Each agent i of age j at time t is characterized by two state variables: asset holdings $a_{i,j,t}$ and idiosyncratic labor productivity $\gamma_{i,j,t}$.

The idiosyncratic labor productivity process follows a two-state Markov chain that takes values γ_l and γ_h with transition matrix Π.

Newborn agents begin with an initial distribution $\pi = [0.5, 0.5]$ over these productivity states.

127.2.3 Labor supply

An agent with productivity $\gamma_{i,j,t}$ supplies $l(j)\gamma_{i,j,t}$ efficiency units of labor.

$l(j)$ is a deterministic age-specific labor efficiency units profile.

An agent's effective labor supply depends on a life-cycle efficiency profile and an idiosyncratic stochastic process.

127.2.4 Initial conditions

Newborns start with zero assets $a_{i,0,t} = 0$.

Initial idiosyncratic productivities are drawn from distribution π.

Agents leave no bequests and have terminal value function $V_J(a) = 0$.

127.3 Production

A representative firm operates a constant returns to scale Cobb-Douglas production:

$$Y_t = Z_t K_t^\alpha L_t^{1-\alpha}$$

where:

- K_t is aggregate capital
- L_t is aggregate efficiency units of labor
- Z_t is total factor productivity
- α is the capital share

Capital does not depreciate, so the rental rate r_t below is a net rate of return.

127.4 Government

The government follows a fiscal policy that includes debt, taxes, transfers, and government spending.

The government issues one-period debt D_t to finance its operations and collects revenues through a flat-rate tax τ_t on both labor and capital income.

The government also implements age-specific lump-sum taxes or transfers $\delta_{j,t}$ that can redistribute resources across different age groups.

Additionally, it makes government purchases G_t for public goods and services.

The government budget constraint at time t is

$$D_{t+1} - D_t = r_t D_t + G_t - T_t$$

where total tax revenues T_t satisfy

$$T_t = \tau_t w_t L_t + \tau_t r_t (D_t + K_t) + \frac{1}{J} \sum_j \delta_{j,t}$$

All quantities here are per capita, which is why the age-specific lump sum taxes enter with the population weights $1/J$.

127.5 Activities in factor markets

At each time $t \geq 0$, agents supply labor and capital.

127.5.1 Age-specific labor supplies

Agents of age $j \in \{0, 1, ..., J-1\}$ supply labor according to:

- Their deterministic age-efficiency profile $l(j)$
- Their current idiosyncratic productivity shock $\gamma_{i,j,t}$

Each agent supplies $l(j)\gamma_{i,j,t}$ effective units of labor and earns a competitive wage w_t per effective unit, subject to a flat tax rate τ_t on labor earnings.

127.5.2 Asset market participation

Summarizing activities in the asset market, all agents, regardless of age $j \in \{0, 1, ..., J-1\}$, can:

- Hold assets $a_{i,j,t}$ (subject to borrowing constraints)
- Earn a risk-free one-period return r_t on savings
- Pay capital income taxes at flat rate τ_t
- Receive or pay age-specific transfers $\delta_{j,t}$

127.5.3 Key features

Lifecycle patterns shape economic behavior across ages:

- Labor productivity varies systematically with age according to the profile $l(j)$, while asset holdings follow a lifecycle pattern of accumulation during the first part of life and decumulation late in life.
- There is no retirement in this model, since $l(j) > 0$ at every age, so agents draw down assets late in life because they approach the end of life and not because they stop working.
- Age-specific fiscal transfers $\delta_{j,t}$ redistribute resources across generations.

Within-cohort heterogeneity creates dispersion among agents of the same age:

- Agents of the same age differ in their asset holdings $a_{i,j,t}$ due to different histories of idiosyncratic productivity shocks, their current productivities $\gamma_{i,j,t}$, and consequently their labor incomes and financial wealth.

Cross-cohort interactions determine equilibrium outcomes through market aggregation:

- All cohorts participate together in factor markets, with asset supplies from all cohorts determining aggregate capital and effective labor supplies from all cohorts determining aggregate labor.
- Equilibrium prices reflect both lifecycle and redistributive forces.

127.6 Representative firm's problem

A representative firm chooses capital and effective labor to maximize profits

$$\max_{K,L} Z_t K_t^\alpha L_t^{1-\alpha} - r_t K_t - w_t L_t$$

First-order necessary conditions imply that

$$w_t = (1-\alpha) Z_t (K_t/L_t)^\alpha$$

and

$$r_t = \alpha Z_t (K_t/L_t)^{\alpha-1}$$

127.7 Households' problems

A household's value function satisfies a Bellman equation

$$V_{j,t}(a,\gamma) = \max_{c,a'} \{u(c) + \beta \mathbb{E}[V_{j+1,t+1}(a',\gamma')]\}$$

where maximization is subject to

$$c + a' = (1 + r_t(1-\tau_t))a + (1-\tau_t) w_t l(j) \gamma - \delta_{j,t}$$

$$c \geq 0, \qquad a' \geq 0$$

and a terminal condition $V_{J,t}(a,\gamma) = 0$

The constraint $a' \geq 0$ rules out borrowing, so an agent can self-insure only by accumulating assets.

That is the sense in which markets are incomplete here.

127.8 Population dynamics

The joint probability density function $\mu_{j,t}(a,\gamma)$ of asset holdings and idiosyncratic labor productivity evolves according to

- For newborns ($j = 0$):

$$\mu_{0,t+1}(a',\gamma') = \begin{cases} \pi(\gamma') & \text{if } a' = 0, \\ 0, & \text{otherwise} \end{cases}$$

Each cohort density integrates to one, so this density carries the cohort weight $1/J$ in the aggregates below.

- For other cohorts:

$$\mu_{j+1,t+1}(a',\gamma') = \int \mathbf{1}_{\sigma_{j,t}(a,\gamma)=a'} \Pi(\gamma,\gamma') \mu_{j,t}(a,\gamma) d(a,\gamma)$$

where $\sigma_{j,t}(a,\gamma)$ is the optimal saving policy function.

127.9 Equilibrium

An equilibrium consists of:

- Value functions $V_{j,t}$
- Policy functions $\sigma_{j,t}$
- Joint probability distributions $\mu_{j,t}$
- Prices r_t, w_t
- Government policies $\tau_t, D_t, \delta_{j,t}, G_t$

that satisfy the following conditions

- Given prices and government policies, value and policy functions solve households' problems
- Given prices, the representative firm maximizes profits
- Government budget constraints are satisfied
- Markets clear:
  - Asset market: $K_t = \frac{1}{J}\sum_j \int a\mu_{j,t}(a,\gamma)d(a,\gamma) - D_t$
  - Labor market: $L_t = \frac{1}{J}\sum_j \int l(j)\gamma\mu_{j,t}(a,\gamma)d(a,\gamma)$

Relative to the model presented in *Transitions in an Overlapping Generations Model*, the present model adds

- Heterogeneity within generations due to productivity shocks
- A precautionary savings motive
- More re-distributional effects
- More complicated transition dynamics

127.10 Implementation

Using tools in Discrete State Dynamic Programming, we solve our model by combining value function iteration with equilibrium price determination.

A sensible approach is to nest a discrete DP solver inside an outer loop that searches for market-clearing prices.

For a candidate sequence of prices interest rates r_t and wages w_t, we can solve individual households' dynamic programming problems using either value function iteration or policy iteration to obtain optimal policy functions.

We then deduce associated stationary joint probability distributions of asset holdings and idiosyncratic labor efficiency units for each age cohort.

This will give us an aggregate capital supply (from household savings) and a labor supply (from the age-efficiency profile and productivity shocks).

We can then compare these with capital and labor demand from firms, compute deviations between factor market supplies and demands, then update price guesses until we find market-clearing prices.

To construct transition dynamics, we can compute sequences of time-varying prices by using *backward induction* to compute value and policy functions, and *forward iteration* for the distributions of agents across states:

1. Outer loop (market clearing)
   - Guess initial prices (r_t, w_t)

- Iterate until asset and labor markets clear
- Use firms' first-order necessary conditions to update prices

2. Inner loop (individual dynamic programming)
   - For each age cohort:
     - Discretize asset and productivity state space
     - Use value function iteration or policy iteration
     - Solve for optimal savings policies
     - Compute stationary distributions
3. Aggregation
   - Sum across individual states within each cohort
   - Sum across cohorts both
     - Aggregate capital supply, and
     - Aggregate effective labor supply
   - Take into account population weights $1/J$
4. Transition dynamics
   - Backward induction:
     - Start from final steady state
     - Solve sequence of value functions
   - Forward iteration:
     - Start from initial distribution
     - Track cohort distributions over time
   - Market clearing in each period:
     - Solve for price sequences
     - Update until all markets clear in all periods

We start coding by defining helper functions that describe preferences, firms, and government budget constraints.

```
ϕ, k_bar = 0., 0.

@jax.jit
def V_bar(a):
    "Terminal value function depending on the asset holding."

    return - ϕ * (a - k_bar) ** 2
```

```
ν = 0.5

@jax.jit
def u(c):
    "Utility from consumption."

    return c ** (1 - ν) / (1 - ν)
```

(continues on next page)

(continued from previous page)

```
l1, l2, l3 = 0.5, 0.05, -0.0008

@jax.jit
def l(j):
    "Age-specific wage profile."

    return l1 + l2 * j + l3 * j ** 2
```

Let's define a `Firm` namedtuple that contains parameters governing the production technology.

```
Firm = namedtuple("Firm", ("α", "Z"))

def create_firm(α=0.3, Z=1):

    return Firm(α=α, Z=Z)
```

```
firm = create_firm()
```

The following helper functions link aggregates (K, L) and prices (w, r) that emerge from the representative firm's first-order necessary conditions.

```
@jax.jit
def KL_to_r(K, L, firm):

    α, Z = firm

    return Z * α * (K / L) ** (α - 1)

@jax.jit
def KL_to_w(K, L, firm):

    α, Z = firm

    return Z * (1 - α) * (K / L) ** α
```

We use a function `find_τ` to find flat tax rates that balance the government budget constraint given other policy variables that include debt levels, government spending, and transfers.

```
@jax.jit
def find_τ(policy, price, aggs):

    D, D_next, G, δ = policy
    r, w = price
    K, L = aggs

    # each cohort has mass 1/J, so per capita transfers are δ.sum()/J
    J = δ.shape[-1]
    num = r * D + G - D_next + D - δ.sum(axis=-1) / J
    denom = w * L + r * (D + K)

    return num / denom
```

We use a namedtuple `Household` to store parameters that characterize households' problems.

```
Household = namedtuple("Household", ("j_grid", "a_grid", "y_grid",
                                     "Π", "β", "init_μ", "VJ"))
```

(continues on next page)

(continued from previous page)

```
def create_household(
        a_min=0., a_max=40, a_size=200,
        Π=[[0.9, 0.1], [0.1, 0.9]],
        y_grid=[0.5, 1.5],
        β=0.96, J=50
    ):

    j_grid = jnp.arange(J)

    a_grid = jnp.linspace(a_min, a_max, a_size)

    y_grid, Π = map(jnp.array, (y_grid, Π))
    y_size = len(y_grid)

    # Population distribution of new borns
    init_μ = jnp.zeros((a_size * y_size))

    # Newborns are endowed with zero asset
    # and equal probability of y
    init_μ = init_μ.at[:y_size].set(1 / y_size)

    # Terminal value V_bar(a)
    VJ = jnp.empty(a_size * y_size)
    for a_i in range(a_size):
        a = a_grid[a_i]
        VJ = VJ.at[a_i*y_size:(a_i+1)*y_size].set(V_bar(a))

    return Household(j_grid=j_grid, a_grid=a_grid, y_grid=y_grid,
                     Π=Π, β=β, init_μ=init_μ, VJ=VJ)
```

```
hh = create_household()
```

We apply discrete state dynamic programming tools.

Initial steps involve preparing rewards and transition matrices R and Q for our discretized Bellman equations.

```
@jax.jit
def populate_Q(household):

    j_grid, a_grid, y_grid, Π, β, init_μ, VJ = household

    num_state = a_grid.size * y_grid.size
    num_action = a_grid.size

    Q = jsp.linalg.block_diag(*[Π]*a_grid.size)
    Q = Q.reshape((num_state, num_action, y_grid.size))
    Q = jnp.tile(Q, a_grid.size).T

    return Q

@jax.jit
def populate_R(j, r, w, τ, δ, household):

    j_grid, a_grid, y_grid, Π, β, init_μ, VJ = household

    num_state = a_grid.size * y_grid.size
```

(continues on next page)

(continued from previous page)

```
    num_action = a_grid.size

    a = jnp.reshape(a_grid, (a_grid.size, 1, 1))
    y = jnp.reshape(y_grid, (1, y_grid.size, 1))
    ap = jnp.reshape(a_grid, (1, 1, a_grid.size))
    c = (1 + r*(1-τ)) * a + (1-τ) * w * l(j) * y - δ[j] - ap

    return jnp.reshape(jnp.where(c > 0, u(c), -jnp.inf),
                       (num_state, num_action))
```

127.11 Computing a steady state

We first compute a steady state.

Given guesses of prices and taxes, we can use backwards induction to solve for value functions and optimal consumption and saving policies at all ages.

The function `backwards_opt` solves for optimal values by applying the discretized bellman operator backwards.

We use `jax.lax.scan` to facilitate sequential and recurrent computations efficiently.

```
@jax.jit
def backwards_opt(prices, taxes, household, Q):

    r, w = prices
    τ, δ = taxes

    j_grid, a_grid, y_grid, Π, β, init_μ, VJ = household
    J = j_grid.size

    num_state = a_grid.size * y_grid.size
    num_action = a_grid.size

    def bellman_operator_j(V_next, j):
        "Solve household optimization problem at age j given Vj+1"

        Rj = populate_R(j, r, w, τ, δ, household)
        vals = Rj + β * Q.dot(V_next)
        σ_j = jnp.argmax(vals, axis=1)
        V_j = vals[jnp.arange(num_state), σ_j]

        return V_j, (V_j, σ_j)

    js = jnp.arange(J-1, -1, -1)
    init_V = VJ

    # Iterate from age J to 1
    _, outputs = jax.lax.scan(bellman_operator_j, init_V, js)
    V, σ = outputs
    V = V[::-1]
    σ = σ[::-1]

    return V, σ
```

```
r, w = 0.05, 1
τ, δ = 0.15, np.zeros(hh.j_grid.size)

Q = populate_Q(hh)
```

```
V, σ = backwards_opt([r, w], [τ, δ], hh, Q)
```

Let's time the computation with `block_until_ready()` to ensure that all JAX operations are complete

```
%time backwards_opt([r, w], [τ, δ], hh, Q)[0].block_until_ready();
```

```
CPU times: user 1.64 ms, sys: 0 ns, total: 1.64 ms
Wall time: 50.8 ms
```

From the optimal consumption and saving choices by each cohort, we can compute a joint probability distribution of asset levels and idiosyncratic productivity levels in a steady state.

```
@jax.jit
def popu_dist(σ, household, Q):

    j_grid, a_grid, y_grid, Π, β, init_μ, VJ = household

    J = household.j_grid.size
    num_state = household.a_grid.size * household.y_grid.size

    def update_popu_j(μ_j, j):
        "Update population distribution from age j to j+1"

        Qσ = Q[jnp.arange(num_state), σ[j]]
        μ_next = μ_j @ Qσ

        return μ_next, μ_next

    js = jnp.arange(J-1)

    # iterate from age 1 to J
    _, μ = jax.lax.scan(update_popu_j, init_μ, js)
    μ = jnp.concatenate([init_μ[jnp.newaxis], μ], axis=0)

    return μ
```

```
μ = popu_dist(σ, hh, Q)
```

Let's time the computation

```
%time popu_dist(σ, hh, Q)[0].block_until_ready();
```

```
CPU times: user 52.8 ms, sys: 4.08 ms, total: 56.9 ms
Wall time: 55.7 ms
```

Below we plot the marginal distribution of savings for each age group.

```
for j in [0, 5, 20, 45, 49]:
    plt.plot(hh.a_grid, jnp.sum(μ[j].reshape((hh.a_grid.size, hh.y_grid.size)),␣
↪axis=1), label=f'j={j}', lw=2)
```

(continues on next page)

(continued from previous page)

```
plt.legend()
plt.xlabel('a')
plt.ylabel(r'$\sum_\gamma \mu_j(a, \gamma)$')

plt.show()
```

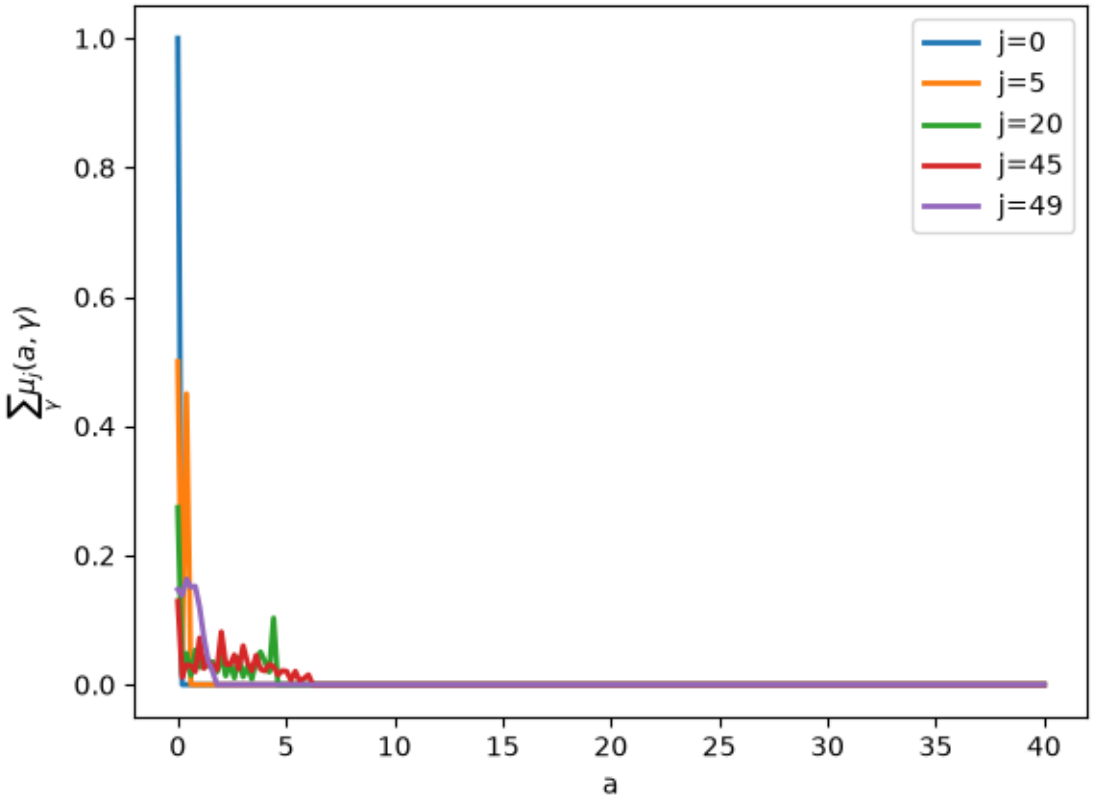

Fig. 127.1: Marginal distribution of assets by age

A grid that is too narrow would distort these distributions by piling probability mass on the highest asset level.

Let's verify that this does not happen here.

```
top_mass = μ.reshape((hh.j_grid.size, hh.a_grid.size,
                      hh.γ_grid.size))[:, -1, :].sum() / hh.j_grid.size
print(f"population share at a_max = {hh.a_grid[-1]:.0f}: {top_mass:.3%}")
```

```
population share at a_max = 40: 0.000%
```

Exercise 127.15.1 asks what happens when the upper bound binds.

These marginal distributions confirm that new agents enter the economy with no asset holdings.

- the blue $j = 0$ distribution has mass only at $a = 0$.

As agents age, at first they gradually accumulate assets.

- the orange $j = 5$ distribution puts positive mass on positive but low asset levels
- the green $j = 20$ distribution puts positive mass on a much wider range of asset levels.
- the red $j = 45$ distribution is even wider

At a later age, they gradually deplete their asset holdings.

- the purple $j = 49$ distribution illustrates this

At the end of life, they will have drawn down all of their assets.

Let's now look at age-specific optimal saving policies that generate the preceding marginal distributions of assets at different ages.

We'll plot some saving functions with the following Python code.

```
σ_reshaped = σ.reshape(hh.j_grid.size, hh.a_grid.size, hh.y_grid.size)
j_labels = [f'j={j}' for j in [0, 5, 20, 45, 49]]

fig, axs = plt.subplots(1, 2, figsize=(14, 5))

axs[0].plot(hh.a_grid, hh.a_grid[σ_reshaped[[0, 5, 20, 45, 49], :, 0].T], lw=2)
axs[0].plot(hh.a_grid, hh.a_grid, '--')
axs[0].set_xlabel("$a_{j}$")
axs[0].set_ylabel("$a^*_{j+1}$")
axs[0].legend(j_labels+['45 degree line'])
axs[0].set_title(r"Optimal saving policy, low $\gamma$")

axs[1].plot(hh.a_grid, hh.a_grid[σ_reshaped[[0, 5, 20, 45, 49], :, 1].T], lw=2)
axs[1].plot(hh.a_grid, hh.a_grid, '--')
axs[1].set_xlabel("$a_{j}$")
axs[1].set_ylabel("$a^*_{j+1}$")
axs[1].legend(j_labels+['45 degree line'])
axs[1].set_title(r"Optimal saving policy, high $\gamma$")

plt.show()
```

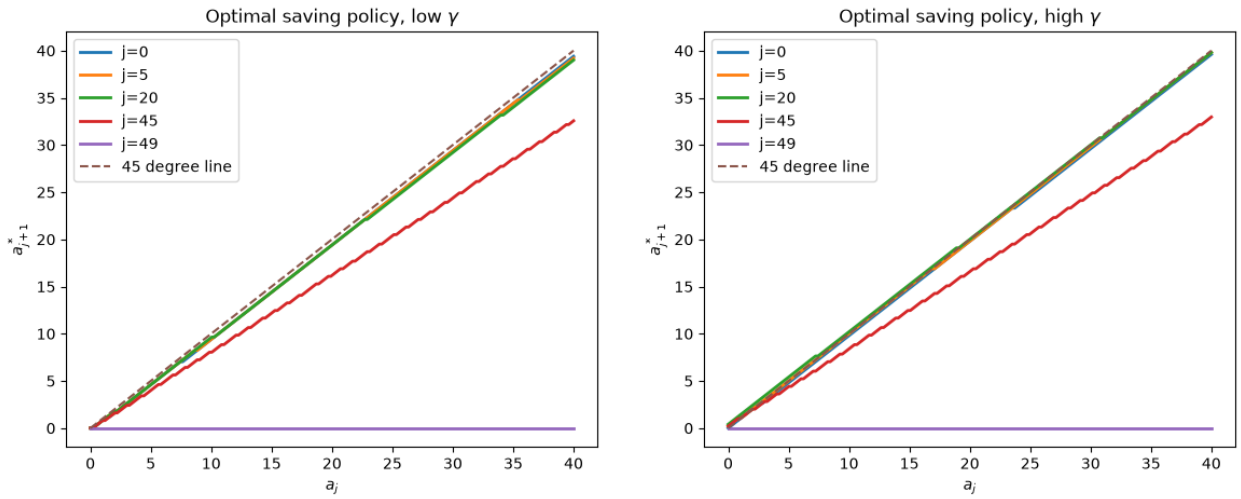

Fig. 127.2: Optimal saving policies by age

From an implied stationary population distribution, we can compute the aggregate labor supply L and private savings A.

```
@jax.jit
def compute_aggregates(μ, household):

    j_grid, a_grid, y_grid, Π, β, init_μ, VJ = household

    J, a_size, y_size = j_grid.size, a_grid.size, y_grid.size

    μ = μ.reshape((J, household.a_grid.size, household.y_grid.size))

    # Compute private savings
    a = a_grid.reshape((1, a_size, 1))
    A = (a * μ).sum() / J

    y = y_grid.reshape((1, 1, y_size))
    lj = l(j_grid).reshape((J, 1, 1))
    L = (lj * y * μ).sum() / J

    return A, L
```

```
A, L = compute_aggregates(μ, hh)
A, L
```

```
(Array(1.8474663, dtype=float32), Array(1.0781993, dtype=float32))
```

The capital stock in this economy equals $A - D$.

```
D = 0
K = A - D
```

The firm's optimality conditions imply interest rate r and wage rate w.

```
KL_to_r(K, L, firm), KL_to_w(K, L, firm)
```

```
(Array(0.20578183, dtype=float32), Array(0.82273746, dtype=float32))
```

The implied prices (r, w) differ from our guesses, so we must update our guesses and iterate until we find a fixed point.

This is our outer loop.

127.12 Transition dynamics

We compute transition dynamics using a function `path_iteration`.

In an outer loop, we iterate over guesses of prices and taxes.

In an inner loop, we compute the optimal consumption and saving choices by each cohort j in each time t, then find the implied evolution of the joint distribution of assets and productivities.

We then update our guesses of prices and taxes given the aggregate labor supply and capital stock in the economy.

We use `solve_backwards` to solve for optimal saving choices given price and tax sequences and `simulate_forward` to compute the evolution of the joint distributions.

We require two steady states as inputs: the initial steady state to provide the initial condition for `simulate_forward`, and the final steady state to provide continuation values for `solve_backwards`.

```

The following algorithm describes the path iteration procedure:

Algorithm 127.12.1 (AK-Aiyagari transition path algorithm)

Inputs Given initial steady state ss_1, final steady state ss_2, time horizon T, and policy sequences (D, G, δ)

Output Compute equilibrium transition paths for value functions V, policy functions σ, distributions μ, and prices (r, w, τ)

1. Initialize from steady states:
   - $(V_1, \sigma_1, \mu_1) \leftarrow ss_1$ *(Initial steady state)*
   - $(V_2, \sigma_2, \mu_2) \leftarrow ss_2$ *(Final steady state)*
   - $(r, w, \tau) \leftarrow initialize_prices(T)$ *(Linear interpolation)*
   - $error \leftarrow \infty, i \leftarrow 0$
2. **While** $error > \varepsilon$ and $i \leq max_iter$:
   1. $i \leftarrow i + 1$
   2. $(r_{\text{old}}, w_{\text{old}}, \tau_{\text{old}}) \leftarrow (r, w, \tau)$
   3. **Backward induction:** For $t \in [T, 1]$:
      - For $j \in [0, J-1]$ *(age groups)*:
        - $V[t, j] \leftarrow \max_{a'}\{u(c) + \beta\mathbb{E}[V[t+1, j+1]]\}$
        - $\sigma[t, j] \leftarrow \arg\max_{a'}\{u(c) + \beta\mathbb{E}[V[t+1, j+1]]\}$
   4. **Forward simulation:** For $t \in [1, T]$:
      - $\mu[t] \leftarrow \Gamma(\sigma[t], \mu[t-1])$ *(Distribution evolution)*
      - $K[t] \leftarrow \int a \, d\mu[t] - D[t]$ *(Aggregate capital)*
      - $L[t] \leftarrow \int l(j)\gamma \, d\mu[t]$ *(Aggregate labor)*
      - $r[t] \leftarrow \alpha Z(K[t]/L[t])^{\alpha-1}$ *(Interest rate)*
      - $w[t] \leftarrow (1-\alpha)Z(K[t]/L[t])^{\alpha}$ *(Wage rate)*
      - $\tau[t] \leftarrow solve_budget(r[t], w[t], K[t], L[t], D[t], G[t])$
   5. Compute convergence metric:
      - $error \leftarrow \|r - r_{\text{old}}\| + \|w - w_{\text{old}}\| + \|\tau - \tau_{\text{old}}\|$
   6. Update prices with dampening:
      - $r \leftarrow \lambda r + (1-\lambda) r_{\text{old}}$
      - $w \leftarrow \lambda w + (1-\lambda) w_{\text{old}}$
      - $\tau \leftarrow \lambda \tau + (1-\lambda) \tau_{\text{old}}$
3. **Return** $(V, \sigma, \mu, r, w, \tau)$

```

We can now compute equilibrium transitions that are ignited by fiscal policy reforms.

127.13 Experiment 1: an immediate tax cut

At $t = 0$, the government unexpectedly announces that it will issue debt.

From $t = 0$ to 19, debt D_{t+1} increases linearly for 20 periods, reaching the new target level $D_{20} = D_0 + 1 = \bar{D} + 1$.

Government spending $\bar{G}$ and transfers $\bar{\delta}_j$ remain constant.

The debt path is the policy; the flat rate tax τ_t is then whatever balances the government budget at each date.

At the announcement the residual tax rate drops well below its initial value, which is why we call this an immediate tax cut.

It then climbs steadily as debt accumulates, and once debt stops growing it settles permanently above its initial value, because the government must service the larger debt forever.

We want to compute the equilibrium transition path.

Our first step is to prepare appropriate policy variable arrays `D_seq`, `G_seq`, `δ_seq`

We'll compute a τ_seq that balances government budgets.

```
T = 150

D_seq = jnp.ones(T+1) * D_ss1
D_seq = D_seq.at[:21].set(D_ss1 + jnp.linspace(0, 1, 21))
D_seq = D_seq.at[21:].set(D_seq[20])

G_seq = jnp.ones(T) * G_ss1

δ_seq = jnp.repeat(δ_ss1, T).reshape((T, δ_ss1.size))
```

In order to iterate the path, we need to first find its destination, which is the new steady state under the new fiscal policy.

```
ss2 = find_ss(hh, firm, [D_seq[-1], G_seq[-1], δ_seq[-1]], Q)
```

We can use path_iteration to find equilibrium transition dynamics.

Setting the key argument verbose=True tells the function path_iteration to display convergence information.

```
paths = path_iteration(ss1, ss2, [D_seq, G_seq, δ_seq], hh, firm, Q, verbose=True)
```

```
Iteration    1: error = 8.831175e-02
Iteration    2: error = 2.078297e-02
Iteration    3: error = 5.341858e-03
Iteration    4: error = 9.897855e-04
Iteration    5: error = 3.227252e-04
Iteration    6: error = 5.921904e-05
```

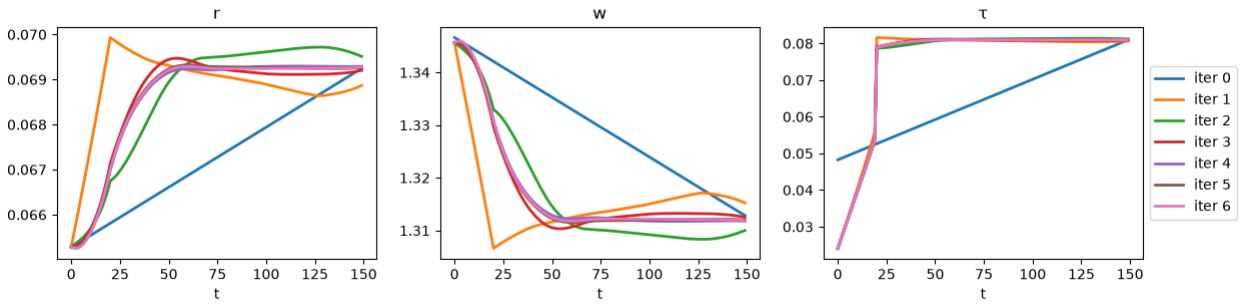

Fig. 127.3: Price path iterations for an immediate tax cut

Having successfully computed transition dynamics, let's study them.

```
V_seq, σ_seq, μ_seq = paths[:3]
K_seq, L_seq = paths[3:5]
r_seq, w_seq = paths[5:7]
τ_seq, D_seq, G_seq, δ_seq = paths[7:11]
```

```
ap = hh.a_grid[σ_seq[0]]
```

```
j = jnp.reshape(hh.j_grid, (hh.j_grid.size, 1, 1))
lj = l(j)
a = jnp.reshape(hh.a_grid, (1, hh.a_grid.size, 1))
y = jnp.reshape(hh.y_grid, (1, 1, hh.y_grid.size))
```

```
t = 0

ap = hh.a_grid[σ_seq[t]]
δ = δ_seq[t].reshape((hh.j_grid.size, 1, 1))

inc = (1 + r_seq[t]*(1-τ_seq[t])) * a \
        + (1-τ_seq[t]) * w_seq[t] * lj * y - δ
inc = inc.reshape((hh.j_grid.size, hh.a_grid.size * hh.y_grid.size))

c = inc - ap

c_mean0 = (c * μ_seq[t]).sum(axis=1)
```

We care about how the policy change affects consumption across cohorts and across time.

We can study age-specific average consumption levels.

```
for t in [1, 10, 20, 50, 149]:

    ap = hh.a_grid[σ_seq[t]]
    δ = δ_seq[t].reshape((hh.j_grid.size, 1, 1))

    inc = (1 + r_seq[t]*(1-τ_seq[t])) * a + (1-τ_seq[t]) * w_seq[t] * lj * y - δ
    inc = inc.reshape((hh.j_grid.size, hh.a_grid.size * hh.y_grid.size))

    c = inc - ap

    c_mean = (c * μ_seq[t]).sum(axis=1)

    plt.plot(range(hh.j_grid.size), c_mean-c_mean0, label=f't={t}', lw=2)

plt.legend()
plt.xlabel(r'j')
plt.ylabel(r'$\Delta$ mean $C(j)$')
plt.show()
```

To summarize the transition, we can plot paths as we did in *Transitions in an Overlapping Generations Model*.

But unlike the setup in that two-period lived overlapping generations model, we no longer have representative old and young agents.

- now we have 50 cohorts of different ages at each time

To proceed, we construct two age groups of equal size – young and old.

- at age 25, someone moves from being young to becoming old

```
ap = hh.a_grid[σ_ss1]
J = hh.j_grid.size
δ = δ_ss1.reshape((hh.j_grid.size, 1, 1))

inc = (1 + r_ss1*(1-τ_ss1)) * a + (1-τ_ss1) * w_ss1 * lj * y - δ
inc = inc.reshape((hh.j_grid.size, hh.a_grid.size * hh.y_grid.size))

c = inc - ap

Cy_ss1 = (c[:J//2] * μ_ss1[:J//2]).sum() / (J // 2)
Co_ss1 = (c[J//2:] * μ_ss1[J//2:]).sum() / (J // 2)
```

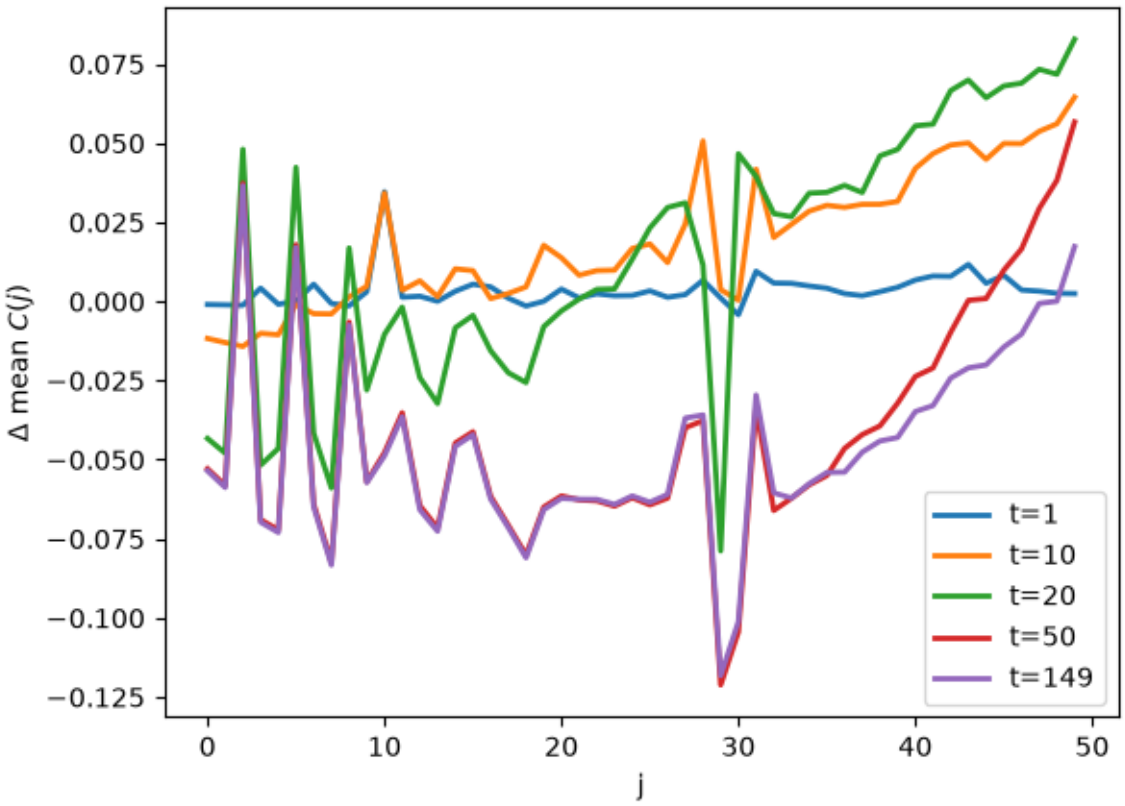

Fig. 127.4: Change in mean consumption by age

```
T = σ_seq.shape[0]
J = σ_seq.shape[1]

Cy_seq = np.empty(T)
Co_seq = np.empty(T)

plt.show()
```

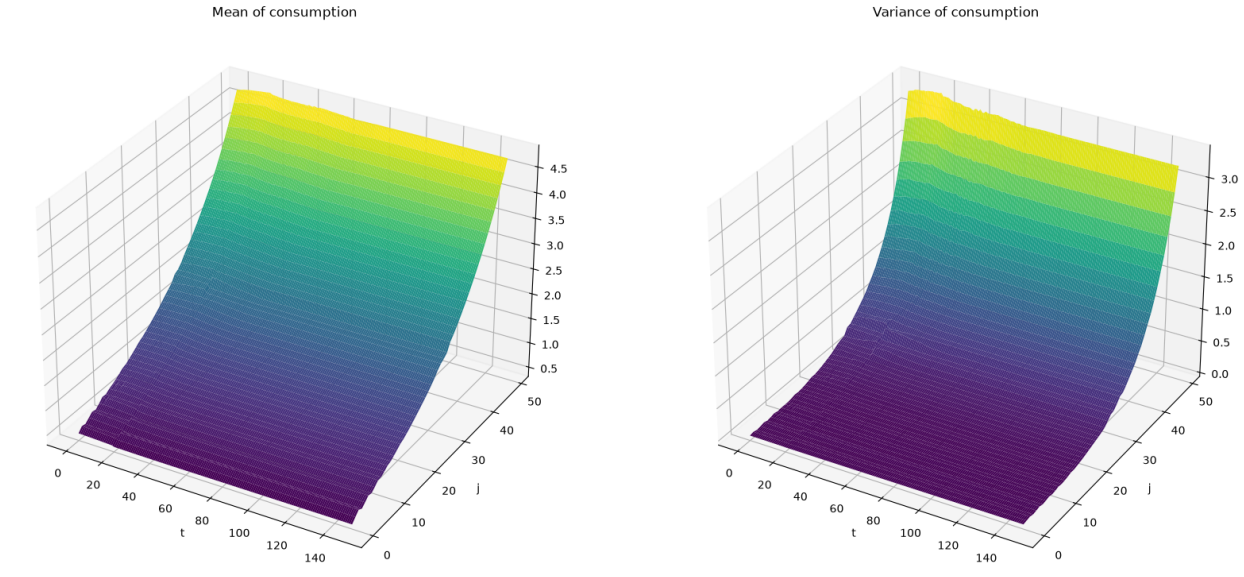

Fig. 127.6: Consumption mean and variance over age and time

127.14 Experiment 2: a preannounced tax cut

Now the government announces at time 0 that it will issue the same amount of debt, but will start doing so only after 20 periods.

As in Experiment 1, the tax rate is residual: it falls while the debt is being issued, from $t = 20$ to $t = 40$, and settles permanently above its initial level thereafter.

We will use the same key toolkit `path_iteration`.

We must specify `D_seq` appropriately.

```
T = 150

D_t = 20
D_seq = jnp.ones(T+1) * D_ss1
D_seq = D_seq.at[D_t:D_t+21].set(D_ss1 + jnp.linspace(0, 1, 21))
D_seq = D_seq.at[D_t+21:].set(D_seq[D_t+20])

G_seq = jnp.ones(T) * G_ss1

δ_seq = jnp.repeat(δ_ss1, T).reshape((T, δ_ss1.size))
```

```
ss2 = find_ss(hh, firm, [D_seq[-1], G_seq[-1], δ_seq[-1]], Q)
```

```
paths = path_iteration(ss1, ss2, [D_seq, G_seq, δ_seq],
                       hh, firm, Q, verbose=True)
```

```
Iteration    1: error = 5.251274e-02
Iteration    2: error = 1.731133e-02
Iteration    3: error = 3.894093e-03
Iteration    4: error = 7.399297e-04
Iteration    5: error = 2.448352e-04
Iteration    6: error = 4.188173e-05
```

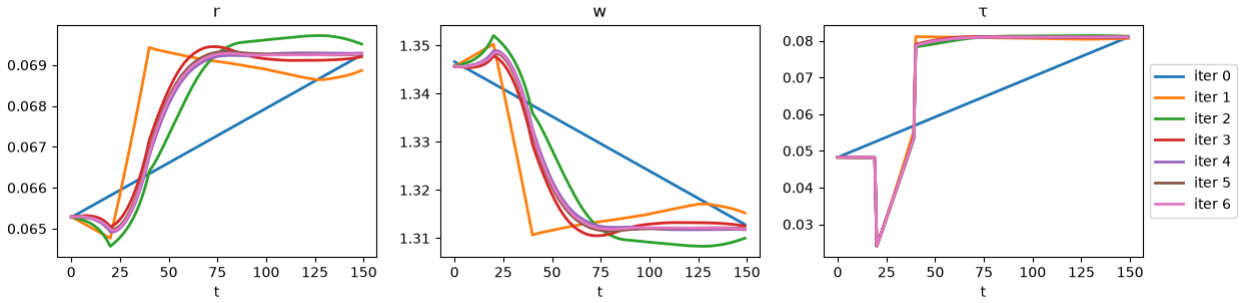

Fig. 127.7: Price path iterations for a preannounced tax cut

```
V_seq, σ_seq, μ_seq = paths[:3]
K_seq, L_seq = paths[3:5]
r_seq, w_seq = paths[5:7]
τ_seq, D_seq, G_seq, δ_seq = paths[7:11]
```

```
T = σ_seq.shape[0]
J = σ_seq.shape[1]
```

(continues on next page)

(continued from previous page)

```
Cy_seq = np.empty(T)
Co_seq = np.empty(T)

for t in range(T):
    ap = hh.a_grid[σ_seq[t]]
    δ = δ_seq[t].reshape((hh.j_grid.size, 1, 1))

    inc = (1 + r_seq[t]*(1-τ_seq[t])) * a + (1-τ_seq[t]) * w_seq[t] * lj * y - δ
    inc = inc.reshape((hh.j_grid.size, hh.a_grid.size * hh.y_grid.size))

    c = inc - ap

    Cy_seq[t] = (c[:J//2] * μ_seq[t, :J//2]).sum() / (J // 2)
    Co_seq[t] = (c[J//2:] * μ_seq[t, J//2:]).sum() / (J // 2)
```

Below we plot the transition paths of the economy.

```
fig, axs = plt.subplots(3, 3, figsize=(14, 10))

# Cy (j=0-24)
axs[0, 0].plot(Cy_seq, lw=2)
axs[0, 0].hlines(Cy_ss1, 0, T, color='r', linestyle='--')
axs[0, 0].set_title('Cy (j < 25)')

# Cy (j=25-49)
axs[0, 1].plot(Co_seq, lw=2)
axs[0, 1].hlines(Co_ss1, 0, T, color='r', linestyle='--')
axs[0, 1].set_title(r'Co (j $\geq$ 25)')

names = ['K', 'L', 'r', 'w', 'τ', 'D', 'G']
for i in range(len(names)):
    i_var = i + 3
    i_axes = i + 2

    row_i = i_axes // 3
    col_i = i_axes % 3

    axs[row_i, col_i].plot(paths[i_var], lw=2)
    axs[row_i, col_i].hlines(ss1[i_var], 0, T, color='r', linestyle='--')
    axs[row_i, col_i].set_title(names[i])

# ylims
axs[1, 0].set_ylim([ss1[4]-0.1, ss1[4]+0.1])
axs[2, 2].set_ylim([ss1[9]-0.1, ss1[9]+0.1])

plt.show()
```

Notice how prices and quantities respond immediately, well before the policy is implemented at $t = 20$.

Agents who foresee the coming tax cut, and the permanently higher tax rate that follows it, adjust their savings right away.

Let's zoom in on how the capital stock responds.

```
# K
i_var = 3
```

(continues on next page)

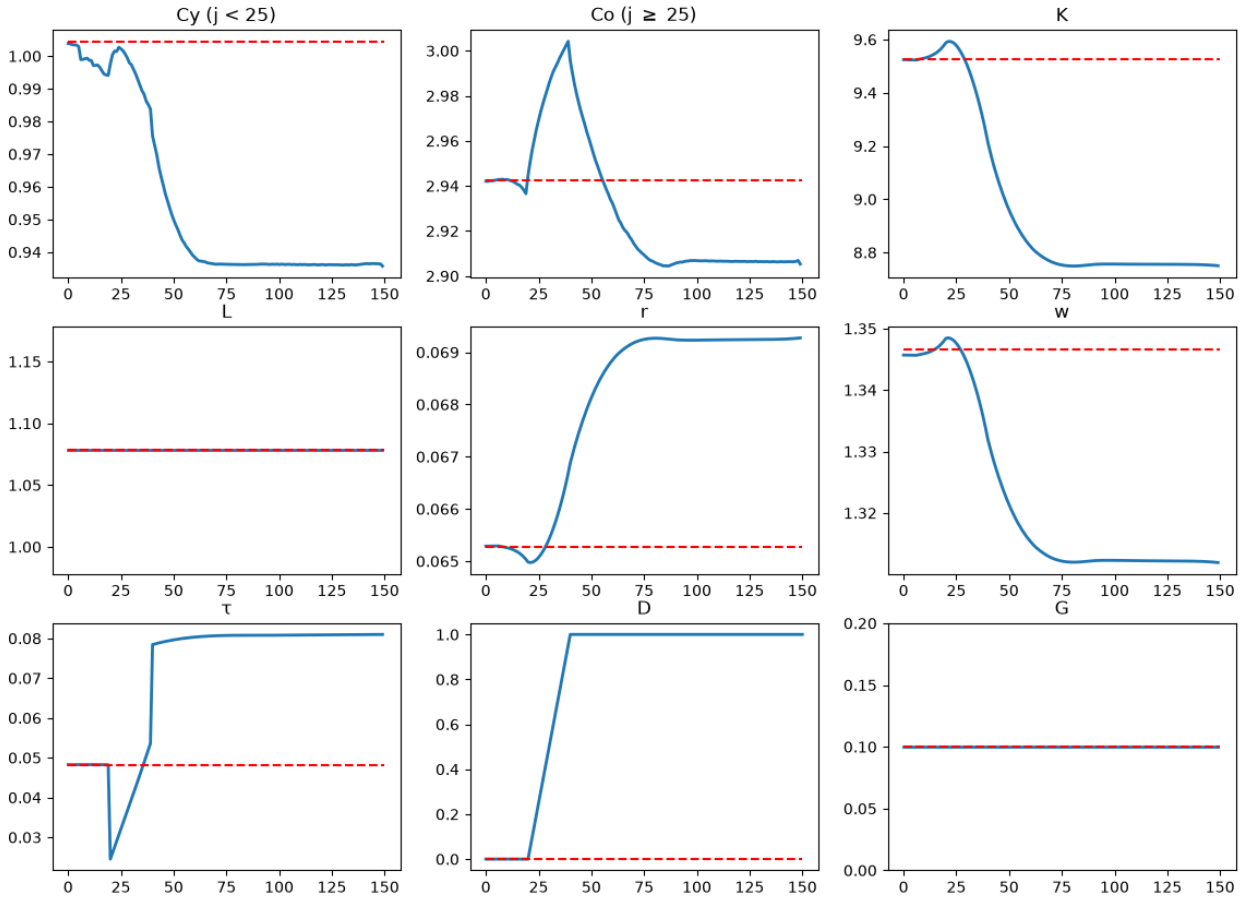

Fig. 127.8: Transition after a preannounced tax cut

(continued from previous page)

```
K_path = paths[i_var][:25]

K_lo = min(float(K_path.min()), float(ss1[i_var]))
K_hi = max(float(K_path.max()), float(ss1[i_var]))
pad = 0.1 * (K_hi - K_lo)

plt.plot(K_path, lw=2)
plt.hlines(ss1[i_var], 0, 25, color='r', linestyle='--')
plt.axvline(20, color='k', linestyle='--', linewidth=0.5)
plt.text(17, K_lo - 0.5 * pad, r'tax cut')
plt.ylim([K_lo - pad, K_hi + pad])
plt.ylabel("K")
plt.xlabel("t")
plt.show()
```

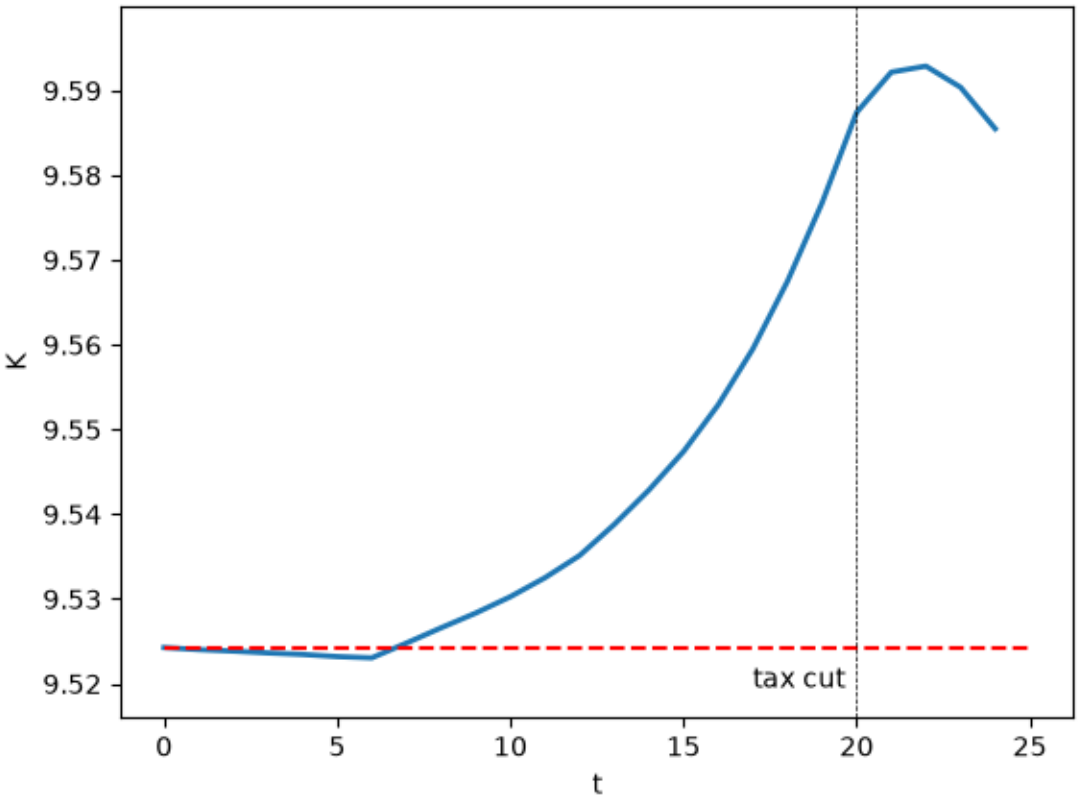

Fig. 127.9: Capital stock around the tax cut

After the tax cut is implemented at $t = 20$, aggregate capital decreases because government debt crowds out private capital.

In the few periods just before $t = 20$, individuals save more.

The reason is that the tax cut raises the *after-tax* return $r_t(1 - \tau_t)$ at $t = 20$, even though the pre-tax return r_t is falling then, so saving into $t = 20$ becomes more attractive.

Because that extra saving raises the capital stock, the pre-tax interest rate dips, reaching its lowest value just before the policy takes effect.

In the first few periods after the announcement the two forces nearly cancel and the capital stock is almost flat, with the saving response building up as the implementation date approaches.

We can also plot evolutions of means and variances of consumption by different cohorts along a transition path.

```
Cmean_seq = np.empty((T, J))
Cvar_seq = np.empty((T, J))

for t in range(T):
    ap = hh.a_grid[σ_seq[t]]
    δ = δ_seq[t].reshape((hh.j_grid.size, 1, 1))

    inc = (1 + r_seq[t]*(1-τ_seq[t])) * a + (1-τ_seq[t]) * w_seq[t] * lj * y - δ
    inc = inc.reshape((hh.j_grid.size, hh.a_grid.size * hh.y_grid.size))

    c = inc - ap

    Cmean_seq[t] = (c * μ_seq[t]).sum(axis=1)
    Cvar_seq[t] = (
        (c - Cmean_seq[t].reshape((J, 1))) ** 2 * μ_seq[t]).sum(axis=1)
```

ax2.set_ylabel(r"j")

plt.show()
```

127.15 Exercises

Exercise 127.15.1

Our asset grid runs from 0 to $a_{\max} = 40$.

A grid whose upper bound binds would make the computed equilibrium an artifact of the grid rather than a property of the model.

1. Re-solve the steady state with $a_{\max} \in \{10, 20\}$, holding the number of grid points fixed at 200.

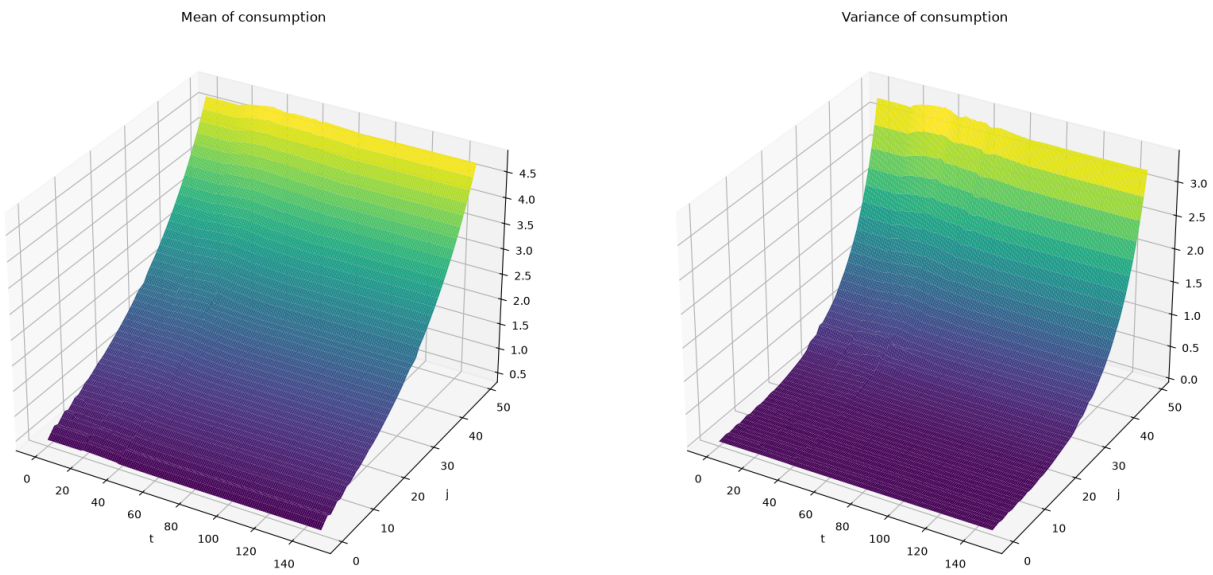

Fig. 127.10: Consumption surfaces for the preannounced tax cut

2. For each case report aggregate capital K, the interest rate r, the flat rate tax τ, and the share of the population at the top grid point.
3. What do you conclude about using $a_{\max} = 10$?

Solution

```
def ss_for_a_max(a_max):
    "Solve the steady state for a given upper bound on assets."
    h = create_household(a_max=a_max)
    Q_h = populate_Q(h)
    out = find_ss(h, firm, [0, 0.1, np.zeros(h.j_grid.size)], Q_h)
    μ_h = out[2].reshape((h.j_grid.size, h.a_grid.size, h.y_grid.size))
    top = float(μ_h[:, -1, :].sum() / h.j_grid.size)
    return float(out[3]), float(out[5]), float(out[7]), top

print(f"{'a_max':>6}  {'K':>7}  {'r':>7}  {'τ':>7}  {'mass at a_max':>14}")
for a_max in [10, 20, 40]:
    K_a, r_a, τ_a, top = ss_for_a_max(a_max)
    print(f"{a_max:>6}  {K_a:>7.3f}  {r_a:>7.4f}  {τ_a:>7.4f}  {top:>13.1%}")
```

```
a_max        K        r        τ   mass at a_max
   10    6.622   0.0843   0.0538          30.6%
   20    8.872   0.0686   0.0493           5.8%
   40    9.524   0.0653   0.0482           0.0%
```

With $a_{\max} = 10$, roughly thirty percent of the population is pinned at the upper bound.

Those agents would like to hold more assets than the grid permits, so measured capital is far too low and the interest rate far too high.

Raising the bound to 40 empties the top of the grid and moves K up by about forty percent and r down by nearly two

percentage points.

The lesson is that an upper bound must be checked, not assumed: a grid is wide enough only when almost no probability mass reaches its edge.

Exercise 127.15.2

How much of the capital stock is accounted for by precautionary saving against idiosyncratic labor productivity risk?

Hold the mean of γ at one and shrink the spread, comparing $\gamma \in \{0.9, 1.1\}$ and $\gamma \in \{0.75, 1.25\}$ with the baseline $\gamma \in \{0.5, 1.5\}$.

Report K, L, r, and τ in each case, and explain the direction of the effect.

Solution

```
print(f"{'γ_grid':>16}  {'K':>7}  {'L':>7}  {'r':>7}  {'τ':>7}")
for γ_grid in [[0.9, 1.1], [0.75, 1.25], [0.5, 1.5]]:
    h = create_household(γ_grid=γ_grid)
    Q_h = populate_Q(h)
    out = find_ss(h, firm, [0, 0.1, np.zeros(h.j_grid.size)], Q_h)
    print(f"{str(γ_grid):>16}  {float(out[3]):>7.3f}  {float(out[4]):>7.4f}"
          f"  {float(out[5]):>7.4f}  {float(out[7]):>7.4f}")
```

```
          γ_grid        K        L        r        τ
      [0.9, 1.1]    9.088   1.0782   0.0674   0.0489
    [0.75, 1.25]    9.246   1.0782   0.0671   0.0487
      [0.5, 1.5]    9.524   1.0782   0.0653   0.0482
```

Aggregate labor L is the same in all three economies, because the productivity chain is symmetric and its mean is one in each case.

Capital nevertheless rises with the spread, from about 9.1 to about 9.5, and the interest rate falls by roughly twenty basis points.

The extra capital is precautionary saving: an agent who cannot borrow and cannot insure labor income holds a buffer stock of assets against a run of low productivity draws, and a wider spread calls for a bigger buffer.

The effect is non-linear, since most of it appears when we move from $\{0.75, 1.25\}$ to $\{0.5, 1.5\}$.

Note

It is tempting to shut down risk completely by setting $\gamma_l = \gamma_h$.
Doing so is numerically treacherous.
Without idiosyncratic risk, every agent of a given age chooses the same point on the asset grid, so aggregate asset supply becomes a step function of r and the price iteration can cycle rather than converge.
This is one reason for the iteration cap in `find_ss`.

Exercise 127.15.3

This exercise builds an unfunded social security system like the one studied in *Experiment 4 of the two-period model*.

Let the government tax each young agent and pay each old agent, with

$$\delta_j = \begin{cases} d & j < 25 \\ -d & j \geq 25 \end{cases}$$

so that $\sum_j \delta_j = 0$ and the scheme is balanced period by period.

1. Compute steady states for $d \in \{0, 0.1, 0.25\}$ and report K, r, w, and τ.
2. Report mean consumption of the young half and the old half of the population.
3. Compare your findings with the two-period model.

Solution

```
a_vec = hh.a_grid.reshape((1, hh.a_grid.size, 1))
y_vec = hh.y_grid.reshape((1, 1, hh.y_grid.size))
l_vec = l(hh.j_grid).reshape((hh.j_grid.size, 1, 1))
J = hh.j_grid.size

print(f"{'d':>5}  {'K':>7}  {'r':>7}  {'w':>7}  {'τ':>7}"
      f"  {'c young':>8}  {'c old':>7}")
for d in [0.0, 0.1, 0.25]:
    δ_ss = np.zeros(J)
    δ_ss[:J//2], δ_ss[J//2:] = d, -d
    out = find_ss(hh, firm, [0, 0.1, δ_ss], Q)
    σ_d, μ_d = out[1], out[2]
    K_d, r_d, w_d, τ_d = (float(out[3]), float(out[5]),
                          float(out[6]), float(out[7]))

    ap_d = hh.a_grid[σ_d].reshape((J, hh.a_grid.size, hh.y_grid.size))
    c_d = ((1 + r_d * (1 - τ_d)) * a_vec
           + (1 - τ_d) * w_d * l_vec * y_vec
           - δ_ss.reshape((J, 1, 1)) - ap_d)
    c_mean = (c_d * μ_d.reshape(ap_d.shape)).sum(axis=(1, 2))

    print(f"{d:>5.2f}  {K_d:>7.3f}  {r_d:>7.4f}  {w_d:>7.4f}  {τ_d:>7.4f}"
          f"  {c_mean[:J//2].mean():>8.4f}  {c_mean[J//2:].mean():>7.4f}")
```

```
    d        K        r        w        τ   c young    c old
0.00    9.524   0.0653   1.3466   0.0482    1.0045   2.9427
0.10    9.212   0.0668   1.3329   0.0487    0.9212   2.9841
0.25    8.707   0.0696   1.3103   0.0496    0.7918   3.0462
```

The transfer scheme is balanced at every date, so it collects no net revenue and the flat rate tax τ barely moves.

Even so, it contracts the economy: capital falls from 9.5 to 8.7 as d rises to 0.25, the interest rate rises, and the wage falls.

The young consume less because they are taxed, and the old consume more because they are subsidized, but the young also save less, both because their income is lower and because the promised transfer substitutes for their own saving.

This is the same crowding out that *Experiment 4 of the two-period model* displays.

What the long-lived model adds is the observation that the transfer is collected from exactly those agents whose precautionary motive is strongest, namely the young, who hold the fewest assets with which to buffer labor income risk.

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the “play” icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

In addition to what’s in Anaconda, this lecture will need the following library

```
!pip install jax
```

128.1 Overview

This lecture describes two computational experiments about alternative ways to move gradually from an unfunded (pay-as-you-go) to a fully funded social security system, following Huang *et al.* [1997].

As populations age, pay-as-you-go social security systems have faced financial difficulties.

This situation has led some of today's policy makers and policy advisors to think that today's citizens would be better off if earlier policy makers had set up a fully-funded retirement system.

But starting from where we are today, a transition to a fully funded system creates distributional challenges because older generations who contributed to the unfunded system could lose benefits.

To study possibilities quantitatively, this lecture employs a general equilibrium overlapping generations model that modifies the Auerbach and Kotlikoff [1987] environment by incorporating

- risk-sensitive preferences
- uncertainty about lifetimes
- uninsurable labor income risk
- a theory of consumption distributions within and across cohorts

By employing the discounted risk-sensitive linear-quadratic preferences of Hansen and Sargent [1995], the model yields linear decision rules for individual consumption and savings.

This makes it computationally feasible to track the joint distribution of consumption and wealth across cohorts.

This lecture relates to two other lectures:

- *Transitions in an Overlapping Generations Model* studies how taxes, transfers, and debt affect capital accumulation in a two-period OLG model, introducing the Auerbach and Kotlikoff [1987] framework that this lecture extends.
- *A Long-Lived, Heterogeneous Agents, Overlapping Generations Model* studies how fiscal policy interacts with precautionary savings in a long-lived OLG model, using discrete dynamic programming rather than the linear-quadratic approach adopted here.

We use the following imports and configurations

```
import jax
import jax.numpy as jnp
from jax import jit, vmap
import jax.lax as lax
import numpy as np
import matplotlib.pyplot as plt
from collections import namedtuple

# Enable 64-bit precision
jax.config.update("jax_enable_x64", True)
```

128.2 Model

128.2.1 Environment

The economy consists of overlapping generations of finitely lived individuals who may live up to $T_0 + 1$ years and an infinitely lived government.

Individual consumers and the government can invest at a common risk-free gross rate of return.

That rate is constant when we treat the economy as a small open economy, and it varies over time when we close the economy and let marginal products determine factor prices.

During the first $T_1 + 1$ periods of life, consumers receive labor income that they allocate among consumption, taxes, and asset accumulation.

During the final $T_0 - T_1$ periods of life (retirement), consumers receive social security benefits and dissave by drawing down their assets.

The government taxes income from capital and labor, issues debt, purchases goods, and pays retirement benefits.

For any variable z, we use subscript t to denote age, argument s in parentheses to denote calendar time, and superscript $s - t$ to denote date of birth, so that $z^{s-t}(s) \equiv z_t(s) \equiv z_t^{s-t}(s)$.

Several symbols are close cousins, so we record them here.

Symbol	Meaning
t, T_0, T_1	age, maximum age, retirement age
s, s_1, s_2, s_3	calendar time and the dates that bound the reform
α_t	probability of surviving from age t to $t+1$
$\tilde{\alpha}$, $\tilde{A}$	capital's share and the scale factor in the production function
σ, σ_d	risk-sensitivity parameter and the standard deviation of the income shock
γ_t	preference shock in the one-period return function
ε_t, ϵ_{t+1}	age-efficiency of labor and the random shock
$T_t(s)$	taxes paid by an age-t person at time s
$\mathcal{T}_t$, $\mathcal{D}_t$, $\mathcal{S}_t$	the three operators in the risk-sensitive Riccati recursion

128.2.2 Demographics

At date s, a cohort of measure $N_0(s)$ consumers is born who live during periods $s, s+1, \ldots, s+T_0$.

As a cohort ages, its members face random survival according to age-to-age survival probabilities $\{\alpha_t\}_{t=0}^{T_0}$, where α_t is the probability of surviving from age t to $t+1$.

Let $N_t(s)$ be the number of age-t people alive at time s and let n be the constant gross rate of population growth.

The size of age group t at time s satisfies

$$N_t(s) = \lambda_t \cdot N_0(s-t)$$

where $\lambda_t = \prod_{j=0}^{t-1} \alpha_j$ for $t = 0, \ldots, T_0$, with $\lambda_0 = 1$, and births follow $N_0(s) = n^s \cdot N_0(0)$.

The population fraction of cohort t at each time s is

$$f_t = \frac{\lambda_t \cdot n^{-t}}{\sum_{\tau=0}^{T_0} \lambda_\tau \cdot n^{-\tau}}$$

and total population at time s is

$$N(s) = N_0(0) \cdot n^s \cdot \sum_{t=0}^{T_0} n^{-t} \cdot \lambda_t.$$

128.2.3 Distributions and aggregates

Individuals face life span uncertainty and labor income shocks.

They self-insure by accumulating risk-free assets (government bonds and physical capital), while properly taking into account the social security benefits that they anticipate receiving.

Let ϵ_0^t denote the history of random shocks that an individual has received from birth to age t.

The state vector $x_t(s) = x_t(s; \epsilon_0^t, x_0)$ measures the stock of assets as well as information variables a consumer uses to forecast future preferences or opportunities.

The model delivers consumption as a time- and age-dependent linear function of the state vector

$$c_t(s; \epsilon_0^t, x_0) = \eta_{ct}(s) \cdot x_t(s; \epsilon_0^t, x_0)$$

where the state vector follows a linear law of motion

$$x_{t+1}(s+1; \epsilon_0^{t+1}, x_0) = A_t(s) \cdot x_t(s; \epsilon_0^t, x_0) + C_t(s) \cdot \epsilon_{t+1}$$

with ϵ_{t+1} a martingale difference sequence satisfying $E(\epsilon_{t+1}|J_t) = 0$, $E(\epsilon_{t+1} \cdot \epsilon'_{t+1}|J_t) = I$, and $J_t = (\epsilon_0^t, x_0)$.

The model delivers probability distributions for state vectors.

Let $\mu_t(s) = E[x_t(s)]$ and $\Sigma_t(s) = E[(x_t(s) - \mu_t(s))(x_t(s) - \mu_t(s))']$.

These moments satisfy

$$\mu_{t+1}(s+1) = A_t(s) \cdot \mu_t(s)$$

$$\Sigma_{t+1}(s+1) = A_t(s) \cdot \Sigma_t(s) \cdot A_t(s)' + C_t(s) \cdot C_t(s)'$$

Per capita aggregate consumption is

$$c(s)/N(s) = \sum_{t=0}^{T_0} \mu_{ct}(s) \cdot f_t$$

where $\mu_{ct}(s)$ is the mean consumption of age-t people at time s.

The distribution of consumption within age cohort t has mean $\mu_{ct}(s) = \eta_{ct}(s) \cdot \mu_t(s)$ and variance $\Sigma_{ct}(s) = \eta_{ct}(s) \cdot \Sigma_t(s) \cdot \eta_{ct}(s)'$.

128.2.4 Resource constraint

The economy-wide physical resource constraint is

$$g(s) \cdot N(s) + \sum_{t=0}^{T_0} c_t(s) \cdot N_t^{s-t} + K(s) = R(s-1) \cdot K(s-1) + w(s) \cdot \sum_{t=0}^{T_1} \varepsilon_t \cdot N_t^{s-t} + N_0(s) \cdot k_{-1}(s)$$

where $g(s)$ is per capita government purchases, $K(s-1)$ is physical capital, $R(s-1) = 1 + r(s-1) - \delta$ is the gross return on assets, ε_t is the exogenous efficiency endowment of age-t people, $w(s)$ is the base wage rate, $N_0(s) \cdot k_{-1}(s)$ is capital brought by newborns, and δ is the depreciation rate.

Dividing by the population $N(s)$ and writing $k(s) = K(s)/N(s)$, $\bar{c}(s) = \sum_t \mu_{ct}(s) f_t$, and $\bar{\varepsilon} = \sum_t \varepsilon_t f_t$ puts the constraint in the per capita form that our code iterates on:

$$k(s) = R(s-1)\left[\frac{k(s-1)}{n} + f_0 k_{-1}\right] + w(s)\bar{\varepsilon} - g(s) - \bar{c}(s) \tag{128.1}$$

We also report two ratios below, each built from GDP measured as the sum of capital and labor income,

$$\text{GDP}(s) = r(s-1)\left[\frac{k(s-1)}{n} + f_0 k_{-1}\right] + w(s)\bar{\varepsilon}$$

128.2.5 Factor prices

We consider two alternative assumptions about factor prices:

- *Small open economy:* $r(s-1) = r$ and $w(s) = w$ are exogenous and constant.
- *Closed economy:* Factor prices are determined by marginal products from a Cobb-Douglas production function:

$$r(s-1) = \tilde{A} \cdot \tilde{\alpha} \cdot (K(s-1)/\tilde{N}(s))^{\tilde{\alpha}-1}, \qquad w(s) = (1-\tilde{\alpha}) \cdot \tilde{A} \cdot (K(s-1)/\tilde{N}(s))^{\tilde{\alpha}}$$

where $\tilde{N}(s) = \sum_{t=0}^{T_1} \varepsilon_t \cdot N_t^{s-t}$ is aggregate labor input in efficiency units and $\tilde{\alpha}$ is capital's share of income.

128.2.6 Consumers' problems

Individual consumers face an overlapping-generations version of a classic consumption-saving problem (see *The Permanent Income Model*).

Working-age consumers ($t \leq T_1$) receive labor income $w(s) \cdot \varepsilon_t + d_t$, where d_t is an AR(1) process

$$d_t = \rho_d \cdot d_{t-1} + \xi_t$$

with ξ_t being Gaussian white noise with variance σ_d^2.

The budget constraint at age t and time s is

$$c_t(s) + a_t(s) = R(s-1) \cdot a_{t-1}(s-1) + w(s) \cdot \varepsilon_t + S_t(s) - T_t(s) + d_t \tag{128.2}$$

where $a_{t-1}(s-1)$ is asset holdings at the beginning of age t, $S_t(s)$ is social security benefits (zero while working, $S(s)$ when retired), and taxes are $T_t(s) = \tau_0(s) + \tau_\ell(s)(w(s) \cdot \varepsilon_t + d_t) + \tau_a(s)(R(s-1)-1) \cdot a_{t-1}(s-1)$.

Following Hansen and Sargent [1995], preferences over stochastic consumption processes are defined recursively by

$$U_t = -(\pi \cdot c_t - \gamma_t)^2/2 + \beta_t \cdot \mathcal{R}_t(U_{t+1})$$

where $\mathcal{R}_t(U_{t+1}) = (2/\sigma) \cdot \log E[\exp(\sigma \cdot U_{t+1}/2)|J_t]$, σ is the risk-sensitivity parameter, and $\beta_t = \bar{\beta} \cdot \alpha_t$ is the survival-adjusted discount factor.

This preference specification delivers linear decision rules while allowing a form of risk-sensitivity that induces a type of precautionary savings.

When $\sigma = 0$, the recursion collapses to $U_t = -(\pi c_t - \gamma_t)^2/2 + \beta_t E_t U_{t+1}$, an ordinary discounted quadratic objective whose decision rules satisfy **certainty equivalence**: they do not depend on the volatility σ_d of the income shock.

When $\sigma < 0$, the operator $\mathcal{R}_t$ puts extra weight on bad continuation outcomes, so the consumer behaves as if pessimistic about future shocks.

Certainty equivalence then fails, decision rules depend on the noise statistics CC', and the consumer saves more.

Exercise 128.12.2 measures how much more.

128.2.7 Government

The government purchases goods, pays social security benefits, taxes capital and labor income, confiscates accidental bequests, and issues one-period bonds.

The government budget constraint is

$$g(s) \cdot N(s) + \sum_{t=T_1+1}^{T_0} S_t(s) \cdot N_t^{s-t} + R(s-1) \cdot \sum_{t=1}^{T_0} b_{t-1}(s-1) \cdot N_t^{s-t} =$$

$$\sum_{t=0}^{T_0} N_t^{s-t} \{\tau_a(s)[R(s-1)-1] \cdot a_{t-1}(s-1) + \tau_\ell(s) \cdot w(s) \cdot \varepsilon_t\} + \tau_0 \cdot N(s) +$$

$$\sum_{t=0}^{T_0} b_t(s) \cdot N_t^{s-t} + R(s-1) \cdot \sum_{t=0}^{T_0} (1-\alpha_t) \cdot k_t(s-1) \cdot N_t^{s-t-1}$$

where $b_t(s)$ is government debt held by age-t individuals at time s and the last term represents the bequest tax.

A transition between fiscal regimes is described by dates $0 \leq s_1 < s_2 < s_3$:

- Before $s = 0$: initial stationary equilibrium
- At $s = 0$: government announces a policy change
- $s \in [s_1, s_2)$: fiscal parameters and the social security system change
- $s \geq s_2$: new constant policy parameters
- $s \geq s_3$: final stationary equilibrium

128.2.8 Equilibrium

We define the following objects:

- An **allocation** is a stochastic process for $\{c_t(s), a_t(s)\}_{s=0}^{s_3}$ for $t = 0, \ldots, T_0$, and a sequence $\{K(s)\}_{s=0}^{s_3}$.
- A **government policy** is a sequence $\{b(s), g(s), \tau_\ell(s), S(s), \tau_a(s)\}_{s=0}^{s_3}$.
- A **price system** is a sequence $\{w(s), r(s-1)\}_{s=0}^{s_3}$.

An **equilibrium** is an allocation, a price system, and a government policy such that

1. given the price sequence and government policy, the allocation solves households' optimum problems,
2. the allocation and government policy satisfy the government budget constraint at each date s,
3. the asset market clears, so that household assets equal physical capital plus government debt, $\sum_t a_t(s) N_t^{s-t} = K(s) + \sum_t b_t(s) N_t^{s-t}$, and
4. the goods market clears, which is the resource constraint (128.1).

In the closed economy, condition 4 together with the firm's first-order conditions determines factor prices; in the small open economy, factor prices are given and condition 4 determines how much the economy borrows from or lends to the rest of the world.

In a **stationary equilibrium**, all variables are independent of calendar time s, which simplifies the government budget constraint to

$$g + \sum_{t=T_1+1}^{T_0} S_t \cdot f_t + [R/n - 1] \cdot \bar{b} = \tau_a (R-1) \cdot \sum_{t=0}^{T_0} a_{t-1} \cdot f_t + \tau_\ell \cdot \sum_{t=0}^{T_1} w \cdot \varepsilon_t \cdot f_t + \frac{R}{n} \cdot \sum_{t=0}^{T_0} (1-\alpha_t) \cdot a_t \cdot f_t$$

where $\bar{b}$ is per capita government debt in steady state.

128.2.9 Transition dynamics

The following diagram shows the age-time structure during the transition.

Each horizontal line represents the lifetime of one cohort, and the vertical dashed lines mark the policy change dates s_1 and s_2.

```
fig, ax = plt.subplots(figsize=(8, 5))

birth_range = np.arange(-60, 41, 5)

ax.hlines(birth_range, birth_range, birth_range + 60, 'k', linewidth=1)
ax.vlines([0, 40], -60, 40, 'k', linestyle='--', linewidth=0.5)

ax.set_ylabel("date born")
ax.set_xlabel("time")

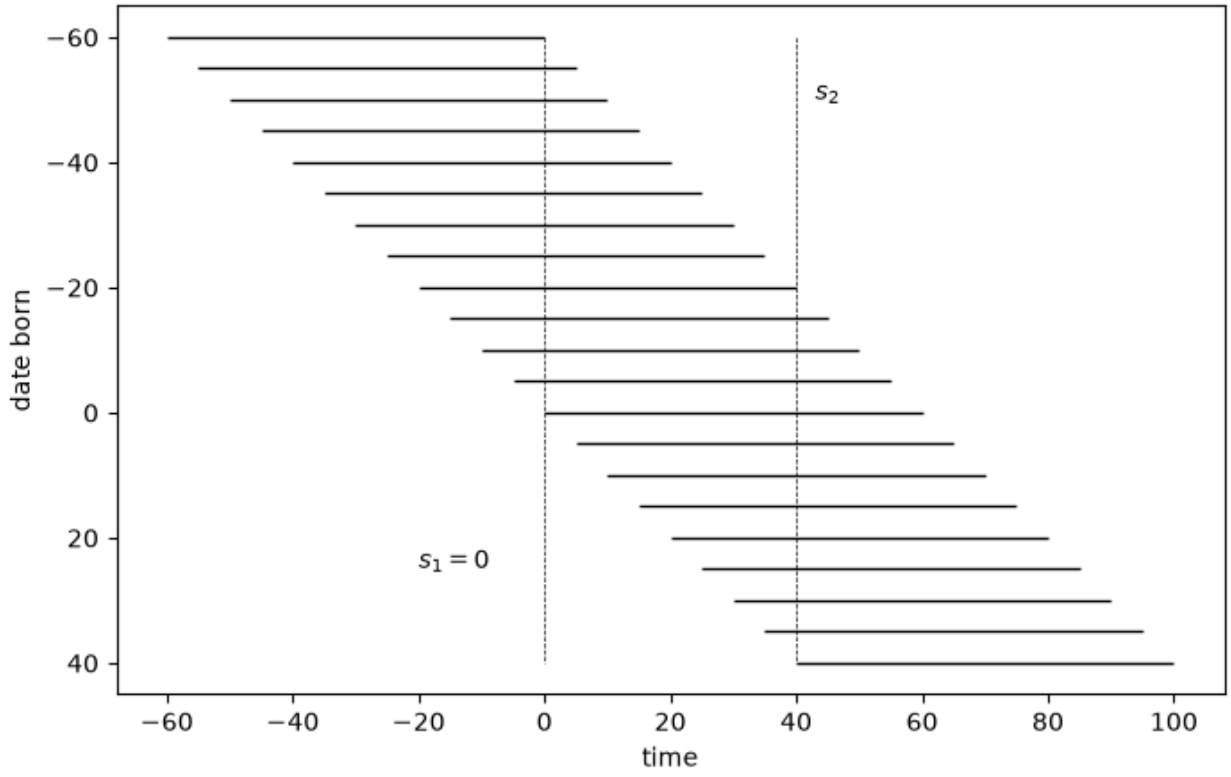

Fig. 128.1: Age-time diagram for overlapping generations

Small open economy

With fixed factor prices, the transition has a clear structure:

- Cohorts born before $s_1 - T_0$ die before the policy change and are unaffected.
- Cohorts alive at s_1 must recalculate their consumption-saving plans for their remaining lifetimes.
- Cohorts born between s_1 and s_2 face time-varying tax and benefit rates, while those born after s_2 face constant parameters.
- The transition ends at $s_3 = s_2 + T_0$ when the last cohort that experienced the policy change has died.

Because factor prices are fixed, we can compute the transition by solving decision rules for cohorts born at dates $s_1 - T_0 - 1, \ldots, s_2$.

For any date s, aggregate consumption is computed by summing across all living cohorts (along a vertical line in the age-time diagram), weighted by their population fractions.

Closed economy

With endogenous factor prices, the transition is more complex:

- Factor prices continue to evolve after policy parameters stabilize at s_2, so we follow Auerbach and Kotlikoff [1987] and truncate at $s_3 = s_2 + 2T_0$.
- The computation requires nested iteration: an inner loop determines labor income tax rates, and an outer loop adjusts interest rates to clear factor markets.
- Changes in saving behavior affect capital accumulation, which alters marginal products and feeds back into household decisions.
- Lower interest rates benefit young workers through higher wages but hurt retirees through lower returns on savings.

128.3 Two experiments

We explore two strategies for transitioning to a fully funded social security system.

In experiment 1, the government terminates social security benefits but compensates entitled generations through a one-time increase in government debt.

In experiment 2, the government retains social security benefits but temporarily raises taxes to accumulate physical capital, the returns from which eventually finance social security payments.

Both proposals aim to finance a transition to fully funded social security without leaving existing generations worse off, but they entail different amounts of intergenerational risk-sharing.

We compute both experiments under fixed and endogenous factor prices and compare outcomes below.

128.4 Computation strategy

128.4.1 Dynamic program

An individual consumer's problem can be formulated as a discounted risk-sensitive linear control problem (see *LQ Control: Foundations*).

Let $x_t = [a_{t-1}, z_t]'$ where z_t is the vector of shocks.

The optimal value function takes the form $U_t = x_t' \cdot P_t \cdot x_t + \xi_t$.

The recursive problem is

$$U_t = \max_{u_t} \left\{ u_t' Q_t u_t + x_t' R_t x_t + \frac{2\beta_t}{\sigma} \log E_t[\exp(\sigma U_{t+1}/2)] \right\}$$

subject to $x_{t+1} = A_t x_t + B_t u_t + C_t w_{t+1}$.

We deploy two operators

$$\begin{aligned}
\mathcal{T}_t(P) &= P + \sigma P C_t \left(I - \sigma C_t' P C_t\right)^{-1} C_t' P \\
\mathcal{D}_t(W) &= R_t + A_t' \left[\beta_t W - \beta_t^2 W B_t \left(Q_t + \beta_t B_t' W B_t\right)^{-1} B_t' W\right] A_t \\
\mathcal{S}_t(k, P) &= \beta_t k - (\beta_t/\sigma) \log\det\left(I - \sigma C_t' P C_t\right)
\end{aligned}$$

that we use to construct a value function recursion $P_t = (\mathcal{D}_t \circ \mathcal{T}_t) P_{t+1}$, $\xi_t = \mathcal{S}_t(\xi_{t+1}, P_{t+1})$, and an optimal control

$$u_t = -F_t x_t, \qquad F_t = \beta_t \left[Q_t + \beta_t B_t' \mathcal{T}_t(P_{t+1}) B_t\right]^{-1} B_t' \mathcal{T}_t(P_{t+1}) A_t.$$

The operator $\mathcal{T}_t$ is where risk sensitivity enters: at $\sigma = 0$ it is the identity, so the decision rule F_t ignores C_t and certainty equivalence holds.

Operators $\mathcal{T}_t$, $\mathcal{D}_t$, $\mathcal{S}_t$ and decision rule F_t are constructed in `solve_riccati_step`.

Given value function parameters (P_{t+1}, ξ_{t+1}) at the next age, it constructs the state-space matrix A_t, applies the cross-product trick, evaluates the Riccati operators, and returns the optimal decision rule F_t, the closed-loop matrix $A_t^o = A_t - BF_t$, and the updated (P_t, ξ_t)

```
def solve_riccati_step(
        ε_t, β_t, Ind_work_t,
        RR, w, τ_l, τ_a, τ_0, benef,
        P_next, ξ_next,
        ρ_d, σ, B, C, R, Q, H):
    """One backward step of the risk-sensitive Riccati recursion."""

    A = jnp.array([
        [RR * (1.0 - τ_a) + τ_a,
         (1.0 - τ_l) * w * ε_t
         - τ_0 + benef * (1.0 - Ind_work_t),
         (1.0 - τ_l) * Ind_work_t],
        [0.0, 1.0, 0.0],
        [0.0, 0.0, ρ_d]
    ])

    Q_scalar = Q[0, 0]
    Q_inv_scalar = 1.0 / Q_scalar
    Q_inv = jnp.array([[Q_inv_scalar]])
```

(continues on next page)

(continued from previous page)

```
    # Cross-product trick: A* = A - B Q^{-1} H
    A = A - B @ Q_inv @ H

    # 𝒞_t operator
    CTP = C.T @ P_next @ C
    PP_scalar = 1.0 - σ * CTP[0, 0]
    PP_inv_scalar = 1.0 / PP_scalar
    PC = P_next @ C
    CP = C.T @ P_next
    TP = P_next + σ * PP_inv_scalar * (PC @ CP)

    # 𝒟_t operator and decision rule F_t
    BTB_scalar = (B.T @ TP @ B)[0, 0]
    Q_BTB_scalar = Q_scalar + β_t * BTB_scalar
    Q_BTB_inv_scalar = 1.0 / Q_BTB_scalar
    BT_TP = B.T @ TP
    BT_TP_A = BT_TP @ A
    F = β_t * Q_BTB_inv_scalar * BT_TP_A

    TP_B = TP @ B
    middle = (β_t * TP
              - β_t**2 * Q_BTB_inv_scalar
              * (TP_B @ BT_TP))
    P = R + A.T @ middle @ A

    # 𝒪_t operator
    log_det_PP = jnp.log(PP_scalar)
    ξ = jnp.where(
        σ != 0.0,
        β_t * (ξ_next - log_det_PP / σ),
        β_t * (ξ_next + CTP[0, 0])
    )

    Ao = A - B @ F
    F = F + Q_inv @ H

    return F.squeeze(), Ao, P, ξ
```

128.4.2 State space preparation

The budget constraint (128.2) and the income process can be written in state-space form.

Let $x_t = [a_{t-1}(s-1),\ 1,\ d_t]'$, $u_t = c_t(s)$, and $w_{t+1} = \epsilon_{t+1}$, so that

$$x_{t+1} = A_t x_t + B u_t + C w_{t+1}$$

where

$$A_t = \begin{bmatrix} R(s-1)(1-\tau_t^a(s)) + \tau_t^a(s) & (1-\tau_\ell(s))w(s)\varepsilon_t - \tau_0(s) + S_t(s) & \mathbf{1}_t^{\text{work}}(1-\tau_\ell(s)) \\ 0 & 1 & 0 \\ 0 & 0 & \rho_d \end{bmatrix},$$

$$B = \begin{bmatrix} -1 \\ 0 \\ 0 \end{bmatrix},$$

$$C = \begin{bmatrix} 0 \\ 0 \\ \sigma_d \end{bmatrix}$$

and $\mathbf{1}_t^{\text{work}}$ indicates whether the agent is of working age.

The per-period return $-\frac{1}{2}(\pi c_t - \gamma)^2$ introduces a cross-product term H between the control and the state.

This is eliminated using the cross-product trick (see *Eliminating Cross Products*):

$$A^* = A - BQ^{-1}H, \qquad R^* = R - H'Q^{-1}H.$$

128.4.3 Means and covariances

Define $A_o = A - BF$ as the closed-loop transition matrix, so that $x_{t+1} = A_o x_t + C w_{t+1}$ and unconditional moments satisfy

$$\mu_{t+1} = A_{o,t}\mu_t, \qquad \Sigma_{t+1} = A_{o,t}\Sigma_t A_{o,t}' + CC'.$$

The moment recursion is implemented as `forward_moment_step`, which propagates the mean vector and covariance matrix by one age step and computes consumption statistics as by-products.

```
def forward_moment_step(μx_t, Σx_t, Ao_t, F_t, CCT):
    """One step of the forward moment recursion."""

    μx_next = Ao_t @ μx_t
    μc_t = -F_t @ μx_t
    Σx_next = CCT + Ao_t @ Σx_t @ Ao_t.T
    Vc_t = F_t @ Σx_t @ F_t.T
    return μx_next, μc_t, Σx_next, Vc_t
```

128.4.4 Computing transitions

A cohort born at s lives during $s, s+1, \ldots, s+T_0$ and works during $s, s+1, \ldots, s+T_1$.

Let $0 \leq s_1 < s_2 < s_3$.

- At $s = 0$, the government announces a policy change between $s = s_1$ and $s = s_2$.
- From $s = s_2$, government policies are constant forever.
- From $s = s_3$, convergence to the final stationary equilibrium is achieved (in the small open economy, $s_3 = s_2 + T_0$).

The affected cohorts are those born at $s = s_1 - T_0, s_1 - T_0 + 1, \ldots, s_2$.

In all exercises, we set $T_0 = 65$, $T_1 = 43$, $s_1 = 0$, and $s_2 = 40$.

128.5 Calibration

The model parameters are set as follows.

128.5.1 Preference parameters

Parameter	Description	Value
$\{\alpha_t\}_{t=0}^{T_0}$	Age-to-age survival probabilities	Faber [1982]
π	Consumption preference parameter	1.0
σ	Risk-sensitivity parameter	-0.05
$\bar{\gamma}$	Preference shock parameter	7.0
$\tilde{\beta}$	Discount factor	0.986
T_0	Maximum age	65
T_1	Retirement age	43
n	Gross population growth rate	1.012

128.5.2 Technology parameters

Parameter	Description	Value
k_{-1}	Initial capital endowment	4.0
σ_d	Standard deviation of income shock	0.85
ρ_d	Persistence of income shock	0.8
δ	Depreciation rate	0.06
$\{\varepsilon_t\}_{t=0}^{T_1}$	Age-efficiency profile	Hansen [1993]
w	Base wage rate (exogenous)	5.0147
r	Return on capital (exogenous)	0.1275
$\tilde{A}$	Production function scaling (endogenous)	2.2625
$\tilde{\alpha}$	Capital share (endogenous)	0.40

```
N_GRID_SS = 10
TOL_SS = 1e-10

T0 = 65   # maximum lifespan (ages 21 to 86)
T1 = 43   # working life length (retire at 65)

UNIT_GRID = jnp.linspace(0.0, 1.0, N_GRID_SS)
AGE_INDICES = jnp.arange(T0 + 2)
```

The hidden code cell below defines the age-efficiency profile $\{\varepsilon_t\}$ and the survival probabilities $\{\alpha_t\}$ based on Faber [1982] and Hansen [1993].

128.6 Individual optimality

128.6.1 Steady-state computation

With `solve_riccati_step` and `forward_moment_step` in hand, the steady-state computation proceeds in three phases.

Algorithm 128.6.1 (Steady-state computation)

1. **Backward recursion:** scan from age T_0 down to 0. At each age t, call `solve_riccati_step` to obtain decision rule F_t, closed-loop matrix A_t^o, value-function matrix P_t, and certainty-equivalent ξ_t.
2. **Forward simulation:** scan from age 0 up to T_0. At each age t, call `forward_moment_step` to propagate mean $\mu_{x,t}$ and covariance $\Sigma_{x,t}$ of the state vector, and record mean consumption $\mu_{c,t}$ and its variance $V_{c,t}$.
3. **Budget imbalance:** aggregate across cohorts. Sum tax revenues (labor, capital, lump-sum), subtract benefit payments, add accidental bequests, and return the government budget gap.

Phase 1. The backward recursion scans from age T_0 to 0, applying `solve_riccati_step` at each age

```
def _ss_backward_recursion(
        ε_arr, β_arr, Ind_work,
        RR, w, τ_l, τ_a, τ_0, benef,
        P_end, ξ_end,
        ρ_d, σ, B, C, R, Q, H):
    """Backward Riccati scan over all ages."""

    ε_rev = ε_arr[::-1]
    β_rev = β_arr[::-1]
    Ind_work_rev = Ind_work[::-1]

    def backward_step(carry, inputs):
        P_next, ξ_next = carry
        ε_t, β_t, Ind_work_t = inputs
        F, Ao, P, ξ = solve_riccati_step(
            ε_t, β_t, Ind_work_t,
            RR, w, τ_l, τ_a, τ_0, benef,
            P_next, ξ_next,
            ρ_d, σ, B, C, R, Q, H
        )
        return (P, ξ), (F, Ao, P, ξ)

    init_carry = (P_end, ξ_end)
    _, (F_rev, Ao_rev, P_rev, ξ_rev) = lax.scan(
        backward_step, init_carry,
        (ε_rev, β_rev, Ind_work_rev)
    )
```

(continues on next page)

(continued from previous page)

```
    F_arr = F_rev[::-1]
    Ao_arr = Ao_rev[::-1]
    P_inner = P_rev[::-1]
    ξ_inner = ξ_rev[::-1]

    P_arr = jnp.concatenate(
        [P_inner, P_end[None, :, :]], axis=0
    )
    ξ_arr = jnp.concatenate(
        [ξ_inner, jnp.array([ξ_end])]
    )

    return F_arr, Ao_arr, P_arr, ξ_arr
```

Phase 2. The forward recursion propagates means and covariances from age 0 to T_0

```
def _ss_forward_simulation(
        Ao_arr, F_arr, x0, Σ0, C):
    """Forward moment scan using forward_moment_step."""

    CCT = C @ C.T

    def forward_step(carry, inputs):
        μx_t, Σx_t = carry
        Ao_t, F_t = inputs
        result = forward_moment_step(
            μx_t, Σx_t, Ao_t, F_t, CCT
        )
        μx_next, μc_t, Σx_next, Vc_t = result
        return (μx_next, Σx_next), \
            (μx_next, μc_t, Σx_next, Vc_t)

    init_carry = (x0, Σ0)
    _, (μx_scn, μc_arr, Σx_scn, Vc_arr) = lax.scan(
        forward_step, init_carry, (Ao_arr, F_arr)
    )

    μx_arr = jnp.concatenate(
        [x0[None, :], μx_scn], axis=0
    )
    Σx_arr = jnp.concatenate(
        [Σ0[None, :, :], Σx_scn], axis=0
    )

    return μx_arr, μc_arr, Σx_arr, Vc_arr
```

Phase 3. Aggregating tax revenues, benefit payments, and accidental bequests across cohorts gives the government budget gap

```
def _ss_budget_imbalance(
        μx_arr, ε_arr, frac, n, α_arr,
        RR, w, τ_l, τ_a, τ_0, benef,
        G, Gb, Ind_work):
    """Aggregate tax revenues and expenditures."""

    μa_arr = μx_arr[1:, 0]
```

(continues on next page)

(continued from previous page)

```
    μa_last_arr = μx_arr[:-1, 0]

    τ_l_tot = jnp.sum(τ_l * ε_arr * w * frac)
    τ_a_tot = jnp.sum(
        τ_a * (RR - 1.0) * μa_last_arr * frac
    )
    τ_0_tot = jnp.sum(τ_0 * frac)

    retired_mask = 1.0 - Ind_work
    benef_tot = jnp.sum(benef * frac * retired_mask)

    Beq = jnp.sum(
        RR * (1.0 - α_arr) * frac * μa_arr / n
    )

    T_tot = τ_l_tot + τ_a_tot + τ_0_tot + Beq
    diff = (G + benef_tot - T_tot
            + (RR / n - 1.0) * Gb)

    return diff
```

A steady state is found when the budget gap equals zero.

`ss_imbalance` chains the three phases into a single JIT-compiled function: backward recursion, forward simulation, and budget gap

```
@jit
def ss_imbalance(price, policy, α_arr, ε_arr, frac,
                 n, β_arr, ρ_d, σ, B, C, R, Q, H,
                 P_end, ξ_end, x0, Σ0, Ind_work):

The initial fiscal policy sets a social security replacement rate of $\theta = 0.6$

```
aveinc = tech.w * sum(hh.ε_arr) / (hh.T1 + 1)
θ = 0.6
benef_0 = aveinc * θ

G_0 = 1.44          # government purchases
Gb_0 = 2.8 * G_0    # government debt
τ_l_0 = 0.3385      # labor income tax
τ_a_0 = 0.30        # capital income tax
τ_0_0 = 0           # lump-sum tax

RR, w = tech.RR, tech.w
```

128.6.2 Initial and terminal steady states

The initial steady state features a calibrated replacement rate ($\theta = 0.6$), positive social security benefits, and government expenditure and debt set to match targets.

The transition dates are $s_1 = 0$ and $s_2 = 40$, with horizons $S = 140$ (exogenous prices) and $S = 200$ (endogenous prices).

```
S_exo = 140
S_endo = 200
S1, S2 = 0, 40
S3 = S2 + 2 * hh.T0

RR_exo, w_exo = tech.RR, tech.w
```

Two helper functions build the price and policy arrays that the transition solver expects.

Under the small open economy assumption, prices are constant over time.

```
def make_exo_price_seq(S, RR, w):
    """Construct constant price sequence for small open economy."""

    return jnp.column_stack([jnp.full(S + 2, RR), jnp.full(S + 2, w)])
```

The policy sequence sets τ_ℓ to the initial steady-state value before s_1 and to the terminal value after s_2, while holding all other fiscal instruments constant.

```
def make_policy_seq(S, ss0_τl, ss1_τl, S1, S2, τ_a, τ_0, benef, G, Gb):
    """Construct policy sequence with initial/terminal
    τ_l and constant other policies."""

    policy_seq = jnp.empty((S + 2, 6))
    policy_seq = policy_seq.at[:S1 + 1, 0].set(ss0_τl)
    policy_seq = policy_seq.at[S2 + 1:, 0].set(ss1_τl)
    policy_seq = policy_seq.at[:, 1].set(τ_a)
    policy_seq = policy_seq.at[:, 2].set(τ_0)
    policy_seq = policy_seq.at[:, 3].set(benef)
    policy_seq = policy_seq.at[:, 4].set(G)
    policy_seq = policy_seq.at[:, 5].set(Gb)
    return policy_seq
```

```
ss0 = find_ss_exo((RR, w), (τ_a_0, τ_0_0, benef_0, G_0, Gb_0), hh, tech)

print(f"Initial Steady State (s < 0):")
print(f"  Labor tax τ_l = {ss0.τ_l:.4f}")
print(f"  Interest rate r - δ = {ss0.r - tech.δ:.4f}")
print(f"  Capital/GDP = {ss0.k2gdp:.4f}")
print(f"  Debt/GDP = {ss0.debt2gdp:.4f}")
```

```
Initial Steady State (s < 0):
  Labor tax τ_l = 0.3383
  Interest rate r - δ = 0.0675
  Capital/GDP = 3.1615
  Debt/GDP = 0.5899
```

The equilibrium labor tax rate reproduces the calibration target $\tau_\ell = 0.3385$ reported in the table above, which is a useful check on the steady-state solver.

The calibration has a second property that matters for everything that follows.

The production parameters $\tilde{A}$ and $\tilde{\alpha}$ have been chosen so that, at the capital-labor ratio of this initial steady state, the Cobb-Douglas marginal products equal the exogenous prices (r, w) that the small open economy takes as given.

```
ε_bar_check = float(jnp.sum(hh.frac * hh.ε_arr))
K_eff_check = ss0.k_bar / hh.n + float(hh.frac[0] * hh.x0[0])
k_per_eff = K_eff_check / ε_bar_check

print(f"capital share implied by (r, w, K/L): "
      f"{tech.r * K_eff_check / (tech.r * K_eff_check + tech.w * ε_bar_check):.4f}"
      f"   (calibrated α̃ = {tech.α_tilde})")
print(f"A implied by the r equation:  "
      f"{tech.r / (tech.α_tilde * k_per_eff ** (tech.α_tilde - 1)):.4f}")
print(f"A implied by the w equation:  "
      f"{tech.w / ((1 - tech.α_tilde) * k_per_eff ** tech.α_tilde):.4f}"
      f"   (calibrated A = {tech.A})")
```

```
capital share implied by (r, w, K/L): 0.4002   (calibrated α̃ = 0.4)
A implied by the r equation:  2.2639
A implied by the w equation:  2.2620   (calibrated A = 2.2625)
```

The two price regimes therefore coincide at the initial steady state.

That is what makes our fixed-price and endogenous-price experiments comparable, and it is why we may reuse the household objects computed at fixed prices when we construct the initial steady state of the closed economy below.

Exercise 128.12.1 asks you to verify that these parameters are implied by the price targets rather than free.

The following figure traces how the equilibrium labor tax rate varies with government debt in the terminal steady state (no social security)

```
Gb_arr = np.linspace(0.5 * Gb_0, 1.5 * Gb_0, 20)
τl_arr = np.empty_like(Gb_arr)
debt2gdp_arr = np.empty_like(Gb_arr)

for i, Gb in enumerate(Gb_arr):
    ss = find_ss_exo((RR, w), (τ_a_0, τ_0_0, 0, G_0, Gb), hh, tech)
    τl_arr[i] = ss.τ_l
    debt2gdp_arr[i] = ss.debt2gdp

fig, ax = plt.subplots()
ax.plot(τl_arr, debt2gdp_arr, lw=2)
ax.hlines(ss0.debt2gdp, τl_arr.min(),
          np.maximum(τl_arr.max(), ss0.τ_l), linestyle='--', color='r')
ax.scatter(ss0.τ_l, ss0.debt2gdp)
ax.text(ss0.τ_l * 0.95, ss0.debt2gdp * 0.95, "ss0")
ax.text(0.07, 0.4, r"ss1($G_b$)")
ax.set_xlabel(r'$\tau_\ell$')
ax.set_ylabel('debt/GDP')
plt.show()
```

Higher government debt requires larger interest payments, so the equilibrium labor tax rises.

The marked point shows the initial steady state.

To set the terminal steady state, we need to invert this relationship: given a target debt-to-GDP ratio, find the debt level $\bar{b}$ and the associated τ_ℓ.

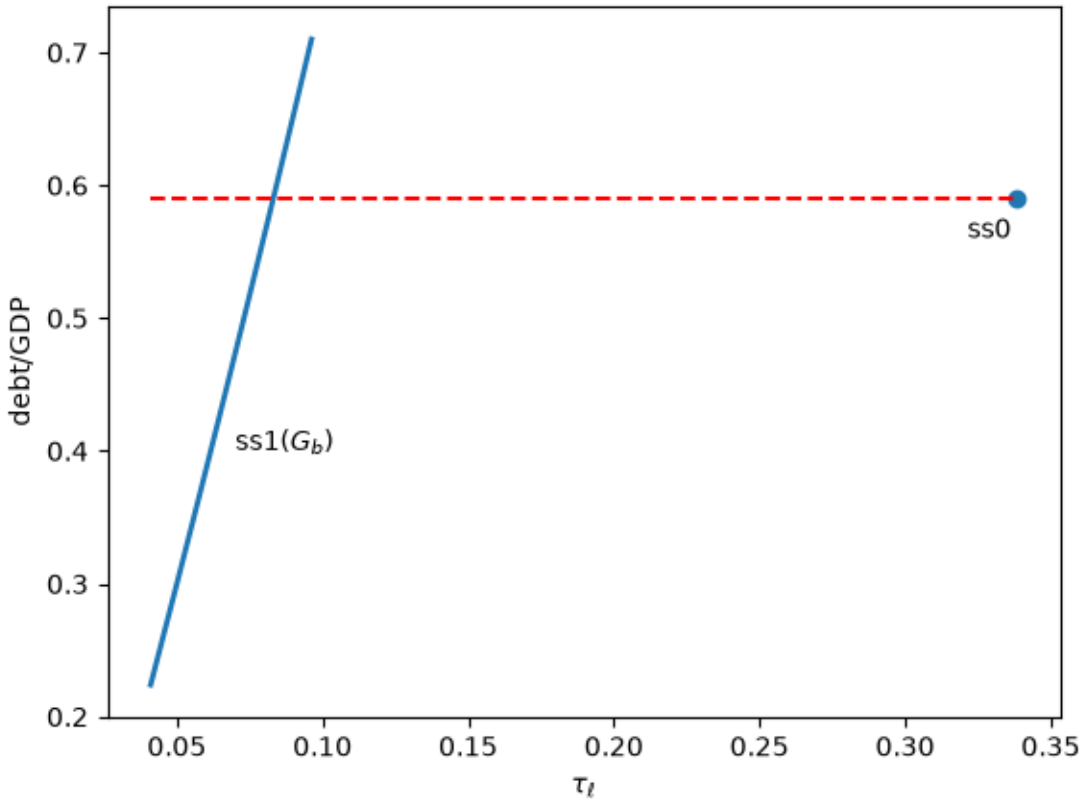

Fig. 128.4: Debt-to-GDP ratio as a function of the labor tax rate

```

```

128.7 Transition path computation

The transition path describes how the economy moves from the initial steady state (with social security) to the terminal steady state (after reform).

This is more complex than the steady-state computation because prices and policies change over time, so each cohort faces a unique lifetime sequence of tax and benefit rates.

`solve_backwards` solves the household problem backward in time during the transition, computing optimal decision rules $F_t(s)$ and closed-loop transition matrices $A_t^o(s)$ at each calendar date s and age t.

```
@jit
def solve_backwards(
        price_seq, policy_seq,
        P_arr_ss1, ξ_arr_ss1,
        ε_arr, β_arr, Ind_work,
```

(continues on next page)

128.7.1 Shooting method

To find the correct transition tax rate, we use a shooting method.

If the tax rate is too low, debt explodes; if it is too high, debt falls below the target.

The equilibrium tax rate is found where the terminal debt exactly hits the target.

We start by computing two transition paths with different trial tax rates to illustrate the shooting method

```
price_seq = make_exo_price_seq(S_exo, RR, w)
policy_seq_base = make_policy_seq(S_exo, ss0.τ_l, ss1.τ_l, S1, S2,
                                  τ_a_0, τ_0_0, 0, G_0, Gb_0)

τ_l_low = 0.14
τ_l_high = 0.17

_, μx_seq1, μc_seq1, k_seq1, Gb_seq1, _, _ = transition_paths(
    τ_l_low, price_seq, policy_seq_base, ss0, ss1, hh, tech,
    S_exo, S1, S2, ss0.μx_arr, ss0.Σx_arr)

_, μx_seq2, μc_seq2, k_seq2, Gb_seq2, _, _ = transition_paths(
    τ_l_high, price_seq, policy_seq_base, ss0, ss1, hh, tech,
    S_exo, S1, S2, ss0.μx_arr, ss0.Σx_arr)
```

We can plot the resulting debt paths to see how they differ under the two trial tax rates

```
fig, ax = plt.subplots(figsize=(10, 5))
ax.plot(Gb_seq1, 'b-', linewidth=2,
        label=f'$\\tau_\\ell$ = {τ_l_low:.2f} (too low)')
ax.plot(Gb_seq2, 'r-', linewidth=2,
        label=f'$\\tau_\\ell$ = {τ_l_high:.2f} (too high)')
ax.axhline(ss1.Gb, color='k', linestyle='--',
           label=f'Target $G_b$ = {ss1.Gb:.2f}')
ax.axvspan(S1, S2, alpha=0.1, color='yellow', label='Transition period')
ax.set_xlabel('time')
```

(continues on next page)

(continued from previous page)

```
ax.set_ylabel('government debt')
ax.legend()
plt.show()
```

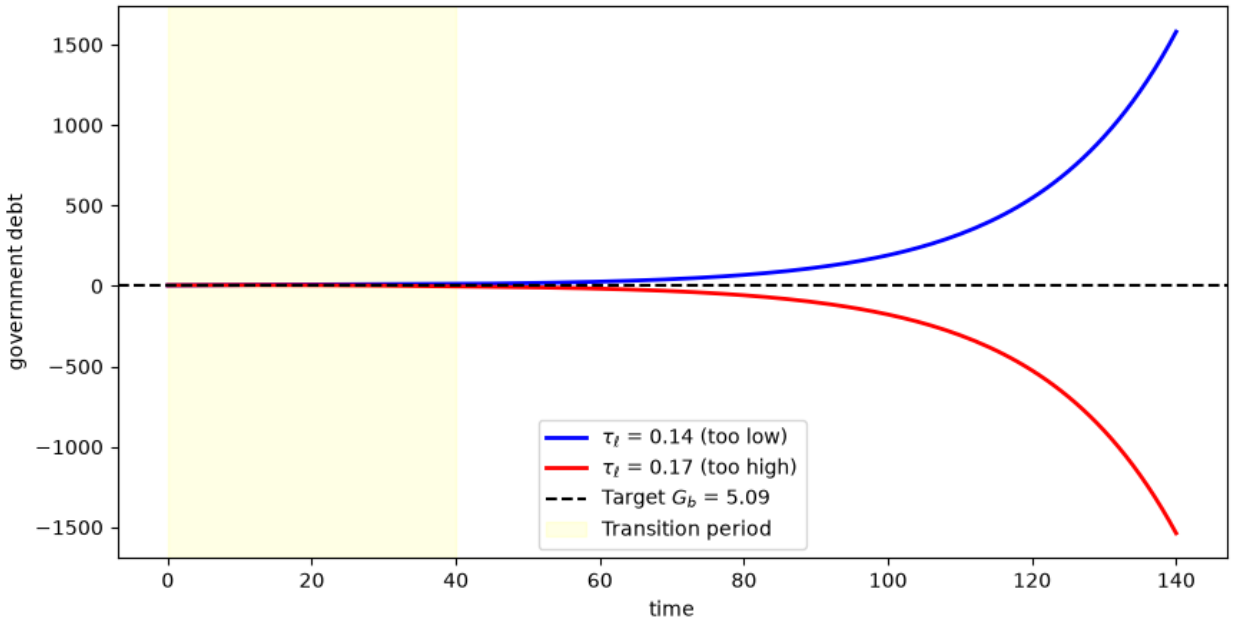

Fig. 128.5: Shooting method for finding the transition tax rate

The blue curve shows government debt increasing over time when the tax rate is too low, while the red curve shows debt falling below the target when the tax rate is too high.

The equilibrium transition tax rate lies between these two extremes, at the value where terminal debt exactly matches the target G_b.

Bisection automates this shooting procedure.

For Experiment 1, each cohort alive at s_1 must also be compensated by the present value of the social security benefits it would have received under the original system.

`_compute_compensation` evaluates this present value for a single cohort identified by its remaining lifetime.

```

plt.show()
```

The left panel shows the labor tax rate dropping during the transition because the government no longer needs to fund social security benefits.

The right panel shows government debt converging from its initial level to the new steady-state level, with the shaded region marking the transition period $[s_1, s_2)$.

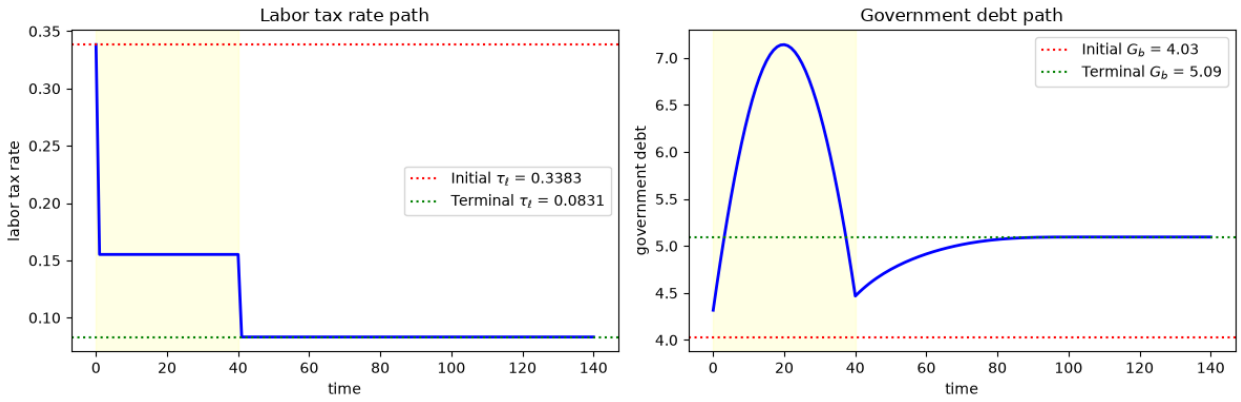

Fig. 128.6: Baseline transition path (no compensation)

128.8 Experiment 1: compensation through debt

In this experiment, the government terminates social security benefits but compensates affected generations.

Each cohort receives a transfer equal to the present value of the benefits they would have received – an actuarially fair buy-out.

Algorithm 128.8.1 (Fixed factor prices – Experiment 1 (buy-out))

Here $s_3 = s_2 + T_0 = 105$.

Step 1. Set up parameters.

Step 2. Solve the initial stationary equilibrium with constant social security benefit S: fix $\tau_a, \tau_0, S, G, \bar{b}$ and solve for $\tau_\ell = \tau_{\ell,0}$ such that the government budget balances:

```
F(τ_ℓ) = government budget imbalance
Find root of F(τ_ℓ) = 0.
```

Step 3. Solve the terminal stationary equilibrium with no social security: search over $\bar{b}$ so that the debt-to-GDP ratio matches a target:

```
H(Gb) = debt-to-GDP given Gb
       (internally solves F(τ_ℓ; Gb) = 0)
Find root of H(Gb) = target.
```

The associated labor tax is $\tau_{\ell,2}$.

Step 4. Solve the transition path: at $s = 0 = s_1$, all cohorts alive lose benefits and a cohort of age t receives a one-time compensation equal to the present value of lost benefits, discounted at the after-tax return $\tilde{R}(s) = R(s)[1-\tau_a(s)] + \tau_a(s)$:

$$\text{comp}_t = \sum_{j=0}^{T_0-t} \left[S_{t+j} + w\varepsilon_{t+j}\left(\tau_\ell(s+j) - \tau_{\ell,0}\right)\right] \prod_{i=0}^{j} \tilde{R}(s+i)^{-1},$$

where S_{t+j} is the benefit that an age-$(t+j)$ person would have received under the old regime, and zero while that person is still working.

The second term inside the brackets compensates a cohort for the change in labor taxes that it faces over the rest of its life, with $\tau_\ell(s+j)$ equal to $\tau_{\ell,1}$ during $[s_1, s_2)$ and $\tau_{\ell,2}$ thereafter, so that the buy-out leaves the present value of

each cohort's lifetime resources unchanged.

The government sets $\tau_{\ell,1}$ during $[s_1, s_2)$ and $\tau_{\ell,2}$ from s_2 onwards, with a one-time expenditure increase of $\sum f_t \, \text{comp}_t$ at s_1.

Find $\tau_{\ell,1}$ such that terminal government debt matches the target:

```
J(τ_ℓ) = terminal debt carryover
Find root of J(τ_ℓ) = Gb_terminal.
```

128.8.1 Fixed prices

We hold factor prices fixed and construct the price and policy sequences for the transition.

The benefit difference vector `benef_diff_exp1` records the per-period benefit loss for each age: retirees lose their old-regime benefits, while workers are unaffected.

```
ss1_exp1_exo = ss1

price_seq_exp1_exo = make_exo_price_seq(S_exo, RR_exo, w_exo)
policy_seq_exp1_exo = make_policy_seq(S_exo, ss0.τ_l, ss1.τ_l, S1, S2,
                                      τ_a_0, τ_0_0, 0, G_0, Gb_0)

benef_diff_exp1 = jnp.zeros(hh.T0 + 1)
benef_diff_exp1 = benef_diff_exp1.at[hh.T1 + 1:].set(ss0.benef)
```

Passing `compensation_data` to `find_transition_exo` turns the buy-out on: that function sets `comp_mult` to one and passes it to `apply_compensation`, which scales each cohort's compensation by it.

We solve for the transition tax rate with and without the buy-out, so that we can compare the two paths.

```
# Solve with buyout
τ_l_exp1_exo_bo, results_exp1_exo_bo = find_transition_exo(
    price_seq_exp1_exo, policy_seq_exp1_exo, ss0, ss1_exp1_exo,
    hh, tech, S_exo, S1, S2,
    compensation_data=(benef_diff_exp1, ss0.τ_l)
)

# Solve without buyout (for comparison)
τ_l_exp1_exo_nb, results_exp1_exo_nb = find_transition_exo(
    price_seq_exp1_exo, policy_seq_exp1_exo, ss0, ss1_exp1_exo,
    hh, tech, S_exo, S1, S2
)
```

We compare the transition paths with and without buy-out compensation.

```
exp1_exo = {
    'ss0': ss0, 'ss1': ss1_exp1_exo,
    'τ_l_buyout': τ_l_exp1_exo_bo, 'τ_l_no_buyout': τ_l_exp1_exo_nb,
    'results_buyout': results_exp1_exo_bo,
    'results_no_buyout': results_exp1_exo_nb,
    'hh': hh, 'tech': tech
}
```

The following figure shows how the buy-out reshapes initial asset holdings across cohorts.

```
# Extract results
_, μx_seq_bo, μc_seq_bo, k_seq_bo, Gb_seq_bo, _, _ = exp1_exo['results_buyout']
results_nb = exp1_exo['results_no_buyout']
_, μx_seq_nb, μc_seq_nb, k_seq_nb, Gb_seq_nb, _, _ = results_nb

# Mean assets by age at time s=0 (with vs without buyout)

axes[1].set_xlabel('age (t)')
axes[1].set_ylabel('compensation')
axes[1].set_title('Compensation by age, added to initial assets')
axes[1].legend()

plt.tight_layout()
plt.show()
```

Retirees receive the largest compensation because they were expecting benefits for the remainder of their lives.

Older workers receive significant compensation, while young workers receive little because they have their entire working lives to adjust.

The declining profile among retirees reflects the actuarial calculation: older retirees have fewer remaining years of expected benefits.

We now plot the aggregate transition paths for the labor tax, government debt, capital, and consumption under both schemes.

(continued from previous page)

```
plt.suptitle(
    'Consumption paths by cohort, Experiment 1',
    fontsize=14, y=1.02
)
plt.show()
```

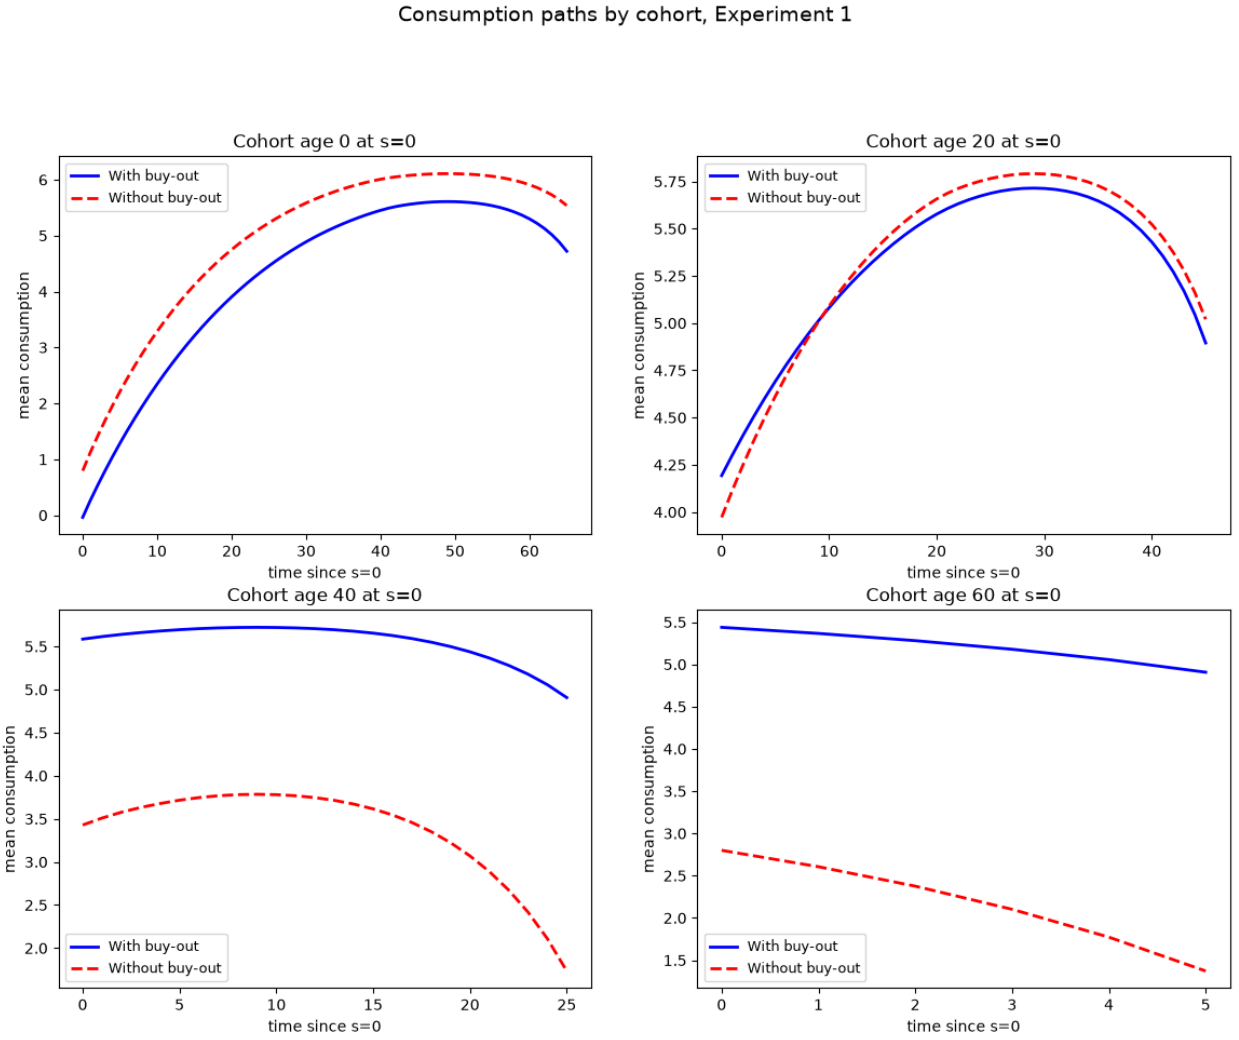

Fig. 128.9: Cohort consumption paths in Experiment 1

Young workers (age 0) show nearly identical consumption paths because they receive little compensation and have decades to adjust their savings.

Near-retirement workers (age 40) exhibit more noticeable differences as the buyout compensation partially offsets their lost benefits.

Retirees (age 60) show the most dramatic difference: without compensation, their consumption drops sharply when benefits end, whereas the buyout scheme maintains higher consumption by replacing the lost income.

128.8.2 Endogenous prices

With endogenous factor prices, changes in saving behavior affect capital accumulation, which alters marginal products and feeds back into household decisions.

Algorithm 128.8.2 (Endogenous factor prices)

Here $s_3 = s_2 + 2T_0 = 170$.

Steps 1–3 are the same as *Algorithm 128.8.1*, with an outer fixed-point loop over factor prices to clear factor markets in steady state.

Step 4. The factor price sequences are now endogenous.

Wrap the fixed-price transition solver in a relaxation loop:

```
T(R_seq):
  1. Compute the wage sequence from R_seq via Cobb-Douglas.
  2. Taking prices as given, find root of J(τ_ℓ) = Gb_terminal.
  3. Compute the implied capital path, then the implied R*.
  Return R* - R_seq.

Iterate T(R_seq) = 0 with relaxation until convergence.
```

We iterate on the price sequence until factor markets clear.

```
@jit
def compute_factor_prices(k_prod, ε_bar, A, α, δ):
    """Compute factor prices from Cobb-Douglas."""

    k_per_eff = k_prod / ε_bar
    r = A * α * (k_per_eff ** (α - 1))
    w = A * (1 - α) * (k_per_eff ** α)
    RR = 1 + r - δ
    return r, w, RR
```

With endogenous prices, finding a steady state requires an outer fixed-point loop: solve the household problem at given prices, compute the implied capital stock, update prices via Cobb-Douglas marginal products, and repeat until convergence.

```
def find_ss_endo(
        debt2gdp_target, policy_target,
        hh, tech, RR_init=None, w_init=None,
        max_iter=50, tol=1e-5, verbose=False):
    """Find steady state with endogenous factor prices."""

    τ_a, τ_0, benef, G = policy_target
    ε_bar = float(jnp.sum(hh.frac * hh.ε_arr))

    RR = RR_init if RR_init else tech.RR
    w = w_init if w_init else tech.w

    relaxation = 0.3

    for iteration in range(max_iter):
        try:
            ss = ss_target_debt2gdp_exo(
```

(continues on next page)

(continued from previous page)

```
                debt2gdp_target,
                (τ_a, τ_0, benef, G),
                (RR, w), hh, tech
            )
        except ValueError:
            RR = RR * 0.99
            continue

        K_eff = ss.k_bar / hh.n + float(hh.frac[0] * hh.x0[0])
        r_new, w_new, RR_new = compute_factor_prices(
            K_eff, ε_bar,

        )
        r_new = float(r_new)
        w_new = float(w_new)
        RR_new = float(RR_new)
        price_diff = abs(RR_new - RR) + abs(w_new - w)

        if verbose and iteration % 5 == 0:
            print(f"    SS iter {iteration}: "
                  f"RR={RR:.6f}, w={w:.4f}, "
                  f"k_bar={ss.k_bar:.4f}")

        if price_diff < tol:
            if verbose:
                print(f"    Converged at iteration {iteration}")
            break

        RR = RR + relaxation * (RR_new - RR)
        w = w + relaxation * (w_new - w)

    return ss_target_debt2gdp_exo(
        debt2gdp_target,
        (τ_a, τ_0, benef, G),
        (RR, w), hh, tech
    )
```

The price iteration also needs an initial guess for the transition price path and a way to update it after each inner solve.

The function `init_price_seq_interp` linearly interpolates between the two steady-state price vectors, while `_update_prices_from_capital` recomputes factor prices from the capital path via Cobb-Douglas marginal products.

```
def init_price_seq_interp(S, S1, S3, ss0_RR, ss0_w, ss1_RR, ss1_w):
    """Linearly interpolate price sequence between steady states."""

    s_indices = jnp.arange(S + 2)
    t_frac = jnp.clip((s_indices - S1) / (S3 - S1), 0.0, 1.0)

    RR_seq = ss0_RR + t_frac * (ss1_RR - ss0_RR)
    w_seq = ss0_w + t_frac * (ss1_w - ss0_w)

    RR_seq = jnp.where(s_indices <= S1, ss0_RR, RR_seq)
    w_seq = jnp.where(s_indices <= S1, ss0_w, w_seq)
    RR_seq = jnp.where(s_indices >= S3, ss1_RR, RR_seq)
    w_seq = jnp.where(s_indices >= S3, ss1_w, w_seq)
```

(continues on next page)

(continued from previous page)

)
plt.show()
```

The top-left panel shows that the transition tax rate is similar under both price assumptions, but the bottom panels reveal important differences in factor prices.

As the capital stock rises during the transition, the interest rate falls and the wage rises under endogenous pricing, while these remain constant under the small open economy assumption.

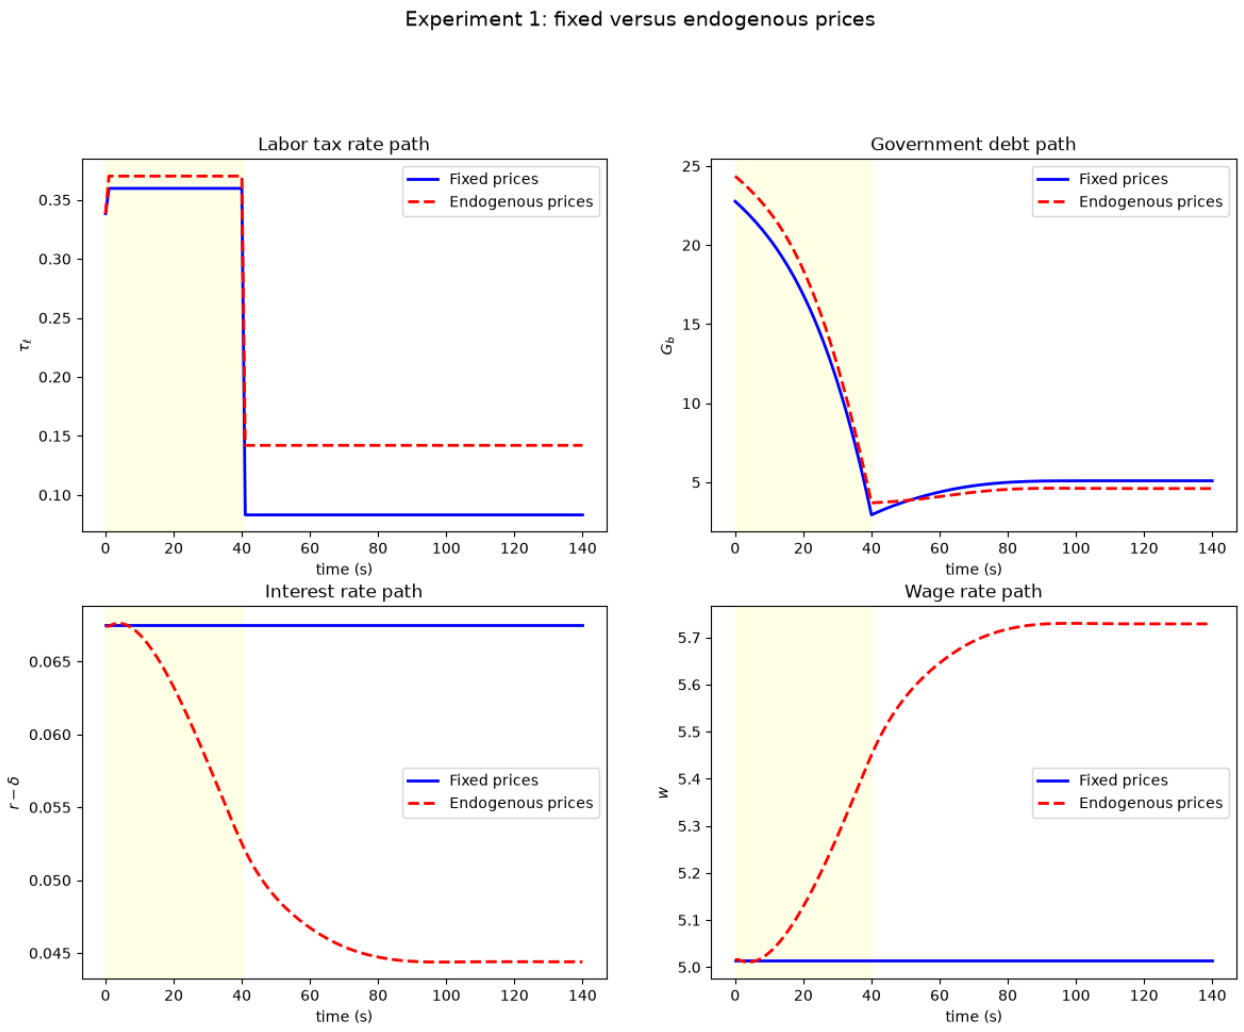

Fig. 128.10: Experiment 1 under fixed and endogenous prices

These price effects create additional redistributive consequences beyond those intended by the policy change: lower interest rates benefit young workers through higher wages, but hurt retirees through lower returns on savings.

128.9 Experiment 2: government capital accumulation

In Experiment 2, the government maintains social security benefits but temporarily raises taxes to accumulate physical capital.

The returns from this capital eventually finance the social security payments, so that in the terminal steady state the government is a net creditor rather than a debtor.

Unlike Experiment 1, which eliminates benefits, this approach preserves the social insurance function of social security – namely, insurance against life span risk and partial insurance against labor income volatility.

By having the government save on behalf of households, the economy can achieve higher capital accumulation while maintaining the intergenerational insurance that social security provides.

Algorithm 128.9.1 (Fixed factor prices – Experiment 2 (government funding))

Here $s_3 = s_2 + T_0 = 105$.

Steps 1–3 are the same as *Algorithm 128.8.1*, except that social security benefits are maintained and the target debt-to-GDP ratio is negative (the government becomes a net creditor).

The right target induces the government to accumulate sufficient capital to finance benefits from asset returns.

Step 4 is the same root-finding procedure over $\tau_{\ell,1}$, but without compensation payments.

We first compute the terminal steady state under fixed prices, targeting a negative debt-to-GDP ratio that makes the government a net creditor.

The target is chosen so that the income on the government's assets is enough to pay for social security benefits forever.

In the stationary equilibrium the government's net asset income per capita is $[R/n - 1](-\bar{b})$, and the benefit bill is $\sum_{t>T_1} S_t f_t$, so a first guess at the required asset position solves

$$\left[\frac{R}{n} - 1\right](-\bar{b}) = \sum_{t>T_1} S_t f_t$$

```
benefit_bill = float(jnp.sum(benef_0 * hh.frac * (1.0 - hh.Ind_work)))
Rn_net = tech.RR / hh.n - 1.0

print(f"benefit bill per capita        = {benefit_bill:.4f}")
print(f"net asset income per unit debt = {Rn_net:.4f}")
print(f"implied asset position b_bar   = {-benefit_bill / Rn_net:.4f}")
```

```
benefit bill per capita        = 0.4979
net asset income per unit debt = 0.0548
implied asset position b_bar   = -9.0793
```

The targets below ask for a slightly larger asset position than this calculation, which leaves some room for the government to keep financing its purchases g with distorting taxes.

Exercise 128.12.3 compares the two numbers.

```
debt2gdp_target_exp2_exo = -1.1785
ss1_exp2_exo = ss_target_debt2gdp_exo(
    debt2gdp_target_exp2_exo,
    (τ_a_0, τ_0_0, benef_0, G_0),
    (RR_exo, w_exo), hh, tech
)
```

With the terminal steady state in hand, bisection over the transition tax rate gives the equilibrium path under fixed prices.

```
# Price and policy sequences
price_seq_exp2_exo = make_exo_price_seq(S_exo, RR_exo, w_exo)
policy_seq_exp2_exo = make_policy_seq(
    S_exo, ss0.τ_l, ss1_exp2_exo.τ_l,
    S1, S2,
    τ_a_0, τ_0_0, benef_0, G_0, Gb_0
)

# Solve (no compensation)
τ_l_exp2_exo, results_exp2_exo = find_transition_exo(
    price_seq_exp2_exo, policy_seq_exp2_exo, ss0, ss1_exp2_exo,
    hh, tech, S_exo, S1, S2
)
```

The results are packaged for the cross-experiment comparison below.

```
(carryover_exp2, μx_seq_exp2_exo,
 μc_seq_exp2_exo, k_seq_exp2_exo,
 Gb_seq_exp2_exo, F_seq_exp2_exo,
 Ao_seq_exp2_exo) = results_exp2_exo

plt.suptitle('Comparison of all four reform scenarios', fontsize=14, y=1.02)
plt.show()
```

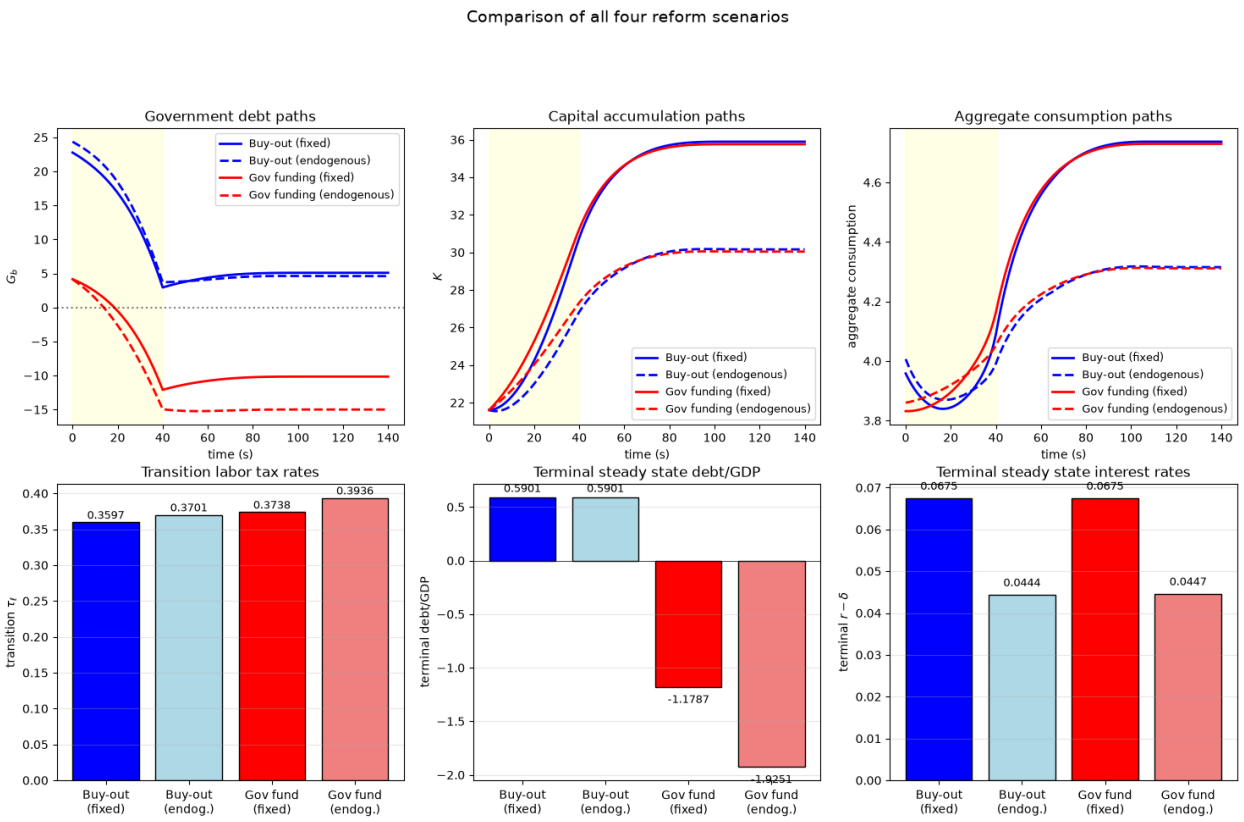

Fig. 128.11: Comparison of the four reform scenarios

The top row compares transition dynamics: the buy-out scheme (blue) accumulates higher debt during the transition due to compensation payments, while the government funding scheme (red) leads to large negative debt as the government becomes a net creditor.

The bottom-left bar chart shows that government funding requires higher transition tax rates than the buy-out scheme because benefit payments continue alongside capital accumulation.

Under endogenous pricing, the larger capital stock reduces the marginal product of capital and hence interest rates, as shown in the bottom-right panel.

To compare the two reforms we need numbers, not only paths.

The first summary collects the transition tax rate and the terminal steady state of each scenario.

```
summary = [
    ('buy-out, fixed prices',    exp1_exo['τ_l_buyout'],  exp1_exo['ss1']),
    ('buy-out, endogenous',      exp1_endo['τ_l_buyout'], exp1_endo['ss1']),
    ('gov funding, fixed',       exp2_exo['τ_l_trans'],   exp2_exo['ss1']),
    ('gov funding, endogenous',  exp2_endo['τ_l_trans'],  exp2_endo['ss1']),
]

print(f"{'scenario':>24}  {'τ_l trans':>9}  {'τ_l final':>9}"
      f"  {'K/GDP':>7}  {'debt/GDP':>8}  {'r − δ':>7}")
for name, τ_trans, ss in summary:
    print(f"{name:>24}  {τ_trans:>9.4f}  {ss.τ_l:>9.4f}"
          f"  {ss.k2gdp:>7.4f}  {ss.debt2gdp:>8.4f}  {ss.r - tech.δ:>7.4f}")
```

```
                scenario  τ_l trans  τ_l final    K/GDP  debt/GDP    r − δ
  buy-out, fixed prices     0.3597     0.0831   4.1567    0.5901   0.0675
    buy-out, endogenous     0.3701     0.1420   3.8640    0.5901   0.0444
     gov funding, fixed     0.3738     0.1390   4.1493   -1.1787   0.0675
gov funding, endogenous     0.3936     0.2333   3.8549   -1.9251   0.0447
```

The second summary asks which reform a person born into the terminal steady state would prefer.

Because the value function is $U_t = x_t' P_t x_t + \xi_t$, the welfare of a newborn follows directly from objects that we have already computed.

```
def newborn_welfare(ss):
    "Expected lifetime utility of an agent born into a steady state."

    return float(hh.x0 @ ss.P_arr[0] @ hh.x0 + ss.ξ_arr[0])

print(f"{'steady state':>34}  {'U of a newborn':>14}")
for name, ss in [
    ('initial, pay-as-you-go', ss0),
    ('terminal, buy-out (no benefits)', exp1_exo['ss1']),
    ('terminal, government funding', exp2_exo['ss1']),
]:
    print(f"{name:>34}  {newborn_welfare(ss):>14.2f}")
```

```
                       steady state  U of a newborn
           initial, pay-as-you-go         -262.74
  terminal, buy-out (no benefits)         -192.18
     terminal, government funding         -180.88
```

A newborn prefers either reform to the pay-as-you-go system that we started from.

These are fixed-price steady states, so the wage is the same in all three rows; what lifts welfare is the labor tax rate, which falls from 0.34 to 0.08 under the buy-out and to 0.14 under government funding.

Between the two reforms, a newborn prefers government funding.

That scheme taxes labor more heavily than the buy-out does, but it keeps paying social security benefits, which continue to insure against life span risk and to provide partial insurance against labor income risk, and a newborn values those benefits more than the extra taxes cost.

This comparison ranks steady states.

It says nothing about the generations alive during the transition, whose fortunes the cohort consumption paths plotted above describe.

128.10 Distribution surfaces

The 3D surface plots below show how assets and consumption evolve over both the age dimension and calendar time.

```
# Compute variances for 3D plotting
def compute_variances(results, ss0, hh):
    """Compute variance sequences from transition results."""

    _, μx_seq, μc_seq, k_seq, Gb_seq, F_seq, Ao_seq = results

    # Convert to numpy
    μx_seq = np.array(μx_seq)
    μc_seq_full = np.array(μc_seq)
    F_seq = np.array(F_seq)
    Ao_seq = np.array(Ao_seq)
    Σx_arr_ss0 = np.array(ss0.Σx_arr)
    Σ0 = np.array(hh.Σ0)
    C = np.array(hh.C)

    # Get actual dimensions from data
    S_plus_1 = Ao_seq.shape[0]  # S+1
    T0_plus_1 = Ao_seq.shape[1]  # T0+1

    Σx_seq = np.empty((S_plus_1 + 1, T0_plus_1 + 1, hh.n_x, hh.n_x))
    Vc_seq = np.empty((S_plus_1, T0_plus_1))
    Va_seq = np.empty((S_plus_1, T0_plus_1))

    Σx_seq[:, 0] = Σ0

    exp1_endo['results'], exp1_endo['ss0'], hh
)
μa_af, Va_af, μc_af, Vc_af = compute_variances(
```

(continues on next page)

(continued from previous page)

```
    exp2_exo['results'], exp2_exo['ss0'], hh
)
μa_ae, Va_ae, μc_ae, Vc_ae = compute_variances(
    exp2_endo['results'], exp2_endo['ss0'], hh
)

case_names = [
    'Buy-out (fixed)', 'Buy-out (endogenous)',
    'Gov funding (fixed)', 'Gov funding (endogenous)'
]

def plot_surface_grid(
        data_cases, case_names, zlabel,
        suptitle, cmap='viridis',
        transform=None):
    """Plot 2x2 grid of 3D surfaces for age-time data."""

    fig = plt.figure(figsize=(16, 12))
    for i, (data, name) in enumerate(zip(data_cases, case_names)):
        Z = transform(data) if transform is not None else data
        n_time, n_age = Z.shape
        X, Y = np.meshgrid(np.arange(n_age), np.arange(n_time))
        ax = fig.add_subplot(2, 2, i + 1, projection='3d')
        ax.plot_surface(X, Y, Z, cmap=cmap, edgecolor='none', alpha=0.8)
        ax.set_xlabel('age (t)')
        ax.set_ylabel('time (s)')
        ax.set_zlabel(zlabel)
        ax.set_title(name)
    plt.suptitle(suptitle, fontsize=14, y=1.02)
    plt.tight_layout()
    plt.show()
```

Each surface shows the joint distribution across age (t) and calendar time (s), revealing life-cycle patterns, transition dynamics, and cross-cohort heterogeneity.

The mean asset surfaces display the hump-shaped life-cycle profile of asset holdings, with peak assets shifting as working generations increase their saving in response to the reform.

```
plot_surface_grid(
    [μa_bf, μa_be, μa_af, μa_ae],
    case_names, 'Mean assets',
    'Mean asset holdings by age and time'
)
```

The asset variance surfaces show how cumulative income shocks cause dispersion to increase with age, with the transition potentially altering the rate of dispersion growth.

```
plot_surface_grid(
    [Va_bf, Va_be, Va_af, Va_ae],
    case_names, 'Std. dev. of assets',
    'Asset std. dev. by age and time',
    cmap='plasma', transform=np.sqrt
)
```

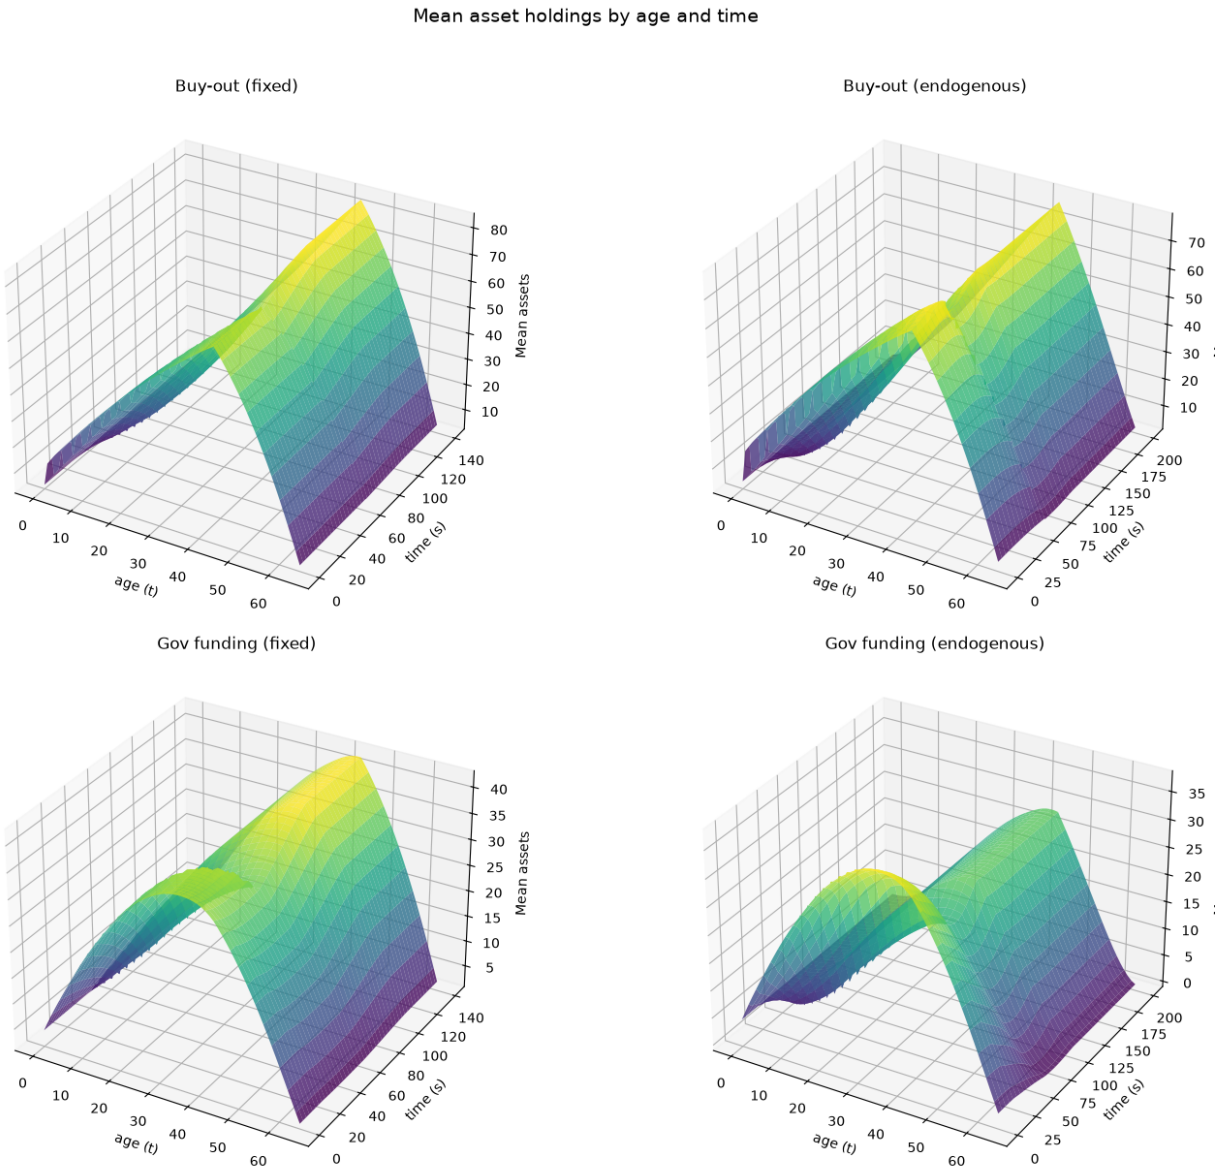

Fig. 128.12: Mean assets by age and time

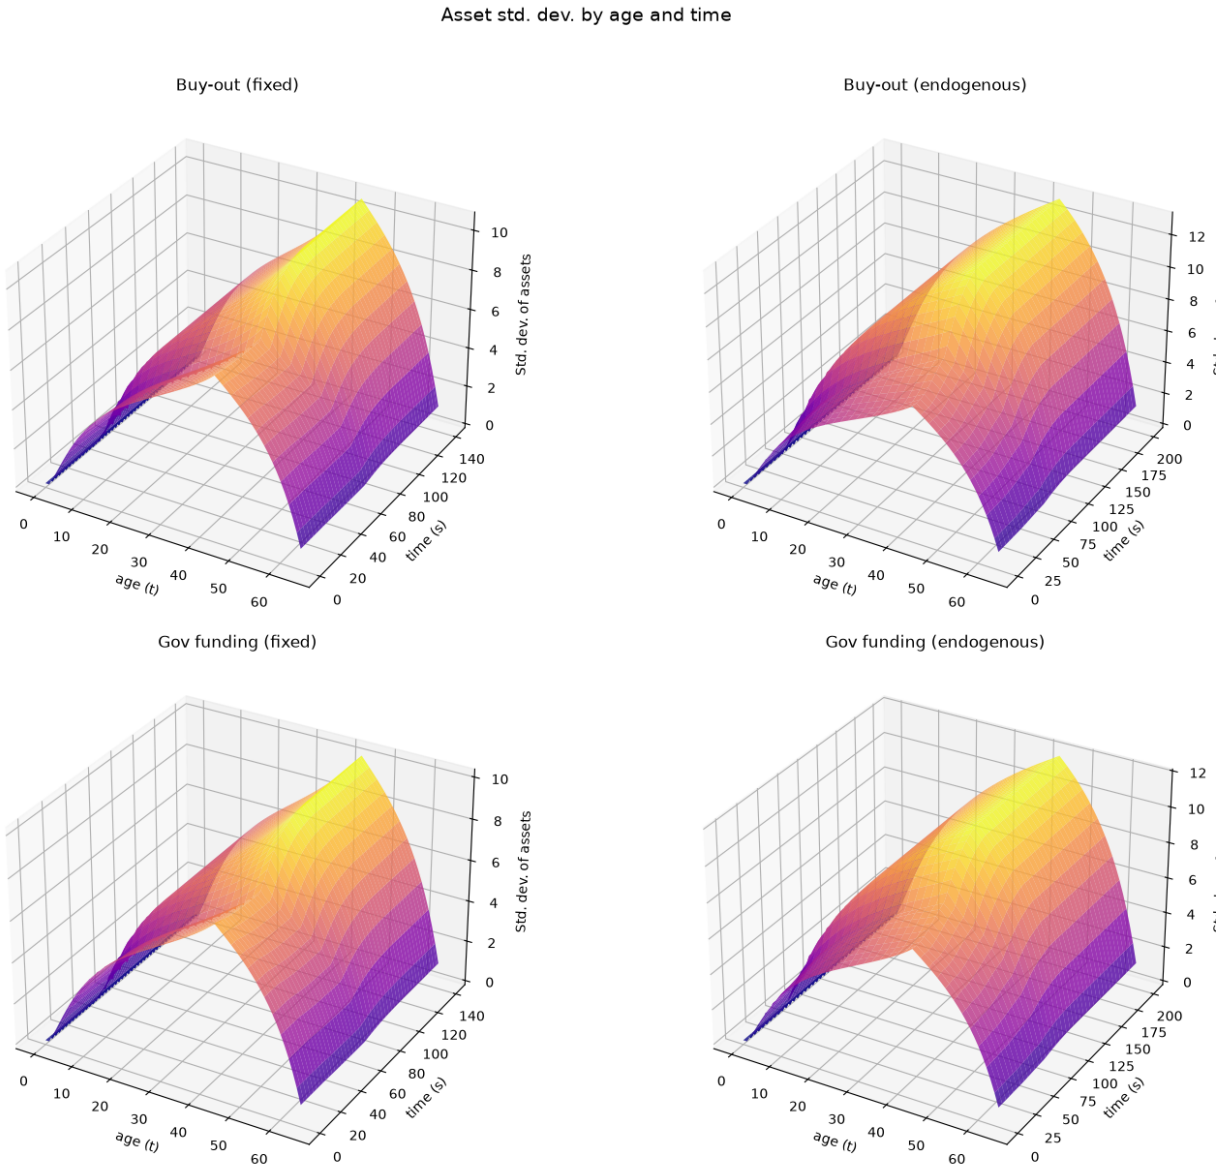

Fig. 128.13: Asset dispersion by age and time

The mean consumption surfaces reflect the optimal consumption path, which should be smooth across ages due to the permanent income hypothesis underlying the model.

```
plot_surface_grid(
    [μc_bf, μc_be, μc_af, μc_ae],
    case_names, 'Mean consumption',
    'Mean consumption by age and time',
    cmap='coolwarm'
)
```

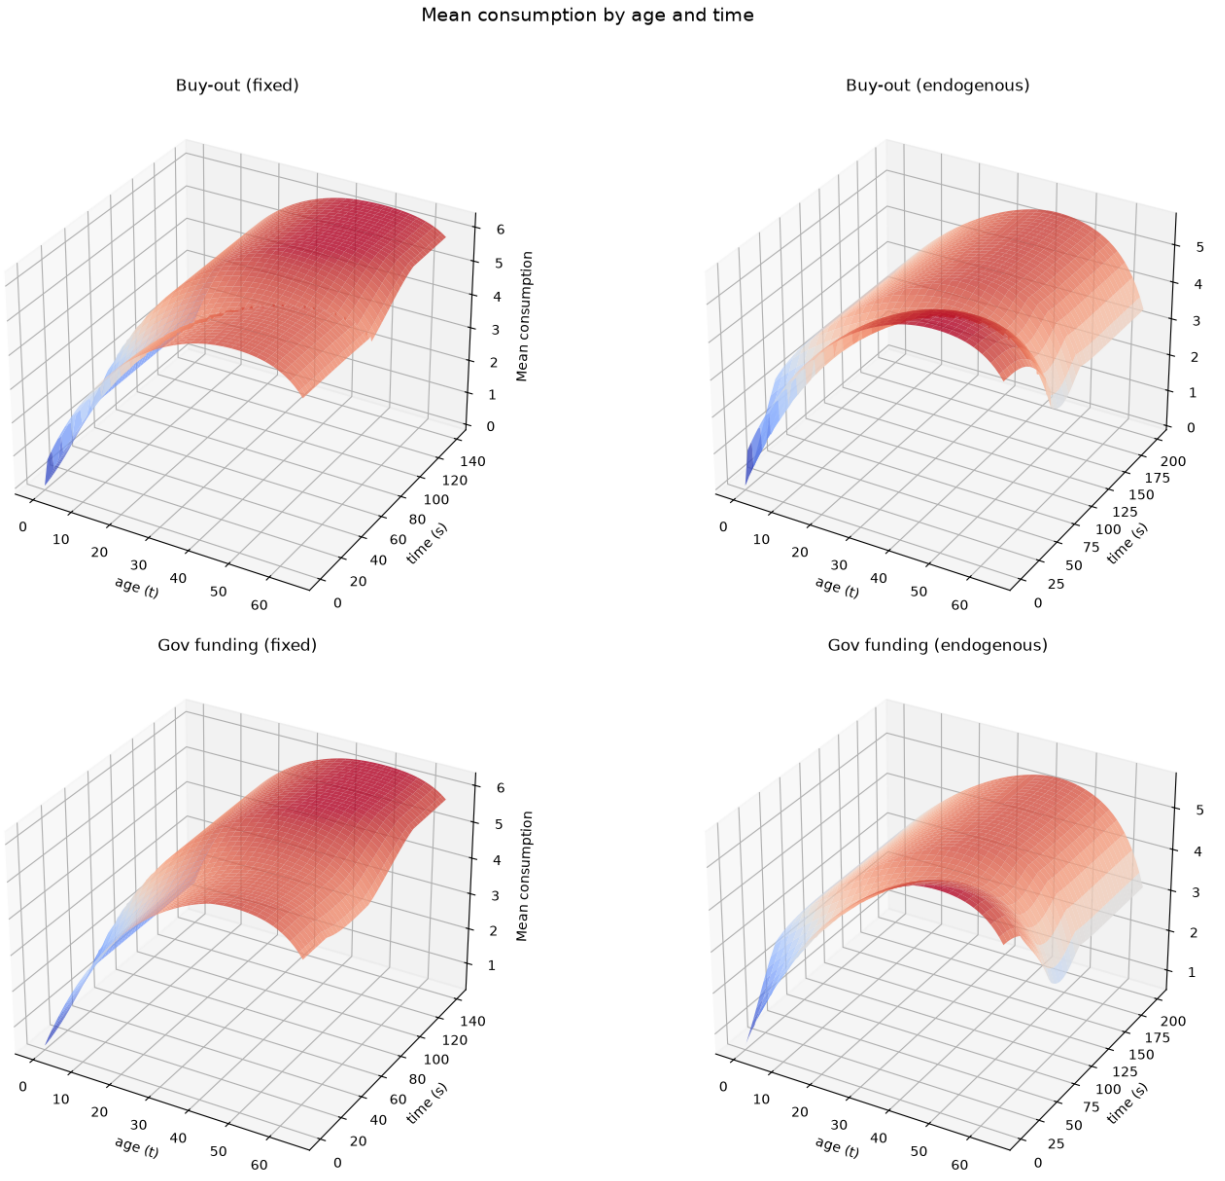

Fig. 128.14: Mean consumption by age and time

The consumption variance surfaces show how within-cohort consumption dispersion builds up with age as income shocks accumulate, and how it is reshaped along the transition.

Note that consumption dispersion is not a by-product of certainty equivalence: with $\sigma = -0.05$ the decision rules themselves depend on the volatility of income, as Exercise 128.12.2 confirms.

```
plot_surface_grid(
    [Vc_bf, Vc_be, Vc_af, Vc_ae],
    case_names, 'Std. dev. of consumption',
    'Consumption std. dev. by age and time',
    cmap='magma', transform=np.sqrt
)
```

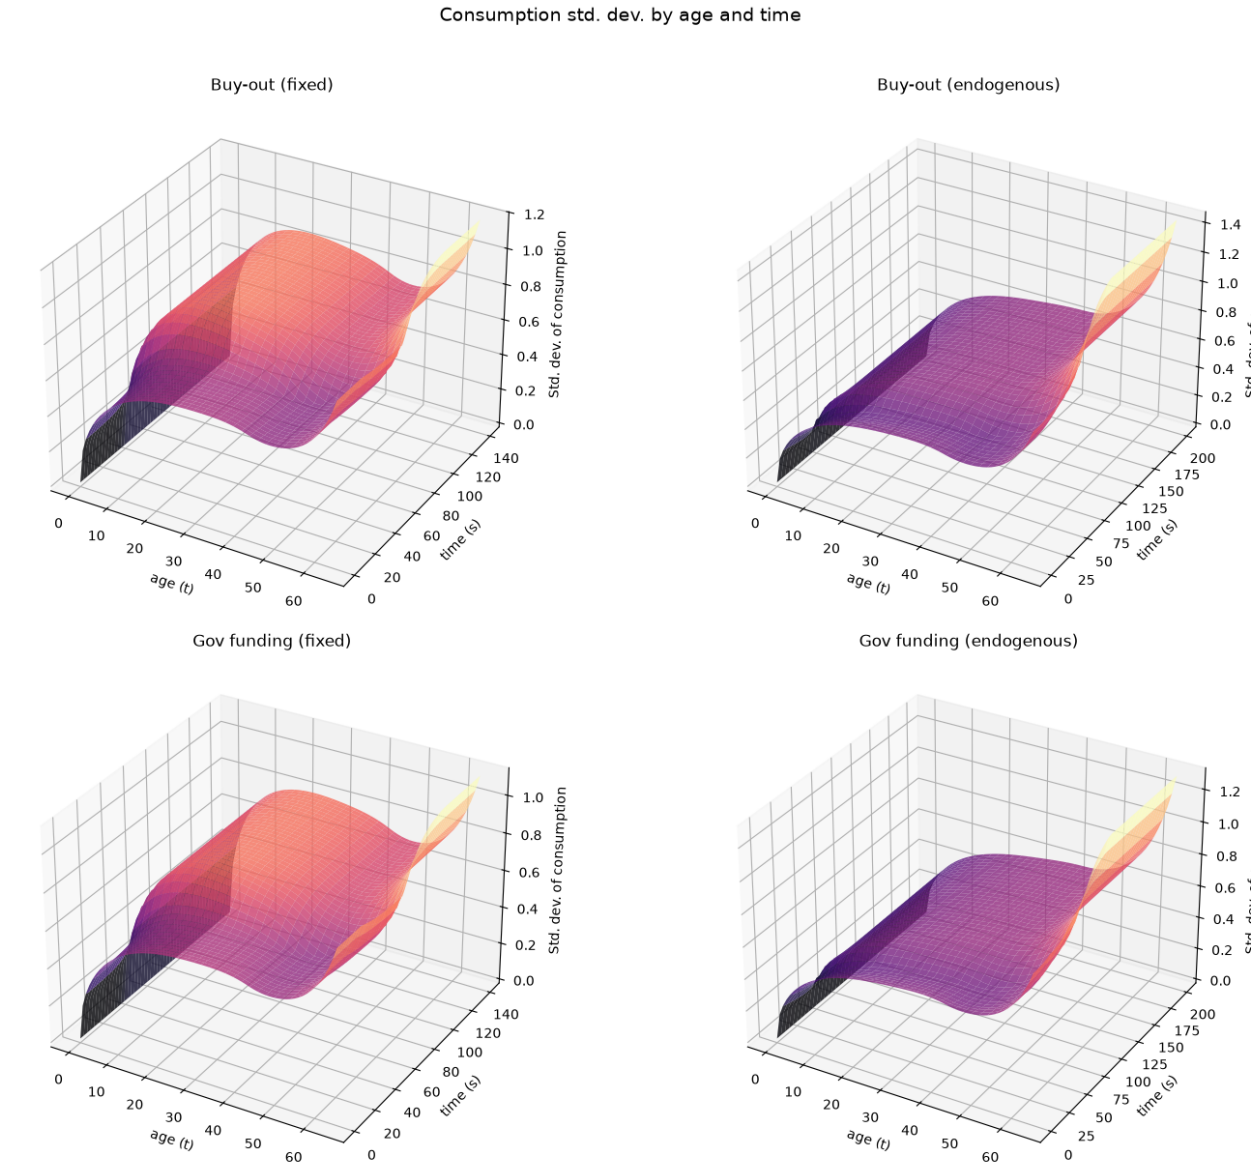

Fig. 128.15: Consumption dispersion by age and time

128.11 Concluding remarks

We set out to compare two ways of moving from an unfunded to a fully funded social security system, following Huang *et al.* [1997].

Both reforms raise the capital stock substantially, lifting capital relative to GDP from about 3.2 to about 4.2 when factor prices are fixed, and to about 3.9 when they are endogenous.

Both also cut the equilibrium labor tax rate, from 0.34 to between 0.08 and 0.23 depending on the reform and the price regime.

They differ in who bears the cost and in what is preserved.

The buy-out of Experiment 1 settles the government's obligations to existing generations by issuing debt, which keeps those generations whole but leaves future ones without social insurance.

The government funding of Experiment 2 keeps paying benefits and accumulates assets instead, which requires higher taxes during the transition but preserves insurance against life span risk and against labor income risk.

A newborn in the terminal steady state prefers the second reform.

Three features of the model do most of the work in these calculations.

Risk-sensitive preferences make saving respond to the volatility of labor income, so that the precautionary motive, rather than the life-cycle motive alone, shapes the aggregate capital stock.

Life span uncertainty gives social security an insurance role that a pure pay-as-you-go transfer scheme would not have.

And the linearity of the decision rules lets us track entire distributions of consumption and wealth, both across cohorts and over calendar time, which is what the surfaces plotted above display.

Readers who want the same questions posed in simpler settings can compare *Transitions in an Overlapping Generations Model*, where transitions can be computed by hand, and *A Long-Lived, Heterogeneous Agents, Overlapping Generations Model*, where precautionary saving arises from a borrowing constraint rather than from risk-sensitive preferences.

128.12 Exercises

Exercise 128.12.1

The calibration table lists $\tilde{A} = 2.2625$ and $\tilde{\alpha} = 0.40$ for the closed economy, and $r = 0.1275$ and $w = 5.0147$ for the small open economy.

This exercise shows that the first pair is implied by the second.

1. Let $K_{\text{eff}} = \bar{k}/n + f_0 k_{-1}$ be the capital available for production per capita in the initial steady state, and $\bar{\varepsilon} = \sum_t \varepsilon_t f_t$ aggregate labor in efficiency units. Explain why $\tilde{\alpha} = rK_{\text{eff}}/(rK_{\text{eff}} + w\bar{\varepsilon})$.
2. Given $\tilde{\alpha}$, compute $\tilde{A}$ from the marginal product of capital, and then again from the marginal product of labor.
3. Suppose instead that we wanted a capital share of $\tilde{\alpha} = 0.33$ while keeping the same (r, w) targets. What goes wrong?

Solution

Part 1. With a Cobb-Douglas technology and constant returns to scale, payments to capital and labor exhaust output, so $Y = rK + wL$.

Capital's share of income is then $rK/Y = rK/(rK + wL)$, and for Cobb-Douglas production that share equals the exponent $\tilde{\alpha}$.

Parts 2 and 3.

```
ε_bar_ex = float(jnp.sum(hh.frac * hh.ε_arr))
K_eff_ex = ss0.k_bar / hh.n + float(hh.frac[0] * hh.x0[0])
k_pe_ex = K_eff_ex / ε_bar_ex

α_implied = tech.r * K_eff_ex / (tech.r * K_eff_ex + tech.w * ε_bar_ex)
print(f"K_eff = {K_eff_ex:.4f},  ε̄ = {ε_bar_ex:.4f},  K/L = {k_pe_ex:.4f}")
print(f"implied capital share = {α_implied:.4f}  (calibrated {tech.α_tilde})")

for α_try in [tech.α_tilde, 0.33]:
    A_from_r = tech.r / (α_try * k_pe_ex ** (α_try - 1))
    A_from_w = tech.w / ((1 - α_try) * k_pe_ex ** α_try)
    print(f"α̃ = {α_try:.2f}: A from r = {A_from_r:.4f}, "
          f"A from w = {A_from_w:.4f}")
```

```
K_eff = 21.4550,  ε̄ = 0.8175,  K/L = 26.2433
implied capital share = 0.4002  (calibrated 0.4)
α̃ = 0.40: A from r = 2.2639, A from w = 2.2620
α̃ = 0.33: A from r = 3.4494, A from w = 2.5462
```

At $\tilde{\alpha} = 0.40$ the two values of $\tilde{A}$ agree with each other and with the calibrated 2.2625.

At $\tilde{\alpha} = 0.33$ they disagree: no single scale factor can reproduce both prices, because the capital-labor ratio of the initial steady state and the two price targets already determine the capital share.

Pinning down (r, w) and the steady-state capital stock therefore leaves no freedom in $(\tilde{A}, \tilde{\alpha})$, which is exactly why the small open economy and the closed economy start from the same place.

Exercise 128.12.2

How much saving does risk sensitivity induce?

Recompute the initial steady state for $\sigma \in \{0, -0.05, -0.1\}$, holding all other parameters at their calibrated values, and report the per capita capital stock, the equilibrium labor tax rate, and capital relative to GDP.

Explain why the case $\sigma = 0$ deserves the name certainty equivalence.

Solution

```
print(f"{'σ':>7}  {'k_bar':>8}  {'τ_l':>7}  {'K/GDP':>7}")
for σ_try in [0.0, -0.05, -0.1]:
    hh_try = create_household(σ=σ_try)
    ss_try = find_ss_exo(
        (tech.RR, tech.w),
        (τ_a_0, τ_0_0, benef_0, G_0, Gb_0),
        hh_try, tech
    )
    print(f"{σ_try:>7.2f}  {ss_try.k_bar:>8.4f}  {ss_try.τ_l:>7.4f}"
          f"  {ss_try.k2gdp:>7.4f}")
```

```
      σ     k_bar      τ_l    K/GDP
   0.00   16.1981   0.3787   2.6324
  -0.05   21.6096   0.3383   3.1615
  -0.10   28.1911   0.2906   3.6782
```

Moving from $\sigma = 0$ to the calibrated $\sigma = -0.05$ raises the capital stock by about a third, and a further doubling of risk sensitivity raises it by another third.

The extra capital widens the tax base, so the labor tax rate that balances the same budget falls by about four percentage points between the first two rows.

At $\sigma = 0$ the operator $\mathcal{T}_t$ is the identity, so P_t and the decision rule F_t never see the shock loading C_t.

Consumption then responds only to the conditional mean of future income, which is the certainty equivalence property of ordinary linear-quadratic problems.

At $\sigma < 0$ the term $\sigma P C_t (I - \sigma C_t' P C_t)^{-1} C_t' P$ makes F_t depend on $C_t C_t'$, and the consumer accumulates a buffer against income risk.

Exercise 128.12.3

This exercise examines the debt target behind Experiment 2 and the long-run welfare ranking of the two reforms.

1. Compute the per capita benefit bill $\sum_{t>T_1} S_t f_t$ and the asset position $\bar{b}$ at which the government's net asset income $[R/n - 1](-\bar{b})$ exactly pays for it.
2. Compare that number with the asset position that the lecture's target of -1.1785 for debt relative to GDP actually delivers, and report the net asset income and the labor tax rate in that steady state.
3. Compute the welfare of a newborn in the initial steady state and in the two terminal steady states under fixed prices. Which reform does a newborn prefer, and why?

Solution

```
benefit_bill_ex = float(jnp.sum(benef_0 * hh.frac * (1.0 - hh.Ind_work)))
Rn_ex = tech.RR / hh.n - 1.0

print(f"benefit bill                = {benefit_bill_ex:.4f}")
print(f"R/n - 1                     = {Rn_ex:.4f}")
print(f"b_bar that just funds it    = {-benefit_bill_ex / Rn_ex:.4f}\n")

ss_exp2 = exp2_exo['ss1']
print(f"lecture target -1.1785 gives b_bar = {ss_exp2.Gb:.4f}")
print(f"  net asset income = {-Rn_ex * ss_exp2.Gb:.4f}"
      f"  versus benefits = {benefit_bill_ex:.4f}")
print(f"  labor tax τ_l = {ss_exp2.τ_l:.4f}"
      f"  versus {ss0.τ_l:.4f} initially")
```

```
benefit bill                = 0.4979
R/n - 1                     = 0.0548
b_bar that just funds it    = -9.0793

lecture target -1.1785 gives b_bar = -10.1573
  net asset income = 0.5570  versus benefits = 0.4979
  labor tax τ_l = 0.1390  versus 0.3383 initially
```

The asset position that exactly funds benefits is about -9.1, while the target used in the lecture delivers about -10.2.

The government therefore accumulates a little more than social security alone requires, and the surplus lets it cut the labor tax rate from 0.34 to about 0.14 even though it is still paying benefits and still buying goods.

```
print(f"{'steady state':>34}  {'U of a newborn':>14}")
for name, ss_w in [
    ('initial, pay-as-you-go', ss0),
    ('terminal, buy-out (no benefits)', exp1_exo['ss1']),
    ('terminal, government funding', exp2_exo['ss1']),
]:
    print(f"{name:>34}  {newborn_welfare(ss_w):>14.2f}")
```

```
                       steady state  U of a newborn
           initial, pay-as-you-go         -262.74
  terminal, buy-out (no benefits)         -192.18
     terminal, government funding         -180.88
```

A newborn ranks government funding first, the buy-out second, and the initial pay-as-you-go system last.

Because these are fixed-price steady states, the wage is the same in all three; what lifts welfare above the initial steady state is the lower labor tax rate that both reforms deliver.

Government funding then does better than the buy-out, despite its higher labor tax, because it continues to pay benefits that insure against outliving one's assets and against low labor income draws.

Remember that this ranking compares steady states, so it leaves out the transition costs borne by generations alive at the time of the reform.

129.1 Overview

The Social Security trustees project that the reserves of the Old-Age and Survivors Insurance trust fund will run out during 2032 [Board of Trustees, Federal Old-Age and Survivors Insurance and Federal Disability Insurance Trust Funds, 2026].

The program cannot borrow.

Unless Congress acts, current law then reduces every benefit by a common factor $\phi_t \leq 1$ that makes the program's cash flow balance: a worker entitled to a scheduled benefit b^{sch} collects $\phi_t b^{sch}$.

We call ϕ_t the **payable factor**.

It is not a policy parameter that somebody chooses.

It is an equilibrium object, because the quantity it scales depends on decisions that workers take while looking ahead at it:

- a worker who expects a smaller pension works longer and saves more
- a worker inside the claiming window just before the cut has a reason to file early, while benefits are still paid in full

- a worker who expects to live longer has a reason to file late, because the actuarial reward for waiting is fixed by statute

Those decisions determine taxable payroll and the scheduled benefit bill, which are exactly the two quantities that determine ϕ_t.

This lecture studies that fixed point, following Sargent and Shi [2026].

We write down the ledger that current law prescribes, define the map that sends a path for the payable factor into another path for the payable factor, and compute its fixed point in a quantitative overlapping generations model with

- a life cycle from age 20 to age 100 with projected mortality
- permanent heterogeneity in earnings ability and in the taste for work
- the statutory benefit formula, the actuarial adjustment for the claim age, the taxable maximum, and the taxation of benefits
- retirement and benefit claiming as **separate** irreversible decisions

The exercises then put the machinery to work: on the oscillation that a decreasing map produces, on raising the full retirement age, on what it would cost to guarantee scheduled benefits instead, and on how much of the long-run cut is the work of rising life expectancy.

Several symbols recur, so we record them here.

Symbol	Meaning
ϕ_t	payable factor: the common fraction of scheduled benefits actually paid
F_t, r^F	trust fund balance and the rate credited on it
N_t	population; every other aggregate is per capita
Pay_t, B_t^{sch}	per capita taxable payroll and the per capita scheduled benefit bill
τ^{ss}, κ_b, $\bar{y}$	payroll tax rate, tax rate on benefits received, taxable maximum
AIME, PIA, ψ	the earnings record, the benefit it buys, and the rate at which the record accrues
AF(χ), FRA, ς	actuarial factor at claim age χ, the full retirement age, and a benefit scale
R, χ	a worker's retirement age and claim age
j, t	age index (0 at age 20) and calendar year
e, h	permanent earnings ability and taste for work
ℓ_j, Ω	survival from age 20 to age $20+j$, and $\sum_j \beta^j \ell_j$
$\tilde{R}$, a_0, $\mathcal{W}$	after-tax gross return, assets on hand, and lifetime resources

This lecture is a companion to *Two Computations to Fund Social Security*, which studies two ways of moving from an unfunded to a fully funded system in the model of Huang *et al.* [1997].

Here nobody moves to a funded system: we ask what current law does on its own, and what it would cost to stop it.

Two other lectures supply background: *Transitions in an Overlapping Generations Model* introduces the Auerbach and Kotlikoff [1987] overlapping generations framework, and *A Long-Lived, Heterogeneous Agents, Overlapping Generations Model* adds uninsurable idiosyncratic risk to it.

We use the following imports.

```
import numpy as np
import matplotlib.pyplot as plt
from collections import namedtuple
from scipy.optimize import fsolve, brentq
```

129.2 The institution

Social Security's ledger is a stock, F_t, and two flows.

The fund earns an administered rate r^F on the special issue Treasury securities it holds, it receives the payroll tax, and it pays benefits.

Writing N_t for the population, Pay_t for per capita taxable payroll, and B_t^{sch} for the per capita scheduled benefit bill, the ledger evolves as

$$F_{t+1} = (1 + r^F)F_t + N_t \left(Rev_t - \phi_t B_t^{sch} \right), \qquad F_t \geq 0, \tag{129.1}$$

where program revenue is the payroll tax plus the tax that returns to the program on the benefits it pays,

$$Rev_t = \tau^{ss} Pay_t + \kappa_b \phi_t B_t^{sch}. \tag{129.2}$$

The restriction $F_t \geq 0$ in (129.1) is the law: the program may not borrow.

It is what forces ϕ_t below one.

The program pays the largest common fraction of scheduled benefits that its resources allow,

$$\phi_t = \min \left\{ 1, \ \frac{(1 + r^F)F_t + N_t \tau^{ss} Pay_t}{N_t (1 - \kappa_b) B_t^{sch}} \right\}. \tag{129.3}$$

The numerator is what the program can draw on: the balance it carries in plus the payroll tax it collects.

The denominator is what it owes, net of the benefit tax that comes back to it.

We date depletion at the first year the fund is empty,

$$t^{dep} = \min\{t : F_t = 0\},$$

and we call $t^{dep} - 1$ the **first shortfall year**, the year in which the program pays out its last reserves and the first year in which $\phi_t < 1$.

> **Note**
>
> The trustees date "reserve depletion" to the year the reserves run out, which is the first shortfall year here.
>
> Their projected 2032 is therefore our $t^{dep} - 1$, and the first year in which the whole benefit is cut is 2033.

From t^{dep} on the fund is empty and (129.3) collapses to a cash flow condition,

$$\phi_t = \frac{\tau^{ss} Pay_t}{(1 - \kappa_b) B_t^{sch}}, \qquad t \geq t^{dep}. \tag{129.4}$$

129.2.1 The payable factor is a fixed point

Equation (129.4) looks like a formula for ϕ_t, but both Pay_t and B_t^{sch} are built from decisions that workers make while looking at the whole future path $\{\phi_s\}$.

Let Φ be the map that takes a candidate path $\{\phi_s\}_{s \geq 0}$, hands it to workers, collects the taxable payroll and scheduled benefits that their optimal decisions generate, runs the ledger (129.1), and returns the payable path (129.3) that the ledger implies.

An equilibrium payable path is a fixed point,

$$\{\phi_t\} = \Phi(\{\phi_t\}). \tag{129.5}$$

Important

Φ is a **decreasing** map.

Raise the candidate path and benefits become more valuable, so workers claim earlier and retire earlier; taxable payroll falls and the scheduled bill rises; (129.3) then returns a *smaller* number.

Successive guesses therefore alternate around the fixed point rather than approaching it from one side.

Whether the alternation dies out depends on how strongly workers respond, and Exercise 129.9.1 finds dates at which it does not: the undamped iteration settles into a two-cycle and stays there.

Every computation below therefore takes a damped step.

One consequence of (129.4) is worth recording before we compute anything.

In a long run in which the fund is empty and the economy has settled down, the payable factor is pinned by the program's **cost rate**, the ratio of scheduled benefits to taxable payroll:

$$\phi_\infty = \frac{\tau^{ss}}{(1-\kappa_b)} \cdot \frac{Pay_\infty}{B^{sch}_\infty}. \tag{129.6}$$

Everything demographic and behavioral that matters for the long-run benefit cut reaches it through that one ratio.

129.3 A model we can solve quickly

Sargent and Shi [2026] compute general equilibrium transition paths of an economy with idiosyncratic earnings risk, a neoclassical firm, a consolidated government budget constraint, and a cross-section of 80,000 workers per age.

That calculation takes about 22 hours on an A100 GPU.

The model below keeps the institution exactly and strips the economy down until the whole fixed point runs in about a minute on a laptop.

What this lecture leaves out

- **Prices are fixed.** The interest rate and the wage do not respond. In the paper, capital deepens as workers save against a smaller pension, the capital–output ratio rises from 3.00 to 3.19, and the interest rate falls from 6.0 to 5.3 percent.
- **There is no government budget constraint outside the program.** In the paper, depletion removes the Social Security deficit from the consolidated budget, so the labor tax *falls* from 0.220 to 0.190: current law delivers a benefit cut to retirees and a tax cut to workers in the same year.
- **There is no idiosyncratic earnings risk and no borrowing constraint**, so the life cycle has a closed form. Workers differ only in permanent ability and in their taste for work.
- **Annuity markets are complete**, so there are no accidental bequests and no bequest motive.
- **Benefits are scaled rather than extended.** The program's spousal and survivor benefits go to additional beneficiaries; here a single scale factor on each worker's own benefit matches the aggregate cost instead, which raises individual replacement rates by about a seventh.

- **Demography is stylized**, a smooth birth path and a Gompertz mortality table calibrated to the trustees' dependency ratios, rather than the published population projection.

What survives is the part this lecture is about: an endogenous payable factor, and claiming and retirement decisions that respond to it.

129.3.1 Parameters

Units are the average wage index of 2025, so one model unit is \$72,025 and mean earnings per worker are one.

The statutory amounts – the taxable maximum, the two bend points of the benefit formula, the payroll tax rate, the actuarial factors, the trust fund balance – take their legislated or recorded 2025 values.

The tax rates on labor, capital and consumption follow Kitao [2014], and the discount factor, the interest rate, the dispersion of earnings ability and the rate credited on the fund are those of Sargent and Shi [2026].

Two parameters are chosen inside this model, and we say which below.

```
AWI = 72025.07          # average wage index, 2025: dollars per model unit
AGE0, J = 20, 81        # ages 20 ... 100
Y0, T = 2026, 120       # first transition year, horizon
YEARS = np.arange(Y0, Y0+T+1)

Params = namedtuple('Params', [
    'β', 'η', 'r', 'τ_l', 'τ_k', 'τ_c', 'τ_ss', 'κ_b', 'r_F',
    'ycap', 'bend', 'prate', 'FRA', 'ψ', 'σ_a', 'σ_η', 'g_m', 'bscale', 'F_ratio'])

par = Params(
    β=0.9739,            # discount factor
    η=0.81,              # disutility of work (calibrated)
    r=0.060,             # interest rate
    τ_l=0.22, τ_k=0.30, τ_c=0.05,          # labor, capital, consumption taxes
    τ_ss=0.106,          # OASI payroll tax rate
    κ_b=0.03891,         # tax on benefits received
    r_F=0.02,            # rate credited on the trust fund
    ycap=176100/AWI,     # taxable maximum
    bend=np.array([1226.0, 7391.0])*12/AWI,    # PIA bend points
    prate=np.array([0.90, 0.32, 0.15]),        # PIA replacement rates
    FRA=67,              # full retirement age
    ψ=0.055,             # AIME accrual (a 35 year moving average)
    σ_a=0.315,           # dispersion of earnings ability
    σ_η=0.16,            # dispersion of the taste for work
    g_m=0.007,           # annual mortality improvement
    bscale=1.145,        # benefit scale ς (calibrated)
    F_ratio=1.6255)      # 2025 reserves relative to benefit payments

def after_tax_R(p):
    "The gross after-tax return on saving."
    return 1 + p.r*(1 - p.τ_k)
```

The benefit formula has two pieces.

The **primary insurance amount** is a concave, piecewise linear function of a worker's average indexed earnings, with marginal replacement rates 0.90, 0.32 and 0.15 on the three segments.

The **actuarial factor** $\mathrm{AF}(\chi)$ multiplies it, and depends on the age χ at which the worker files: the statutory rule reduces benefits by $5/9$ of one percent per month for the first 36 months of early claiming and $5/12$ of one percent per month beyond that, and adds a delayed retirement credit of 8 percent a year after the full retirement age.

```
def claim_factors(fra=67, lo=62, hi=70):
    "Statutory actuarial factors AF(χ) for claim ages lo ... hi."
    out = []
    for a in range(lo, hi+1):
        if a <= fra:
            m = (fra - a)*12
            out.append(round(1 - (min(m, 36)*(5/9) + max(m-36, 0)*(5/12))/100, 4))
        else:
            out.append(round(1 + 0.08*(a - fra), 4))
    return np.array(out)

def pia(aime, p):
    "The primary insurance amount: a concave piecewise-linear function of AIME."
    s0 = np.minimum(aime, p.bend[0])
    s1 = np.clip(aime - p.bend[0], 0.0, p.bend[1] - p.bend[0])
    s2 = np.maximum(aime - p.bend[1], 0.0)
    return p.prate[0]*s0 + p.prate[1]*s1 + p.prate[2]*s2

X_GRID = np.arange(62, 71)
print("claim age     ", X_GRID)
print("AF(χ) at FRA 67", claim_factors(67))
print("AF(χ) at FRA 69", claim_factors(69))
```

```
claim age      [62 63 64 65 66 67 68 69 70]
AF(χ) at FRA 67 [0.7    0.75   0.8    0.8667 0.9333 1.     1.08   1.16   1.24  ]
AF(χ) at FRA 69 [0.6    0.65   0.7    0.75   0.8    0.8667 0.9333 1.     1.08  ]
```

Fig. 129.1 shows the progressivity of the program on the left and its price of waiting on the right.

```
fig, axes = plt.subplots(1, 2, figsize=(11, 4))

grid = np.linspace(0, 3, 400)
axes[0].plot(grid, pia(grid, par), lw=2)
for b in par.bend:
    axes[0].axvline(b, color='k', ls=':', lw=1)
axes[0].set_xlabel('AIME, multiples of the average wage')
axes[0].set_ylabel('primary insurance amount')
axes[0].set_title('the benefit formula, with its bend points')

axes[1].plot(X_GRID, claim_factors(67), 'o-', lw=2, label='full retirement age 67')
axes[1].plot(X_GRID, claim_factors(69), 's-', lw=2, label='full retirement age 69')
axes[1].axhline(1.0, color='k', lw=0.8)
axes[1].set_xlabel('claim age $\\chi$')
axes[1].set_ylabel('actuarial factor $\\mathrm{AF}(\\chi)$')
axes[1].set_title('the reward for waiting')
axes[1].legend()
plt.tight_layout()
plt.show()
```

A worker whose earnings record is below the first bend point replaces 90 cents of every dollar; one above the second replaces 15.

Waiting from 62 to 70 raises the benefit by 77 percent, and the schedule is statutory: it does not move when mortality improves, and it does not move when the payable factor falls.

Exercise 129.9.2 raises the full retirement age, which is the orange line.

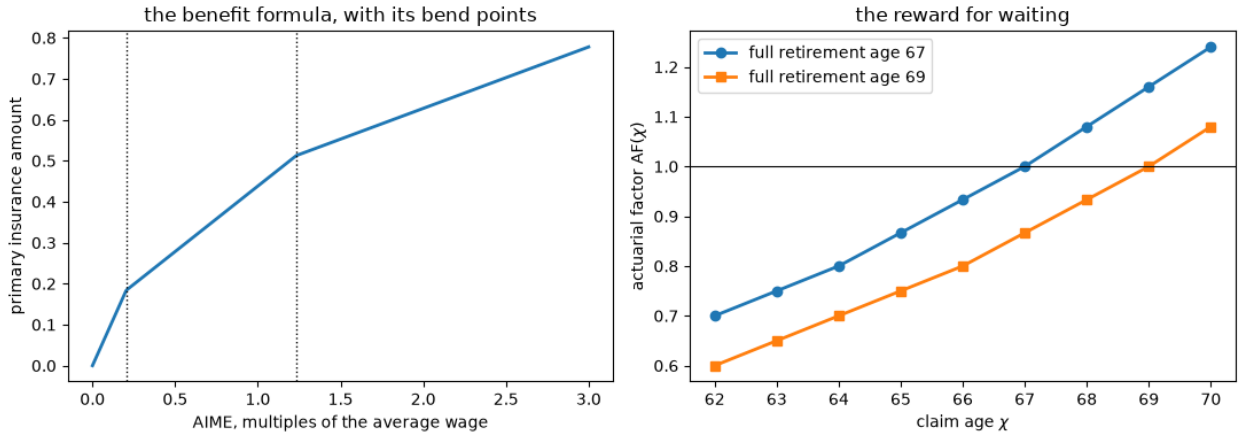

Fig. 129.1: The benefit formula is progressive and the reward for waiting is statutory

129.3.2 Demography

Mortality follows a Gompertz–Makeham force of mortality that improves at 0.7 percent a year until 2085 and is frozen afterwards, so that the economy settles into a stationary equilibrium inside the horizon.

Cohort sizes grow at one rate before 1990 and another after, and we pick the two rates so that the model reproduces the trustees' aged dependency ratio in 2025 and in 2085: the population aged 65 and over per person aged 20 to 64 rises from 0.32 to 0.50.

```
def mortality(age, year, p):
    "Force of mortality by age and calendar year; improvement stops in 2085."
    yr = np.minimum(year, 2085)
    return (5e-4 + 2.5e-5*np.exp(0.095*age))*np.exp(-p.g_m*(yr - 2025))

def cohort_survival(entry_years, p):
    "ℓ[c, j]: probability of reaching age 20+j, cohort by cohort."
    ent = np.asarray(entry_years, float).reshape(-1, 1)
    j = np.arange(J).reshape(1, -1)
    s = np.exp(-mortality(AGE0 + j, ent + j, p))
    s[:, -1] = 0.0
    return np.concatenate([np.ones((len(ent), 1)),
                           np.cumprod(s[:, :-1], axis=1)], axis=1)

YS = 1990           # the year the growth rate of entering cohorts changes

def entry_sizes(g, years):
    "Size of the cohort that turns 20 in each year."
    y = np.asarray(years, float)
    return np.where(y <= YS, np.exp(g[0]*(y - YS)), np.exp(g[1]*(y - YS)))

def population(g, years, p):
    "N[j, t]: people of age 20+j in each calendar year."
    years = np.atleast_1d(years)
    out = np.zeros((J, len(years)))
    for j in range(J):
        ent = years - j
        out[j] = entry_sizes(g, ent)*cohort_survival(ent, p)[:, j]
    return out
```

(continues on next page)

(continued from previous page)

```
def dependency(g, t, p):
    "People aged 65 and over per person aged 20 to 64."
    n = population(g, [t], p)[:, 0]
    return n[45:].sum()/n[:45].sum()

g_pop = fsolve(lambda g: [dependency(g, 2025, par) - 0.32,
                          dependency(g, 2085, par) - 0.50], [0.02, 0.0])

print(f"entry cohorts grow at {g_pop[0]:.4f} before {YS} and {g_pop[1]:.4f} after")
for t in (2025, 2035, 2055, 2085):
    print(f"   dependency ratio in {t}: {dependency(g_pop, t, par):.3f}")
print(f"   life expectancy at 20 of the cohort of 2026: "
      f"{20 + cohort_survival([2026], par)[0].sum():.1f}")
```

```
entry cohorts grow at 0.0103 before 1990 and -0.0020 after
   dependency ratio in 2025: 0.320
   dependency ratio in 2035: 0.370
   dependency ratio in 2055: 0.449
   dependency ratio in 2085: 0.500
   life expectancy at 20 of the cohort of 2026: 84.3
```

Fig. 129.2 is the engine of everything that follows, so it is worth looking at.

```
span = np.arange(2000, 2121)
fig, axes = plt.subplots(1, 2, figsize=(11, 4))

axes[0].plot(span, [dependency(g_pop, t, par) for t in span], lw=2)
axes[0].plot([2025, 2085], [0.32, 0.50], 'o', ms=7, color='C1',
             label='trustees')
axes[0].set_xlabel('year')
axes[0].set_ylabel('people 65 and over per person 20 to 64')
axes[0].legend()

for t, style in ((2026, '-'), (2085, '--')):
    n_t = population(g_pop, [t], par)[:, 0]
    axes[1].plot(AGE0 + np.arange(J), n_t/n_t.sum(), style, lw=2, label=str(t))
axes[1].set_xlabel('age')
axes[1].set_ylabel('share of the population')
axes[1].legend()
plt.tight_layout()
plt.show()
```

Two forces push the dependency ratio up, and the model carries both.

Cohorts entering the labor force stopped growing, so the base of the pyramid stops widening.

Mortality keeps improving, so its top keeps filling in.

Exercise 129.9.4 separates them.

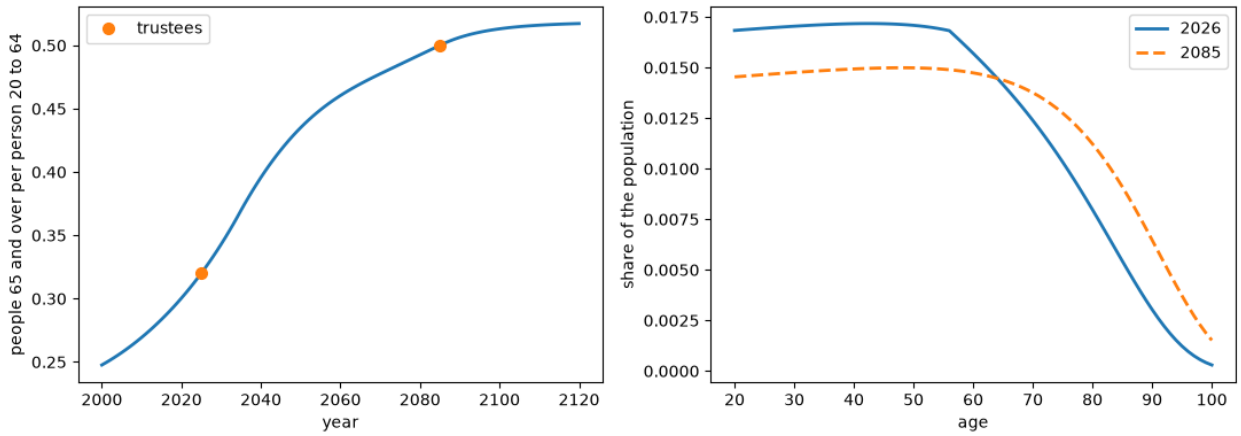

Fig. 129.2: Cohorts stopped growing and lives keep lengthening

129.3.3 Earnings and types

Earnings are the wage times a hump shaped age-efficiency profile that peaks at age 50, times a permanent ability draw.

Workers also differ in their taste for work.

Both are five point discretizations of lognormal distributions, so there are 25 types.

```
def efficiency():
    "Age-efficiency profile, normalized to mean one over ages 20 to 64."
    j = np.arange(J)
    e = np.exp(0.0583*j - 0.000972*j**2)
    return e/e[:45].mean()

ε = efficiency()

def types(p, n=5):
    "Permanent earnings ability and taste for work, on a tensor grid."
    x, w = np.polynomial.hermite_e.hermegauss(n)
    w = w/w.sum()
    e = np.exp(p.σ_a*x); e = e/(w*e).sum()
    h = np.exp(p.σ_η*x)
    E, H = np.meshgrid(e, h, indexing='ij')
    return E.ravel(), H.ravel(), np.outer(w, w).ravel()
```

Earnings rise with experience, peak at age 50, and decline thereafter.

```
fig, ax = plt.subplots(figsize=(7, 3.6))
ax.plot(AGE0 + np.arange(J), ε, lw=2)
ax.set_xlabel('age')
ax.set_ylabel('efficiency units of labor')
ax.set_xlim(20, 80)
plt.tight_layout()
plt.show()
```

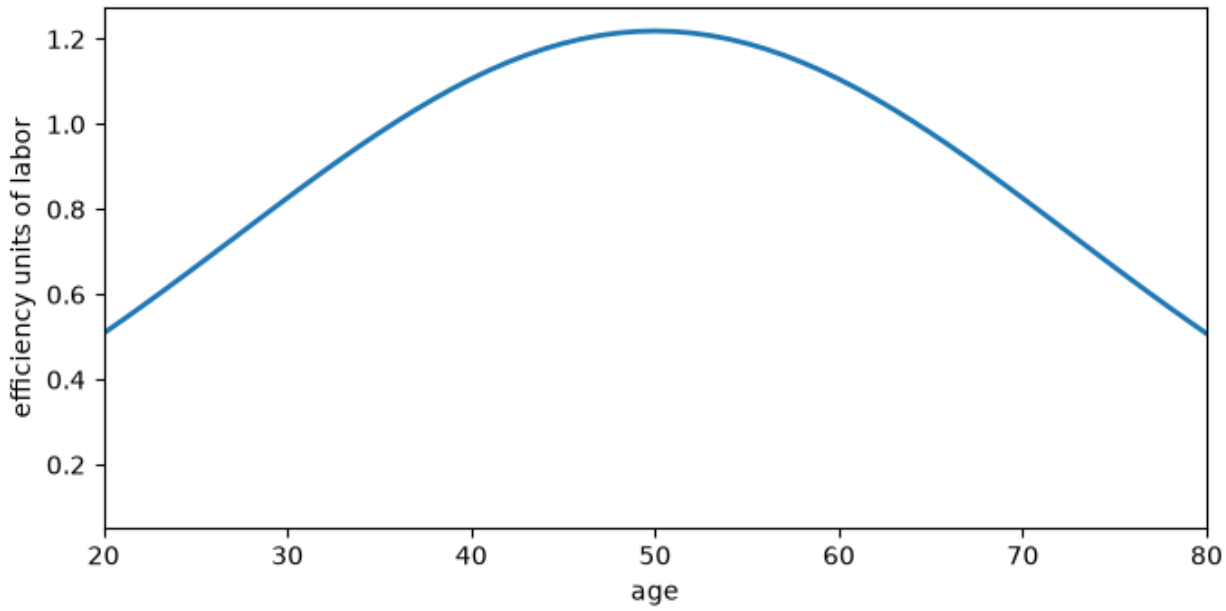

Fig. 129.3: Earnings peak at age 50 and decline thereafter

129.3.4 The worker's problem

A worker chooses when to stop working and when to file for benefits.

Both decisions are irreversible, and they are separate: Coile *et al.* [2002] and the literature that follows them establish that leaving the labor force and claiming a benefit are distinct events.

Write R for the retirement age, χ for the claim age, and ℓ_j for the probability of surviving from age 20 to age $20 + j$.

A worker of type (e, h) ranks plans by

$$\sum_j \beta^j \ell_j [\log c_j - \eta\, h\, n_j], \qquad n_j = \mathbf{1}\{j < R - 20\}, \tag{129.7}$$

where e is permanent earnings ability, h is the taste for work, and ηh is therefore the worker's own disutility of a year of work.

We normalize the wage to one.

While working, a worker earns $y_j = \varepsilon_j e$, pays the labor tax and the payroll tax on earnings up to the taxable maximum $\bar{y}$, and accumulates the earnings record

$$\text{AIME}_{j+1} = \text{AIME}_j + \psi\, \mathbf{1}\{j < R - 20\}\big(\min(y_j, \bar{y}) - \text{AIME}_j\big),$$

an exponentially weighted moving average whose effective window of $2/\psi - 1 \approx 35$ years approximates the statutory highest-35-years rule.

Once filed, the worker collects

$$b_j = \varsigma\, \phi_t\, \text{AF}(\chi)\, \text{PIA}(\text{AIME}_j),$$

taxed at κ_b, where ς is a benefit scale that the calibration below sets.

It stands in for the spousal and survivor benefits that a model of single workers leaves out.

With complete annuity markets and log utility the consumption problem has a closed form.

Annuities pay the gross return $\tilde{R}/s_j$ to a survivor, where $\tilde{R} = 1 + r(1-\tau_k)$ and s_j is the one-period survival probability, because the balances of those who die are shared among those who live.

Compounding those returns turns survival into a discount factor: a unit of income received at age $20+j$ is worth $\ell_j \tilde{R}^{-j}$ at age 20, and the lifetime budget constraint is

$$(1+\tau_c)\sum_j \ell_j \tilde{R}^{-j} c_j = a_0 + \sum_j \ell_j \tilde{R}^{-j} m_j(R,\chi) \equiv \mathcal{W}(R,\chi), \tag{129.8}$$

where m_j is net income at age j: earnings net of the two taxes while working, and the payable benefit net of its own tax once filed.

Because the annuity return and the survival probability cancel, the Euler equation is the one from a model without mortality,

$$c_j = c_0(\beta\tilde{R})^j.$$

Substituting it into (129.8) gives $(1+\tau_c)c_0\Omega = \mathcal{W}$ with $\Omega = \sum_j \beta^j \ell_j$, and substituting it into (129.7) gives

$$\sum_j \beta^j \ell_j \log c_j = \Omega \log c_0 + \log(\beta\tilde{R}) \sum_j j\,\beta^j \ell_j.$$

The second term does not depend on the plan, and neither does the $\log[(1+\tau_c)\Omega]$ that comes out of $c_0 = \mathcal{W}/[(1+\tau_c)\Omega]$.

Dropping both leaves a two-dimensional discrete choice:

$$\max_{R,\,\chi} \;\; \Omega \log \mathcal{W}(R,\chi) \;-\; \eta\, h \sum_{j<R-20} \beta^j \ell_j. \tag{129.9}$$

The first term is the present value of everything the plan delivers, including the whole future path of the payable factor.

The second is the cost of the extra years of work.

A worker who is already alive when the news arrives solves the same problem from where it stands.

Write j_0 for its age index in 2026.

Then both sums in (129.9) run from j_0 rather than from 0, with ℓ_j and β^j measured from j_0; a_0 in (129.8) is the wealth it has accumulated by then; and the decisions it has already taken are not up for reconsideration.

That is what the arguments `j0`, `a0` and `plan0` carry in the code below.

Nothing there is special to 2026: Exercise 129.9.5 uses the same code to let workers re-plan in the year a surprise arrives.

Note

The paper also models the **retirement earnings test**, which withholds the benefits of a claimant who keeps working before the full retirement age and then credits them back by advancing the effective claim age.

For a worker who leaves work at or before the full retirement age the credit matches the withholding one for one, so filing earlier than retirement is payoff neutral in this deterministic model.

We therefore impose $\chi \geq \min(R, 70)$ and drop the test.

Claiming remains a separate decision: a worker may file at retirement or wait, up to age 70.

The restriction does bind on one margin.

A worker who means to work past the full retirement age could file at 62, have the benefits withheld until the test stops applying, and then collect at the credited factor while still working.

That option is not quite equivalent to filing later, and this model rules it out.

We enumerate the admissible plans and index every cohort alive along the transition.

```
R_GRID = np.arange(58, 73)
# a worker files no earlier than it stops working, and no later than 70
PLANS = np.array([(R, X) for R in R_GRID for X in X_GRID if X >= min(R, 70)])
R_P, X_P = PLANS[:, 0], PLANS[:, 1]
NP = len(PLANS)

ENTRY = np.arange(Y0-J+1, Y0+T+1)       # entry year of every cohort ever alive
NC = len(ENTRY)
ENT_IX = {y: i for i, y in enumerate(ENTRY)}
IDX = np.array([[ENT_IX[t-j] for t in YEARS] for j in range(J)])

print(f"{NP} admissible plans, {NC} cohorts")
```

```
83 admissible plans, 201 cohorts
```

The retirement grid runs from 58 to 72, and it binds for the two most extreme tastes for work, which carry 1.1 percent of the population each.

Widening it to 50 to 80 moves those two types to 56 and 73 and moves nothing else: the depletion year, both mean ages, and the payable factor to four decimals are the same.

We keep the narrow grid, which is about twice as fast.

Everything that does not depend on the payable path is built once.

```

    return F, ψ
```

129.5 The economy before the news

Workers alive in 2026 made their plans expecting benefits to be paid in full forever.

We solve that economy first.

It supplies two things that the transition needs: the retirement and claim decisions that cohorts have **already executed** by 2026, and the assets they carry into 2026.

It also supplies the scale for the third, the opening trust fund balance, which we set below to the recorded end-of-2025 reserves of 1.63 times annual benefit payments.

```
def income_path(W, ψ, R, X, rows=slice(None)):
    "Net income at every age at the chosen plans, for all rows or a subset."
    p = W.p
    e, entry, R, X = W.e[rows], W.entry[rows], R[rows], X[rows]
```

(continues on next page)

(continued from previous page)

```
    aime = np.zeros(len(e))

wts = W.w[mask]/W.w[mask].sum()
print(f"cohort entering in 2026:  mean retirement age {(R_pre[mask]*wts).sum():.2f}, "
      f"mean claim age {(X_pre[mask]*wts).sum():.2f}")
print(f"cost rate in 2026: {Ben_pre[0]/Pay_pre[0]:.4f}"
      f"   (trustees for 2025: 0.1362)")
```

```
cohort entering in 2026:  mean retirement age 64.76, mean claim age 66.49
cost rate in 2026: 0.1350   (trustees for 2025: 0.1362)
```

Two parameters were chosen to make those two numbers come out.

The disutility of work η sets the retirement age: the cohort entering in 2026 retires at 64.8 on average, against the median retirement age of 64.5 that Sargent and Shi [2026] target.

The benefit scale ς sets the cost rate, and brings it within about a tenth of a percentage point of the trustees' 2025 figure.

The claim age is not targeted, and the model misses it by more: this cohort files at 66.5 on average, a year and a half later than the 65.0 the paper matches.

Claiming later than the data is a bias to keep in mind when reading the transition below, where the claim age is one of the two margins doing the work.

Two more statistics that nothing was fitted to are worth printing, because both bear on how hard the model pushes the two margins.

```
def replacement_rate(W, R, X):
    "The first benefit received, relative to earnings in the last year of work."
    p = W.p
    aime, last, first = (np.zeros(W.C) for _ in range(3))
    AFx = np.interp(X, X_GRID, W.AF)
    for j in range(J):
        work = (j < R - AGE0).astype(float)
        y = ε[j]*W.e*work
        capped = np.minimum(y, p.ycap)*work
        last = np.where(R - AGE0 - 1 == j, y, last)
        first = np.where(X - AGE0 == j, p.bscale*AFx*pia(aime, p), first)
        aime = aime + p.ψ*work*(capped - aime)
    return first/np.maximum(last, 1e-12)

print(f"replacement rate, cohort entering in 2026:      {rr:.3f}")
print(f"   at the statutory formula, without ς:         {rr/par.bscale:.3f}")

shares = {int(a): float(W.w[mask][X_pre[mask] == a].sum()/W.w[mask].sum())
          for a in X_GRID}
print("   claim ages chosen:",
      {a: round(v, 3) for a, v in shares.items() if v > 0.005})
```

```
replacement rate, cohort entering in 2026:      0.492
   at the statutory formula, without ς:         0.430
   claim ages chosen: {66: 0.767, 68: 0.222, 70: 0.009}
```

The first number exposes something that the benefit scale ς does quietly.

Spousal and survivor benefits are paid to *additional people*; here the whole 14.5 percent lands on each worker's own benefit.

So a worker in this model collects about a seventh more than the statutory formula would pay it, and the incentives to retire and to file are correspondingly stronger.

Matching the program's aggregate cost with a model of single workers has to distort something, and this is where it goes.

The second number exposes the other limitation.

Claiming piles up on a single age, and nobody files at 62.

In the data, and in the paper, there are large spikes at 62 and at the full retirement age; the forces that produce the spike at 62 – liquidity constraints, health, the bad earnings draw that ends a career – are exactly the ones this version leaves out.

129.6 Solving for the equilibrium payable path

Now give workers the news.

Starting from $\phi_t \equiv 1$, we apply Φ, take a damped step toward the result, and repeat.

The step length starts at one half and anneals toward a floor, as in the solver of Sargent and Shi [2026].

```
def transition(W, F0, plan0, a0, iters=40, tol=1e-4,
               v0=0.5, anneal=0.92, floor=0.08, verbose=True):
    "Damped iteration on the payable path."
```

(continues on next page)

(continued from previous page)

```
    ψ = np.ones(T+1)
    for k in range(iters):
        R, X, _, _, _ = solve_plans(W, ψ, W.j0, plan0=plan0,
                                    a0=a0.reshape(W.C, 1))
        pay, ben = flows(W, ψ, R, X, W.j0)
        Pay, Ben = aggregate(W, pay, ben)
        F, ψ_new = fund_and_phi(W, Pay, Ben, F0)
        gap = np.abs(ψ_new - ψ).max()
        ν = max(ν0*anneal**k, floor)
        ψ = (1-ν)*ψ + ν*ψ_new
        if verbose and k % 5 == 0:
            print(f"   iteration {k:>3}   step {ν:.3f}   gap {gap:.2e}"
                  f"   ψ in 2033 {ψ[2033-Y0]:.4f}")
        if gap < tol:
            break
    return dict(ψ=ψ, F=F, R=R, X=X, Pay=Pay, Ben=Ben)

F0 = par.F_ratio*W.Npop[0]*Ben_pre[0]
base = transition(W, F0, (R_pre, X_pre), a26)
```

```
   iteration   0   step 0.500   gap 5.23e-01   ψ in 2033 0.9725
   iteration   5   step 0.330   gap 4.31e-02   ψ in 2033 0.7717
   iteration  10   step 0.217   gap 1.51e-02   ψ in 2033 0.7578
   iteration  15   step 0.143   gap 1.72e-02   ψ in 2033 0.7560
   iteration  20   step 0.094   gap 1.18e-02   ψ in 2033 0.7555
   iteration  25   step 0.080   gap 1.44e-02   ψ in 2033 0.7553
   iteration  30   step 0.080   gap 1.41e-02   ψ in 2033 0.7551
   iteration  35   step 0.080   gap 1.48e-02   ψ in 2033 0.7550
```

The converged path gives the two dates and the size of the cut.

```
ψ, F = base['ψ'], base['F']
depletion = YEARS[np.argmax(F[:-1] <= 1e-12)]
shortfall = YEARS[np.argmax(ψ < 1)]
print(f"first shortfall year: {shortfall}")
print(f"depletion year:       {depletion}")
print(f"ψ in {shortfall}: {ψ[shortfall-Y0]:.3f},  in {depletion}: {ψ[depletion-Y0]:.
↪3f},"
      f"  in the long run: {ψ[-1]:.3f}")
```

```
first shortfall year: 2032
depletion year:       2033
ψ in 2032: 0.952,  in 2033: 0.755,  in the long run: 0.482
```

The dates are the trustees' dates, and the first full-year cut is close to theirs: they project that continuing income will cover about 78 percent of scheduled benefits in the first year the fund is empty.

Neither date was targeted.

The calibration fixed the cost rate of a single year, 2025, and took the opening balance from the record; the year in which that balance runs out is then whatever the cash flows of the intervening years make it, and those depend on the claiming and retirement decisions that the falling payable factor itself provokes.

```
fig, axes = plt.subplots(1, 2, figsize=(11, 4))
axes[0].plot(YEARS, F[:-1]/(W.Npop*base['Ben']), lw=2)
axes[0].set_title('trust fund reserves / annual scheduled benefits')
```

(continues on next page)

(continued from previous page)

```
axes[1].plot(YEARS, ψ, lw=2)
axes[1].set_title('payable factor $\\phi_t$')
axes[1].set_ylim(0, 1.05)
for ax in axes:
    ax.axvline(depletion, color='k', ls='--', lw=1, alpha=0.7)
    ax.set_xlabel('year')
    ax.set_xlim(Y0, 2120)
plt.tight_layout()
plt.show()
```

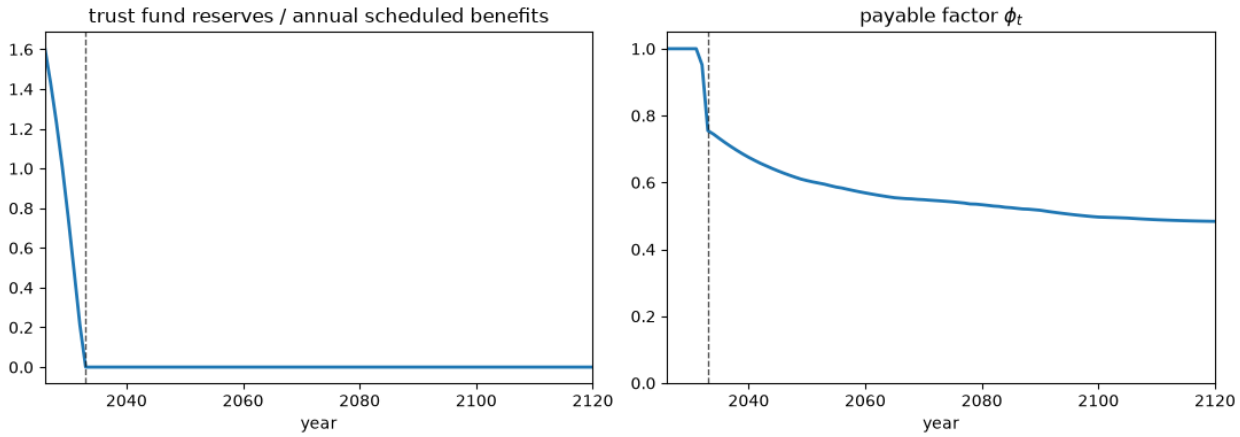

Fig. 129.4: The reserves run out in 2032 and the payable factor keeps falling after the cut

The payable factor does not settle at the level it reaches on the day the fund empties.

It falls further for the rest of the century, because the dependency ratio keeps rising.

By (129.6) the long-run cut is governed entirely by the program's cost rate, and we can check that identity on the computed path.

```
cost = base['Ben']/base['Pay']
print(f"terminal cost rate: {cost[-1]:.4f}")
print(f"τ_ss/[(1-κ_b)·cost rate] = {par.τ_ss/((1-par.κ_b)*cost[-1]):.4f}"
      f"   against ψ_∞ = {ψ[-1]:.4f}")
```

```
terminal cost rate: 0.2291
τ_ss/[(1-κ_b)·cost rate] = 0.4814   against ψ_∞ = 0.4816
```

129.7 Claiming and retirement along the transition

Both decisions respond to the path of ϕ_t, and both reverse direction at the cut.

```
def flow_ages(W, R, X):
    "Population weighted mean age of new retirees and of new claimants."
    wt = W.w.reshape(NC, W.NE)[0]
    age = (AGE0 + np.arange(J)).reshape(J, 1, 1)
```

(continues on next page)

(continued from previous page)

```
    hitR = (R.reshape(1, NC, W.NE) == age)*wt
    hitX = (X.reshape(1, NC, W.NE) == age)*wt
    nR = np.take_along_axis(hitR.sum(axis=2), IDX, axis=1)*W.share
    nX = np.take_along_axis(hitX.sum(axis=2), IDX, axis=1)*W.share
    ages = (AGE0 + np.arange(J)).reshape(J, 1)
    return ((nR*ages).sum(axis=0)/np.maximum(nR.sum(axis=0), 1e-12),
            (nX*ages).sum(axis=0)/np.maximum(nX.sum(axis=0), 1e-12))

mean_R, mean_X = flow_ages(W, base['R'], base['X'])
```

The two ages move together, and both turn at the cut.

```
fig, ax = plt.subplots(figsize=(8, 4))
ax.plot(YEARS, mean_R, lw=2, label='mean age of new retirees')
ax.plot(YEARS, mean_X, lw=2, label='mean age of new claimants')
ax.axvline(depletion, color='k', ls='--', lw=1, alpha=0.7)
ax.set_xlabel('year')
ax.set_ylabel('age')
ax.set_xlim(Y0, 2075)
ax.legend()
plt.tight_layout()
plt.show()
```

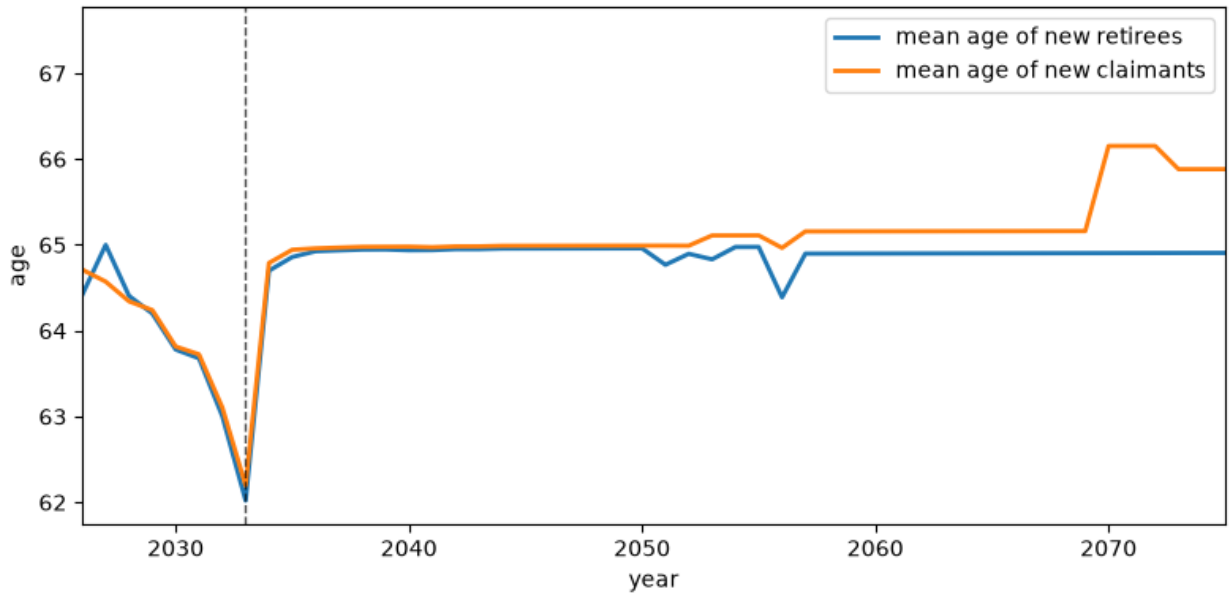

Fig. 129.5: Claiming and retirement rush forward before the cut and reverse after it

As the fund runs down there is a **rush**.

Both ages fall year after year from 2026, and the mean age of new claimants reaches 62.2 in the first year the fund is empty, against 64.7 at the start.

Workers inside the claiming window file as early as they can, because filing fixes the actuarial factor while the payments made in those years are still paid in full or nearly so.

A worker who waits instead collects under the reduced factors of later years.

The year after, the pattern reverses: there is nothing left to rush for, and both ages jump back above 64.5 and then drift up, to 65.3 and 66.6 in the long run.

The pension is smaller, so careers lengthen; and mortality keeps improving while the actuarial schedule stays at its statutory values, so a later claim buys the higher benefit for more years.

Past about 2075 the mean claim age chatters between two adjacent integers, which is why Fig. 129.5 stops there; the note on computation below explains why.

```
fig, axes = plt.subplots(1, 2, figsize=(11, 4))
axes[0].plot(YEARS, base['Pay'], lw=2, label='taxable payroll')
axes[0].plot(YEARS, base['Ben'], lw=2, label='scheduled benefits')
axes[0].legend()
axes[0].set_title('per capita, model units')
axes[1].plot(YEARS, cost, lw=2)
axes[1].set_title('cost rate: scheduled benefits / taxable payroll')
for ax in axes:
    ax.axvline(depletion, color='k', ls='--', lw=1, alpha=0.7)
    ax.set_xlabel('year')
    ax.set_xlim(Y0, 2120)
plt.tight_layout()
plt.show()
```

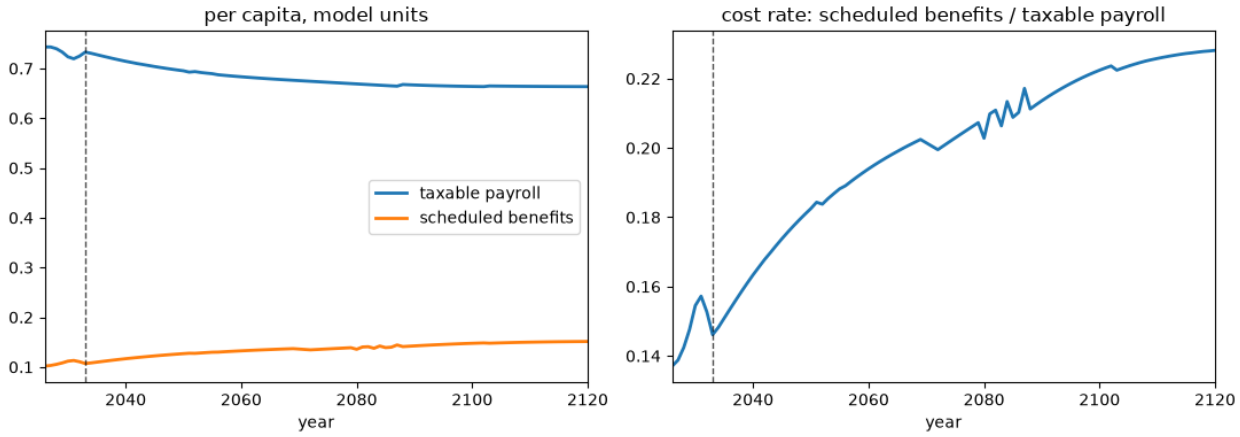

Fig. 129.6: Payroll gains arrive at once, the benefits of later claiming decades later

The benefit formula runs on two clocks, and the right panel of Fig. 129.6 shows both.

Longer careers add contributors to taxable payroll **immediately**.

Later filing lowers the scheduled bill immediately, by reducing the number of claimants, and raises it only **decades later**, when the delayed filers collect benefits carrying higher actuarial factors.

The cost rate therefore bumps up in the years before the cut, as the rush adds claimants, and then falls back for a year or two afterwards, as filing is deferred again, before resuming its climb.

Once the fund is empty, (129.4) makes the payable factor exactly proportional to the inverse of the cost rate, so that dip is a benefit cut that does not happen.

At the cost rate of 2031 the formula would pay $\phi = 0.702$; what workers' own responses deliver in 2033 is 0.755.

Sargent and Shi [2026] find the asymmetry strong enough that the payable factor recovers for a few years after the cut before resuming its decline.

Here the recovery shows up in the cost rate but not in ϕ_t itself: the dip is not large enough to outrun a dependency ratio that is still rising.

129.7.1 Who rushes

The flow means hide who is doing the rushing, so it is worth looking at the decisions one cohort at a time.

Fig. 129.7 plots, against a worker's age in 2026, the plan it had made before the news and the plan it chooses after.

```
ages26 = np.arange(21, 91)

def by_age26(vals):
    "Weighted mean of a decision across the types of each cohort alive in 2026."
    out = np.zeros(len(ages26))
    for i, a in enumerate(ages26):
        m = W.entry == Y0 - (a - AGE0)
        out[i] = (vals[m]*W.w[m]).sum()/W.w[m].sum()
    return out

fig, axes = plt.subplots(1, 2, figsize=(11, 4))
for ax, before, after, title in (
        (axes[0], R_pre, base['R'], 'retirement age'),
        (axes[1], X_pre, base['X'], 'claim age')):
    ax.plot(ages26, by_age26(before), lw=2, label='planned before the news')
    ax.plot(ages26, by_age26(after), lw=2, ls='--', label='chosen after')
    ax.set_xlabel('age in 2026')
    ax.set_ylabel('age')
    ax.set_title(title)
axes[0].legend()
plt.tight_layout()
plt.show()
```

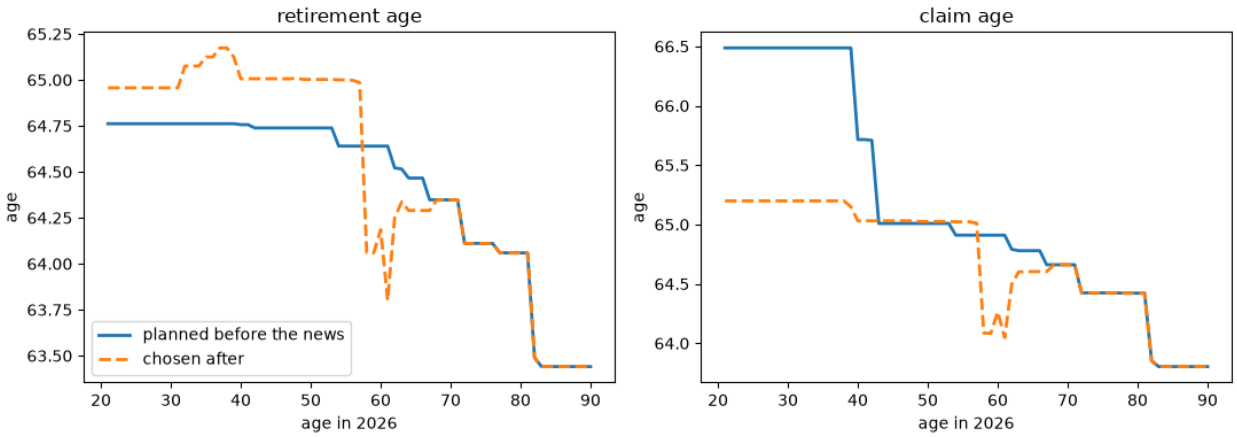

Fig. 129.7: Irreversibility binds the old, while the young work longer but file sooner

Three groups appear in Fig. 129.7.

Workers who have already retired and filed by 2026 sit on top of their old plans, because both decisions are irreversible: the two lines coincide at the right of each panel.

Workers in or near the claiming window move first and move earliest: they file sooner than they had meant to, and some of them leave work sooner too, to collect while benefits are still paid in full.

Workers in their forties and younger go the other way on one margin and with the crowd on the other.

They work longer, because their pension is smaller.

But they file **sooner** than they had planned, by more than a year: with the payable factor falling from one year to the next, a benefit deferred is a benefit collected at a lower factor, and that headwind works against the actuarial reward for waiting.

129.7.2 A worker's life cycle

What the news does to one worker is easier to see than what it does to an aggregate.

Fig. 129.8 follows the median type of the cohort entering in 2026 through its whole life, before and after.

```
R_b, X_b, wealth_b, Om_b, _ = solve_plans(W, ψ, W.j0, plan0=(R_pre, X_pre),
                                          a0=a26.reshape(W.C, 1))

def life_profile(W_, ψ_, R, X, wealth, Om, row):
    "Net income, consumption and assets by age for a single worker."
    p = W_.p
    m = income_path(W_, ψ_, R, X, rows=[row])[:, 0]
    c = wealth[row]/((1+p.τ_c)*Om[row])*(p.β*after_tax_R(p))**np.arange(J)
    a = np.zeros(J)
    for j in range(J-1):
        s = W_.ell[row, j+1]/W_.ell[row, j]
        a[j+1] = (after_tax_R(p)/s)*(a[j] + m[j] - (1+p.τ_c)*c[j])
    return m, c, a

row = np.where(W.entry == 2026)[0][12]          # the median type
before = life_profile(W, np.ones(T+1), R_pre, X_pre, wealth_pre, Om_pre, row)
after = life_profile(W, ψ, R_b, X_b, wealth_b, Om_b, row)
```

Three panels: what the worker receives, what it spends, and what it holds.

```
age = AGE0 + np.arange(J)
fig, axes = plt.subplots(1, 3, figsize=(13, 3.8))
for k, ttl in enumerate(('net income', 'consumption', 'assets')):
    axes[k].plot(age, before[k], lw=2, label='before the news')
    axes[k].plot(age, after[k], lw=2, ls='--', label='after')
    axes[k].set_title(ttl)
    axes[k].set_xlabel('age')
    axes[k].set_xlim(20, 90)
axes[0].legend()
plt.tight_layout()
plt.show()

print(f"retirement age {R_pre[row]} -> {R_b[row]},  claim age {X_pre[row]} -> {X_
 ↪b[row]}")
print(f"peak assets    {before[2].max():.2f} -> {after[2].max():.2f}")
```

```
retirement age 65 -> 65,  claim age 66 -> 65
peak assets    7.53 -> 9.86
```

This worker's retirement age does not move – the choice is an integer, and an aggregate that moves by a year moves because different workers switch at different dates – but it files a year earlier, it consumes less at every age, and it carries about a third more assets into retirement.

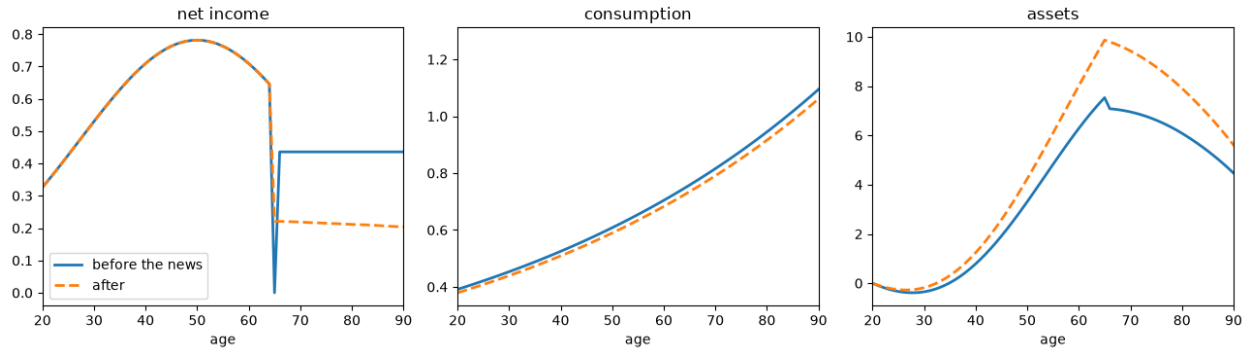

Fig. 129.8: A smaller pension means less consumption, more saving, and no bridge year

The income panel of Fig. 129.8 shows one more thing that the plan before the news was willing to pay for.

Retiring at 65 and filing at 66 leaves a year with no income at all, bridged out of savings, in exchange for a permanently higher actuarial factor.

That bridge is the first thing the news takes away.

The upward tilt of consumption is $\beta\tilde{R} > 1$: this worker is patient enough, at an after-tax return of 4.2 percent, to want a rising profile.

The third panel is the saving response that, in general equilibrium, would deepen the capital stock and raise the wage, and with it taxable payroll: the channel this lecture shuts off and the paper keeps.

129.8 How this compares with the full model

The table collects what the stripped-down model delivers next to the general equilibrium numbers of Sargent and Shi [2026].

```
rows = [("first shortfall year",            f"{shortfall}",            "2032"),
        ("fund empty from",                 f"{depletion}",            "2033"),
        ("ψ in the first full-cut year",    f"{ψ[depletion-Y0]:.3f}",  "0.773"),
        ("ψ in the long run",               f"{ψ[-1]:.3f}",            "0.546"),
        ("mean claim age, 2026",            f"{mean_X[0]:.1f}",        "65.0"),
        ("mean claim age, long run",        f"{mean_X[-1]:.1f}",       "69.2"),
        ("mean retirement age, 2026",       f"{mean_R[0]:.1f}",        "62.7"),
        ("mean retirement age, long run",   f"{mean_R[-1]:.1f}",       "66.2"),
        ("cost rate, 2026",                 f"{cost[0]:.3f}",          "0.136")]

print(f"{'':34}{'this lecture':>14}{'the paper':>12}")
for name, mine, theirs in rows:
    print(f"{name:34}{mine:>14}{theirs:>12}")
```

```
                                  this lecture   the paper
first shortfall year                      2032        2032
fund empty from                           2033        2033
ψ in the first full-cut year             0.755       0.773
ψ in the long run                        0.482       0.546
mean claim age, 2026                      64.7        65.0
mean claim age, long run                  66.6        69.2
mean retirement age, 2026                 64.4        62.7
```

(continues on next page)

(continued from previous page)

```
mean retirement age, long run                65.3        66.2
cost rate, 2026                             0.137       0.136
```

The dates agree and the direction of every response agrees.

Two things do not, and both are worth seeing plainly.

The long-run cut is deeper here, 0.482 against 0.546.

Prices are fixed in this lecture, so the capital deepening that raises the wage, and with it taxable payroll, is missing; and the demography here is a smooth stylization rather than the trustees' projection.

The behavioral responses are also **smaller** here than in the paper, not merely centered differently.

Over the transition the mean retirement age rises by 0.9 years against the paper's 3.5, and the mean claim age by 1.9 against 4.2.

Three features of the stripped-down model mute them: workers face no idiosyncratic earnings risk, so nobody is pushed across a threshold by a bad draw; each worker's choice is an integer, so a type responds only when the gain crosses a whole year; and prices do not move, so the wage never rewards the longer careers.

The retirement *levels* need one more caution: the paper's 62.7 is a mean pulled down by a left tail of early retirements that idiosyncratic shocks produce, and its median, which is what the calibration here was matched to, is 64.5.

What the general equilibrium model adds

A tax cut arrives with the benefit cut. Depletion removes the Social Security deficit from the consolidated federal budget, so the labor tax falls from 0.220 to 0.190 in the long run. Current law cuts retirees' benefits and workers' taxes in the same year.

Capital deepens. Every working cohort saves against a smaller pension, the capital–output ratio rises from 3.00 to 3.19, the interest rate falls from 6.0 to 5.3 percent, and the wage rises.

Financing a bailout is expensive, and the ranking is not the ranking of capital. Paying every scheduled benefit in full costs a newborn in the terminal steady state 4.8 percent of lifetime consumption under consumption taxation, 8.7 percent under capital taxation and 11.6 percent under wage taxation. The capital tax contracts capital the most and is still cheaper than the wage tax, which distorts the retirement margin through which the economy had relieved the pressure on the program, and shrinks its own base.

One program reform changes the arithmetic. Raising the full retirement age from 67 to 69 delays depletion by ten years and raises the long-run payable factor from 0.546 to 0.621. Raising the taxable maximum and cutting the top replacement rate move the incidence and leave the depletion year where it is.

The announcement date redistributes among the living. A bailout is worth about $+4.5$ percent of remaining lifetime consumption to a worker aged 60 in 2026 and about -2 percent to a worker aged 25.

Computing the full model

The paper's solver has the same shape as the one above and differs in scale.

The worker's problem is a dynamic program with assets, an idiosyncratic productivity shock, permanent ability, the earnings record and the claim status as states, solved by backward induction over 81 ages and 150 calendar years; the cross-section is a panel of $80{,}000$ workers per age cell, simulated forward with common random numbers so that every scenario faces the same workers and the same shocks.

Stationary equilibria are found with Anderson acceleration, and the transition is a damped iteration on prices, the bequest transfer, the payable path and a transitory tax rate, as here.

The code is written in JAX and runs on an A100 GPU: about 22 hours from a cold start for the full set of experiments, or about an hour to replay the stored converged paths.

The paper also reports a residual that damping does not remove.

Because the period is a year, the iteration can cycle between two adjacent first shortfall years, each implying the other.

Our own iteration stalls in the same way, for a related reason: retirement and claim ages are integers, so a mass of workers switches discontinuously, and Φ is not continuous.

In the output above, the gap stops falling at about 10^{-2} while the payable factor printed beside it settles to the fourth decimal.

129.9 Exercises

Exercise 129.9.1

The box above claims that Φ is a decreasing map, and that is the reason every iteration here is damped.

Check it, in two steps.

1. Take the converged path, raise it by five percentage points in every year from 2033 on, and apply Φ once. Does the image rise or fall?
2. Run the iteration **undamped**, that is, with $\phi_{k+1} = \Phi(\phi_k)$, for twenty steps starting from $\phi \equiv 1$, and plot the payable factor in 2040 and in 2080 against the iteration count. Compare both with a damped iteration. Does the undamped iteration converge?

Solution

For part 1, one application of the operator is one call each to `solve_plans`, `flows`, `aggregate` and `fund_and_phi`.

```
def Phi(W, ψ, F0, plan0, a0):
    "One application of the operator Φ."
    R, X, _, _, _ = solve_plans(W, ψ, W.j0, plan0=plan0, a0=a0.reshape(W.C, 1))
    pay, ben = flows(W, ψ, R, X, W.j0)
    Pay, Ben = aggregate(W, pay, ben)
    return fund_and_phi(W, Pay, Ben, F0)[1]

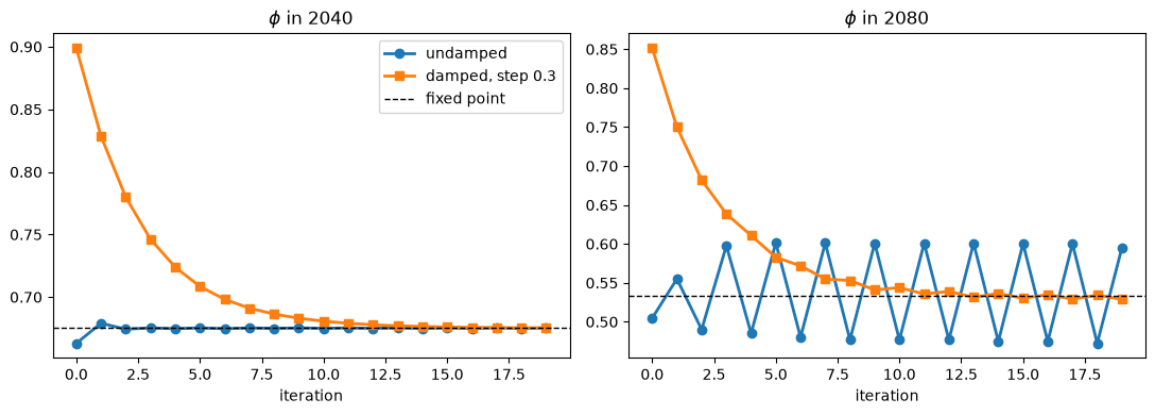
ψ_up = ψ.copy()
ψ_up[depletion-Y0:] += 0.05

im_0 = Phi(W, ψ, F0, (R_pre, X_pre), a26)
im_up = Phi(W, ψ_up, F0, (R_pre, X_pre), a26)

k = 2050 - Y0
print(f"ψ in 2050:            {ψ[k]:.4f}  ->  raised to {ψ_up[k]:.4f}")
print(f"Φ(ψ) in 2050:         {im_0[k]:.4f}  ->  {im_up[k]:.4f}")
print(f"mean change in Φ(ψ) over 2033-2100: "
      f"{(im_up - im_0)[depletion-Y0:2100-Y0].mean():+.4f}")
```

```
ψ in 2050:            0.6056  ->  raised to 0.6556
Φ(ψ) in 2050:         0.6044  ->  0.6004
mean change in Φ(ψ) over 2033-2100: -0.0027
```

The image moves the other way: a more generous promise brings earlier claiming and earlier retirement, which lowers taxable payroll and raises the scheduled bill, so the program can pay a smaller fraction.



For part 2, an iteration on a decreasing map alternates around its fixed point, and whether the alternation dies out depends on how strong the response is.

```
def trace(ν, years=(2040, 2080), n=20):
    "Payable factor at selected dates along an iteration with step ν."
    φ_k = np.ones(T+1)
    out, gaps = [], []
    for _ in range(n):
        φ_new = Phi(W, φ_k, F0, (R_pre, X_pre), a26)
        gaps.append(np.abs(φ_new - φ_k).max())
        φ_k = (1-ν)*φ_k + ν*φ_new
        out.append([φ_k[y-Y0] for y in years])
    return np.array(out), np.array(gaps)

un, gap_un = trace(1.0)
dp, gap_dp = trace(0.3)

fig, axes = plt.subplots(1, 2, figsize=(11, 4))
for k, y in enumerate((2040, 2080)):
    axes[k].plot(un[:, k], 'o-', lw=2, label='undamped')
    axes[k].plot(dp[:, k], 's-', lw=2, label='damped, step 0.3')
    axes[k].axhline(φ[y-Y0], color='k', ls='--', lw=1, label='fixed point')
    axes[k].set_title(f'$\\phi$ in {y}')
    axes[k].set_xlabel('iteration')
axes[0].legend()
plt.tight_layout()
plt.show()

print(f"undamped, largest residual after 20 steps: {gap_un[-1]:.3f}")
print(f"damped,   largest residual after 20 steps: {gap_dp[-1]:.3f}")
```

```
undamped, largest residual after 20 steps: 0.168
damped,   largest residual after 20 steps: 0.025
```

In 2040 the undamped iteration alternates and settles: the response of claiming and retirement to the payable factor is weak enough at that date that Φ is a contraction there.

In 2080 it is not.

The undamped sequence locks into a two-cycle between about 0.48 and 0.60 and stays there: each payable factor calls forth decisions that justify the other one, and the iteration never stops swinging between them.

The damped sequence settles between the two.

This is why every solver in this lecture takes a fractional step, and why Sargent and Shi [2026] anneal theirs toward a floor.

Exercise 129.9.2

Of the reforms that Sargent and Shi [2026] study, only one moves the depletion date: raising the full retirement age from 67 to 69.

The reform is announced in 2026 and applies to everyone at once, current beneficiaries included.

It works entirely through the actuarial factor: at a full retirement age of 69 the factor is about 13 percent lower at every claim age, which is the gap between the two lines in the right panel of Fig. 129.1, and the claim window still closes at 70, so a worker can recover only part of the cut by filing later.

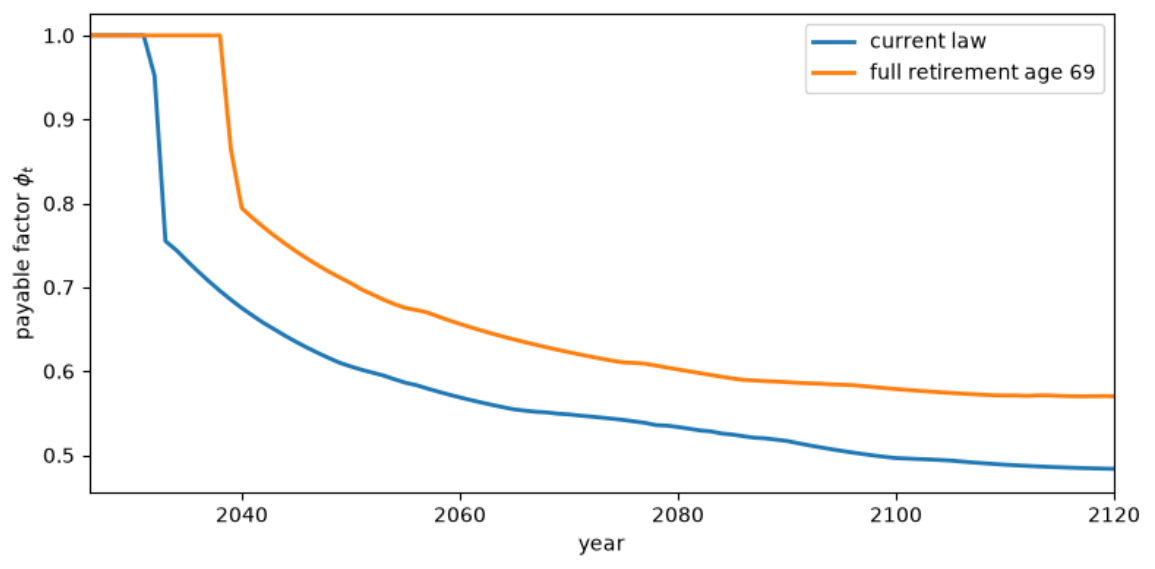
Compute the reformed transition and report the depletion year and the long-run payable factor.

By how many years is depletion delayed, and how much of the long-run benefit cut does the reform undo?

Solution

Only the actuarial schedule changes, so we build a new `World` with `FRA=69` and run the same transition from the same initial conditions.

```
W69 = World(par._replace(FRA=69), g_pop)
base69 = transition(W69, F0, (R_pre, X_pre), a26, verbose=False)



ψ69, F69 = base69['ψ'], base69['F']
dep69 = YEARS[np.argmax(F69[:-1] <= 1e-12)]

print(f"{'':28}{'FRA 67':>10}{'FRA 69':>10}")
print(f"{'depletion year':28}{depletion:>10}{dep69:>10}")
print(f"{'ψ in the long run':28}{ψ[-1]:>10.3f}{ψ69[-1]:>10.3f}")
print(f"{'cost rate in the long run':28}"
      f"{cost[-1]:>10.3f}{(base69['Ben']/base69['Pay'])[-1]:>10.3f}")
```

```
                            FRA 67    FRA 69
depletion year                2033      2040
ψ in the long run            0.482     0.568
cost rate in the long run    0.229     0.195
```

The reform lifts the whole payable path, and the gap between the two never closes.

```
fig, ax = plt.subplots(figsize=(8, 4))
ax.plot(YEARS, ψ, lw=2, label='current law')
ax.plot(YEARS, ψ69, lw=2, label='full retirement age 69')
ax.set_xlabel('year')
ax.set_ylabel('payable factor $\\phi_t$')
ax.set_xlim(Y0, 2120)
ax.legend()
plt.tight_layout()
plt.show()
```

Depletion is delayed by seven years, from 2033 to 2040, against the ten years the paper reports.

The long-run cut falls from 51.8 to 43.2 percent of scheduled benefits, so the reform undoes about a sixth of it.

It does that work because it cuts the scheduled bill at once, for current beneficiaries as well as future ones, so the fund lasts longer and the cash flow condition (129.4) clears at a higher payable factor forever after.

It does not restore scheduled benefits; it lowers them.

A worker's *paid* benefit is the product of the two factors, and the reform raises one by cutting the other.

Exercise 129.9.3

Suppose that instead of letting the cut happen, Congress guarantees every scheduled benefit, $\phi_t = 1$ forever, and pays for it by raising the payroll tax τ^{ss} to a new constant from 2026 on.

1. Find the rate that balances the program's cash flow in the long run, taking into account that workers respond to it.
2. Compute the consumption equivalent variation of the guarantee for cohorts entering between 2026 and 2096. Under the closed form (129.9), a cohort's lifetime value is $V = \Omega \log \mathcal{W} - \eta h D$, so the compensation that equates the two economies is $\lambda = \exp\left(\sum_i w_i \Delta V_i / \Omega\right) - 1$.
3. Do the same for the workers who are **already alive** in 2026, as a function of their age. Who gains from the guarantee and who pays for it?

Solution

For part 1, with $\phi_t \equiv 1$ there is no fixed point in ϕ left to solve: we need only the payroll tax at which the program's long-run cash flow balances, and workers' responses to that tax are inside *Pay* and B^{sch}.

```
def program_gap(τ, plan0, a0):
    "Long-run cash flow of the program when every benefit is paid in full."
    W_τ = World(par._replace(τ_ss=τ), g_pop)
    R, X, _, _, _ = solve_plans(W_τ, np.ones(T+1), W_τ.j0,
                                plan0=plan0, a0=a0.reshape(W_τ.C, 1))
```

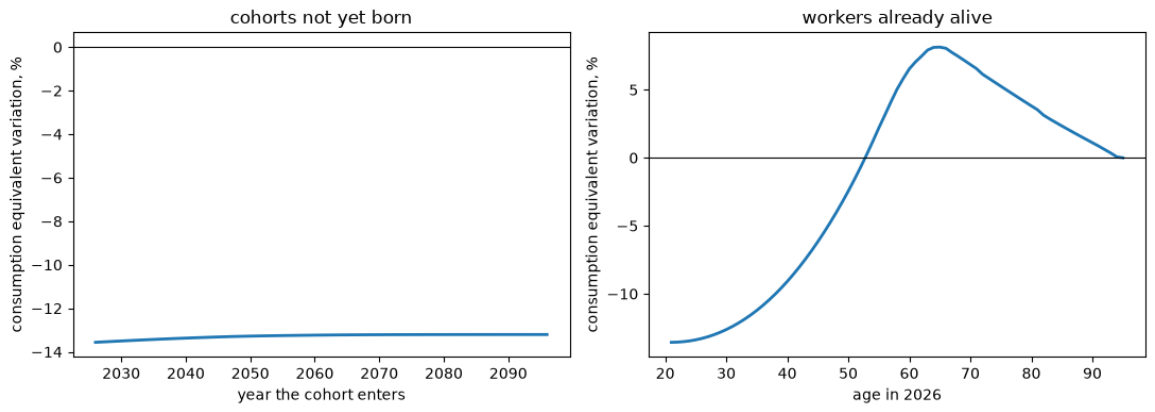
```
    pay, ben = flows(W_τ, np.ones(T+1), R, X, W_τ.j0)
    Pay, Ben = aggregate(W_τ, pay, ben)
    return τ*Pay[-1] - (1-par.κ_b)*Ben[-1]

τ_star = brentq(lambda τ: program_gap(τ, (R_pre, X_pre), a26), 0.10, 0.40, xtol=1e-
↪4)
print(f"payroll tax that funds the guarantee: {τ_star:.4f}"
      f"   (current law: {par.τ_ss})")
```

```
payroll tax that funds the guarantee: 0.2229   (current law: 0.106)
```

For part 2, we read the lifetime values off `solve_plans` in the two economies.

```
def cohort_values(W_, ψ_, plan0, a0):
    "Lifetime value of every row, and the weights and Ω needed to aggregate."
    R, X, wealth, Om, Dw = solve_plans(W_, ψ_, W_.j0, plan0=plan0,
                                       a0=a0.reshape(W_.C, 1))
    V = Om*np.log(wealth) - (W_.p.η*W_.η)*Dw
    return V, Om



V_dep, Om_dep = cohort_values(W, ψ, (R_pre, X_pre), a26)
W_bail = World(par._replace(τ_ss=τ_star), g_pop)
V_bail, _ = cohort_values(W_bail, np.ones(T+1), (R_pre, X_pre), a26)

def cev(entry_year):
    "Consumption equivalent variation of the guarantee, cohort by cohort."
    m = W.entry == entry_year
    wts = W.w[m]/W.w[m].sum()
    return np.exp(((V_bail[m] - V_dep[m])*wts).sum()/Om_dep[m][0]) - 1

entries = np.arange(2026, 2097)
λ_new = np.array([cev(y) for y in entries])
ages = np.arange(21, 96)
λ_old = np.array([cev(Y0 - (a - AGE0)) for a in ages])

fig, axes = plt.subplots(1, 2, figsize=(11, 4))
axes[0].plot(entries, 100*λ_new, lw=2)
axes[0].set_xlabel('year the cohort enters')
axes[0].set_title('cohorts not yet born')
axes[1].plot(ages, 100*λ_old, lw=2)
axes[1].set_xlabel('age in 2026')
axes[1].set_title('workers already alive')
for ax in axes:
    ax.axhline(0, color='k', lw=0.8)
    ax.set_ylabel('consumption equivalent variation, %')
plt.tight_layout()
plt.show()

print(f"entering in 2026: {100*λ_new[0]:+.2f} percent")
print(f"entering in 2096: {100*λ_new[-1]:+.2f} percent")
for a in (25, 45, 60, 65, 80):
    print(f"   aged {a} in 2026: {100*λ_old[a-21]:+.2f} percent")
```

```
entering in 2026: −13.56 percent
entering in 2096: −13.20 percent
   aged 25 in 2026: −13.39 percent
   aged 45 in 2026: −6.18 percent
   aged 60 in 2026: +6.54 percent
   aged 65 in 2026: +8.14 percent
   aged 80 in 2026: +3.82 percent
```

Every entering cohort is worse off, by about thirteen percent of lifetime consumption, and the cost barely depends on the entry date.

An entering cohort pays the higher payroll tax across its whole working life, to restore the benefits of the retirees of those years, and collects its own restored benefit only decades later, by which time the number of retirees per worker is higher still.

In Sargent and Shi [2026] the losses grow with the entry date, because their financing tax steps up from a transitory to a higher terminal rate partway through the transition, so later cohorts spend more of their lives under the higher rate.

Here the financing rate is one constant from 2026 on, so every entering cohort faces the same schedule and the profile is nearly flat.

That is the finding of Sargent and Shi [2026] for all three of their financing instruments, and the mechanism here is the same one.

The right panel is the other half of the story, and it is the paper's result on timing and incidence.

The cohorts already alive in 2026 divide sharply.

A worker aged 25 loses about as much as a cohort that has yet to enter.

A worker in the late fifties or sixties **gains**: the restored benefit arrives within a few years, and the higher payroll tax falls on the few working years that remain.

Retirees gain without paying at all, except through the general equilibrium channels this model suppresses.

The crossover is a little above age 50.

Sargent and Shi [2026] find the same pattern with a smaller spread, because their wage tax is a broader instrument than a doubled payroll tax, and because their general equilibrium prices move.

What the lecture model cannot say is which instrument is cheapest, because that comparison runs through those prices and through the taxes the guarantee displaces.

Exercise 129.9.4

Two forces raise the dependency ratio in this model: cohorts entering the labor force stopped growing, and mortality keeps improving.

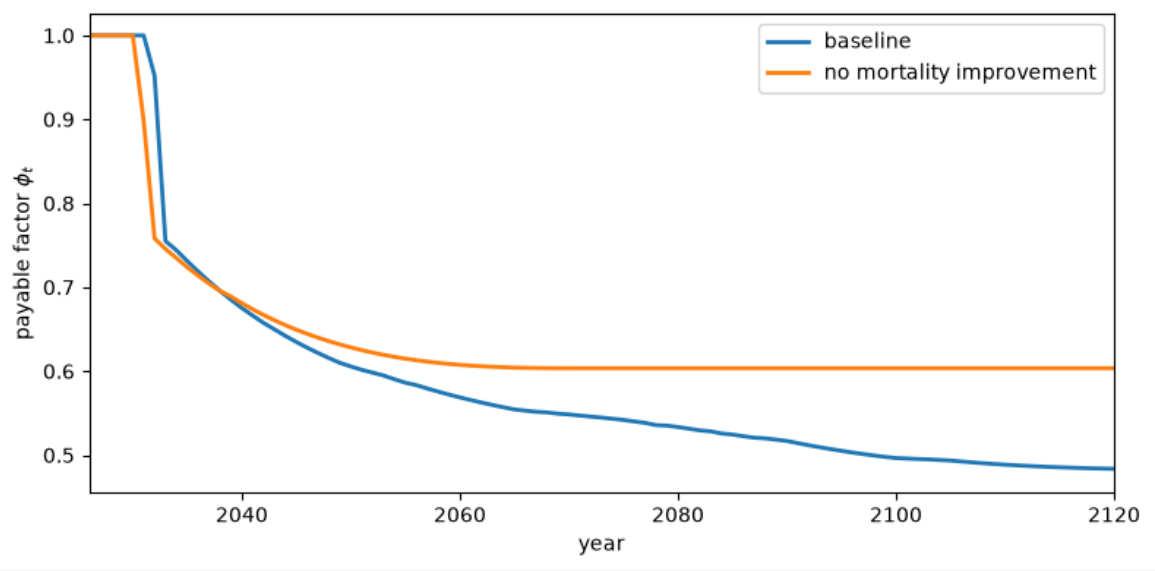
Separate them.

Hold the birth path fixed and switch the mortality improvement off, `par._replace(g_m=0.0)`, so that the life table of 2025 applies forever.

1. What happens to the dependency ratio in 2085, and to the long-run payable factor?
2. What happens to the depletion year? Explain why it moves so much less than the long-run cut does.
3. What happens to the claim age, and what does that tell you about why claiming drifts later in the baseline?

Solution

We rerun the transition in a `World` that keeps the 2025 life table forever.



```
W0 = World(par._replace(g_m=0.0), g_pop)        # same cohorts, the 2025 life table␣
↪forever
flat = transition(W0, F0, (R_pre, X_pre), a26, verbose=False)
dep0 = YEARS[np.argmax(flat['F'][:-1] <= 1e-12)]
mR0, mX0 = flow_ages(W0, flat['R'], flat['X'])

print(f"{'':28}{'baseline':>11}{'no gains':>11}")
print(f"{'life expectancy at 20, 2086':28}"
      f"{20+cohort_survival([2086], par)[0].sum():>11.1f}"
      f"{20+cohort_survival([2086], par._replace(g_m=0.0))[0].sum():>11.1f}")
print(f"{'dependency ratio, 2085':28}{dependency(g_pop, 2085, par):>11.3f}"
      f"{dependency(g_pop, 2085, par._replace(g_m=0.0)):>11.3f}")
print(f"{'depletion year':28}{depletion:>11}{dep0:>11}")
print(f"{'ψ in the long run':28}{ψ[-1]:>11.3f}{flat['ψ'][-1]:>11.3f}")
print(f"{'cost rate in the long run':28}{cost[-1]:>11.3f}"
      f"{(flat['Ben']/flat['Pay'])[-1]:>11.3f}")
print(f"{'mean claim age, long run':28}{mean_X[-1]:>11.2f}{mX0[-1]:>11.2f}")
```

```
                            baseline   no gains
life expectancy at 20, 2086     85.1       80.8
dependency ratio, 2085         0.500      0.428
depletion year                  2033       2032
ψ in the long run              0.482      0.603
cost rate in the long run      0.229      0.183
mean claim age, long run       66.65      64.98
```

The two paths separate only slowly, which is the point: longevity does its work in the long run.

```
fig, ax = plt.subplots(figsize=(8, 4))
ax.plot(YEARS, ψ, lw=2, label='baseline')
ax.plot(YEARS, flat['ψ'], lw=2, label='no mortality improvement')
ax.set_xlabel('year')
ax.set_ylabel('payable factor $\\phi_t$')
ax.set_xlim(Y0, 2120)
ax.legend()
plt.tight_layout()
plt.show()
```

Longer lives are a large part of the long-run problem.

Holding the birth path fixed, they account for about a quarter of the long-run benefit cut: the payable factor settles at 0.60 rather than 0.48.

The depletion year hardly moves, and the reason is visible in (129.3).

The date at which the reserves run out is set by the cash flow of the next few years, which the cohorts already alive determine; improvements in mortality accumulate slowly, and most of what they will do to the cost rate still lies decades ahead when the fund empties.

The long run is where they do their work.

The claim age settles at 65.0 rather than 66.6.

That is the mechanism the lecture asserted for later claiming and had not tested.

The actuarial schedule $\mathrm{AF}(\chi)$ is statutory and frozen, so when mortality improves, waiting buys the higher benefit for more years, and workers wait.

Switch the improvement off and the drift disappears.

Exercise 129.9.5

Exercise 129.9.3 guaranteed scheduled benefits from 2026, with workers told in 2026 and taxed from 2026.

Sargent and Shi [2026] also study the opposite timing, which they call the **unanticipated** scenario.

The government says nothing and does nothing.

Workers believe current law, plan against the cut they expect, and save against it.

Then, in the year the reserves are spent, the government announces the guarantee and raises the financing tax at once.

The cut that workers had expected never happens.

Reproduce that experiment here, and compare it with the immediate bailout of Exercise 129.9.3.

1. Roll the baseline economy forward to the first shortfall year and collect the state it carries there: the assets each worker has accumulated and the retirement and claim decisions it has already executed.

2. Let workers re-plan in that year under $\phi_t = 1$ and the payroll tax τ^*, using the `at_year` argument of `solve_plans`.
3. Value the three economies for the workers alive in 2026 and report the consumption equivalent variation of each bailout against the depletion baseline. Who prefers the surprise?

Solution

Consumption is $c_0(\beta\tilde{R})^{j-j_0}$ from whenever a worker last re-planned, so assets follow a one-line recursion along the baseline path.

```
t_star = shortfall                          # the year the reserves are spent
j_star = np.clip(t_star - W.entry, 0, J-1)

c0_b = wealth_b/((1+par.τ_c)*Om_b)          # the baseline plan, re-optimized in 2026
m_b = income_path(W, ψ, R_b, X_b)

a, A = np.zeros(W.C), np.zeros((J, W.C))
for j in range(J-1):
    a = np.where(j == W.j0, a26, a)         # the 2026 cross-section enters here
    A[j] = a
    surv = W.ell[:, j+1]/np.maximum(W.ell[:, j], 1e-12)
    c = c0_b*(par.β*after_tax_R(par))**np.maximum(j - W.j0, 0)
    a = np.where(j >= W.j0,
                 (after_tax_R(par)/np.maximum(surv, 1e-12))
                 * (a + m_b[j] - (1+par.τ_c)*c), 0.0)
A[J-1] = a
a_star = A[j_star, np.arange(W.C)]

old = W.entry == Y0 - 40                    # the cohort aged 60 in 2026
print(f"assets of a worker aged 60 in 2026: {a26[old].mean():.2f} in 2026,"
      f" {a_star[old].mean():.2f} in {t_star}")
```

```
assets of a worker aged 60 in 2026: 8.18 in 2026, 9.25 in 2032
```

Now the surprise.

The same `solve_plans` re-plans at `t_star`, freezing the decisions already executed by then.

```
R_n, X_n, wealth_n, Om_n, _ = solve_plans(
    W_bail, np.ones(T+1), j_star, plan0=(R_b, X_b),
    a0=a_star.reshape(W.C, 1), at_year=t_star)
c0_n = wealth_n/((1+par.τ_c)*Om_n)

R_i, X_i, wealth_i, Om_i, _ = solve_plans(          # the immediate bailout again
    W_bail, np.ones(T+1), W.j0, plan0=(R_pre, X_pre), a0=a26.reshape(W.C, 1))
c0_i = wealth_i/((1+par.τ_c)*Om_i)
```

We value the three economies directly, by summing utility along each worker's actual consumption and work path rather than by the closed form of Exercise 129.9.3.

```
ages_j = np.arange(J)
βR = par.β*after_tax_R(par)

def consumption(c0, j0, j_switch=None, c0_new=None):
    "Consumption at every age, with an optional replan at j_switch."
    c = c0[None, :]*βR**np.maximum(ages_j[:, None] - j0[None, :], 0)
    if j_switch is not None:
        c_new = c0_new[None, :]*βR**np.maximum(ages_j[:, None] - j_switch[None, :],
 ↪ 0)
        c = np.where(ages_j[:, None] >= j_switch[None, :], c_new, c)
    return c

def working(R, R_new=None, j_switch=None):
    w = (ages_j[:, None] < (R - AGE0)[None, :]).astype(float)
    if R_new is not None:
        w = np.where(ages_j[:, None] >= j_switch[None, :],
                     (ages_j[:, None] < (R_new - AGE0)[None, :]).astype(float), w)
    return w

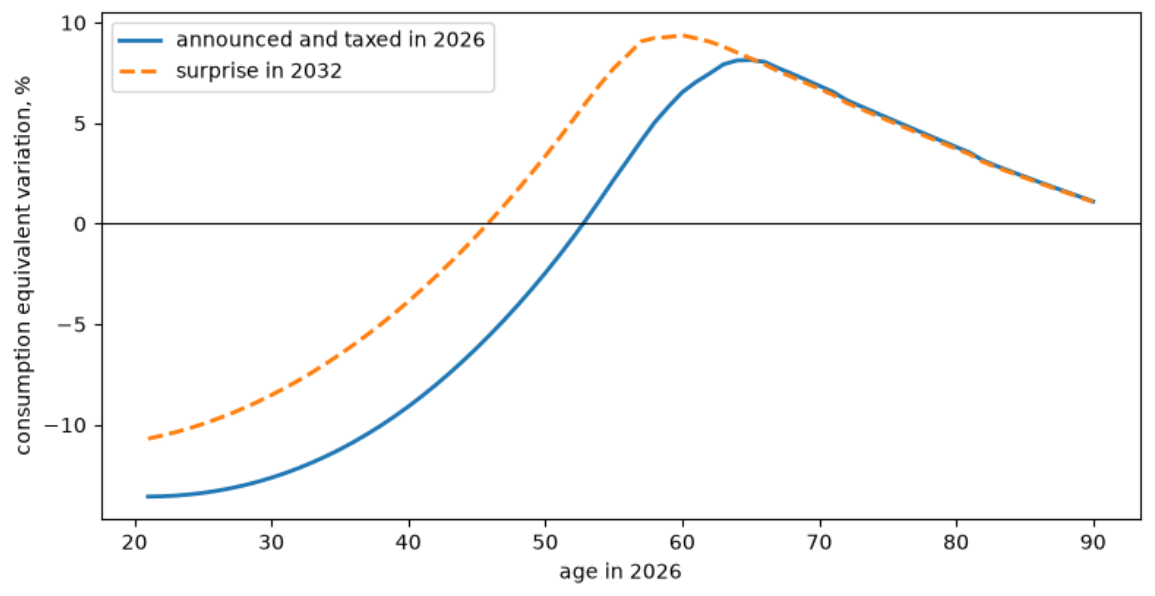
def lifetime_value(W, c, work, j0):
    "Σ_{j≥j0} β^{j-j0} ℓ_{j|j0} [log c_j - η h n_j], for every row."
    p = W.p
    wt = (p.β**ages_j)[:, None]*W.ell.T
    u = np.log(np.maximum(c, 1e-12)) - (p.η*W.η)[None, :]*work
    keep = ages_j[:, None] >= j0[None, :]
    return (np.where(keep, wt*u, 0.0).sum(axis=0)
            / ((p.β**j0)*W.ell[np.arange(W.C), j0]))

V_dep = lifetime_value(W, consumption(c0_b, W.j0), working(R_b), W.j0)
V_imm = lifetime_value(W, consumption(c0_i, W.j0), working(R_i), W.j0)
V_sur = lifetime_value(W, consumption(c0_b, W.j0, j_star, c0_n),
                       working(R_b, R_n, j_star), W.j0)

def cev_age(V1, V0, age):
    m = W.entry == Y0 - (age - AGE0)
    wts = W.w[m]/W.w[m].sum()
    return np.exp(((V1 - V0)[m]*wts).sum()/Om_b[m][0]) - 1
```

Before reading the answer, it is worth checking the machinery against Exercise 129.9.3, which computed the immediate bailout a different way.

```
print(f"{'age in 2026':>12}{'this exercise':>15}{'exercise 3':>12}")
for a in (25, 45, 60, 80):
    print(f"{a:>12}{100*cev_age(V_imm, V_dep, a):>15.2f}"
          f"{100*λ_old[a-21]:>12.2f}")
```



```
  age in 2026  this exercise  exercise 3
           25         -13.39      -13.39
           45          -6.18       -6.18
           60           6.54        6.54
           80           3.82        3.82
```

The two agree, so we can compare the timings.

```
ages_alive = np.arange(21, 91)
λ_imm = np.array([cev_age(V_imm, V_dep, a) for a in ages_alive])
λ_sur = np.array([cev_age(V_sur, V_dep, a) for a in ages_alive])

fig, ax = plt.subplots(figsize=(8, 4.2))
ax.plot(ages_alive, 100*λ_imm, lw=2, label='announced and taxed in 2026')
ax.plot(ages_alive, 100*λ_sur, lw=2, ls='--', label=f'surprise in {t_star}')
ax.axhline(0, color='k', lw=0.8)
ax.set_xlabel('age in 2026')
ax.set_ylabel('consumption equivalent variation, %')
ax.legend()
plt.tight_layout()
plt.show()

print(f"{'age in 2026':>12}{'immediate':>11}{'surprise':>10}{'gain':>8}")
for a in (25, 35, 45, 55, 65, 75, 85):
    i, u = 100*λ_imm[a-21], 100*λ_sur[a-21]
    print(f"{a:>12}{i:>11.2f}{u:>10.2f}{u-i:>8.2f}")
```

```
age in 2026  immediate  surprise    gain
         25     -13.39     -9.96    3.43
         35     -11.22     -6.50    4.72
         45      -6.18     -0.58    5.59
         55       2.19      7.73    5.54
         65       8.14      8.22    0.08
         75       5.26      5.14   -0.12
         85       2.34      2.29   -0.05
```

Everyone with working years left prefers the surprise, and those in middle age prefer it by a lot.

The reason is arithmetic: both economies end up paying every scheduled benefit in full, and the surprise collects six fewer years of the higher tax.

The age at which a worker stops losing from the guarantee falls from 53 to 46.

Nobody is ever actually cut, because the rescue lands in the year the reserves are spent, the year before the first full cut would have fallen.

The gain is largest in middle age, 5.6 percent at 45, where many taxed years lie ahead and retirement is near enough that the mis-planning costs little.

It is smaller for the young, who pay the higher tax for most of their lives either way.

For workers in their seventies and beyond, who have already retired and filed, the surprise is very slightly **worse**.

They pay no payroll tax under either timing, so deferring it gains them nothing, and they spent six years consuming as though their benefits were about to be cut.

That consumption they did not take is a loss that the announcement would have spared them.

Sargent and Shi [2026] find the same ranking under wage-tax financing, with one addition this model cannot produce: in general equilibrium the assets that workers accumulate against a cut that never comes *are* the economy's capital stock when the rescue arrives, so waiting also leaves a higher wage behind it.

Here prices do not move, and the whole gain is the deferred tax.

Exercise 129.9.6

Everything in this lecture rests on one calibration.

Two of its numbers deserve a sensitivity check: the demographic target, and the interest rate at which workers discount.

1. Recalibrate the birth path to an aged dependency ratio in 2085 of 0.45 and of 0.55, instead of the trustees' 0.50, and recompute the long run.
2. Recompute it at interest rates of 5 and 7 percent, holding the preference parameters at their calibrated values.
3. Which of the two moves the long-run benefit cut, and which moves behavior? Explain what you find using (129.6).

Solution

Each case is a fresh economy: new demography or new prices change the plans made before the news as well as the transition, so we re-solve both.

Twenty-five damped steps are enough for three decimals here.

```
def long_run(p, g, label):
    "Solve one economy end to end and report its long run."
    W_ = World(p, g)
    R0_, X0_, a0_, _, Ben0_, _, _ = pre_transition(W_)
    res = transition(W_, p.F_ratio*W_.Npop[0]*Ben0_[0], (R0_, X0_), a0_,
                     iters=25, verbose=False)
    mR_, mX_ = flow_ages(W_, res['R'], res['X'])
    print(f"{label:26}{YEARS[np.argmax(res['F'][:-1] <= 1e-12)]:>7}"
          f"{res['ψ'][-1]:>8.3f}{(res['Ben']/res['Pay'])[-1]:>8.3f}"
          f"{res['Pay'][-1]:>9.3f}{res['Ben'][-1]:>10.4f}{mR_[-1]:>8.1f}")

print(f"{'':26}{'deplete':>7}{'ψ_∞':>8}{'cost':>8}{'payroll':>9}{'benefits':>10}{
 ↪'retire':>8}")
long_run(par, g_pop, "baseline")
for target in (0.45, 0.55):
    g_t = fsolve(lambda g: [dependency(g, 2025, par) - 0.32,
                            dependency(g, 2085, par) - target], [0.02, 0.0])
    long_run(par, g_t, f"dependency 2085 = {target}")
for r_alt in (0.05, 0.07):
    long_run(par._replace(r=r_alt), g_pop, f"interest rate = {r_alt}")
```

	deplete	ψ_∞	cost	payroll	benefits	retire
baseline	2033	0.482	0.229	0.663	0.1519	65.3
dependency 2085 = 0.45	2034	0.531	0.208	0.677	0.1408	64.9
dependency 2085 = 0.55	2033	0.440	0.251	0.647	0.1622	65.5
interest rate = 0.05	2033	0.488	0.227	0.705	0.1597	68.5
interest rate = 0.07	2033	0.500	0.221	0.613	0.1355	62.0

Demography moves the long-run cut, and the interest rate essentially does not.

Five points of the dependency ratio are worth about five points of the payable factor, in the opposite direction.

The interest rate moves the payable factor by one or two points while moving the average retirement age by **six and a half years**, from 68.5 at five percent to 62.0 at seven.

Equation (129.6) says why.

The long-run cut depends on behavior only through the cost rate, the ratio of the scheduled bill to taxable payroll, and the two columns beside it show what each experiment does to the numerator and the denominator.

A higher dependency ratio pushes them in opposite directions: fewer workers to tax, more retirees to pay.

A higher interest rate pushes them in the same direction, and by almost the same proportion: shorter careers shrink taxable payroll, and the earlier claiming that comes with them buys a lower actuarial factor, so the scheduled bill shrinks too.

The ratio hardly notices.

This is the two-clock structure of the benefit formula seen from the long run rather than from the transition: the same career decision that sets what a worker contributes also sets what the worker is owed, and in a stationary economy the two very nearly cancel.

130.1 Overview

A **mean field game** describes a continuum of small agents, each of whom solves a dynamic optimization problem whose payoff depends on what everybody else is doing, summarized by the cross-sectional distribution of states.

The framework was introduced by Lasry and Lions [2007] and, independently, by Huang *et al.* [2006].

It pairs two partial differential equations:

- a **Hamilton-Jacobi-Bellman** equation that runs backward in time and describes an individual's optimal choice, given paths for the aggregates
- a **Kolmogorov forward** equation that runs forward in time and describes how the distribution of individual states evolves, given those choices

An equilibrium requires that the aggregates that agents take as given are the ones that their own decisions generate.

Readers of *Rational Expectations Equilibrium* will recognize that requirement: it is the "Big Y, little y" idea, now applied to an entire distribution rather than to a single number.

The same pair of equations is the workhorse of continuous-time heterogeneous-agent macroeconomics; see Achdou *et al.* [2022].

This lecture studies a tractable special case in which the payoff is quadratic and the state evolves linearly, following Alvarez and Argente [2026].

Agents care about the cross-sectional average *state* X, through a matrix Θ_X, and about the cross-sectional average *action* $\mathcal{A}$, through a matrix $\Theta_{\mathcal{A}}$.

The main result is a striking simplification:

Note

The equilibrium of the mean field game solves the algebraic Riccati equation of a *single-agent* linear quadratic regulator problem, in which the curvature matrices Q and Γ of the return in an agent's own state and own action are replaced by the **effective curvatures**

$$Q + \Theta_X \qquad \text{and} \qquad \Gamma + \Theta_{\mathcal{A}}.$$

Everything we know about the linear regulator can therefore be brought to bear on the equilibrium: existence conditions, uniqueness, comparative statics, and numerical methods.

Four lessons organize the lecture:

- **Effective curvature** (*Effective curvature*). Aggregate dynamics depend on strategic interaction only through the effective curvatures, which measure how fast an agent's marginal returns fall when everybody moves together.
- **Individual versus aggregate** (*Aggregate and individual dynamics*). An agent's deviation from the cross-sectional mean depends only on Q and Γ, which measure how fast her marginal returns fall when she moves alone, so individual (micro) and aggregate (macro) adjustment speeds differ: three years against five in our capital example.
- **The missing intercept** (*Aggregate shocks and identification*). Regressions with time effects see only deviations from the mean, while strategic interaction lives entirely in the time effects.
- **Marginal versus total** (*The planner*). A planner responds to how the *total* return changes when everybody moves together, not to how an agent's marginal return changes, and that can make the planner's allocation either slower or faster than the equilibrium.

We illustrate them with two economic examples from Alvarez and Argente [2026]: an industry equilibrium with capital accumulation, and a multiproduct pricing problem with Kimball demand.

A sequel, *Linear Quadratic Mean Field Games: Extensions*, adds cross terms between states and actions, forcing processes, and interactions through higher moments of the cross-sectional distribution.

Riccati equations appear in several other QuantEcon lectures:

- *LQ Control: Foundations* introduces the linear regulator and its Riccati equation
- *Lagrangian for LQ Control* studies the state-costate system and its stable invariant subspace, which is exactly the structure we meet below
- *Markov Perfect Equilibrium* studies dynamic games with *finitely many* players, where each player has a Riccati equation and the equations are coupled
- *A First Look at the Kalman Filter* presents the Riccati equation that is dual to the control problem

Let's start with some imports:

```
import numpy as np
import matplotlib.pyplot as plt
from matplotlib.patches import Patch
from matplotlib.lines import Line2D
from scipy.linalg import solve_continuous_are, expm
from scipy.optimize import brentq
```

130.2 The environment

There is a continuum of agents.

An individual has state $x \in \mathbb{R}^n$ and takes an action $\alpha \in \mathbb{R}^k$.

The cross-sectional average state and action are

$$X = \int x\, m(x) dx, \qquad \mathcal{A} = \int \alpha^*(x)\, m(x) dx,$$

where m is the density of the state across agents and α^* is the optimal policy.

The period return is

$$F(x, X) + R(\alpha, \mathcal{A}) = -\tfrac{1}{2} x^\top Q x - X^\top \Theta_X x - \tfrac{1}{2} \alpha^\top \Gamma \alpha - \mathcal{A}^\top \Theta_{\mathcal{A}} \alpha. \tag{130.1}$$

This is not the most general quadratic return.

A second-order approximation to a general return also produces cross terms between states and actions, which *Linear Quadratic Mean Field Games: Extensions* takes up.

It also produces terms that involve only the aggregates, which do not affect an individual's choices but do matter for a planner, as we will see in *The planner*.

We omit constants, which do not affect choices, and linear terms, which affect steady-state levels but not the dynamics of deviations from them.

The individual state follows

$$dx = (B\alpha - Ax) dt + \Sigma^{1/2} dW, \tag{130.2}$$

where W is an n-dimensional Brownian motion and shocks are purely idiosyncratic for now.

Agents discount at rate $\rho > 0$.

We assume that Q and Γ are positive definite, that Σ is positive semi-definite, that B has full row rank, and that Θ_X and $\Theta_{\mathcal{A}}$ are symmetric.

Symmetry of the interaction matrices is a genuine restriction.

The own-curvature matrix Q can always be taken to be symmetric, because $x^\top Q x$ depends only on the symmetric part of Q, but $X^\top \Theta_X x$ pairs two different vectors, and the antisymmetric part of Θ_X does affect choices.

It is, however, a restriction on payoffs rather than on behavior: the pricing example below has asymmetric best responses but a symmetric Θ_X.

130.2.1 Complements and substitutes

From (130.1), the cross derivative between an agent's own state and the average state is $-\Theta_X$, and between her own action and the average action it is $-\Theta_{\mathcal{A}}$.

So

- states are **strategic complements** when $-\Theta_X$ is positive definite, i.e. when Θ_X is negative definite
- states are **strategic substitutes** when Θ_X is positive definite

and similarly for actions.

We compare symmetric matrices with the Loewner order, in which $\Theta_1 \preceq \Theta_2$ means that $\Theta_2 - \Theta_1$ is positive semi-definite.

In that order, *smaller* Θ means *more* complementarity.

Note

The monotonicity condition that Lasry and Lions [2007] impose to obtain uniqueness corresponds here to Θ_X being positive semi-definite, that is, to strategic *substitutability* in states.

We will not need it: under the symmetry assumptions above, and provided $\Gamma + \Theta_{\mathcal{A}}$ is positive definite, there is at most one equilibrium whether interactions are complements or substitutes.

Linear Quadratic Mean Field Games: Extensions shows how uniqueness can fail once interactions between states and actions are allowed to be asymmetric.

130.2.2 Equilibrium

Taking the paths $\{X(t), \mathcal{A}(t)\}$ as given, an agent's value function satisfies the HJB equation

$$\rho u(x,t) = -\tfrac{1}{2} x^\top Q x - X(t)^\top \Theta_X x + H(u_x(x,t), x, \mathcal{A}(t)) + \tfrac{1}{2}\operatorname{tr}(\Sigma u_{xx}(x,t)) + u_t(x,t), \tag{130.3}$$

where the Hamiltonian is

$$H(p, x, \mathcal{A}) = \max_\alpha \left\{ -\tfrac{1}{2}\alpha^\top \Gamma \alpha - \mathcal{A}^\top \Theta_{\mathcal{A}} \alpha + p^\top (B\alpha - Ax) \right\},$$

with maximizer $\alpha^*(p, \mathcal{A}) = \Gamma^{-1}(B^\top p - \Theta_{\mathcal{A}} \mathcal{A})$.

The density evolves according to the Kolmogorov forward equation

$$m_t(x,t) = -\operatorname{div}\left(H_p(u_x(x,t), x, \mathcal{A}(t)) m(x,t)\right) + \tfrac{1}{2}\operatorname{tr}(\Sigma m_{xx}(x,t)), \tag{130.4}$$

and an **equilibrium** is a value function, a density, and paths for X and $\mathcal{A}$ that satisfy (130.3), (130.4), and the consistency requirements that X and $\mathcal{A}$ really are the cross-sectional averages implied by m and by the optimal policy.

130.3 Solving the individual problem

Given the aggregate paths, an individual faces a time-varying linear quadratic regulator problem, so her value function is quadratic:

$$u(x,t) = \beta_0(t) + \beta_1(t)^\top x + \tfrac{1}{2} x^\top \beta_2(t) x.$$

Substituting into (130.3) and matching terms of each order gives three differential equations.

The one for β_2 is

$$\dot{\beta}_2 = Q - \beta_2 B\Gamma^{-1}B^\top\beta_2 + \beta_2 A + A^\top\beta_2 + \rho\beta_2. \tag{130.5}$$

Notice what is *absent* from (130.5): neither interaction matrix appears.

The curvature of an individual's value function is therefore the same as it would be if she were alone in the world.

Because the individual problem is concave and stationary, $\beta_2(t)$ equals the constant $\bar{\beta}_2$, the negative definite solution of

$$\bar{\beta}_2 B\Gamma^{-1}B^\top\bar{\beta}_2 = Q + \rho\bar{\beta}_2 + \bar{\beta}_2 A + A^\top\bar{\beta}_2. \tag{130.6}$$

This is the familiar algebraic Riccati equation of *LQ Control: Foundations*, written in continuous time.

The optimal action is

$$\alpha^*(x,t) = \Gamma^{-1}\left[B^\top(\beta_1(t) + \bar{\beta}_2 x) - \Theta_{\mathcal{A}}\mathcal{A}(t)\right].$$

Averaging across agents and solving the resulting fixed point in $\mathcal{A}$ gives

$$\mathcal{A}(t) = (\Gamma + \Theta_{\mathcal{A}})^{-1}B^\top\left(\beta_1(t) + \bar{\beta}_2 X(t)\right). \tag{130.7}$$

Equation (130.7) is where the action interaction first bites: each agent responds to the average action, and solving for the average that is consistent with everyone doing so replaces Γ by $\Gamma + \Theta_{\mathcal{A}}$.

130.4 A state-costate system

Two objects now remain: the linear coefficient $\beta_1(t)$ of the value function, and the aggregate state $X(t)$.

Matching the terms in the HJB equation that are linear in x gives

$$\dot{\beta}_1 = (\rho I + A^\top)\beta_1 + \Theta_X X - \bar{\beta}_2 B\Gamma^{-1}\left(B^\top\beta_1 - \Theta_{\mathcal{A}}\mathcal{A}\right),$$

and averaging the state equation across agents gives $\dot{X} = B\mathcal{A} - AX$, because the idiosyncratic shocks average out.

Substituting (130.7) into both equations gives a pair of linear differential equations,

$$\begin{bmatrix}\dot{\beta}_1 \\ \dot{X}\end{bmatrix} = \mathcal{H}\begin{bmatrix}\beta_1 \\ X\end{bmatrix}, \qquad \mathcal{H} = \begin{bmatrix}\rho I + A^\top - \bar{\beta}_2 D & \Theta_X + \bar{\beta}_2(B\Gamma^{-1}B^\top - D)\bar{\beta}_2 \\ D & -A + D\bar{\beta}_2\end{bmatrix}, \tag{130.8}$$

where we abbreviate

$$D \equiv B(\Gamma + \Theta_{\mathcal{A}})^{-1}B^\top.$$

This is a **state-costate** system of exactly the kind studied in *Lagrangian for LQ Control*.

The aggregate state X has an initial condition, namely the mean of the initial distribution.

The costate β_1 does not: it must be chosen so that the solution does not violate the agent's transversality condition, which here requires the eigenvalues governing the path to have real parts below $\rho/2$.

Because Θ_X, $B\Gamma^{-1}B^\top$ and D are symmetric, $\mathcal{H} - \frac{\rho}{2}I$ is a Hamiltonian matrix, so its eigenvalues are symmetric about the origin.

It follows that:

Proposition 130.4.1

If λ is an eigenvalue of $\mathcal{H}$, then so are $\rho - \lambda$, $\bar{\lambda}$, and $\rho - \bar{\lambda}$.

So at most n eigenvalues can have real parts below $\rho/2$, and exactly n do when none lies on the line $\text{Re}\,\lambda = \rho/2$.

That pins down a unique stable invariant subspace, and when D is positive definite that subspace can be written as $\beta_1 = SX$ for a single matrix S, so there is at most one equilibrium.

This is the standard connection between algebraic Riccati equations and invariant subspaces of Hamiltonian matrices, treated at length by Lancaster and Rodman [1995].

130.5 The equilibrium Riccati equation

We look for a saddle path along which the costate is a linear function of the state, $\beta_1(t) = SX(t)$.

Substituting into (130.8) gives a quadratic matrix equation for S whose coefficients involve $\bar{\beta}_2$, and a change of variable simplifies it.

Define

$$P \equiv S + \bar{\beta}_2.$$

The new matrix has a natural meaning.

An agent at the mean has marginal value of the state $u_x = \beta_1 + \bar{\beta}_2 X = (S + \bar{\beta}_2)X = PX$, so P maps the aggregate state into the costate of the average agent.

Proposition 130.5.1

An equilibrium is characterized by a symmetric matrix P solving

$$P\,B(\Gamma + \Theta_{\mathcal{A}})^{-1}B^\top\,P = Q + \Theta_X + \rho P + PA + A^\top P,$$

with aggregate dynamics

$$\dot{X} = \left(B(\Gamma + \Theta_{\mathcal{A}})^{-1}B^\top P - A\right)X.$$

The equilibrium requires all eigenvalues of the closed-loop matrix to have real parts below $\rho/2$.

Compare this with the single-agent equation (130.6).

They have *the same form*.

The only difference is that Q has become $Q + \Theta_X$ and Γ has become $\Gamma + \Theta_{\mathcal{A}}$.

Proposition 130.5.2

Suppose $Q + \Theta_X$ and $\Gamma + \Theta_{\mathcal{A}}$ are positive definite.

Then the equilibrium of a linear quadratic mean field game with interaction matrices Θ_X and $\Theta_{\mathcal{A}}$, and its aggregate law of motion, coincide with the solution of a single-agent linear quadratic control problem whose state curvature is $Q + \Theta_X$ and whose action curvature is $\Gamma + \Theta_{\mathcal{A}}$.

This is the organizing result of the lecture.

130.5.1 Effective curvature

We call $Q + \Theta_X$ and $\Gamma + \Theta_{\mathcal{A}}$ the **effective curvatures**.

They have a simple reading.

An agent's marginal return to her state is $-Qx - \Theta_X X$.

If she moves alone, holding X fixed, it falls with slope Q.

If everybody moves together, so that $x = X$, it equals $-(Q + \Theta_X)X$ and falls with slope $Q + \Theta_X$.

The first slope governs an agent's deviations from the crowd, and the second governs the crowd.

The same reading applies to actions, with Γ and $\Gamma + \Theta_{\mathcal{A}}$.

Fig. 130.2 below draws the two slopes for our capital accumulation example.

So strategic interaction does not change the *form* of the problem that determines aggregate dynamics; it changes the *curvatures* that enter it.

An immediate implication is that two models with very different strategic interactions can generate identical aggregate dynamics, provided their effective curvatures agree, and *Aggregate shocks and identification* shows what that means for estimation.

130.5.2 Existence and uniqueness

Since P solves a standard Riccati equation, standard conditions apply.

Define

$$E \equiv Q + \Theta_X + (A^\top + \tfrac{\rho}{2} I)\left[B(\Gamma + \Theta_{\mathcal{A}})^{-1} B^\top\right]^{-1}(A + \tfrac{\rho}{2} I)\,. \tag{130.9}$$

Proposition 130.5.3

Suppose $B(\Gamma + \Theta_{\mathcal{A}})^{-1} B^\top$ is positive definite.

1. There is at most one equilibrium.
2. A necessary condition for a symmetric solution of the equilibrium Riccati equation is that E be positive semi-definite.
3. If $Q + \Theta_X$ is positive definite, an equilibrium exists.

The sufficient condition has a clean reading: *effective* curvature must remain positive in both states and actions.

For states that is $Q + \Theta_X \succ 0$; for actions it is the maintained assumption on $B(\Gamma + \Theta_{\mathcal{A}})^{-1} B^\top$, which holds whenever $\Gamma + \Theta_{\mathcal{A}} \succ 0$.

Complementarity is therefore permissible, but only up to a point.

The two interactions enter E through separate terms, and a larger $\Theta_{\mathcal{A}}$ raises the second, so substitutability in actions can offset complementarity in states.

130.5.3 Aggregate and individual dynamics

The equilibrium splits each agent's state into the cross-sectional mean X and her deviation from it, $z = x - X$.

Using $\beta_1 = (P - \bar{\beta}_2)X$ in the optimal action shows that $\alpha^* - \mathcal{A} = \Gamma^{-1}B^\top \bar{\beta}_2 z$.

Subtracting the aggregate law of motion from the individual one then gives

$$\begin{aligned} \dot{X} &= (DP - A)\, X, \\ dz &= \left(B\Gamma^{-1}B^\top \bar{\beta}_2 - A\right) z\, dt + \Sigma^{1/2} dW, \\ \alpha^* &= (\Gamma + \Theta_{\mathcal{A}})^{-1} B^\top P X + \Gamma^{-1} B^\top \bar{\beta}_2 z. \end{aligned} \tag{130.10}$$

The aggregate follows the equilibrium matrix P.

An agent's deviation from the mean follows the single-agent matrix $\bar{\beta}_2$, and neither interaction matrix appears, because strategic interaction operates through X and $\mathcal{A}$, which drop out of deviations from the mean.

So the deviation of any agent from the crowd moves exactly as the whole economy would move if there were no interactions.

From now on we call these **individual** dynamics, as opposed to **aggregate** dynamics, and we label them "no interactions" in tables and figures.

This split is also the source of the missing intercept that we study in *Aggregate shocks and identification*: data on deviations from the mean reveal only the individual dynamics.

130.6 Computing equilibria

`scipy.linalg.solve_continuous_are(A, B, Q, R)` returns the stabilizing solution $\tilde{P}$ of

$$A^\top \tilde{P} + \tilde{P}A - \tilde{P}BR^{-1}B^\top \tilde{P} + Q = 0.$$

Our equation differs in two ways: our P is negative definite when the effective curvatures are positive definite, and we discount.

Writing $P = -\tilde{P}$ and collecting terms shows that our equation is the standard one with A replaced by $-(A + \frac{\rho}{2} I)$.

The discount rate enters exactly as it does in the "$\rho/2$ shift" familiar from continuous-time control.

When no admissible solution exists, `solve_continuous_are` usually raises an error, but not always: it can return a matrix that does not solve the equation at all.

So our function checks both the Riccati residual and the eigenvalue condition, and raises an error if either fails.

```
def closed_loop(A, B, Γ_eff, P):
    "The matrix governing aggregate dynamics, Ẋ = (B Γ_eff^{-1} B' P - A) X."
    return B @ np.linalg.solve(Γ_eff, B.T @ P) - A

def mfg_riccati(A, B, Q, Γ, ρ, tol=1e-8):
    """
    Solve  P B Γ^{-1} B' P = Q + ρ P + P A + A' P  for the solution P whose
    closed-loop matrix B Γ^{-1} B' P - A has eigenvalues with real parts
    below ρ/2, and raise ValueError if there is none.

    Passing Q + 0_X and Γ + 0_A gives the equilibrium of the mean field game;
    passing Q and Γ gives the single agent's value function curvature.
    """
```

(continues on next page)

(continued from previous page)

```
    n = A.shape[0]
    try:
        P = -solve_continuous_are(-(A + ρ/2 * np.eye(n)), B, Q, Γ)
    except (np.linalg.LinAlgError, ValueError):
        raise ValueError("no admissible solution of the Riccati equation")
    quad = P @ B @ np.linalg.solve(Γ, B.T) @ P
    residual = quad - (Q + ρ*P + P @ A + A.T @ P)
    scale = 1 + np.abs(Q).max() + np.abs(quad).max()
    if (np.abs(residual).max() > tol*scale
            or np.linalg.eigvals(closed_loop(A, B, Γ, P)).real.max() >= ρ/2):
        raise ValueError("no admissible solution of the Riccati equation")
    return P
```

Let's set up a two-dimensional example with complementarity in states and substitutability in actions, the configuration that Alvarez and Argente [2026] obtain from an industry equilibrium with capital accumulation.

```
ρ = 0.05
A = np.array([[0.4, 0.1],
              [0.0, 0.3]])
B = np.eye(2)
Q = np.array([[1.0, 0.2],
              [0.2, 0.8]])
Γ = np.array([[1.0, 0.1],
              [0.1, 1.2]])
Θ_X = np.array([[-0.3, 0.05],      # negative definite: complements in states
                [0.05, -0.2]])
Θ_A = np.array([[0.2, 0.0],        # positive definite: substitutes in actions
                [0.0, 0.1]])

β2 = mfg_riccati(A, B, Q, Γ, ρ)                  # single agent
P = mfg_riccati(A, B, Q + Θ_X, Γ + Θ_A, ρ)       # equilibrium

print("individual curvature β₂ =\n", β2.round(4))
print("\nequilibrium matrix P =\n", P.round(4))
```

```
individual curvature β₂ =
 [[-0.6614 -0.0869]
 [-0.0869 -0.654 ]]

equilibrium matrix P =
 [[-0.5353 -0.134 ]
 [-0.134  -0.5337]]
```

Let's compare aggregate dynamics with individual dynamics, that is, with the dynamics of an agent's deviation from the mean.

```
D = B @ np.linalg.solve(Γ + Θ_A, B.T)

U_ind = closed_loop(A, B, Γ, β2)          # individual dynamics
U_agg = closed_loop(A, B, Γ + Θ_A, P)     # aggregate dynamics

print("individual eigenvalues:", np.linalg.eigvals(U_ind).round(4))
print("aggregate eigenvalues: ", np.linalg.eigvals(U_agg).round(4))
```

```
individual eigenvalues: [-1.0698 -0.8321]
aggregate eigenvalues:  [-0.9025 -0.6423]
```

The aggregate eigenvalues are closer to zero, so the economy as a whole adjusts more slowly than an agent's deviation from it.

This example has complementarity in states and substitutability in actions, and *Persistence* shows that both raise the sum of the eigenvalues; here each eigenvalue moves toward zero as well.

130.6.1 Checking the Hamiltonian structure

Proposition 130.4.1 says the eigenvalues of $\mathcal{H}$ come in pairs $\{\lambda, \rho - \lambda\}$, and that the n eigenvalues with real parts below $\rho/2$ are the ones that govern equilibrium dynamics.

Let's check both claims.

```
BΓB = B @ np.linalg.solve(Γ, B.T)
n = A.shape[0]

Ham = np.block([[ρ*np.eye(n) + A.T - β2 @ D, Θ_X + β2 @ (BΓB - D) @ β2],
                [D,                          -A + D @ β2]])

ev = np.linalg.eigvals(Ham)
print("eigenvalues of ℋ:", np.sort(ev.real).round(4))
print("paired as λ and ρ - λ:",
      np.allclose(np.sort(ev.real), np.sort(ρ - ev.real)))

stable = np.sort(ev.real[ev.real < ρ/2])
print("\nstable half of ℋ:      ", stable.round(4))
print("closed-loop eigenvalues:", np.sort(np.linalg.eigvals(U_agg).real).round(4))
```

```
eigenvalues of ℋ: [-0.9025 -0.6423  0.6923  0.9525]
paired as λ and ρ - λ: True

stable half of ℋ:       [-0.9025 -0.6423]
closed-loop eigenvalues: [-0.9025 -0.6423]
```

The saddle path is the stable invariant subspace of $\mathcal{H}$, exactly as in *Lagrangian for LQ Control*.

130.7 The scalar case

With $n = k = 1$ everything is explicit.

Write $q, a, b, \gamma, \theta_X, \theta_{\mathcal{A}}$ for the scalars, and assume $\gamma + \theta_{\mathcal{A}} > 0$.

The Riccati equation becomes a quadratic, and the admissible root gives the aggregate eigenvalue

$$\lambda = \frac{\rho}{2} - \sqrt{\left(\frac{\rho}{2} + a\right)^2 + \frac{b^2(q + \theta_X)}{\gamma + \theta_{\mathcal{A}}}}. \tag{130.11}$$

When the initial mean $X(0)$ is not zero, an equilibrium exists if and only if the term under the square root is positive,

$$q + \theta_X + \left(\frac{\rho}{2} + a\right)^2 \frac{\gamma + \theta_{\mathcal{A}}}{b^2} > 0, \tag{130.12}$$

and the equilibrium is stable, meaning $\lambda < 0$, if and only if

$$q + \theta_X + a(a + \rho)\frac{\gamma + \theta_{\mathcal{A}}}{b^2} > 0. \tag{130.13}$$

When $q + \theta_X > 0$, as in both of our examples, formula (130.11) displays the two comparative statics at a glance.

More complementarity in *states* (a smaller θ_X) raises λ and makes aggregate dynamics *more* persistent: when others stay away from the steady state, each agent has less reason to return to it.

More complementarity in *actions* (a smaller $\theta_{\mathcal{A}}$) lowers λ and makes dynamics *less* persistent: when others adjust, each agent wants to adjust too.

If $q + \theta_X < 0$, the second comparative static reverses, which is why the general results below assume positive effective curvatures.

130.7.1 Four regions

Conditions (130.12) and (130.13) define two thresholds for the state interaction,

$$\theta^* \equiv -q - a(a+\rho)\frac{\gamma + \theta_{\mathcal{A}}}{b^2}, \qquad \theta^{**} \equiv -q - \left(\frac{\rho}{2} + a\right)^2 \frac{\gamma + \theta_{\mathcal{A}}}{b^2} = \theta^* - \left(\frac{\rho}{2}\right)^2 \frac{\gamma + \theta_{\mathcal{A}}}{b^2},$$

so that $\theta^{**} < \theta^*$.

As θ_X falls, that is, as complementarity in states increases, the economy passes through four regions:

1. if $\theta_X > \theta^*$, the equilibrium is stable and $X(t)$ converges to zero
2. if $\theta_X = \theta^*$, then $\lambda = 0$ and $X(t)$ stays where it starts
3. if $\theta^{**} < \theta_X < \theta^*$, an equilibrium exists but $0 < \lambda < \rho/2$, so $X(t)$ moves away from zero, slowly enough to keep discounted payoffs finite
4. if $\theta_X \leq \theta^{**}$, there is no equilibrium

So stability is lost before existence.

Formulas (130.11) to (130.13) depend on the two interactions only through the ratio $(q + \theta_X)/(\gamma + \theta_{\mathcal{A}})$.

In the $(\theta_X, \theta_{\mathcal{A}})$ plane, every curve along which that ratio is constant is a ray from the point $(-q, -\gamma)$.

So contours of the aggregate eigenvalue, the stability boundary and the existence boundary are all rays from that point.

Let's draw them, taking a large discount rate, $\rho = 0.5$, to widen the band between the two thresholds.

We first write the closed form, and check it against the solver.

```
def scalar_λ(ρ, a, b, q, γ, θ_X, θ_A):
    "Closed-form aggregate eigenvalue in the scalar case."
    return ρ/2 - np.sqrt((ρ/2 + a)**2 + b**2*(q + θ_X)/(γ + θ_A))

def half_life(λ):
    "Time for a state with eigenvalue λ < 0 to close half of a gap."
    return np.log(2)/(-λ)

ρ_s, a, b, q, γ = 0.5, 0.3, 1.0, 1.0, 1.0

errors = []
for θ_X, θ_A in ((0.0, 0.0), (-0.5, 0.0), (0.0, 0.5), (-0.5, 0.5)):
    P_s = mfg_riccati(np.array([[a]]), np.array([[b]]),
                      np.array([[q + θ_X]]), np.array([[γ + θ_A]]), ρ_s)
    λ_num = closed_loop(np.array([[a]]), np.array([[b]]),
                        np.array([[γ + θ_A]]), P_s)[0, 0]
    errors.append(abs(λ_num - scalar_λ(ρ_s, a, b, q, γ, θ_X, θ_A)))
print(f"largest gap between solver and closed form: {max(errors):.1e}")
```

```
largest gap between solver and closed form: 2.2e-16
```

The next figure shades the four regions and draws contours of the half-life of the aggregate state.

```
θ_X_grid = np.linspace(-2.0, 1.0, 400)
θ_A_grid = np.linspace(-0.99, 2.0, 400)

           Line2D([0], [0], color='C0', lw=1.2, label='half-life contours, years')]
ax.legend(handles=handles, loc='center left', bbox_to_anchor=(1.02, 0.5))
ax.set_xlim(-2.0, 1.0)
ax.set_ylim(-1.2, 2.0)
ax.set_xlabel(r'$\theta_X$')
ax.set_ylabel(r'$\theta_{\mathcal{A}}$')
plt.tight_layout()
plt.show()
```

Because the half-life contours are rays from $(-q, -\gamma)$, a move toward complementarity in states can be exactly offset by a move toward substitutability in actions.

The black line is the stability boundary $\theta_X = \theta^*$, and the thin orange band between it and the existence boundary is the third region, in which equilibrium paths diverge.

Our solver respects the boundaries: with $\theta_{\mathcal{A}} = 0$, it returns an admissible solution with $\lambda > 0$ inside the band and raises an error beyond it.

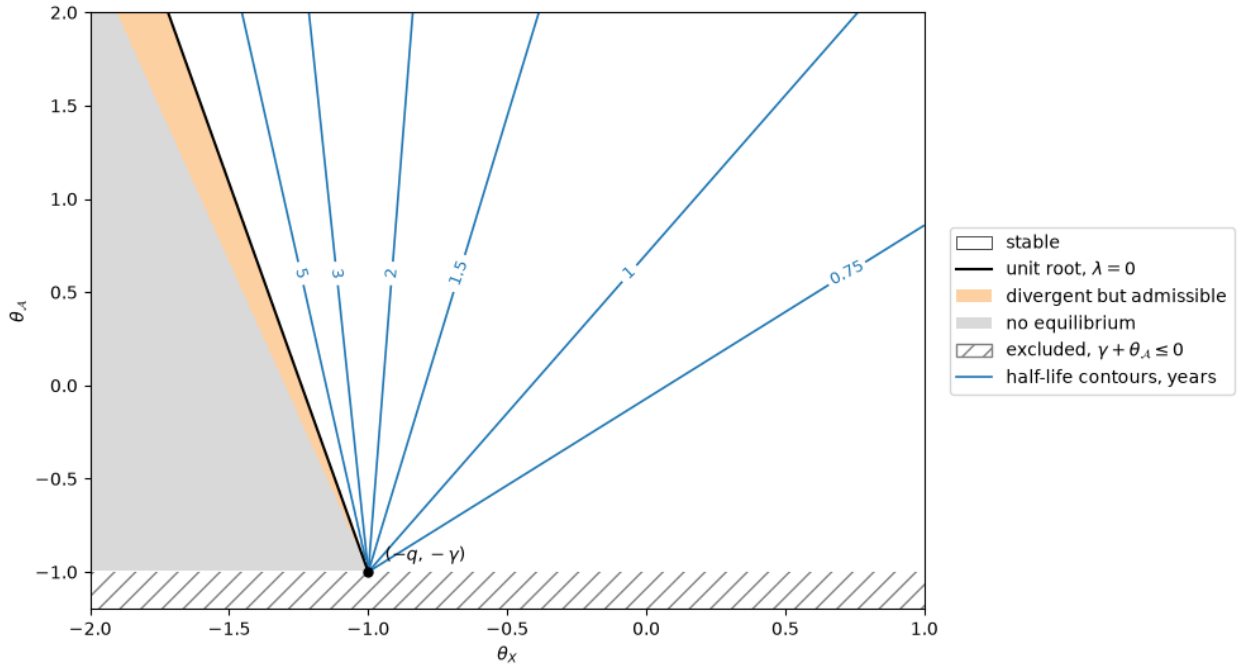

Fig. 130.1: Scalar model regions and half-lives

```

Exercise 130.14.1 asks you to derive (130.11), (130.12) and (130.13).

130.8 An industry equilibrium with capital accumulation

The scalar model is not a toy.

Alvarez and Argente [2026] show that it describes an industry equilibrium with capital accumulation in which *both* kinds of interaction appear, with opposite signs.

There is a continuum of monopolistically competitive firms.

A firm with capital k produces $y = k^\nu$ with $0 < \nu < 1$, and a constant returns sector aggregates the differentiated goods with elasticity of substitution $\eta > 1$.

With the final good as numeraire, a firm that produces y when industry output is Y earns revenue proportional to $y^{1-1/\eta} Y^{1/\eta}$.

So if all other firms hold capital K, operating profit is proportional to

$$\Pi(k, K) = k^{\nu(1-1/\eta)} K^{\nu/\eta}. \tag{130.14}$$

Capital evolves according to

$$dk = (i - \delta k)dt + k\sigma dW.$$

The firm buys investment goods at a price $\mathcal{P}(I)$ that depends on aggregate investment I, and it pays a convex adjustment cost $\psi(i)$, so it chooses investment to maximize

$$\mathbb{E} \int_0^\infty e^{-\rho t} \left[\Pi(k, K) - \mathcal{P}(I)\, i - \psi(i) \right] dt.$$

Let $\bar{\imath} = \delta \bar{k}$ be steady-state investment, normalize $\mathcal{P}(\bar{\imath}) = 1$ and $\psi'(\bar{\imath}) = 0$, and write percentage deviations from the deterministic steady state as

$$x = \frac{k - \bar{k}}{\bar{k}}, \qquad X = \frac{K - \bar{k}}{\bar{k}}, \qquad \alpha = \frac{i - \bar{\imath}}{\bar{\imath}}, \qquad \mathcal{A} = \frac{I - \bar{\imath}}{\bar{\imath}}.$$

A second-order expansion of the return around the steady state, with the objective normalized by $\bar{\Pi} \equiv \Pi(\bar{k}, \bar{k})$, delivers exactly (130.1) with

$$q = -\frac{\bar{k}^2 \Pi_{kk}}{\bar{\Pi}}, \qquad \theta_X = -\frac{\bar{k}^2 \Pi_{kK}}{\bar{\Pi}}, \qquad \gamma = \frac{\delta^2 \bar{k}^2 \psi''(\bar{\imath})}{\bar{\Pi}}, \qquad \theta_{\mathcal{A}} = \frac{\delta^2 \bar{k}^2 \mathcal{P}'(\bar{\imath})}{\bar{\Pi}},$$

while the state equation becomes $dx = \delta(\alpha - x)dt + \sigma dW$ to first order, so that

$$a = b = \delta.$$

Differentiating (130.14) gives closed forms:

$$\begin{aligned} q &= \nu \frac{\eta - 1}{\eta^2} \left[\eta(1 - \nu) + \nu \right] > 0, \\ \theta_X &= -\frac{\eta - 1}{\eta} \frac{\nu^2}{\eta} < 0, \\ q + \theta_X &= \frac{\eta - 1}{\eta} \nu (1 - \nu) > 0. \end{aligned} \tag{130.15}$$

Three features of (130.15) deserve emphasis.

First, $\theta_X < 0$: capital stocks are strategic *complements*, because a larger industry capital stock raises the demand shifter $Y^{1/\eta}$ and hence the marginal profitability of a firm's own capital.

Second, if the supply of investment goods slopes upward then $\mathcal{P}'(\bar{\imath}) > 0$ and so $\theta_{\mathcal{A}} > 0$: investment rates are strategic *substitutes*, because everyone investing at once bids up the price of capital goods.

Third, $q + \theta_X > 0$ for every $\eta > 1$ and every $\nu \in (0, 1)$, so by *Proposition 130.5.3* an equilibrium exists and is unique no matter how strong market power is and no matter how close returns to scale come to constant.

Let's put these formulas into code, and check them against numerical derivatives of the profit function itself.

```
def cap_q(η, ν):
    "Own-state curvature in the capital accumulation example."
    return ν*(η - 1)/η**2*(η*(1 - ν) + ν)

def cap_θ_X(η, ν):
    "State interaction in the capital accumulation example."
    return -(η - 1)/η*ν**2/η

η_c, ν_c = 4.0, 0.7

Π = lambda k, K: k**(ν_c*(1 - 1/η_c))*K**(ν_c/η_c)

h = 1e-5
Π_kk = (Π(1+h, 1) - 2*Π(1, 1) + Π(1-h, 1))/h**2
Π_kK = (Π(1+h, 1+h) - Π(1+h, 1-h) - Π(1-h, 1+h) + Π(1-h, 1-h))/(4*h**2)

print(f"{'':>10}{'finite difference':>20}{'closed form':>15}")
print(f"{'q':>10}{-Π_kk/Π(1, 1):>20.6f}{cap_q(η_c, ν_c):>15.6f}")
print(f"{'θ_X':>10}{-Π_kK/Π(1, 1):>20.6f}{cap_θ_X(η_c, ν_c):>15.6f}")
print(f"{'q + θ_X':>10}{-(Π_kk + Π_kK)/Π(1, 1):>20.6f}"
      f"{(η_c - 1)/η_c*ν_c*(1 - ν_c):>15.6f}")
```

```
             finite difference    closed form
         q            0.249374       0.249375
       θ_X           -0.091875      -0.091875
   q + θ_X            0.157499       0.157500
```

The effective curvature of *Effective curvature* has a concrete meaning here.

The next figure plots the marginal return to a firm's capital, measured relative to $\bar{\Pi}/\bar{k}$, in three experiments.

In the first, one firm changes its capital while the rest of the industry stays at $\bar{k}$, and the marginal return falls with slope $-q$.

In the second, every firm changes its capital together, and the marginal return falls with the smaller slope $-(q+\theta_X)$, because a larger industry raises the demand for each firm's good.

The third line is the marginal revenue of the whole industry when every firm holds the same capital, $\frac{d}{dk}\Pi(k,k) = \nu k^{\nu-1}$.

The second line is exactly $(\eta-1)/\eta$ times the third, because a firm's marginal revenue is only that fraction of the value of its marginal product, so the markup lowers both the level and the slope of the private return.

The third line will matter when we come to the planner.

```
Π_k = lambda k, K: ν_c*(1 - 1/η_c)*k**(ν_c*(1 - 1/η_c) - 1)*K**(ν_c/η_c)
k_grid = np.linspace(0.8, 1.2, 200)       # k̄ = 1, so that Π = 1

fig, ax = plt.subplots(figsize=(8, 4.8))
ax.plot(k_grid, Π_k(k_grid, 1.0), lw=2,
        label=r'$\Pi_k(k, \bar k)$: one firm moves, slope $-q$')
ax.plot(k_grid, Π_k(k_grid, k_grid), lw=2,
        label=r'$\Pi_k(k, k)$: all firms move, slope $-(q+\theta_X)$')
ax.plot(k_grid, ν_c*k_grid**(ν_c - 1), lw=2, ls='--',
        label=r'$\frac{d}{dk}\Pi(k, k)$: industry, slope $-\nu(1-\nu)$')
ax.set_xlabel(r'capital relative to steady state, $k/\bar k$')
ax.set_ylabel(r'marginal return, relative to $\bar\Pi/\bar k$')
ax.set_ylim(0.45, 0.88)
ax.legend(loc='upper right')
```

```

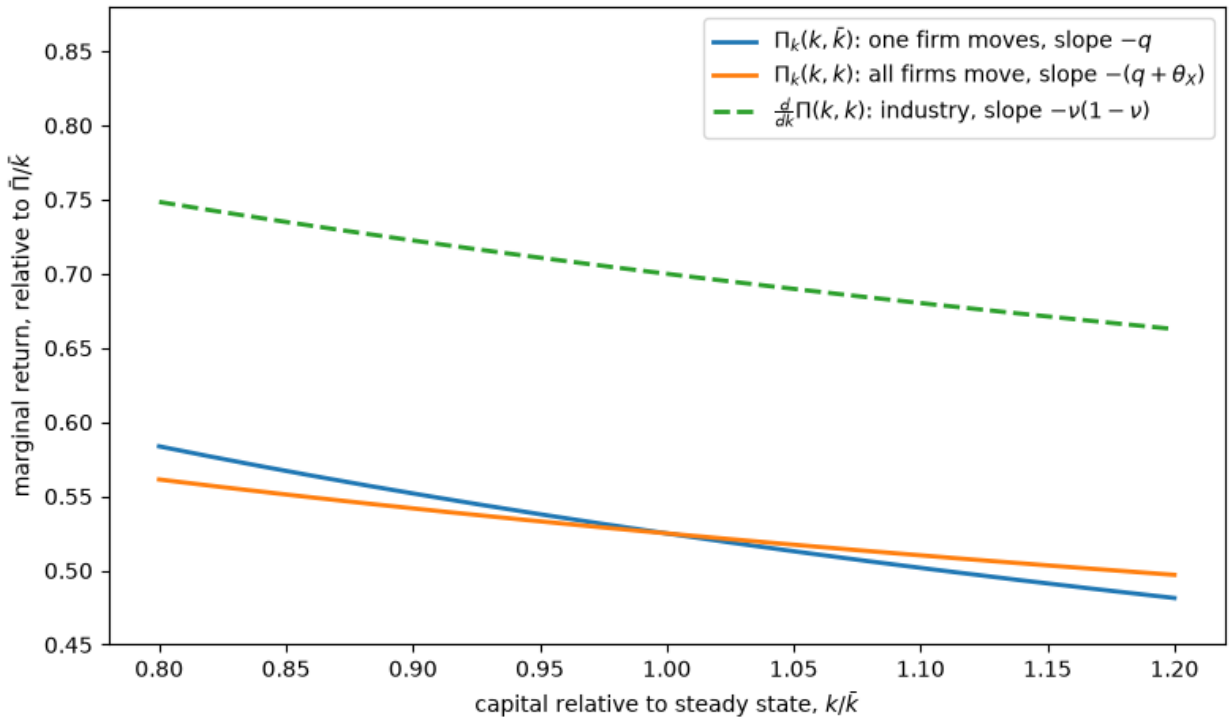

Fig. 130.2: Marginal returns to capital

130.8.1 Calibration

Take annual units, $\delta = 0.10$, $\rho = 0.05$, an elasticity of substitution $\eta = 4$, and returns to scale $\nu = 0.7$.

For investment costs we use a quadratic adjustment cost and a constant-elasticity supply of investment goods,

$$\psi(i) = \frac{\phi}{2}\,\bar{i}\left(\frac{i - \bar{i}}{\bar{i}}\right)^2, \qquad \mathcal{P}(I) = \left(\frac{I}{\bar{i}}\right)^{1/\varepsilon_s},$$

which satisfy the normalizations $\psi'(\bar{i}) = 0$ and $\mathcal{P}(\bar{i}) = 1$.

The steady-state Euler equation $\Pi_k(\bar{k}, \bar{k}) = \rho + \delta$ gives $\bar{k}^{1-\nu} = \nu(\eta - 1)/[\eta(\rho + \delta)]$, and substituting into the formulas for γ and $\theta_{\mathcal{A}}$ gives

$$\gamma = \phi\,\delta\bar{k}^{1-\nu}, \qquad \theta_{\mathcal{A}} = \frac{\delta\bar{k}^{1-\nu}}{\varepsilon_s}.$$

We choose $\phi = 1/7$, so that a firm that ignores the industry closes half of a capital gap in three years, and $\varepsilon_s = 35/9 \approx 3.9$, a moderately elastic supply of investment goods chosen so that $\theta_{\mathcal{A}} = 0.09$.

With these values $\gamma = 0.05$.

Exercise 130.14.2 asks you to derive these formulas.

```
ρ_c, δ_c = 0.05, 0.10
ψ_c, ε_s_c = 1/7, 35/9

def cap_scale(η, ν, ρ=ρ_c, δ=δ_c):
    "δ k̄^{1-ν}, which converts ψ and 1/ε_s into γ and θ_A."
    return δ*ν*(η - 1)/(η*(ρ + δ))

γ_c = ψ_c*cap_scale(η_c, ν_c)
θ_A_c = cap_scale(η_c, ν_c)/ε_s_c
q_c, θ_X_c = cap_q(η_c, ν_c), cap_θ_X(η_c, ν_c)

λ_c = scalar_λ(ρ_c, δ_c, δ_c, q_c, γ_c, θ_X_c, θ_A_c)

θ_star_c = -q_c - δ_c*(δ_c + ρ_c)*(γ_c + θ_A_c)/δ_c**2   # stability threshold

print(f"γ = {γ_c:.4f},  θ_A = {θ_A_c:.4f}")
print(f"q = {q_c:.4f},  θ_X = {θ_X_c:.4f},  q + θ_X = {q_c + θ_X_c:.4f}")
print(f"stability threshold θ* = {θ_star_c:.4f}")
print(f"half-life of aggregate capital = {half_life(λ_c):.2f} years")
```

```
γ = 0.0500,  θ_A = 0.0900
q = 0.2494,  θ_X = -0.0919,  q + θ_X = 0.1575
stability threshold θ* = -0.4594
half-life of aggregate capital = 4.99 years
```

Since the technology delivers $q + \theta_X > 0$ and an upward-sloping supply of investment goods delivers $\theta_{\mathcal{A}} > 0$, this example is always in the first of the four regions.

Complementarity in states would have to be five times stronger than the technology implies before the industry's capital stock stopped converging.

130.8.2 How much do the interactions matter?

Because (130.11) depends on θ_X and $\theta_{\mathcal{A}}$ separately, we can switch each interaction off and read the answer.

```
cases = {'no interactions':              (0.0,   0.0),
         'state complementarity only':   (θ_X_c, 0.0),
         'action substitutability only': (0.0,   θ_A_c),
         'equilibrium':                  (θ_X_c, θ_A_c)}

print(f"{'':>30}{'λ':>10}{'half-life':>12}")
for label, (tx, ta) in cases.items():
    λ_case = scalar_λ(ρ_c, δ_c, δ_c, q_c, γ_c, tx, ta)
    print(f"{label:>30}{λ_case:>10.4f}{half_life(λ_case):>12.2f}")
```

```
                                    λ   half-life
                no interactions   -0.2309        3.00
   state complementarity only   -0.1921        3.61
 action substitutability only   -0.1579        4.39
                    equilibrium   -0.1389        4.99
```

Both interactions slow aggregate capital adjustment, and they do so for different reasons.

Complementarity in states means that a firm has less reason to rebuild its capital while the rest of the industry is still below its steady state.

Substitutability in actions means that a burst of industry investment is expensive, so firms spread their investment over time.

Together they stretch the half-life of the industry's capital stock from three years to five.

We will see in *The planner in the capital accumulation example* that a planner would adjust slightly faster than the industry does, once all the terms in the planner's objective are counted.

130.8.3 Individual and aggregate adjustment speeds

By (130.10), a firm's deviation from the industry mean adjusts at the speed of a firm that ignores the industry, so the first row of the table is also the individual half-life: three years, against five for the industry, a ratio of 1.66.

Because state complementarity and action substitutability both slow aggregate adjustment here, individual capital reverts to the mean faster than aggregate capital does.

A researcher who estimated the speed of capital adjustment from firm-level data, and used it to predict the industry's response to an industry-wide shock, would predict a half-life of three years rather than five.

That is the missing intercept of *Aggregate shocks and identification* at work.

The gap is a pure interaction effect: the same technology and the same adjustment costs generate both numbers.

130.8.4 Market power and returns to scale

How does the industry's adjustment speed depend on the two technological parameters?

Because γ and $\theta_{\mathcal{A}}$ are measured relative to profits, they depend on η and ν through $\bar{k}$, so we hold the structural parameters ϕ and ε_s fixed rather than γ and $\theta_{\mathcal{A}}$.

That embeds an assumption of our calibration: the cost of a given percentage change in investment is proportional to the scale of investment $\bar{i}$.

Then

$$\frac{q + \theta_X}{\gamma + \theta_{\mathcal{A}}} = \frac{(1-\nu)(\rho+\delta)}{\delta(\phi + 1/\varepsilon_s)},$$

in which η does not appear: the effective curvature and the investment costs, both measured relative to profits, are proportional to $(\eta - 1)/\eta$.

So by (130.11), market power has no effect on the industry's adjustment speed.

The invariance depends on the scaling of adjustment costs: with a cost $\frac{c}{2}(i - \bar{i})^2$ and c fixed, adjustment costs relative to profits would grow with the steady state, which rises with η, and the industry's half-life would rise from 4.5 years at $\eta = 1.5$ to 5.3 years at $\eta = 12$.

It does affect a single firm's, because

$$\frac{q}{\gamma} = \frac{\rho + \delta}{\phi\,\delta}\left[(1-\nu) + \frac{\nu}{\eta}\right]$$

falls as η rises: with more elastic demand, a firm's revenue is closer to linear in its own capital, so its marginal return falls more slowly as it expands.

```
η_grid = np.linspace(1.2, 12, 200)
ν_grid = np.linspace(0.05, 0.995, 200)

def macro_micro(η, ν):
```

(continues on next page)

(continued from previous page)

```
    "Aggregate and individual half-lives, holding ψ and ε_s fixed."
    γ, θ_A = ψ_c*cap_scale(η, ν), cap_scale(η, ν)/ε_s_c
    q, θ_X = cap_q(η, ν), cap_θ_X(η, ν)
    λ_agg = scalar_λ(ρ_c, δ_c, δ_c, q, γ, θ_X, θ_A)
    λ_ind = scalar_λ(ρ_c, δ_c, δ_c, q, γ, 0.0, 0.0)
    return half_life(λ_agg), half_life(λ_ind)

fig, axes = plt.subplots(1, 2, figsize=(11, 4.2))

hl_agg, hl_ind = np.array([macro_micro(η, ν_c) for η in η_grid]).T
axes[0].plot(η_grid, hl_agg, lw=2, label='aggregate (industry)')
axes[0].plot(η_grid, hl_ind, lw=2, ls='--', label='individual (firm)')
axes[0].set_xlabel('elasticity of substitution $\\eta$')
axes[0].set_title('varying $\\eta$, with $\\nu = 0.7$')

hl_agg, hl_ind = np.array([macro_micro(η_c, ν) for ν in ν_grid]).T
axes[1].plot(ν_grid, hl_agg, lw=2, label='aggregate (industry)')
axes[1].plot(ν_grid, hl_ind, lw=2, ls='--', label='individual (firm)')
axes[1].set_title('varying $\\nu$, with $\\eta = 4$')
axes[1].axhline(np.log(2)/δ_c, color='k', lw=1, alpha=0.6)
axes[1].set_xlabel('returns to scale $\\nu$')
axes[1].annotate('$\\ln 2/\\delta$', (0.08, np.log(2)/δ_c - 0.35))

for ax in axes:
    ax.set_ylabel('half-life in years')
    ax.legend(loc='lower right')
plt.tight_layout()
plt.show()
```

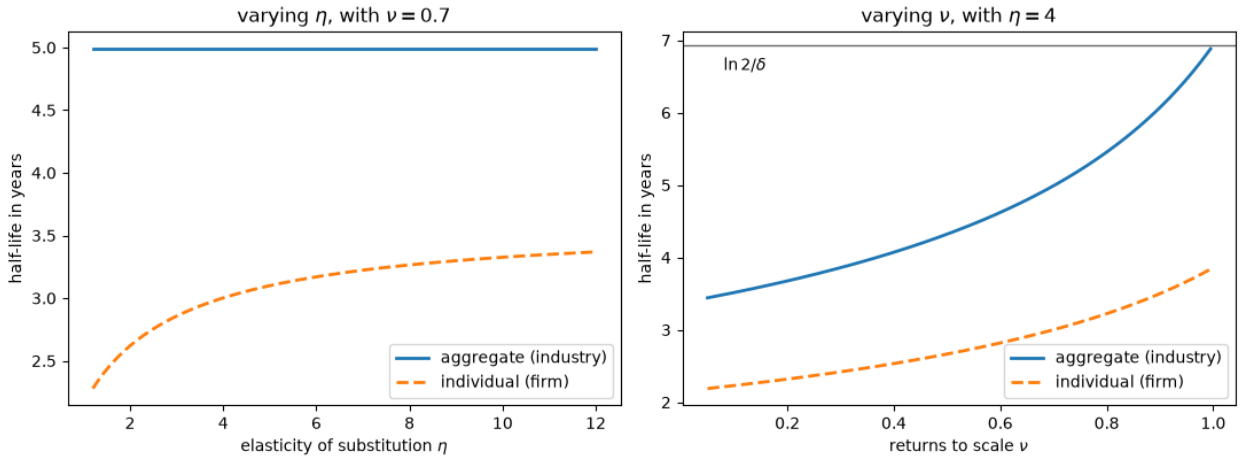

Fig. 130.3: Half-lives of industry and firm capital

The left panel shows both results: the industry's half-life does not move with η, while a single firm's rises from about 2.3 to 3.4 years as competition intensifies.

So the gap between individual and aggregate adjustment is widest when market power is greatest.

The right panel shows that both slow down as returns to scale rise.

As ν approaches 1 the effective curvature $q + \theta_X$ vanishes, and λ approaches $-\delta$: the industry's capital stock then returns

to its steady state almost entirely through depreciation, and aggregate investment barely responds.

Fig. 130.2 shows why: as ν approaches 1, the marginal return $\Pi_k(k, k)$ becomes flat along the diagonal, so an industry-wide capital gap creates almost no incentive to invest differently.

Exercise 130.14.3 asks you to derive these results.

130.8.5 Transition paths

Finally, let's trace out the industry's response to a capital stock that starts ten percent above its steady state.

Aggregate investment follows from the aggregate law of motion: $\dot{X} = \delta(\mathcal{A} - X) = \lambda X$ gives $\mathcal{A}(t) = \frac{\lambda+\delta}{\delta} X(t)$.

```
t_c = np.linspace(0, 25, 300)
X0_c = 0.10

fig, axes = plt.subplots(1, 2, figsize=(11, 4.2))
for label in ('no interactions', 'equilibrium'):
    tx, ta = cases[label]
    λ_case = scalar_λ(ρ_c, δ_c, δ_c, q_c, γ_c, tx, ta)
    path = X0_c*np.exp(λ_case*t_c)
    axes[0].plot(t_c, 100*path, lw=2, label=label)
    axes[1].plot(t_c, 100*(λ_case + δ_c)/δ_c*path, lw=2, label=label)

axes[0].set_ylabel('capital, % above steady state')
axes[1].set_ylabel('investment, % above steady state')
for ax in axes:
    ax.set_xlabel('years')
    ax.axhline(0, color='k', lw=0.8)
axes[0].legend()
plt.tight_layout()
plt.show()
```

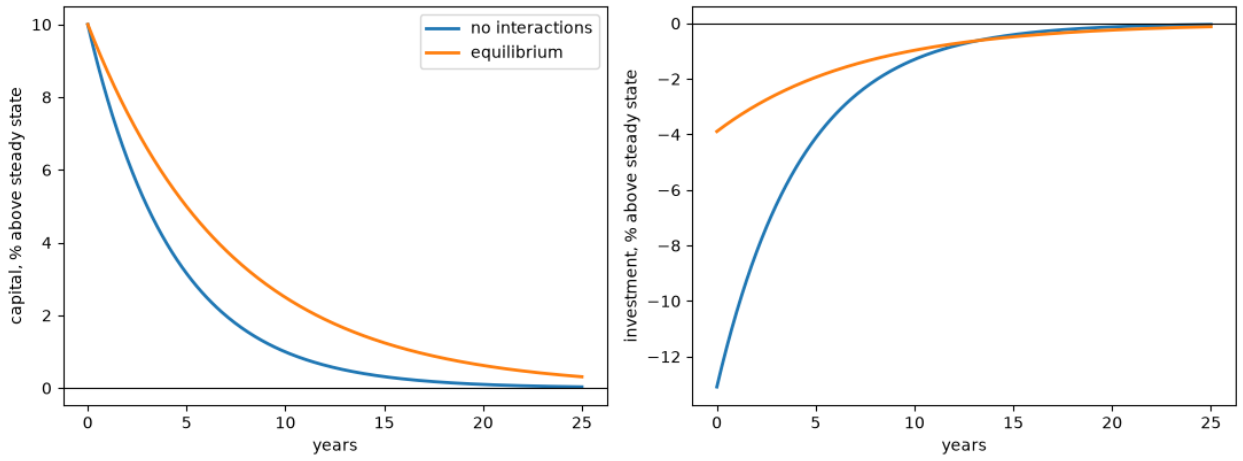

Fig. 130.4: Transition paths of capital and investment

The right panel is the industry's investment response, and it is where the two interactions show up most clearly.

A firm that ignored the industry would cut investment on impact by thirteen percent of its steady-state level; in equilibrium the cut is under four percent, and it is undone much more slowly.

The costate $\beta_1(t) + \bar{\beta}_2 x$ that supports these paths is the marginal value of installed capital, measured as a deviation from its steady-state value; divided by the price of investment goods, it is Tobin's marginal q, not to be confused with the curvature q.

Optimal Growth Under Uncertainty and Tobin's q studies the marginal value of capital when the irreversibility constraint $i \geq 0$ sometimes binds, and shows that the value function remains differentiable even then; the quadratic approximation here sets that nonlinearity aside.

130.9 Aggregate shocks and identification

Now add a shock that hits everyone at once.

Let $\mathcal{J}$ be a compensated jump process, the difference between two independent Poisson processes with equal intensities, so that its increments have mean zero, and suppose

$$dx = (B\alpha - Ax)dt + \Sigma^{1/2} dW + \Upsilon \, d\mathcal{J}.$$

A common Brownian motion would work the same way.

With common noise the value function must keep track of the aggregate state as well as the individual state, so it becomes $v(x, X)$.

Nevertheless, matching coefficients in the recursive HJB equation delivers a result worth emphasizing.

Proposition 130.9.1

With common noise, the matrix P governing aggregate dynamics solves the *same* equilibrium Riccati equation as before.

This is a certainty-equivalence result of the kind familiar from linear quadratic control.

The decomposition (130.10) continues to hold, with $\Upsilon \, d\mathcal{J}$ added to the law of motion of X, and the common shock cancels from the law of motion of an agent's deviation z.

130.9.1 The missing intercept

Researchers often estimate how agents respond to shocks from panel data with time fixed effects, which control for aggregate conditions.

Such regressions identify how an agent responds to her position relative to others, but not the common response of all agents to an aggregate shift, which the time effects absorb; this is the "missing intercept" [Wolf, 2023].

The decomposition (130.10) makes the point exact.

Writing an agent's action in terms of her own state and the mean gives

$$\alpha_{it} = U_{\alpha,z} \, x_{it} + \left(U_{\alpha,X} - U_{\alpha,z}\right) X_t, \qquad U_{\alpha,X} \equiv (\Gamma + \Theta_{\mathcal{A}})^{-1} B^\top P, \qquad U_{\alpha,z} \equiv \Gamma^{-1} B^\top \bar{\beta}_2.$$

A regression of actions on states with time effects estimates the slope $U_{\alpha,z}$, which contains no interaction matrix, while the time effects absorb $(U_{\alpha,X} - U_{\alpha,z})X_t$, which contains all of them.

Proposition 130.9.2

Data on $x(t) - X(t)$ and $\alpha(t) - \mathcal{A}(t)$ contain no information about Θ_X or $\Theta_{\mathcal{A}}$.

> **Note**
>
> Removing time effects from micro data removes exactly the variation that identifies strategic interaction.

To see this in the capital example, consider two industries that are identical except for the strength of complementarity in states: one has $\theta_X = 0$, and the other has twice the calibrated amount.

Let's compute the two policy coefficients for each.

```
def capital_policy(θ_X, θ_A=θ_A_c):
    "Coefficients of investment on X and on z in the capital example."
    one = np.array([[1.0]])
    P_s = mfg_riccati(δ_c*one, δ_c*one, (q_c + θ_X)*one, (γ_c + θ_A)*one, ρ_c)[0, 0]
    β2_s = mfg_riccati(δ_c*one, δ_c*one, q_c*one, γ_c*one, ρ_c)[0, 0]
    return δ_c*P_s/(γ_c + θ_A), δ_c*β2_s/γ_c

industries = (('θ_X = 0', 0.0), ('θ_X = 2 × calibrated', 2*θ_X_c))
print(f"{'':>22}{'slope on z':>12}{'slope on X':>12}")
for label, θ_X_use in industries:
    U_αX, U_αz = capital_policy(θ_X_use)
    print(f"{label:>22}{U_αz:>12.4f}{U_αX:>12.4f}")
```

```
                       slope on z  slope on X
              θ_X = 0     -1.3093     -0.5786
 θ_X = 2 × calibrated     -1.3093     -0.1752
```

The slope on a firm's deviation from the mean is the same in the two industries, and only the slope on the industry mean differs.

Now let's simulate panels of 400 firms from the two industries, using the same shocks for both.

Both start at their steady state with some dispersion across firms, and both are hit at $t = 2$ by a common shock that lowers every firm's capital by ten percent.

```
rng = np.random.default_rng(0)
N, T, dt, σ = 400, 20.0, 0.02, 0.05
steps = int(T/dt)
dW = rng.normal(size=(steps, N))*np.sqrt(dt)      # the same draws for both
x0 = 0.05*rng.normal(size=N)
t_sim = np.arange(steps)*dt

fig, axes = plt.subplots(1, 2, figsize=(11, 4.2))
deviations = []
for k, (label, θ_X_sim) in enumerate(industries):
    U_αX, U_αz = capital_policy(θ_X_sim)
    x = x0.copy()
    X_path, z_path = np.empty(steps), np.empty(steps)
    for s in range(steps):
        if s == int(2.0/dt):
            x = x - 0.10                          # common shock
        X = x.mean()
        α = U_αX*X + U_αz*(x - X)
        X_path[s], z_path[s] = X, x[0] - X
        x = x + δ_c*(α - x)*dt + σ*dW[s]
    deviations.append(z_path)
    tex_label = label.replace('θ_X', r'$\theta_X$')
    axes[0].plot(t_sim, 100*z_path, lw=2.5 - 1.5*k, ls='-' if k == 0 else '--',
```

(continues on next page)

(continued from previous page)

```
                  label=tex_label)
    axes[1].plot(t_sim, 100*X_path, lw=2, label=tex_label)

axes[0].set_title("one firm's deviation from the industry mean")
axes[1].set_title('industry mean')
for ax in axes:
    ax.set_xlabel('years')
    ax.set_ylabel('percent')

print("demeaned paths identical:", np.allclose(*deviations))
```

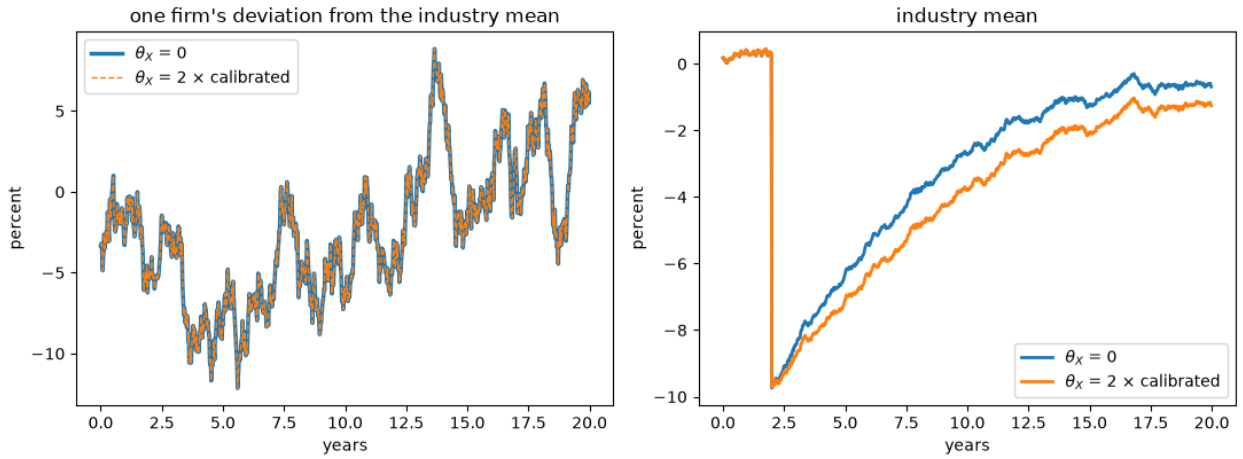

Fig. 130.5: Simulated panels from two industries

```
demeaned paths identical: True
```

The left panel plots one firm's deviation from its industry mean in each economy, and the two lines coincide exactly, so a regression on demeaned data would return identical estimates for the two industries.

The industry means in the right panel differ: after the common shock, the industry with stronger complementarity returns to its steady state more slowly.

The small wiggles in the industry means come from averaging the idiosyncratic shocks of only 400 firms.

The demeaned paths coincide by construction, because the slope on z does not involve θ_X, so the simulation illustrates *Proposition 130.9.2* rather than testing it: it shows what an econometrician would see.

130.9.2 What aggregate data reveal

Aggregate data, by contrast, do carry information about strategic interaction, and can be combined with micro data to recover it.

Collect the four reduced-form matrices that link the aggregate state, the deviations from it and the actions:

$$U_{\dot{X},X} = DP - A, \qquad U_{\dot{z},z} = B\Gamma^{-1}B^\top\bar{\beta}_2 - A, \qquad U_{\alpha,X} = (\Gamma + \Theta_{\mathcal{A}})^{-1}B^\top P, \qquad U_{\alpha,z} = \Gamma^{-1}B^\top\bar{\beta}_2.$$

Proposition 130.9.3

Suppose $\Theta_{\mathcal{A}}$, Γ and ρ are known, that D and Σ are nonsingular, and that $\mathbb{E}[X(t)X(t)^\top]$ is nonsingular for some $t > 0$.

1. If Q, A and B are also known, a time series for X identifies Θ_X.
2. If B is also known, time series for X, z and $\mathcal{A}$ identify Q, Θ_X and A.
3. If $n = k$ and $U_{\alpha,z} - U_{\alpha,X}$ is nonsingular, time series for X, z, α and $\mathcal{A}$ identify Q, Θ_X, A and B.

In every case $\Theta_{\mathcal{A}}$ must be known.

Exercise 130.14.4 walks through the recovery, and shows why Θ_X and $\Theta_{\mathcal{A}}$ cannot be told apart without a normalization.

130.10 Persistence

How do the interactions change aggregate adjustment when $n > 1$?

Throughout this section we follow Alvarez and Argente [2026] and assume that $Q + \Theta_X$ and $\Gamma + \Theta_{\mathcal{A}}$ are positive definite in every economy we compare.

As the scalar case showed, the comparative statics for actions can reverse sign without that assumption.

Proposition 130.10.1

Compare two economies that differ in one interaction matrix only.

1. More complementarity in states makes the stabilizing solution P less negative definite and raises the trace of the closed-loop matrix.
2. More complementarity in actions also makes P less negative definite, but lowers the trace of the closed-loop matrix.

The two kinds of interaction move P in the same direction and the trace in opposite directions because they reach the closed-loop matrix $DP - A$ in different ways.

States act only through P.

Actions also change $D = B(\Gamma + \Theta_{\mathcal{A}})^{-1}B^\top$: more complementarity in actions raises D, so agents respond more strongly to a given marginal value, and the net effect lowers the trace.

The trace is the sum of the eigenvalues, and also the rate at which a set of initial aggregate states contracts in volume, so in a stable equilibrium the first force slows aggregate adjustment on average and the second speeds it up.

Let's check the first part in our two-dimensional example.

```
print(f"{'scale on Θ_X':>14}{'trace':>10}   eigenvalues")
for scale in (0.0, 0.5, 1.0, 1.5):
    P_s = mfg_riccati(A, B, Q + scale*Θ_X, Γ + Θ_A, ρ)
    U_s = closed_loop(A, B, Γ + Θ_A, P_s)
    print(f"{scale:>14}{np.trace(U_s):>10.4f}   {np.linalg.eigvals(U_s).real.round(4)}
 ↪")
```

```
  scale on Θ_X     trace   eigenvalues
           0.0   -1.7933   [-0.9956 -0.7977]
           0.5   -1.6747   [-0.9485 -0.7262]
           1.0   -1.5448   [-0.9025 -0.6423]
           1.5   -1.3988   [-0.857  -0.5418]
```

Raising the scale makes Θ_X more negative, that is, complementarity stronger, and the trace rises as claimed.

A rise in the trace says that the sum of the eigenvalues moves, not that each of them does.

Alvarez and Argente [2026] give a two-dimensional example in which a strict Loewner ordering of the Riccati solutions coexists with eigenvalues that move in opposite directions.

It sets $\rho = 0$, holds D fixed, and compares two effective state curvatures Q_1 and Q_2 with $Q_2 - Q_1$ positive definite, so that the first economy has more complementarity in states.

```
A_ce = np.array([[1.0, 2.0],
                 [2.0, 5.0]])
D_ce = np.array([[1.0, -3.0],
                 [-3.0, 10.0]])
Q_1 = np.array([[2.0, -1.0],
                [-1.0, 1.0]])
Q_2 = np.array([[3.0, 5.0],
                [5.0, 51.0]])

# with B = I, D = (Γ + Θ_A)^{-1}
Γ_ce = np.linalg.inv(D_ce)
P_ce = {}
for label, Q_i in (('Q_1', Q_1), ('Q_2', Q_2)):
    P_ce[label] = mfg_riccati(A_ce, np.eye(2), Q_i, Γ_ce, 0.0)
    U_i = closed_loop(A_ce, np.eye(2), Γ_ce, P_ce[label])
    print(f"{label}: trace {np.trace(U_i):.2f}, "
          f"closed-loop eigenvalues {np.sort(np.linalg.eigvals(U_i).real).round(2)}")

print("\neigenvalues of P_1 - P_2:", np.linalg.eigvalsh(P_ce['Q_1'] - P_ce['Q_2']).
 ↪round(3))
print("A and D commute:", np.allclose(A_ce @ D_ce, D_ce @ A_ce))
```

```
Q_1: trace -9.57, closed-loop eigenvalues [-6.55 -3.02]
Q_2: trace -24.25, closed-loop eigenvalues [-22.68  -1.56]

eigenvalues of P_1 - P_2: [0.281 1.833]
A and D commute: False
```

The Riccati solutions are strictly ordered, $P_1 \succ P_2$, and the first economy has the larger trace, as the theory requires, but only one of its eigenvalues is larger: one mode becomes more persistent and the other less.

What goes wrong is that A and D do not commute.

Since both are symmetric here, that is the same as saying that $D^{-1}A$ is not symmetric, so the closed-loop matrix $DP - A$ need not be similar to a symmetric matrix.

Two restrictions repair this.

Proposition 130.10.2

Hold D fixed and suppose that $D^{-1}A$ is symmetric.

Then more complementarity in states raises every eigenvalue of the closed-loop matrix.

The reason is that $DP - A = D(P - D^{-1}A)$ is similar to the symmetric matrix $D^{1/2}(P - D^{-1}A)D^{1/2}$, whose eigenvalues rise one by one when P rises in the Loewner order.

Proposition 130.10.3

Suppose $A = aI$.

Then the eigenvalues of the closed-loop matrix are real and given by

$$\lambda_j = \frac{\rho}{2} - \sqrt{\left(\frac{\rho}{2} + a\right)^2 + \mu_j},$$

where μ_j are the eigenvalues of $D^{1/2}(Q + \Theta_X)D^{1/2}$.

So more complementarity in states raises every λ_j, more complementarity in actions lowers every λ_j, and mode j is stable if and only if $\mu_j + a(a + \rho) > 0$.

The second result is still genuinely multidimensional.

Aggregate dynamics do decouple into scalar modes, but the coordinates that achieve this mix the eigenvectors of $Q + \Theta_X$ and D, and they differ from the coordinates that decouple individual dynamics, so the model as a whole does not separate into independent one-dimensional decisions.

Exercise 130.14.5 asks you to measure how often eigenvalue-by-eigenvalue monotonicity fails in random economies, and to confirm *Proposition 130.10.2*.

130.11 Multiproduct price setting with Kimball demand

Our second example is multidimensional, and it delivers a surprise.

Alvarez and Argente [2026] study a continuum of "stores", each selling n products with constant marginal costs c_j.

Products within a store are aggregated by a CES price index with elasticity $\bar{\eta}_d$, and stores are aggregated by a symmetric Kimball aggregator [Kimball, 1995].

Let $\eta_D(y)$ be the elasticity of a store's demand with respect to its relative price y, and let $\bar{\eta}_D > 1$ and $\bar{\eta}'_D$ denote its level and its derivative at the symmetric point $y = 1$.

The derivative $\bar{\eta}'_D$ is the **superelasticity** of demand, and it is the reason Kimball demand is so widely used in models of price setting: a positive superelasticity means that a store which raises its prices above the average faces a more elastic demand, which discourages it from moving away from the crowd.

That is strategic complementarity in prices, and it is the mechanism that Klenow and Willis [2016] and much of the subsequent literature rely on for real rigidity.

Writing x and X for log deviations (equivalently, to first order, percentage deviations) of a store's prices and of the average store's prices from the flexible-price level $\bar{p}_i = \bar{c}_i\bar{\eta}_D/(\bar{\eta}_D - 1)$, and $\bar{s}$ for the vector of steady-state expenditure shares,

the curvature matrices are

$$\begin{aligned} Q &= (\bar{\eta}_D - 1)\left[\left(\bar{\eta}_D - \bar{\eta}_d + \frac{\bar{\eta}'_D}{\bar{\eta}_D - 1}\right)\bar{s}\bar{s}^\top + \bar{\eta}_d \operatorname{diag}(\bar{s})\right], \\ \Theta_X &= -\bar{\eta}'_D\,\bar{s}\bar{s}^\top, \\ Q + \Theta_X &= (\bar{\eta}_D - 1)\left[(\bar{\eta}_D - \bar{\eta}_d)\bar{s}\bar{s}^\top + \bar{\eta}_d \operatorname{diag}(\bar{s})\right]. \end{aligned} \tag{130.16}$$

Stare at the third line.

The superelasticity appears in Q and in Θ_X, but it *cancels* from $Q + \Theta_X$.

By *Proposition 130.5.1*, the sum $Q + \Theta_X$ is the only channel through which either matrix reaches aggregate dynamics.

Actions are price changes, and stores pay quadratic Rotemberg costs of changing prices.

The matrix Γ lets that cost depend on which bundle of prices is changed, with negative off-diagonal elements representing economies of scope in repricing of the kind emphasized by Midrigan [2011] and Alvarez and Lippi [2014].

There is no interaction through aggregate actions, so $\Theta_{\mathcal{A}} = 0$.

With constant marginal costs $A = 0$, and to obtain a nontrivial drift we follow Alvarez and Argente [2026] in letting marginal costs, and hence flexible prices, grow at a common rate π.

Let $\bar{p}_i(t)$ be the trend price, which grows at rate π, and measure a price by its percentage deviation from trend, $x_i = p_i/\bar{p}_i - 1$, and the action by the change in the price minus the change in the trend, in units of the trend price, $\alpha_i = (\dot{p}_i - \dot{\bar{p}}_i)/\bar{p}_i$.

Then $\dot{x}_i = \alpha_i - \pi x_i$, so $A = \pi I$: a store that leaves its price change equal to the trend change sees its gap from trend eroded at rate π.

```
def kimball(η_d, η_D, η_D_prime, s):
    "Curvature and state-interaction matrices under Kimball demand."
    s = np.asarray(s, dtype=float)
    ss = np.outer(s, s)
    Q = (η_D - 1)*((η_D - η_d + η_D_prime/(η_D - 1))*ss + η_d*np.diag(s))
    Θ_X = -η_D_prime*ss
    return Q, Θ_X

s_bar = np.array([0.5, 0.3, 0.2])        # three products, unequal shares
η_d, η_D = 6.0, 4.0                      # within-store and across-store elasticities
ρ_K, π_K = 0.04, 0.02                    # discount rate and cost inflation

n_K = len(s_bar)
A_K = π_K*np.eye(n_K)
B_K = np.eye(n_K)
Γ_K = 20.0*(np.eye(n_K) - 0.25*(np.ones((n_K, n_K)) - np.eye(n_K)))

print("Rotemberg cost matrix Γ =\n", Γ_K)
print("\neigenvalues of Γ:", np.linalg.eigvalsh(Γ_K).round(4))
```

```
Rotemberg cost matrix Γ =
 [[20. -5. -5.]
 [-5. 20. -5.]
 [-5. -5. 20.]]

eigenvalues of Γ: [10. 25. 25.]
```

130.11.1 The superelasticity and aggregate dynamics

Now sweep the superelasticity across a wide range, including a negative value, and watch what changes and what does not.

```
print(f"{'η_D'':>6}  {'eigenvalues of Q':>28}  {'eigenvalues of Q + Θ_X':>28}")
for η_Dp in (-3.0, 0.0, 3.0, 10.0):
    Q_K, Θ_K = kimball(η_d, η_D, η_Dp, s_bar)
    print(f"{η_Dp:>6}  {str(np.linalg.eigvalsh(Q_K).round(3)):>28}"
          f"  {str(np.linalg.eigvalsh(Q_K + Θ_K).round(3)):>28}")
```

```
  η_D'              eigenvalues of Q        eigenvalues of Q + Θ_X
  -3.0           [2.598 4.5   7.482]           [3.127 4.766 7.827]
   0.0           [3.127 4.766 7.827]           [3.127 4.766 7.827]
   3.0           [3.435 5.096 8.329]           [3.127 4.766 7.827]
  10.0         [ 3.714  5.694 10.112]           [3.127 4.766 7.827]
```

The own-curvature matrix Q moves a great deal, and Θ_X moves with it, but the effective curvature does not move at all.

Aggregate price dynamics are therefore invariant to the superelasticity.

```
print(f"{'η_D'':>6}  {'aggregate eigenvalues':>34}  {'individual eigenvalues':>34}")
for η_Dp in (-3.0, 0.0, 3.0, 10.0):
    Q_K, Θ_K = kimball(η_d, η_D, η_Dp, s_bar)
    P_K = mfg_riccati(A_K, B_K, Q_K + Θ_K, Γ_K, ρ_K)
    β2_K = mfg_riccati(A_K, B_K, Q_K, Γ_K, ρ_K)
    ev_agg = np.sort(np.linalg.eigvals(closed_loop(A_K, B_K, Γ_K, P_K)).real)
    ev_ind = np.sort(np.linalg.eigvals(closed_loop(A_K, B_K, Γ_K, β2_K)).real)
    print(f"{η_Dp:>6}  {str(ev_agg.round(4)):>34}  {str(ev_ind.round(4)):>34}")
```

```
  η_D'              aggregate eigenvalues             individual eigenvalues
  -3.0           [-0.6527 -0.4882 -0.3836]           [-0.5813 -0.4752 -0.3815]
   0.0           [-0.6527 -0.4882 -0.3836]           [-0.6527 -0.4882 -0.3836]
   3.0           [-0.6527 -0.4882 -0.3836]           [-0.7234 -0.4928 -0.3844]
  10.0           [-0.6527 -0.4882 -0.3836]           [-0.8713 -0.4966 -0.3853]
```

The left block of numbers is identical in every row, and the right block is not.

The superelasticity changes how an individual store behaves without changing how the industry behaves, just as market power did in the capital accumulation example.

Almost all of the movement is in a single mode, because Θ_X is rank one and acts only through the store's price index $\bar{s}^\top x$.

The remaining modes, which involve relative prices within the store, barely move.

Because $A_K = \pi I$, the aggregate eigenvalues are also given in closed form by *Proposition 130.10.3*, with μ_j the eigenvalues of $(\Gamma + \Theta_{\mathcal{A}})^{-1}(Q + \Theta_X)$, which equal those of $D^{1/2}(Q + \Theta_X)D^{1/2}$ when $B = I$.

Let's confirm that the formula matches the solver.

```
Q_K, Θ_K = kimball(η_d, η_D, 3.0, s_bar)
P_K = mfg_riccati(A_K, B_K, Q_K + Θ_K, Γ_K, ρ_K)
ev_solver = np.sort(np.linalg.eigvals(closed_loop(A_K, B_K, Γ_K, P_K)).real)
μ = np.linalg.eigvals(np.linalg.solve(Γ_K, Q_K + Θ_K)).real
ev_formula = np.sort(ρ_K/2 - np.sqrt((ρ_K/2 + π_K)**2 + μ))
print(f"largest gap between formula and solver: {np.abs(ev_solver - ev_formula).
↪max():.1e}")
```

```
largest gap between formula and solver: 5.6e-16
```

130.11.2 Static complementarity

It is worth seeing how much static complementarity we are varying.

Maximizing the static profit function gives the best response $x^*(X) = -Q^{-1}\Theta_X X$, and Alvarez and Argente [2026] show that

$$\frac{\partial x_i^*(X)}{\partial X_j} = \bar{s}_j \frac{\kappa}{1+\kappa}, \qquad \kappa \equiv \frac{\bar{\eta}_D'}{(\bar{\eta}_D - 1)\bar{\eta}_D}. \tag{130.17}$$

We call the row sum of this matrix, $\kappa/(1+\kappa)$, **static pass-through**: it is the response of a store's prices to a uniform one percent rise in its competitors' prices.

The next cell confirms the formula and reports pass-through for each superelasticity.

```
print(f"{'η_D'':>6}{'pass-through':>14}   best response matrix, first row")
for η_Dp in (-3.0, 0.0, 3.0, 10.0):
    Q_K, Θ_K = kimball(η_d, η_D, η_Dp, s_bar)
    BR = -np.linalg.solve(Q_K, Θ_K)
    κ = η_Dp/((η_D - 1)*η_D)
    BR_closed = κ/(1 + κ)*np.outer(np.ones(n_K), s_bar)
    assert np.allclose(BR, BR_closed)
    print(f"{η_Dp:>6}{BR.sum(axis=1)[0]:>14.4f}   {BR[0].round(4)}")

print("\nΘ_X symmetric:          ", np.allclose(Θ_K, Θ_K.T))
print("best response symmetric:", np.allclose(BR, BR.T))
```

```
  η_D'  pass-through   best response matrix, first row
  -3.0       -0.3333   [-0.1667 -0.1    -0.0667]
   0.0        0.0000   [0. 0. 0.]
   3.0        0.2000   [0.1  0.06 0.04]
  10.0        0.4545   [0.2273 0.1364 0.0909]

Θ_X symmetric:           True
best response symmetric: False
```

Static pass-through runs from -33% to $+45\%$ across these rows, and it changes sign with the superelasticity, yet every one of these economies has exactly the same aggregate dynamics.

Note

Stronger static complementarity need not mean more aggregate persistence.

What matters for aggregate dynamics is the effective curvature $Q + \Theta_X$, not the interaction Θ_X or the static best responses on their own.

Notice also that the best response matrix is *not* symmetric, because shares differ across products, while Θ_X is symmetric, as promised in the description of the environment.

130.11.3 Aggregate and individual price paths

The decomposition (130.10) splits a store's prices into the industry average X and its own deviation $z = x - X$.

The first follows the equilibrium matrix P, the second the single-agent matrix $\bar{\beta}_2$.

So the invariance we found should show up as identical paths for the industry and different paths for a store that is out of line.

```
t_K = np.linspace(0, 8, 200)
shock = 0.10*np.ones(n_K)       # ten percent above target, all products

fig, axes = plt.subplots(1, 2, figsize=(11, 4.2))
for k, η_Dp in enumerate((-3.0, 0.0, 3.0, 10.0)):
    Q_K, Θ_K = kimball(η_d, η_D, η_Dp, s_bar)
    P_K = mfg_riccati(A_K, B_K, Q_K + Θ_K, Γ_K, ρ_K)
    β2_K = mfg_riccati(A_K, B_K, Q_K, Γ_K, ρ_K)
    U_agg_K = closed_loop(A_K, B_K, Γ_K, P_K)
    U_ind_K = closed_loop(A_K, B_K, Γ_K, β2_K)
    agg = np.array([s_bar @ expm(U_agg_K*t) @ shock for t in t_K])
    dev = np.array([s_bar @ expm(U_ind_K*t) @ shock for t in t_K])
    label = f"$\\bar\\eta_D' = {η_Dp}$"
    # decreasing line widths, so that four coincident curves remain visible
    axes[0].plot(t_K, 100*agg, lw=6 - 1.5*k, label=label)
    axes[1].plot(t_K, 100*dev, lw=2, label=label)

axes[0].set_title('industry price index, $\\bar s^\\top X(t)$')
axes[1].set_title("one store's deviation, $\\bar s^\\top z(t)$")
for ax in axes:
    ax.set_xlabel('years')
    ax.set_ylabel('percent above target')
    ax.legend()
plt.tight_layout()
plt.show()
```

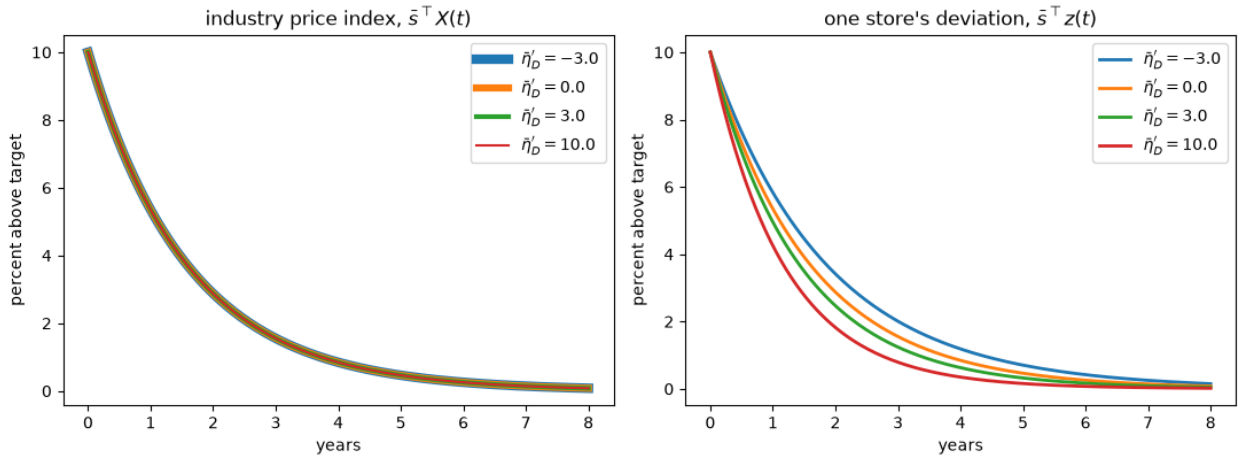

Fig. 130.6: Industry and store price paths

The four curves in the left panel lie exactly on top of one another.

The four curves in the right panel do not: the higher the superelasticity, the faster a store closes a gap between its own

prices and the industry's.

Individual and aggregate price flexibility are governed by different objects, and only the individual one responds to the superelasticity.

130.12 The planner

Is the equilibrium speed of adjustment efficient?

To answer, we compare it with the allocation of a utilitarian planner, who chooses an action $\alpha(x,t)$ for every agent and date to maximize the discounted value of the cross-sectional average of the period return, subject to the Kolmogorov forward equation.

A second-order approximation to a general return also contains terms in the aggregates alone,

$$-\tfrac{1}{2}X^\top \Lambda_X X - \tfrac{1}{2}\mathcal{A}^\top \Lambda_{\mathcal{A}} \mathcal{A},$$

with Λ_X and $\Lambda_{\mathcal{A}}$ symmetric.

An individual takes X and $\mathcal{A}$ as given, so these terms do not affect her choices or the decentralized equilibrium, and we left them out of (130.1).

The planner cannot ignore them, and its period objective is

$$-\tfrac{1}{2}\int x^\top Q x\, m(x)dx - X^\top\left(\Theta_X + \tfrac{1}{2}\Lambda_X\right)X - \tfrac{1}{2}\int \alpha(x)^\top \Gamma \alpha(x)\, m(x)dx - \mathcal{A}^\top\left(\Theta_{\mathcal{A}} + \tfrac{1}{2}\Lambda_{\mathcal{A}}\right)\mathcal{A},$$

where $X = \int x\, m(x)dx$ and $\mathcal{A} = \int \alpha(x) m(x)dx$.

The planner internalizes both sides of each interaction.

Moving one agent's state changes her own payoff and, through X, everybody else's, so the derivative of $-X^\top \Theta_X X$ with respect to the density contributes $-X^\top(\Theta_X + \Theta_X^\top)x$, twice what an individual takes into account.

The aggregate-only term adds $-X^\top \Lambda_X x$, and the same reasoning applies to actions.

Proposition 130.12.1

Whenever the planner's problem has a finite optimum, the planner's allocation coincides with the decentralized equilibrium of an economy whose interaction matrices are $\Theta_X + \Theta_X^\top + \Lambda_X$ and $\Theta_{\mathcal{A}} + \Theta_{\mathcal{A}}^\top + \Lambda_{\mathcal{A}}$.

With symmetric interactions these are $2\Theta_X + \Lambda_X$ and $2\Theta_{\mathcal{A}} + \Lambda_{\mathcal{A}}$, and the planner's Riccati equation is

$$P^{\text{pl}} B(\Gamma + 2\Theta_{\mathcal{A}} + \Lambda_{\mathcal{A}})^{-1} B^\top P^{\text{pl}} = Q + 2\Theta_X + \Lambda_X + \rho P^{\text{pl}} + P^{\text{pl}} A + A^\top P^{\text{pl}}.$$

A finite optimum exists if $Q + 2\Theta_X + \Lambda_X$ and $\Gamma + 2\Theta_{\mathcal{A}} + \Lambda_{\mathcal{A}}$ are positive definite.

Because each interaction matrix appears together with its transpose, the planner never needs them to be symmetric.

Symmetry is a restriction we need for the decentralized equilibrium, not for the planner.

The planner's curvatures have a reading that complements the one in *Effective curvature*.

When everybody moves together, so that $x = X$, the state part of the return including the aggregate-only term is

$$-\tfrac{1}{2}X^\top Q X - X^\top \Theta_X X - \tfrac{1}{2}X^\top \Lambda_X X = -\tfrac{1}{2}X^\top(Q + 2\Theta_X + \Lambda_X)X.$$

So $Q + \Theta_X$ is the slope of an agent's *marginal* return when everybody moves together, while $Q + 2\Theta_X + \Lambda_X$ is the curvature of the *total* return when everybody moves together.

The equilibrium responds to the first and the planner to the second, and the same is true of actions.

The comparative statics of *Persistence* now apply directly, under the assumptions stated there.

Internalizing complementarity in states raises the trace of the closed-loop matrix, which slows aggregate adjustment on average, while internalizing complementarity in actions does the opposite.

The aggregate-only terms can reinforce or offset these forces.

A negative semi-definite Λ_X or a positive semi-definite $\Lambda_{\mathcal{A}}$ slows adjustment further, and the opposite signs speed it up.

So the planner may adjust more slowly or more quickly than the decentralized equilibrium, and statements about individual eigenvalues need the restrictions of *Proposition 130.10.2* or *Proposition 130.10.3*.

Our two-dimensional example has no aggregate-only terms, so we set $\Lambda_X = \Lambda_{\mathcal{A}} = 0$ when we compute its planner's allocation.

```
P_planner = mfg_riccati(A, B, Q + 2*Θ_X, Γ + 2*Θ_A, ρ)
U_pl = closed_loop(A, B, Γ + 2*Θ_A, P_planner)

print("individual eigenvalues:", np.sort(np.linalg.eigvals(U_ind).real).round(4))
print("aggregate eigenvalues: ", np.sort(np.linalg.eigvals(U_agg).real).round(4))
print("planner eigenvalues:   ", np.sort(np.linalg.eigvals(U_pl).real).round(4))
```

```
individual eigenvalues: [-1.0698 -0.8321]
aggregate eigenvalues:  [-0.9025 -0.6423]
planner eigenvalues:    [-0.7786 -0.4039]
```

With complementarity in states and substitutability in actions, both of which the planner internalizes, every planner eigenvalue is closer to zero than the corresponding equilibrium eigenvalue, so the planner's allocation is the most persistent of the three.

Exercise 130.14.6 compares the planner with the equilibrium in other configurations of the interactions.

130.12.1 The planner in the capital accumulation example

The capital accumulation example does have aggregate-only terms, and they change the answer.

Alvarez and Argente [2026] do not work out the planner for this example, so we do it here.

A second-order expansion of the firm's return produces terms in K and I alone, which did not matter for the firm's problem.

They are

$$\Lambda_X = -\frac{\bar{k}^2 \Pi_{KK}}{\bar{\Pi}} = \frac{\nu}{\eta}\left(1 - \frac{\nu}{\eta}\right), \qquad \Lambda_{\mathcal{A}} = \frac{\bar{\imath}^3\, \mathcal{P}''(\bar{\imath})}{\bar{\Pi}} = \theta_{\mathcal{A}}\, \frac{\bar{\imath}\, \mathcal{P}''(\bar{\imath})}{\mathcal{P}'(\bar{\imath})},$$

where the second comes from the term $\frac{1}{2}\bar{\imath}\,\mathcal{P}''(\bar{\imath})(I - \bar{\imath})^2$ in the expansion of investment spending $i\,\mathcal{P}(I)$.

Adding the state interaction twice gives a clean result,

$$q + 2\theta_X + \Lambda_X = \nu(1 - \nu),$$

which is the slope of the dashed line in Fig. 130.2, the marginal revenue of the whole industry when every firm holds the same capital.

The equilibrium's effective curvature $\frac{\eta-1}{\eta}\nu(1-\nu)$ is smaller by the factor $(\eta - 1)/\eta$.

A firm's marginal revenue is only $(\eta - 1)/\eta$ of the marginal value of its output, so an industry-wide capital gap changes the private return to investing by less than it changes the value of the industry's output.

For actions, the constant-elasticity supply curve of the calibration gives $\bar{i}\,\mathcal{P}''(\bar{i})/\mathcal{P}'(\bar{i}) = 1/\varepsilon_s - 1$, so the planner's action curvature is $\gamma + (1 + 1/\varepsilon_s)\theta_{\mathcal{A}}$.

That exceeds the equilibrium's $\gamma + \theta_{\mathcal{A}}$, because the planner recognizes that a burst of industry investment raises the price that every firm pays.

So the two sides of the planner's problem pull in opposite directions: on states the planner is faster than the equilibrium, on actions slower.

Let's compute the net effect, and also what we would have found had we doubled the interactions and ignored the aggregate-only terms.

```
def cap_Λ_X(η, ν):
    "Aggregate-only state curvature in the capital accumulation example."
    return ν/η*(1 - ν/η)

Λ_X_c = cap_Λ_X(η_c, ν_c)
Λ_A_c = (1/ε_s_c - 1)*θ_A_c

print(f"Λ_X = {Λ_X_c:.4f},  Λ_A = {Λ_A_c:.4f}")
print(f"q + 2θ_X + Λ_X = {q_c + 2*θ_X_c + Λ_X_c:.4f},  ν(1 - ν) = {ν_c*(1 - ν_c):.4f}
↪")

planner_cases = {'no interactions': (0.0,              0.0),
                 'equilibrium':     (θ_X_c,            θ_A_c),
                 'doubling only':   (2*θ_X_c,          2*θ_A_c),
                 'planner':         (2*θ_X_c + Λ_X_c,  2*θ_A_c + Λ_A_c)}

print(f"\n{'':>16}{'λ':>10}{'half-life':>12}{'investment on impact':>23}")
for label, (tx, ta) in planner_cases.items():
    λ_case = scalar_λ(ρ_c, δ_c, δ_c, q_c, γ_c, tx, ta)
    impact = 100*X0_c*(λ_case + δ_c)/δ_c
    print(f"{label:>16}{λ_case:>10.4f}{half_life(λ_case):>12.2f}{impact:>22.2f}%")
```

```
Λ_X = 0.1444,  Λ_A = -0.0669
q + 2θ_X + Λ_X = 0.2100,  ν(1 - ν) = 0.2100

                        λ   half-life   investment on impact
 no interactions   -0.2309        3.00                -13.09%
     equilibrium   -0.1389        4.99                 -3.89%
   doubling only   -0.1109        6.25                 -1.09%
         planner   -0.1438        4.82                 -4.38%
```

The last column is the change in industry investment, relative to its steady-state level, when the capital stock starts ten percent above its steady state.

At this calibration the state side wins narrowly.

The planner's half-life is 4.8 years against the equilibrium's 5.0, and the planner cuts investment by more on impact.

Doubling the interactions without the aggregate-only terms would have given the opposite answer, a half-life above six years.

Doubling θ_X strengthens the complementarity in states, while Λ_X more than undoes it.

The next figure shows the corresponding paths of investment.

```
fig, ax = plt.subplots(figsize=(8, 4.5))
for label in ('equilibrium', 'doubling only', 'planner'):
    tx, ta = planner_cases[label]
```

(continues on next page)

(continued from previous page)

```
    λ_case = scalar_λ(ρ_c, δ_c, δ_c, q_c, γ_c, tx, ta)
    ls = '--' if label == 'doubling only' else '-'
    ax.plot(t_c, 100*X0_c*(λ_case + δ_c)/δ_c*np.exp(λ_case*t_c), lw=2, ls=ls,␣
↪label=label)
ax.axhline(0, color='k', lw=0.8)
ax.set_xlabel('years')
ax.set_ylabel('investment, % above steady state')
ax.legend()
plt.tight_layout()
plt.show()
```

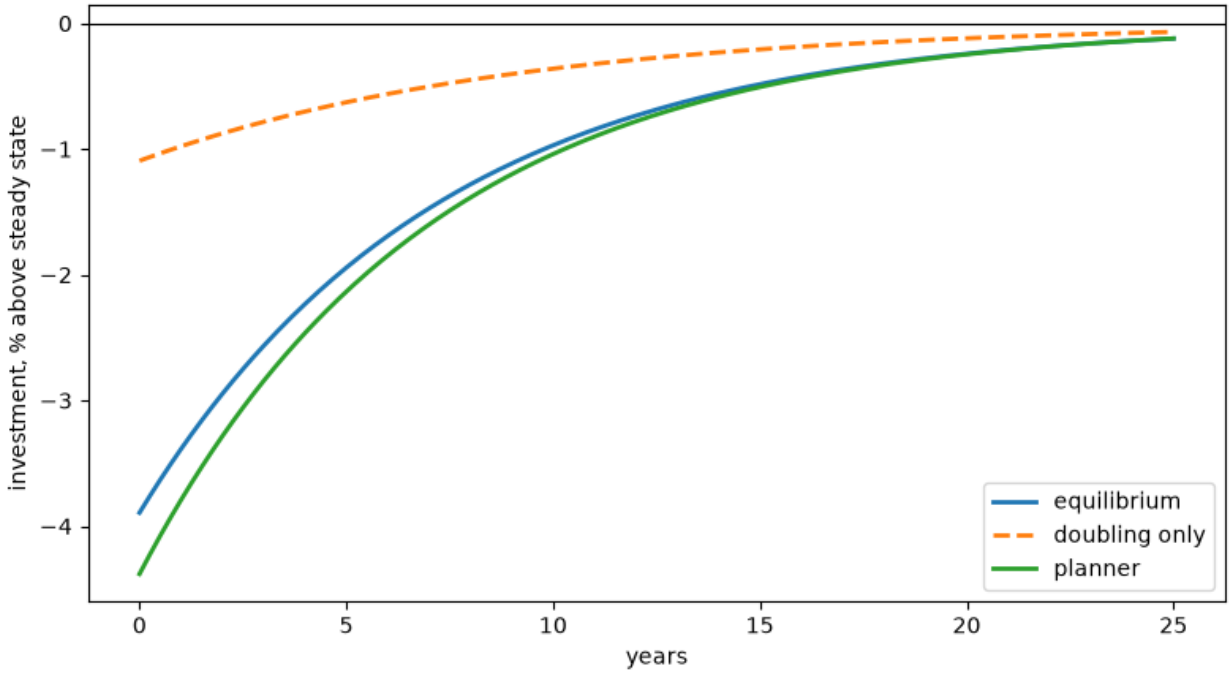

Fig. 130.7: Equilibrium and planner investment paths

Two caveats are worth keeping in mind.

First, the planner maximizes the sum of the firms' payoffs, so it counts the higher price of investment goods as a cost to firms; a planner who also counted the surplus of the suppliers of investment goods would treat part of it as a transfer.

Second, the comparison is local.

Within the quadratic model, the planner's different steady state comes from linear terms, which do not affect the dynamics of deviations.

But as an approximation to the nonlinear economy, the planner's own steady state differs from the equilibrium's (at this calibration it has more capital), and an expansion around it would give somewhat different curvatures.

Exercise 130.14.7 splits the gap between the planner and the equilibrium into its state and action parts, and finds the supply elasticity at which the ranking flips.

130.12.2 The planner in the Kimball example

Alvarez and Argente [2026] point out that in the Kimball example doubling the interaction alone would give a planner the state curvature $Q + 2\Theta_X = (Q + \Theta_X) - \bar{\eta}'_D \bar{s}\bar{s}^\top$, which depends on the superelasticity, and that the aggregate-only term Λ_X restores the cancellation.

The reading above explains why: $Q + 2\Theta_X + \Lambda_X$ is the curvature of a store's profit when its prices equal the industry's, where its relative price is one, so the superelasticity drops out, although the elasticity $\bar{\eta}_D$ still matters through the markup.

With household spending held fixed, Exercise 130.14.8 shows that the planner's state curvature is

$$Q + 2\Theta_X + \Lambda_X = (\bar{\eta}_D - 1)\left[\bar{s}\bar{s}^\top + (2\bar{\eta}_d - 1)V\right], \qquad V \equiv \mathrm{diag}(\bar{s}) - \bar{s}\bar{s}^\top,$$

against $Q + \Theta_X = (\bar{\eta}_D - 1)\left[\bar{\eta}_D \bar{s}\bar{s}^\top + \bar{\eta}_d V\right]$ for the equilibrium.

The planner's curvature is lower in the direction of a proportional increase in all of a store's prices, which changes the store's price level, and higher in directions that change only relative prices.

Let's see what that does to the modes of aggregate dynamics, measuring how much each mode moves the price level by the cosine of the angle between its eigenvector and a vector of ones.

```
ss_bar = np.outer(s_bar, s_bar)
V = np.diag(s_bar) - ss_bar
M_act = (η_D - 1)*(ss_bar + (2*η_d - 1)*V)
Q_K, Θ_K = kimball(η_d, η_D, 3.0, s_bar)

for label, M_use in (('equilibrium', Q_K + Θ_K), ('planner', M_act)):
    U_use = closed_loop(A_K, B_K, Γ_K, mfg_riccati(A_K, B_K, M_use, Γ_K, ρ_K))
    ev, W = np.linalg.eig(U_use)
    for j in np.argsort(ev.real):
        w = W[:, j].real
        cosine = abs(w.sum())/(np.sqrt(n_K)*np.linalg.norm(w))
        print(f"{label:>12}: eigenvalue {ev[j].real:.4f}, "
              f"alignment with the price level {cosine:.2f}")
```

```
equilibrium: eigenvalue -0.6527, alignment with the price level 0.94
equilibrium: eigenvalue -0.4882, alignment with the price level 0.58
equilibrium: eigenvalue -0.3836, alignment with the price level 0.37
    planner: eigenvalue -0.7001, alignment with the price level 0.07
    planner: eigenvalue -0.5372, alignment with the price level 0.10
    planner: eigenvalue -0.2959, alignment with the price level 1.00
```

The price-level mode is the fastest mode in equilibrium and the slowest for the planner: within the quadratic approximation, a cartel of stores would adjust its price level more slowly, and its relative prices more quickly, than the industry does.

Two qualifications apply.

This planner maximizes the stores' joint profits and ignores the households who buy from them, so it is a collusive benchmark rather than an efficient one.

And with household spending fixed, the stores' joint profit keeps rising as all prices rise together, so the cartel has no interior optimum and the comparison is purely local.

Exercise 130.14.8 also shows that with the profit normalization used to compute Q and Θ_X, which drops a factor that does not depend on the store's own prices, the planner's Riccati equation has no symmetric solution, so that planner's problem has no finite optimum.

130.13 Summary

The four lessons of the lecture, with the numbers from our examples:

- **Effective curvature.** Aggregate dynamics solve a single-agent Riccati equation in which Q and Γ become $Q+\Theta_X$ and $\Gamma+\Theta_{\mathcal{A}}$; in the pricing example the superelasticity cancels from $Q+\Theta_X$, so aggregate price dynamics do not depend on it.
- **Individual versus aggregate.** In the capital example a firm's deviation from the industry mean has a half-life of three years, while the industry's capital stock has a half-life of five.
- **The missing intercept.** In simulated panels from two industries that differ only in complementarity, the demeaned paths of firms are identical, and only the industry means differ.
- **Marginal versus total.** The planner's half-life in the capital example is 4.8 years, against 5.0 in equilibrium, while doubling the interactions and ignoring the aggregate-only terms would have given 6.25.

130.14 Exercises

Exercise 130.14.1

This exercise derives the formulas of the scalar case.

1. Write the equilibrium Riccati equation in the scalar case, solve the quadratic, and show that the root satisfying the admissibility condition gives (130.11).
2. Derive the existence condition (130.12) and the stability condition (130.13).
3. With the parameters of the regions figure and $\theta_{\mathcal{A}}=0$, plot λ against θ_X and mark the two thresholds.

Solution

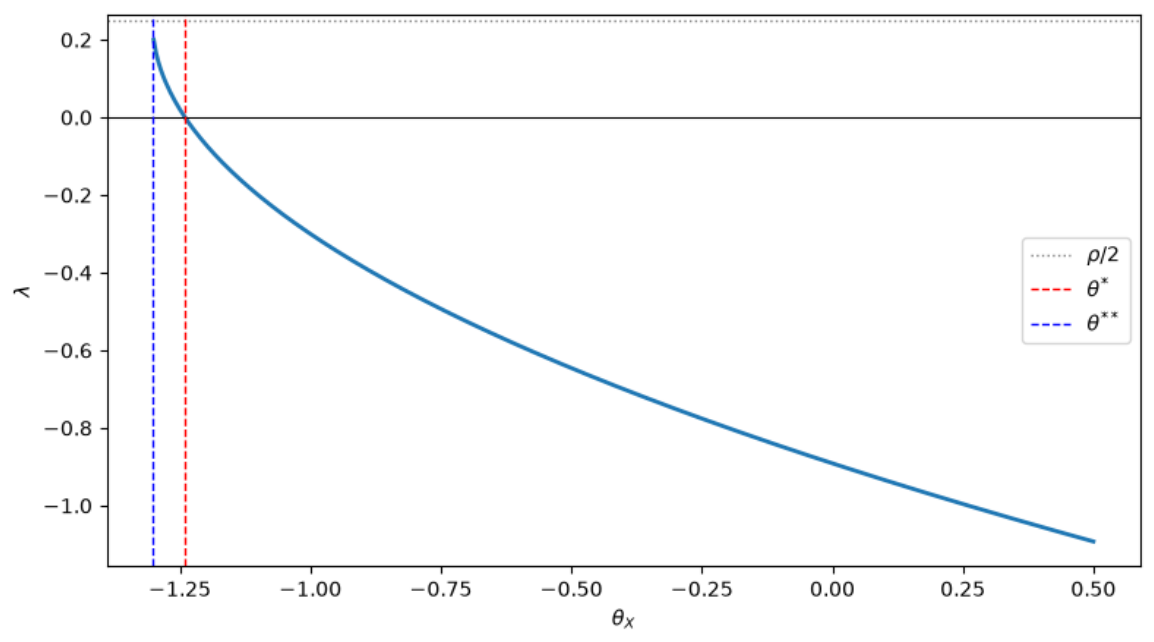
For part 1, with $g\equiv\gamma+\theta_{\mathcal{A}}$ the Riccati equation is $\frac{b^2}{g}p^2=q+\theta_X+(\rho+2a)p$, and the closed-loop eigenvalue is $\lambda=\frac{b^2}{g}p-a$.

Substituting $p=g(\lambda+a)/b^2$ turns the Riccati equation into

$$(\lambda+a)^2-(\rho+2a)(\lambda+a)=\frac{b^2(q+\theta_X)}{g},$$

a quadratic in λ whose roots are $\frac{\rho}{2}\pm\sqrt{(\frac{\rho}{2}+a)^2+b^2(q+\theta_X)/g}$.

The two roots are symmetric about $\rho/2$, as *Proposition 130.4.1* requires, and only the smaller one satisfies the admissibility condition $\lambda<\rho/2$.



For part 2, a real root exists when the term under the square root is nonnegative, and the admissible root lies strictly below $\rho/2$ when it is positive, which gives (130.12).

The admissible root is negative when $\sqrt{(\rho/2+a)^2+b^2(q+\theta_X)/g}>\rho/2$, which after squaring gives (130.13).

For part 3, we evaluate the closed form along a line of θ_X values, using the thresholds `θ_star` and `θ_2star` computed in the lecture.

```
θ_line = np.linspace(-1.30, 0.5, 400)
inside_line = (ρ_s/2 + a)**2 + b**2*(q + θ_line)/γ
λ_line = np.where(inside_line >= 0,
                  ρ_s/2 - np.sqrt(np.maximum(inside_line, 0)), np.nan)

fig, ax = plt.subplots(figsize=(8, 4.5))
ax.plot(θ_line, λ_line, lw=2)
ax.axhline(0, color='k', lw=0.8)
ax.axhline(ρ_s/2, color='grey', ls=':', lw=1, label=r'$\rho/2$')
ax.axvline(θ_star, color='r', ls='--', lw=1, label=r'$\theta^{*}$')
ax.axvline(θ_2star, color='b', ls='--', lw=1, label=r'$\theta^{**}$')
ax.set_xlabel(r'$\theta_X$')
ax.set_ylabel(r'$\lambda$')
ax.legend()
plt.tight_layout()
plt.show()
```

Moving left along the horizontal axis means stronger complementarity in states.

Persistence rises smoothly until θ^*, where the aggregate state stops converging; between θ^* and θ^{**} equilibrium paths diverge, though slowly enough to keep discounted payoffs finite; below θ^{**} no equilibrium exists at all.

Exercise 130.14.2

This exercise derives the calibration of the capital accumulation example.

1. Use the steady-state Euler equation $\Pi_k(\bar{k}, \bar{k}) = \rho + \delta$ to show that $\bar{k}^{1-\nu} = \nu(\eta - 1)/[\eta(\rho + \delta)]$, and then that $\gamma = \phi\, \delta \bar{k}^{1-\nu}$ and $\theta_{\mathcal{A}} = \delta \bar{k}^{1-\nu}/\varepsilon_s$.
2. Show that all pairs (ϕ, ε_s) with the same value of $\phi + 1/\varepsilon_s$ generate identical *aggregate* dynamics, and verify numerically that they nevertheless imply different individual investment rules.
3. After reading *The planner in the capital accumulation example*, show that these pairs also imply different planner

allocations.

Solution

For part 1, $\Pi_k(k, K) = \nu \frac{\eta-1}{\eta} k^{\nu(1-1/\eta)-1} K^{\nu/\eta}$, so on the diagonal $\Pi_k(\bar{k}, \bar{k}) = \nu \frac{\eta-1}{\eta} \bar{k}^{\nu-1}$.

Setting this equal to $\rho + \delta$, which is the steady-state user cost when $\mathcal{P}(\bar{i}) = 1$ and $\psi'(\bar{i}) = 0$, gives the stated expression for $\bar{k}^{1-\nu}$.

Since $\bar{\Pi} = \bar{k}^\nu$, $\bar{i} = \delta \bar{k}$, $\psi''(\bar{i}) = \phi/\bar{i}$ and $\mathcal{P}'(\bar{i}) = 1/(\varepsilon_s \bar{i})$,

$$\gamma = \frac{\delta^2 \bar{k}^2}{\bar{k}^\nu} \frac{\phi}{\delta \bar{k}} = \phi \, \delta \bar{k}^{1-\nu}, \qquad \theta_{\mathcal{A}} = \frac{\delta^2 \bar{k}^2}{\bar{k}^\nu} \frac{1}{\varepsilon_s \delta \bar{k}} = \frac{\delta \bar{k}^{1-\nu}}{\varepsilon_s}.$$

For part 2, $\gamma + \theta_{\mathcal{A}} = \delta \bar{k}^{1-\nu}(\phi + 1/\varepsilon_s)$, and by (130.11) only this sum matters for λ.

But the individual's Riccati equation (130.6) involves γ alone, so it separates the pairs.

For part 3, the planner's Riccati equation involves $\gamma + 2\theta_{\mathcal{A}} + \Lambda_{\mathcal{A}} = \gamma + (1 + 1/\varepsilon_s)\theta_{\mathcal{A}} = \delta \bar{k}^{1-\nu}(\phi + 1/\varepsilon_s + 1/\varepsilon_s^2)$, so it separates them too.

The table confirms all three claims, reporting half-lives in years.

```
scale = cap_scale(η_c, ν_c)
print(f"{'ψ':>6}{'1/ε_s':>8}{'aggregate':>12}{'individual':>12}{'planner':>10}")
for ψ, inv_ε in ((0.40, 0.00), (0.30, 0.10), (1/7, 9/35), (0.05, 0.35)):
    γ_case, θ_A_case = ψ*scale, inv_ε*scale
    λ_agg = scalar_λ(ρ_c, δ_c, δ_c, q_c, γ_case, θ_X_c, θ_A_case)
    λ_ind = scalar_λ(ρ_c, δ_c, δ_c, q_c, γ_case, 0.0, 0.0)
    λ_pl = scalar_λ(ρ_c, δ_c, δ_c, q_c, γ_case,
                    2*θ_X_c + Λ_X_c, (1 + inv_ε)*θ_A_case)
    print(f"{ψ:>6.3f}{inv_ε:>8.3f}{half_life(λ_agg):>12.4f}"
          f"{half_life(λ_ind):>12.4f}{half_life(λ_pl):>10.4f}")
```

```
     ψ   1/ε_s   aggregate  individual   planner
 0.400   0.000      4.9890      4.3909    4.6210
 0.300   0.100      4.9890      3.9967    4.6535
 0.143   0.257      4.9890      3.0016    4.8198
 0.050   0.350      4.9890      1.8601    4.9636
```

Aggregate dynamics are identical down to the last digit, while the individual half-life ranges from about 4.4 years to under 2.

Aggregate data alone cannot tell a congested market for capital goods from an expensive installation technology.

Data on firms' deviations from the industry mean can, because they reveal γ alone, which is the mirror image of *Proposition 130.9.2*.

Exercise 130.14.3

This exercise derives the results in the subsection on market power and returns to scale.

1. Holding ϕ and ε_s fixed, show that $(q + \theta_X)/(\gamma + \theta_{\mathcal{A}}) = (1 - \nu)(\rho + \delta)/[\delta(\phi + 1/\varepsilon_s)]$ and $q/\gamma = (\rho + \delta)[(1 - \nu) + \nu/\eta]/(\phi\delta)$, and explain why market power affects individual but not aggregate adjustment.
2. Show that $\lambda \to -\delta$ as $\nu \to 1$, for every $\eta > 1$, and that the response of aggregate investment to a capital gap,

$(\lambda+\delta)/\delta$, goes to zero in the same limit. Explain the limit.

Solution

For part 1, from (130.15) and the calibration formulas,

$$\frac{q+\theta_X}{\gamma+\theta_{\mathcal{A}}} = \frac{\frac{\eta-1}{\eta}\nu(1-\nu)}{\frac{\delta\nu(\eta-1)}{\eta(\rho+\delta)}(\phi+1/\varepsilon_s)} = \frac{(1-\nu)(\rho+\delta)}{\delta(\phi+1/\varepsilon_s)}.$$

Both numerator and denominator are proportional to $(\eta-1)/\eta$, the ratio of a firm's marginal revenue to the value of its marginal product.

For a single firm, $q = e(1-e)$ with $e = \nu(\eta-1)/\eta$ the elasticity of a firm's revenue with respect to its own capital, so

$$\frac{q}{\gamma} = \frac{e(1-e)}{\phi e\delta/(\rho+\delta)} = \frac{(\rho+\delta)(1-e)}{\phi\delta} = \frac{\rho+\delta}{\phi\,\delta}\left[(1-\nu)+\frac{\nu}{\eta}\right].$$

Market power changes how fast a single firm's marginal revenue falls as it expands alone, but along the diagonal the industry's revenue is K^ν whatever η is, and the $(\eta-1)/\eta$ factors cancel.

For part 2, $q+\theta_X = \frac{\eta-1}{\eta}\nu(1-\nu) \to 0$, and with $a=b=\delta$,

$$\lambda \to \frac{\rho}{2} - \sqrt{\left(\frac{\rho}{2}+\delta\right)^2} = -\delta.$$

The aggregate law of motion gives $\mathcal{A} = \frac{\lambda+\delta}{\delta}X$, which vanishes as $\lambda \to -\delta$, as the table confirms.

```
print(f"{'ν':>8}{'q + θ_X':>10}{'λ':>10}{'half-life':>11}{'A/X':>9}")
for ν in (0.7, 0.9, 0.99, 0.999, 0.99999):
    γ_ν, θ_A_ν = ψ_c*cap_scale(η_c, ν), cap_scale(η_c, ν)/ε_s_c
    λ_ν = scalar_λ(ρ_c, δ_c, δ_c, cap_q(η_c, ν), γ_ν, cap_θ_X(η_c, ν), θ_A_ν)
    print(f"{ν:>8}{cap_q(η_c,ν) + cap_θ_X(η_c,ν):>10.5f}{λ_ν:>10.5f}"
          f"{half_life(λ_ν):>11.3f}{(λ_ν + δ_c)/δ_c:>9.4f}")
```

```
       ν   q + θ_X         λ  half-life      A/X
     0.7   0.15750  -0.13894      4.989  -0.3894
     0.9   0.06750  -0.11419      6.070  -0.1419
    0.99   0.00743  -0.10149      6.830  -0.0149
   0.999   0.00075  -0.10015      6.921  -0.0015
 0.99999   0.00001  -0.10000      6.931  -0.0000
```

As ν approaches 1 the profit function (130.14) approaches one that is homogeneous of degree one in (k, K) jointly, along which $\Pi_k(k,k)$ does not depend on k.

An industry-wide capital gap then creates almost no incentive to invest differently, and the gap closes almost entirely through depreciation.

The effective curvature approaches zero, the boundary of the sufficient condition $Q+\Theta_X \succ 0$ of *Proposition 130.5.3*, while the existence condition (130.12) continues to hold with room to spare.

The limit $\nu = 1$ itself is not an economy we can study this way: with constant returns the steady-state Euler equation has no solution, and $\bar{k}$ grows without bound as $\nu \to 1$.

Exercise 130.14.4

This exercise works through the identification results of *Aggregate shocks and identification*.

1. Suppose an econometrician knows ρ, Q, A, B, Γ and $\Theta_{\mathcal{A}}$, and estimates the aggregate drift matrix $U_{\dot{X},X}$. Show how to recover Θ_X, and verify your procedure numerically in the two-dimensional example.
2. In the scalar model, show that θ_X and $\theta_{\mathcal{A}}$ are not separately identified: construct a family of pairs that generate identical aggregate dynamics *and* identical policy coefficients.
3. Now suppose the econometrician knows only ρ, Γ and $\Theta_{\mathcal{A}}$, but observes X, z, α and $\mathcal{A}$, so that all four reduced-form matrices are available. Replace B by $\begin{bmatrix} 1 & 0.3 \\ 0 & 0.8 \end{bmatrix}$ in the two-dimensional example, and recover B, A, Q and Θ_X.

Solution

For part 1, invert the definition of the closed-loop matrix to get P, then read Θ_X off the equilibrium Riccati equation:

$$P = D^{-1}\left(U_{\dot{X},X} + A\right), \qquad \Theta_X = PDP - Q - \rho P - PA - A^\top P.$$

Let's apply this to the aggregate drift of the two-dimensional example.

```
U_obs = closed_loop(A, B, Γ + Θ_A, P)       # what the econometrician estimates

P_hat = np.linalg.solve(D, U_obs + A)
Θ_X_hat = P_hat @ D @ P_hat - Q - ρ*P_hat - P_hat @ A - A.T @ P_hat

print("true Θ_X =\n", Θ_X.round(6))
print("\nrecovered Θ_X =\n", Θ_X_hat.round(6))
print(f"\nmaximum error: {np.abs(Θ_X - Θ_X_hat).max():.2e}")
```

```
true Θ_X =
 [[-0.3   0.05]
 [ 0.05 -0.2 ]]

For part 2, formula (130.11) shows that λ depends on the two interactions only through the ratio $(q+\theta_X)/(\gamma+\theta_{\mathcal{A}})$.

Holding that ratio fixed traces out a one-parameter family of observationally equivalent economies, one of the rays in Fig. 130.1.

The policy coefficient cannot break the tie, because $\lambda = b\,U_{\alpha,X} - a$ ties it to λ.

```
ratio = (q + (-0.4))/(γ + 0.3)        # baseline θ_X = -0.4, θ_A = 0.3

print(f"{'θ_A':>7}{'θ_X':>12}{'λ':>12}{'policy coeff':>15}")
for θ_A_alt in (0.3, 0.0, 0.6, 1.0):
    θ_X_alt = ratio*(γ + θ_A_alt) - q
    λ_alt = scalar_λ(ρ_s, a, b, q, γ, θ_X_alt, θ_A_alt)
    print(f"{θ_A_alt:>7.2f}{θ_X_alt:>12.6f}{λ_alt:>12.6f}{(λ_alt + a)/b:>15.6f}")
```

```
      θ_A         θ_X           λ   policy coeff
    0.30   -0.400000   -0.624093      -0.324093
    0.00   -0.538462   -0.624093      -0.324093
    0.60   -0.261538   -0.624093      -0.324093
    1.00   -0.076923   -0.624093      -0.324093
```

Every row describes a different economy, with a different amount of strategic complementarity in states and in actions, yet all of them generate exactly the same aggregate dynamics and the same policy rule.

Distinguishing them requires normalizing one interaction, or bringing outside information to bear.

For part 3, the two drift matrices share A, so

$$U_{\dot{z},z} - U_{\dot{X},X} = B\left(U_{\alpha,z} - U_{\alpha,X}\right)$$

identifies B.

Then $A = BU_{\alpha,X} - U_{\dot{X},X}$, $P = (B^\top)^{-1}(\Gamma + \Theta_{\mathcal{A}})U_{\alpha,X}$ and $\bar{\beta}_2 = (B^\top)^{-1}\Gamma U_{\alpha,z}$.

Finally, the single-agent Riccati equation (130.6) gives Q and the equilibrium one gives Θ_X.

```
B_true = np.array([[1.0, 0.3],
                   [0.0, 0.8]])
Γ_eq = Γ + Θ_A

# the reduced-form matrices the econometrician estimates
β2_true = mfg_riccati(A, B_true, Q, Γ, ρ)

```

Every object is recovered to machine precision, but only because $\Theta_{\mathcal{A}}$ was known: part 2 shows that it cannot be recovered along with the rest.

Exercise 130.14.5

Proposition 130.10.1 says that stronger complementarity in states raises the *trace* of the closed-loop matrix, and the example of Alvarez and Argente [2026] shows that it need not raise every eigenvalue.

How common is that?

1. Draw many random two-dimensional economies: take $B = I$ and $\Theta_{\mathcal{A}} = 0$, let Q and Γ be random positive definite matrices, let Θ_X be random negative definite, and set $\rho = 0.05$. For each draw, compare the equilibrium with interaction Θ_X to the one with $1.5\,\Theta_X$, keeping only draws in which $Q + 1.5\,\Theta_X$ is positive definite. Report how often the trace rises and how often *every* eigenvalue rises.
2. Repeat the experiment with $A = \Gamma^{-1} S$ for a random symmetric S, so that $D^{-1}A = S$ is symmetric, and confirm *Proposition 130.10.2*.

Solution

We write one function for both experiments, taking the rule that draws A as an argument.

```
def compare_draws(draw_A, n_draws=400, seed=3, ρ=0.05):
    """
    Compare equilibria with interactions Θ_X and 1.5 Θ_X in random
    two-dimensional economies with B = I and Θ_A = 0.  draw_A(rng, Γ)
    returns the drift matrix.  Returns the number of draws kept, the number
    in which the trace rose and the number in which every eigenvalue rose.
    """
    rng = np.random.default_rng(seed)
    I2 = np.eye(2)
    kept = trace_rose = eig_rose = 0
    for _ in range(n_draws):
        M = rng.normal(size=(2, 2)); Q_r = M @ M.T + 0.5*I2
        M = rng.normal(size=(2, 2)); Γ_r = M @ M.T + 0.5*I2
        M = rng.normal(size=(2, 2)); Θ_r = -0.2*(M @ M.T)
        A_r = draw_A(rng, Γ_r)
        if np.linalg.eigvalsh(Q_r + 1.5*Θ_r).min() <= 0:
            continue
        J0 = closed_loop(A_r, I2, Γ_r, mfg_riccati(A_r, I2, Q_r + Θ_r, Γ_r, ρ))
        J1 = closed_loop(A_r, I2, Γ_r, mfg_riccati(A_r, I2, Q_r + 1.5*Θ_r, Γ_r, ρ))
        e0 = np.sort(np.linalg.eigvals(J0).real)
        e1 = np.sort(np.linalg.eigvals(J1).real)
        kept += 1
        trace_rose += np.trace(J1) > np.trace(J0) - 1e-10
        eig_rose += np.all(e1 >= e0 - 1e-10)
    return kept, trace_rose, eig_rose

def general_drift(rng, Γ):
    "A random drift matrix with no particular structure."
    return rng.normal(size=(2, 2))*0.3 + 0.4*np.eye(2)

def symmetric_drift(rng, Γ):
    "A random drift matrix with Γ A symmetric, so that D^{-1} A is symmetric."
    M = rng.normal(size=(2, 2))
    return np.linalg.solve(Γ, 0.3*(M + M.T) + 0.4*np.eye(2))

for label, draw_A in (('general A', general_drift), ('D⁻¹A symmetric', symmetric_
↪drift)):
    kept, trace_rose, eig_rose = compare_draws(draw_A)
    print(f"{label:>16}: draws kept {kept}, trace rose {trace_rose}, "
          f"every eigenvalue rose {eig_rose}")
```

```
      general A: draws kept 266, trace rose 266, every eigenvalue rose 228
D^-1A symmetric: draws kept 266, trace rose 266, every eigenvalue rose 266
```

The trace result holds in every draw, as the theory says it must.

With a general drift matrix, eigenvalue-by-eigenvalue monotonicity fails in a minority of draws.

The obstacle is that $D^{-1}A$ need not be symmetric (here A itself is not symmetric), so the closed-loop matrix $DP - A$ need not be similar to a symmetric matrix, and a change that slows adjustment overall can still speed it up along some direction.

When $D^{-1}A$ is symmetric, every eigenvalue rises in every draw, as *Proposition 130.10.2* says.

Note that $Q + \Theta_X$ and D need not commute in either experiment: by *Proposition 130.10.3*, that kind of non-commutativity does not by itself break monotonicity.

Exercise 130.14.6

Compare the planner with the decentralized equilibrium in the two-dimensional example from the lecture, with no aggregate-only terms.

Compute the eigenvalues of the closed-loop matrix for the equilibrium and for the planner in four cases: only complementarity in states (Θ_X as in the lecture, $\Theta_{\mathcal{A}} = 0$); only substitutability in actions ($\Theta_X = 0$, $\Theta_{\mathcal{A}} = 0.2I$); only complementarity in actions ($\Theta_X = 0$, $\Theta_{\mathcal{A}} = -0.2I$); and complementarity in both.

In which cases is the planner's allocation more persistent than the equilibrium? Explain.

Solution

We compute both sets of eigenvalues in each case.

```
def eigen_pair(Θ_X_use, Θ_A_use):
    "Closed-loop eigenvalues for the equilibrium and for the planner."
    P_eq = mfg_riccati(A, B, Q + Θ_X_use, Γ + Θ_A_use, ρ)
    P_pl = mfg_riccati(A, B, Q + 2*Θ_X_use, Γ + 2*Θ_A_use, ρ)
    e_eq = np.sort(np.linalg.eigvals(closed_loop(A, B, Γ + Θ_A_use, P_eq)).real)
    e_pl = np.sort(np.linalg.eigvals(closed_loop(A, B, Γ + 2*Θ_A_use, P_pl)).real)
    return e_eq, e_pl

zero = np.zeros((2, 2))
planner_tests = {'states, complements':  (Θ_X, zero),
                 'actions, substitutes': (zero,  0.2*np.eye(2)),
                 'actions, complements': (zero, -0.2*np.eye(2)),
                 'both complements':     (Θ_X, -0.2*np.eye(2))}

print(f"{'case':24}{'equilibrium':>22}{'planner':>22}   planner slower?")
for label, (tx, ta) in planner_tests.items():
    e_eq, e_pl = eigen_pair(tx, ta)
    slower = bool(np.all(e_pl >= e_eq - 1e-12))
    print(f"{label:24}{str(e_eq.round(4)):>22}{str(e_pl.round(4)):>22}   {slower}")
```

```
case                                  equilibrium               planner   planner␣
↪slower?
states, complements          [-0.9584 -0.673 ]     [-0.8522 -0.4287]   True
actions, substitutes         [-0.9933 -0.7741]     [-0.9344 -0.7284]   True
actions, complements         [-1.1748 -0.9088]     [-1.3325 -1.0151]   False
both complements             [-1.0426 -0.7346]     [-1.0137 -0.4958]   True
```

With only complementarity in states, the planner's allocation is more persistent.

The planner recognizes that when one agent stays away from the steady state, others are content to stay away too, so there is less reason to hurry back.

With only substitutability in actions the planner is also slower, because it recognizes that a burst of adjustment by everyone at once is costly.

With only complementarity in actions the comparison reverses and the planner adjusts faster: it internalizes that when one agent adjusts, others want to adjust as well.

When complementarity is present in both states and actions, the two forces work against each other.

In this calibration the state interaction dominates and the planner is still slower, but that ranking is a quantitative accident, not a theorem.

Exercise 130.14.7

In *The planner in the capital accumulation example* the planner adjusts slightly faster than the equilibrium, because the state side and the action side of its problem pull in opposite directions.

1. Compute the planner's half-life when only the state side is corrected, with state curvature $q + 2\theta_X + \Lambda_X$ and action curvature $\gamma + \theta_{\mathcal{A}}$, and when only the action side is corrected, with $q + \theta_X$ and $\gamma + (1 + 1/\varepsilon_s)\theta_{\mathcal{A}}$.
2. Hold ϕ fixed and let the supply elasticity ε_s vary. Find the elasticity at which the planner and the equilibrium have the same half-life.
3. Repeat part 2 for $\eta \in \{2, 4, 8\}$ and explain how the threshold depends on market power.

Solution

For part 1, we switch on one side of the planner's problem at a time.

```
sides = {'equilibrium':       (θ_X_c,            θ_A_c),
         'state side only':   (2*θ_X_c + Λ_X_c,  θ_A_c),
         'action side only':  (θ_X_c,            2*θ_A_c + Λ_A_c),
         'planner':           (2*θ_X_c + Λ_X_c,  2*θ_A_c + Λ_A_c)}

for label, (tx, ta) in sides.items():
    λ_case = scalar_λ(ρ_c, δ_c, δ_c, q_c, γ_c, tx, ta)
    print(f"{label:>18}: half-life {half_life(λ_case):.2f} years")
```

```
      equilibrium: half-life 4.99 years
  state side only: half-life 4.62 years
 action side only: half-life 5.17 years
          planner: half-life 4.82 years
```

On its own, the state side would cut the half-life to 4.6 years and the action side would raise it to 5.2 years.

For parts 2 and 3, we write the gap between the two half-lives as a function of $1/\varepsilon_s$ and find its root.

```
def planner_gap(inv_ε, η):
    "Planner's half-life minus the equilibrium's, as a function of 1/ε_s."
    scale_η = cap_scale(η, ν_c)
    γ_η, θ_A_η = ψ_c*scale_η, inv_ε*scale_η
    q_η, θ_X_η = cap_q(η, ν_c), cap_θ_X(η, ν_c)
    λ_eq = scalar_λ(ρ_c, δ_c, δ_c, q_η, γ_η, θ_X_η, θ_A_η)
    λ_pl = scalar_λ(ρ_c, δ_c, δ_c, q_η, γ_η,
                    2*θ_X_η + cap_Λ_X(η, ν_c), (1 + inv_ε)*θ_A_η)
    return half_life(λ_pl) - half_life(λ_eq)

for η in (2.0, 4.0, 8.0):
    inv_star = brentq(planner_gap, 0.01, 20.0, args=(η,))
    print(f"η = {η}: half-lives coincide at ε_s = {1/inv_star:.2f}")
```

```
η = 2.0: half-lives coincide at ε_s = 0.89
η = 4.0: half-lives coincide at ε_s = 2.27
η = 8.0: half-lives coincide at ε_s = 4.33
```

With $\eta = 4$, the planner is faster whenever the supply of investment goods is more elastic than about 2.3, which includes the calibrated 3.9, and slower when it is less elastic.

The threshold rises with η.

The planner's advantage on the state side is $\nu(1-\nu) - \frac{\eta-1}{\eta}\nu(1-\nu) = \nu(1-\nu)/\eta$, which shrinks as market power falls.

So in a more competitive industry, a smaller penalty on the action side, which means a more elastic supply of investment goods, is enough to make the planner slower.

Exercise 130.14.8

This exercise derives the planner's state curvature in the Kimball example, and checks it against the profit function itself.

Normalize flexible prices to one, so that the CES weights equal the expenditure shares $\bar{s}$ and marginal costs equal $(\bar{\eta}_D - 1)/\bar{\eta}_D$, and use a Kimball demand whose elasticity at relative price y is $\bar{\eta}_D + \bar{\eta}'_D(y-1)$.

Let $\Phi(p)$ be the CES price index of a store that charges prices p, let $\tilde{p}$ be the other stores' prices, and let $\mathcal{Y}$ be household spending, which we hold fixed.

A store's actual profits are proportional to $\mathcal{Y}/\Phi(\tilde{p})$; Alvarez and Argente [2026] drop this factor, which does not depend on the store's own prices, when they compute Q and Θ_X.

Define

$$V \equiv \operatorname{diag}(\bar{s}) - \bar{s}\bar{s}^\top, \qquad \ell(X) \equiv \frac{1}{1-\bar{\eta}_d} \log \sum_j \bar{s}_j e^{(1-\bar{\eta}_d)X_j},$$

so that ℓ is the log of the store's price index.

1. Show that along the diagonal, where a store's prices equal the industry's, actual profit is proportional to $1 - \frac{\bar{\eta}_D - 1}{\bar{\eta}_D} e^{(\bar{\eta}_d - 1)\ell(X)} \sum_j \bar{s}_j e^{-\bar{\eta}_d X_j}$, and that profit with the factor dropped is proportional to $e^{\ell(X)}$ times that expression.
2. Using $\nabla\ell(0) = \bar{s}$ and $\nabla^2\ell(0) = (1-\bar{\eta}_d)V$, show that $Q + 2\Theta_X + \Lambda_X$ equals $(\bar{\eta}_D - 1)[\bar{s}\bar{s}^\top + (2\bar{\eta}_d - 1)V]$ with actual profits and $[\bar{\eta}_d(2\bar{\eta}_D - 1) - \bar{\eta}_D]V - \bar{\eta}_D\bar{s}\bar{s}^\top$ with the factor dropped.
3. Check both formulas, and the formulas for Q and Θ_X, against finite-difference Hessians of the profit function, for several values of the superelasticity.

4. Using $V\mathbb{1} = 0$, where $\mathbb{1}$ is a vector of ones, show that the first matrix is positive definite whenever $\bar{\eta}_d > 1/2$ and the second is not positive definite. Use the matrix E of (130.9) to show that with the factor dropped the planner's Riccati equation has no symmetric solution.
5. Compare the planner's curvature with the equilibrium's, $Q + \Theta_X = (\bar{\eta}_D - 1)[\bar{\eta}_D \bar{s}\bar{s}^\top + \bar{\eta}_d V]$, in the direction $\mathbb{1}$ and in directions v with $\bar{s}^\top v = 0$.

Solution

For part 1, along the diagonal the relative price $\Phi(p)/\Phi(\tilde{p})$ equals one, so the Kimball demand function is evaluated at a constant.

Revenue from the store's products is $\sum_j p_j \bar{s}_j (p_j/\Phi(p))^{-\bar{\eta}_d} = \Phi(p)^{\bar{\eta}_d} \sum_j \bar{s}_j p_j^{1-\bar{\eta}_d} = \Phi(p) = e^{\ell(X)}$, and costs are $\frac{\bar{\eta}_D - 1}{\bar{\eta}_D} e^{\bar{\eta}_d \ell(X)} \sum_j \bar{s}_j e^{-\bar{\eta}_d X_j}$.

Dividing by $\Phi(\tilde{p}) = e^{\ell(X)}$ gives actual profit.

For part 2, let $g(X) = \sum_j \bar{s}_j e^{-\bar{\eta}_d X_j}$, so that $\log g$ has gradient $-\bar{\eta}_d \bar{s}$ and Hessian $\bar{\eta}_d^2 V$ at zero.

For any function f with $f(0) = 0$, the Hessian of e^f at zero is $\nabla f \nabla f^\top + \nabla^2 f$.

For $e^{(\bar{\eta}_d - 1)\ell} g$, the logarithm has gradient $(\bar{\eta}_d - 1)\bar{s} - \bar{\eta}_d \bar{s} = -\bar{s}$ and Hessian $(\bar{\eta}_d - 1)(1 - \bar{\eta}_d)V + \bar{\eta}_d^2 V = (2\bar{\eta}_d - 1)V$, so its Hessian is $\bar{s}\bar{s}^\top + (2\bar{\eta}_d - 1)V$.

For e^ℓ, the Hessian is $\bar{s}\bar{s}^\top + (1 - \bar{\eta}_d)V$, and for $e^{\bar{\eta}_d \ell} g$ the logarithm has gradient zero and Hessian $\bar{\eta}_d(1 - \bar{\eta}_d)V + \bar{\eta}_d^2 V = \bar{\eta}_d V$.

Both profit functions equal $1/\bar{\eta}_D$ at zero, and dividing the negative Hessians by that value gives the two matrices.

For part 3, we write the profit function and a finite-difference Hessian.

```
def hessian(f, v, h=1e-4):
    "Central finite-difference Hessian of the scalar function f at v."
    m = len(v)
    E = h*np.eye(m)
    hess = np.empty((m, m))
    for i in range(m):
        for j in range(m):
            hess[i, j] = (f(v + E[i] + E[j]) - f(v + E[i] - E[j])
                          - f(v - E[i] + E[j]) + f(v - E[i] - E[j]))/(4*h**2)
    return hess

def store_profit(x, X, η_d, η_D, η_Dp, s, actual=True):
    """
    Profit of a store charging log prices x when all other stores charge X,
    with flexible prices normalized to one.  With actual=False the factor
    Φ(p̃), which does not depend on x, is dropped.
    """
    p, p_others = np.exp(x), np.exp(X)
    Φ = lambda p: (s @ p**(1 - η_d))**(1/(1 - η_d))
    y = Φ(p)/Φ(p_others)
    demand = y**(η_Dp - η_D)*np.exp(-η_Dp*(y - 1))
    mc = (η_D - 1)/η_D
    profit = np.sum((p - mc)*s*(p/Φ(p))**(-η_d))*demand
    return profit/Φ(p_others) if actual else profit

def profit_curvatures(η_d, η_D, η_Dp, s, actual=True):
    "Q, Θ_X and Λ_X from the Hessian of store profits at the steady state."
    n = len(s)
    f = lambda v: store_profit(v[:n], v[n:], η_d, η_D, η_Dp, s, actual)
    v0 = np.zeros(2*n)
    hess = -hessian(f, v0)/f(v0)
    return hess[:n, :n], hess[:n, n:], hess[n:, n:]
```

Now we compare the finite differences with the closed forms.

```

The formulas hold for every superelasticity, and neither planner matrix depends on it.

Dropping the factor leaves Q and Θ_X unchanged, because the store's first-order condition holds at the steady state, but it changes Λ_X.

For part 4, $v^\top V v = \sum_j \bar{s}_j v_j^2 - (\bar{s}^\top v)^2 \geq 0$, with equality only when v is proportional to $\mathbb{1}$, and then $v^\top \bar{s}\bar{s}^\top v > 0$.

So the actual matrix is positive definite whenever $2\bar{\eta}_d - 1 > 0$.

With household spending fixed, an industry-wide price increase lowers quantities, so joint profit is concave in the level of prices.

For the other matrix, $V\mathbb{1} = 0$ and $\bar{s}^\top \mathbb{1} = 1$ give $\mathbb{1}^\top M \mathbb{1} = -\bar{\eta}_D < 0$.

Dropping the factor holds quantities fixed, so raising all prices in proportion raises profit at an increasing rate.

The planner's problem has $\Gamma + 2\Theta_{\mathcal{A}} + \Lambda_{\mathcal{A}} = \Gamma$, so its version of E is $M + (\pi + \rho/2)^2\Gamma$.

```
for label, M_closed in (('actual', M_act), ('factor dropped', M_norm)):
    E_pl = M_closed + (π_K + ρ_K/2)**2*Γ_K
    print(f"{label:>15}: eigenvalues of E {np.linalg.eigvalsh(E_pl).round(3)}")
    try:
        mfg_riccati(A_K, B_K, M_closed, Γ_K, ρ_K)
        print(" "*17 + "the planner's Riccati equation has an admissible solution")
    except ValueError as e:
        print(" "*17 + str(e))
```

```
         actual: eigenvalues of E [ 1.001  7.747 12.948]
                 the planner's Riccati equation has an admissible solution
factor dropped: eigenvalues of E [-1.336  8.795 14.677]
                 no admissible solution of the Riccati equation
```

With the factor dropped, E has a negative eigenvalue, so by *Proposition 130.5.3* no symmetric solution exists, the planner's problem has no finite optimum, and our solver duly raises an error.

For part 5, the equilibrium's curvature in the direction $\mathbb{1}$ is $(\bar{\eta}_D - 1)\bar{\eta}_D$, against $\bar{\eta}_D - 1$ for the planner, smaller by the factor $\bar{\eta}_D$.

A single store that raises its prices loses customers to other stores at elasticity $\bar{\eta}_D$, while stores that raise their prices together keep their revenue and only save on costs.

In directions with $\bar{s}^\top v = 0$, which leave the store's price index unchanged, the equilibrium's curvature is $(\bar{\eta}_D - 1)\bar{\eta}_d\, v^\top \operatorname{diag}(\bar{s})v$ and the planner's is $(\bar{\eta}_D - 1)(2\bar{\eta}_d - 1)\, v^\top \operatorname{diag}(\bar{s})v$, which is larger because $\bar{\eta}_d > 1$.

```
ones = np.ones(n_K)
v = np.array([1.0, -1.0, 0.5])
v = v - (s_bar @ v)*ones                    # now s̄'v = 0
Q_K, Θ_K = kimball(η_d, η_D, 3.0, s_bar)

for name, M_use in (('equilibrium', Q_K + Θ_K), ('planner', M_act)):
    ratio_v = (v @ M_use @ v)/(v @ np.diag(s_bar) @ v)
    print(f"{name:>12}: 1'M1 = {ones @ M_use @ ones:7.3f},   "
          f"v'Mv / v'diag(s̄)v = {ratio_v:7.3f}")
```

```
equilibrium: 1'M1 =  12.000,   v'Mv / v'diag(s̄)v =  18.000
    planner: 1'M1 =   3.000,   v'Mv / v'diag(s̄)v =  33.000
```

This is why the planner adjusts its price level more slowly than the industry does and its relative prices more quickly.

130.15 Further reading

Alvarez and Argente [2026] develop the results in this lecture, along with the two economic examples; their appendices contain the proofs and the derivations behind both examples, and they discuss the planner in the pricing example.

The planner in the capital example, the analysis of market power with structural parameters held fixed, the finite-difference check of the pricing planner, the observation that with their profit normalization that planner has no finite optimum, and the simulated panels are our own illustrations of their results.

Linear Quadratic Mean Field Games: Extensions continues with cross terms between states and actions, forcing processes, and interactions through higher moments.

Carmona and Delarue [2018] give a comprehensive probabilistic treatment of mean field games, and Achdou *et al.* [2022] describe the numerical methods used to solve the coupled partial differential equations when the model is not linear quadratic.

131.1 Overview

This lecture continues *Linear Quadratic Mean Field Games*, and it assumes familiarity with that lecture's theory, through the split into individual and aggregate dynamics, and with its capital accumulation example.

There we studied a continuum of agents whose quadratic payoffs depend on the cross-sectional averages of states and actions, and found that equilibrium aggregate dynamics solve the Riccati equation of a single-agent problem in which strategic interaction changes only the curvatures.

Here we take up three extensions developed by Alvarez and Argente [2026]:

- **Cross terms between states and actions.** The equivalence result survives when the mixed interactions between states and actions satisfy a symmetry restriction, with the mixed interaction subtracted from the own cross term, and uniqueness can fail when they do not.
- **Forcing processes.** States that agents cannot control, such as costs, can be added without changing the Riccati equation of the controlled block, and a pricing example shows that firms pass idiosyncratic and common cost shocks through at different speeds and to different extents.
- **Higher moments.** When payoffs depend on higher moments of the cross-sectional distribution, idiosyncratic risk affects aggregate persistence.

Let's start with some imports:

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.linalg import solve_continuous_are, expm
```

131.2 What we need from the previous lecture

Throughout, lower-case letters denote an agent's own state x and action α, and upper-case or calligraphic letters denote their cross-sectional averages X and $\mathcal{A}$.

In *Linear Quadratic Mean Field Games* an agent has period return and state equation

$$-\tfrac{1}{2}x^\top Q x - X^\top \Theta_X x - \tfrac{1}{2}\alpha^\top \Gamma \alpha - \mathcal{A}^\top \Theta_{\mathcal{A}} \alpha, \qquad dx = (B\alpha - Ax)dt + \Sigma^{1/2} dW,$$

and discounts at rate ρ.

Given the aggregate paths, her value function is $u(x,t) = \beta_0(t) + \beta_1(t)^\top x + \frac{1}{2}x^\top \bar{\beta}_2 x$, where $\bar{\beta}_2$ solves the single-agent Riccati equation and involves neither interaction matrix.

In equilibrium the aggregate state follows $\dot{X} = \left(B(\Gamma + \Theta_{\mathcal{A}})^{-1}B^\top P - A\right) X$, where the symmetric matrix P solves

$$PB(\Gamma + \Theta_{\mathcal{A}})^{-1}B^\top P = Q + \Theta_X + \rho P + PA + A^\top P,$$

and the eigenvalues of the closed-loop matrix must have real parts below $\rho/2$.

That equation comes from a state-costate system whose eigenvalues come in pairs λ and $\rho - \lambda$, so at most half of them lie below $\rho/2$; with $B(\Gamma + \Theta_{\mathcal{A}})^{-1}B^\top$ positive definite, that is what makes the equilibrium unique.

An agent's deviation from the cross-sectional mean, $z = x - X$, follows $dz = (B\Gamma^{-1}B^\top \bar{\beta}_2 - A)z\,dt + \Sigma^{1/2}dW$, in which no interaction matrix appears.

So data on deviations from the mean contain no information about strategic interaction, which is the missing intercept.

Shocks common to all agents, modeled with a compensated jump process $\mathcal{J}$, enter the law of motion of X but leave P unchanged.

We reuse two tools: the closed form for the aggregate eigenvalue in the scalar case,

$$\lambda = \frac{\rho}{2} - \sqrt{\left(\frac{\rho}{2} + a\right)^2 + \frac{b^2(q + \theta_X)}{\gamma + \theta_{\mathcal{A}}}},$$

and the calibration of the capital accumulation example.

In that example a firm with capital k earns $\Pi(k, K) = k^{\nu(1-1/\eta)}K^{\nu/\eta}$ when the rest of the industry holds K, pays an adjustment cost $\psi(i) = \frac{\phi}{2}\bar{i}\left(\frac{i-\bar{i}}{\bar{i}}\right)^2$, and buys investment goods at price $\mathcal{P}(I) = (I/\bar{i})^{1/\varepsilon_s}$.

In percentage deviations from the steady state it maps into the scalar model with $a = b = \delta$, $q + \theta_X = \frac{\eta-1}{\eta}\nu(1-\nu)$, $\gamma = \phi\,\delta\bar{k}^{1-\nu}$ and $\theta_{\mathcal{A}} = \delta\bar{k}^{1-\nu}/\varepsilon_s$, and the calibration gives half-lives of three years for a firm's deviation from the industry mean and five years for the industry.

half-lives: firm 3.00 years, industry 4.99 years
```

131.3 State-action cross terms

The return in *Linear Quadratic Mean Field Games* was not the most general quadratic return.

A second-order approximation to a general period return produces

$$\begin{aligned}\tilde{F}(x, X, \alpha, \mathcal{A}) = &- \tfrac{1}{2}x^\top Q x - X^\top \Theta_X x - \tfrac{1}{2}\alpha^\top \Gamma \alpha - \mathcal{A}^\top \Theta_{\mathcal{A}} \alpha \\ &+ x^\top C \alpha - X^\top \Theta_{X\alpha} \alpha - x^\top \Theta_{x\mathcal{A}} \mathcal{A} \\ &- \tfrac{1}{2}X^\top \Lambda_X X - \tfrac{1}{2}\mathcal{A}^\top \Lambda_{\mathcal{A}} \mathcal{A} - X^\top \Lambda_{X\mathcal{A}} \mathcal{A}.\end{aligned} \tag{131.1}$$

The previous lecture used the first line throughout, and the terms in the aggregates alone in the third line when it studied the planner.

Here we restore the second line.

The own cross term C links an agent's state and action.

It appears when adjustment costs depend on the state as well as on the action, as with investment costs that depend on the investment *rate* [Cooper and Haltiwanger, 2006, Hayashi, 1982].

The mixed interactions appear when the average state affects the marginal return to an agent's action ($\Theta_{X\alpha}$), or the average action affects the marginal return to her state ($\Theta_{x\mathcal{A}}$).

131.3.1 The individual problem

Taking the aggregate paths as given, the agent's first-order condition is now

$$\alpha^*(x,t) = \Gamma^{-1}\left[B^\top u_x(x,t) + C^\top x - \Theta_{\mathcal{A}}\mathcal{A}(t) - \Theta_{X\alpha}^\top X(t)\right],$$

and the curvature of her value function solves

$$(\bar\beta_2 B + C)\Gamma^{-1}(B^\top\bar\beta_2 + C^\top) = Q + \rho\bar\beta_2 + \bar\beta_2 A + A^\top\bar\beta_2. \tag{131.2}$$

The own cross term enters the individual's curvature, but, as before, no interaction matrix does.

Completing the square in the action,

$$-\tfrac{1}{2}x^\top Q x - \tfrac{1}{2}\alpha^\top\Gamma\alpha + x^\top C\alpha = -\tfrac{1}{2}x^\top(Q - C\Gamma^{-1}C^\top)x - \tfrac{1}{2}(\alpha - \Gamma^{-1}C^\top x)^\top\Gamma(\alpha - \Gamma^{-1}C^\top x),$$

shows that the counterpart of $Q \succ 0$ is $Q - C\Gamma^{-1}C^\top \succ 0$, which we assume.

131.3.2 The equilibrium

Aggregating the first-order condition gives

$$(\Gamma + \Theta_{\mathcal{A}})\mathcal{A} = B^\top(\beta_1 + \bar\beta_2 X) + (C - \Theta_{X\alpha})^\top X.$$

It is convenient to track $w \equiv \beta_1 + \bar\beta_2 X$, the marginal value of the state for an agent at the mean.

Differentiating, aggregating, and using (131.2) gives the state-costate system

$$\begin{aligned}\dot w &= (\rho I + A^\top)w + (Q + \Theta_X)X - (C - \Theta_{x\mathcal{A}})\mathcal{A},\\ \dot X &= B\mathcal{A} - AX.\end{aligned} \tag{131.3}$$

The costate equation involves $\Theta_{x\mathcal{A}}$, through which the average action shifts the marginal value of an agent's state.

The aggregate action involves $\Theta_{X\alpha}$, through which the average state shifts the marginal return to her action.

The two need not be equal, but when they are, the system keeps the Hamiltonian structure of the benchmark.

Proposition 131.3.1

Suppose $\Theta_{X\alpha} = \Theta_{x\mathcal{A}}$, and write $\tilde C \equiv C - \Theta_{X\alpha}$.

An equilibrium is characterized by a symmetric matrix P solving

$$(PB + \tilde C)(\Gamma + \Theta_{\mathcal{A}})^{-1}(B^\top P + \tilde C^\top) = Q + \Theta_X + \rho P + PA + A^\top P,$$

with aggregate dynamics

$$\dot X = \left[B(\Gamma + \Theta_{\mathcal{A}})^{-1}(B^\top P + \tilde C^\top) - A\right]X.$$

This is the Riccati equation of a single agent whose return is

$$-\tfrac{1}{2}X^\top(Q + \Theta_X)X - \tfrac{1}{2}\mathcal{A}^\top(\Gamma + \Theta_{\mathcal{A}})\mathcal{A} + X^\top\tilde C\mathcal{A}.$$

If $\Gamma + \Theta_{\mathcal{A}} \succ 0$ and $Q + \Theta_X - \tilde C(\Gamma + \Theta_{\mathcal{A}})^{-1}\tilde C^\top \succ 0$, an equilibrium exists and is unique.

So the equivalence result of *Linear Quadratic Mean Field Games* survives, with one more adjustment: the mixed interaction shifts the effective cross term from C to $C - \Theta_{X\alpha}$.

Completing the square in the effective problem shows that a cross term does two things.

It lowers the effective state curvature to $Q + \Theta_X - \tilde{C}(\Gamma + \Theta_{\mathcal{A}})^{-1}\tilde{C}^\top$, and it changes the effective drift matrix from A to $A - B(\Gamma + \Theta_{\mathcal{A}})^{-1}\tilde{C}^\top$.

The comparative statics of the previous lecture apply to these transformed objects rather than to the interaction matrices themselves.

The dynamics of an agent's deviation from the mean become

$$dz = \left[B\Gamma^{-1}(B^\top \bar{\beta}_2 + C^\top) - A\right] z\, dt + \Sigma^{1/2} dW,$$

which involve the own cross term C but still no interaction matrix, so data on deviations from the mean still contain no information about strategic interaction.

The planner is handled in the same way.

Its effective cross term is $C - \Theta_{X\alpha} - \Theta_{x\mathcal{A}} - \Lambda_{X\mathcal{A}}$, so it needs no restriction on the mixed interactions, which enter only through their sum.

To compute equilibria with cross terms, we extend the solver of *Linear Quadratic Mean Field Games*.

The `s` argument of `solve_continuous_are` replaces $\tilde{P}B$ by $\tilde{P}B + s$ in the quadratic term of the standard Riccati equation, so setting $s = -\tilde{C}$ handles an effective cross term $\tilde{C}$.

As in the previous lecture, the function checks the Riccati residual and the eigenvalue condition, and raises an error if either fails.

```
def closed_loop(A, B, Γ_eff, P, C=None):
    "The matrix governing aggregate dynamics, Ẋ = (B Γ_eff^{-1} (B' P + C') - A) X."
    K = B.T @ P if C is None else B.T @ P + C.T
    return B @ np.linalg.solve(Γ_eff, K) - A

def mfg_riccati(A, B, Q, Γ, ρ, C=None, tol=1e-8):
    """
    Solve  (P B + C) Γ^{-1} (B' P + C') = Q + ρ P + P A + A' P, with C = 0 by
    default, for the solution P whose closed-loop matrix has eigenvalues with
    real parts below ρ/2, and raise ValueError if there is none.
    """
    n, k = B.shape
    C_use = np.zeros((n, k)) if C is None else C
    try:
        P = -solve_continuous_are(-(A + ρ/2 * np.eye(n)), B, Q, Γ, s=-C_use)
    except (np.linalg.LinAlgError, ValueError):
        raise ValueError("no admissible solution of the Riccati equation")
    quad = (P @ B + C_use) @ np.linalg.solve(Γ, B.T @ P + C_use.T)
    residual = quad - (Q + ρ*P + P @ A + A.T @ P)
    scale = 1 + np.abs(Q).max() + np.abs(quad).max()
    if (np.abs(residual).max() > tol*scale
            or np.linalg.eigvals(closed_loop(A, B, Γ, P, C)).real.max() >= ρ/2):
        raise ValueError("no admissible solution of the Riccati equation")
    return P
```

131.3.3 Investment rates and Hayashi adjustment costs

In the capital accumulation example the adjustment cost depends on investment alone.

A common alternative makes it depend on the investment rate,

$$\psi(i,k) = \frac{\phi}{2}\,\delta k\left(\frac{i}{\delta k} - 1\right)^2,$$

which is homogeneous of degree one, as in Hayashi [1982], and which reduces to the cost $\psi(i)$ above when $k = \bar{k}$.

Since $i - \delta k = \delta\bar{k}(\alpha - x)$ in percentage deviations, the normalized cost is $\frac{\gamma}{2}(\alpha - x)^2$ to second order, with the same $\gamma = \phi\,\delta\bar{k}^{1-\nu}$ as before.

Expanding the square shows that the cost adds γ to the own-state curvature and creates an own cross term,

$$q \to q + \gamma, \qquad C = \gamma,$$

while $Q - C\Gamma^{-1}C^\top = q$ is unchanged.

There are no mixed interactions, so $\tilde{C} = \gamma$.

Completing the square in the effective problem of *Proposition 131.3.1* turns the scalar problem into one without a cross term, with the drift $a = \delta$ replaced by

$$\tilde{a} = \delta - \frac{\delta\gamma}{\gamma + \theta_{\mathcal{A}}} = \frac{\delta\,\theta_{\mathcal{A}}}{\gamma + \theta_{\mathcal{A}}}$$

and the effective state curvature $q + \theta_X + \gamma - \gamma^2/(\gamma + \theta_{\mathcal{A}}) = q + \theta_X + \gamma\theta_{\mathcal{A}}/(\gamma + \theta_{\mathcal{A}})$.

So the aggregate eigenvalue is

$$\lambda = \frac{\rho}{2} - \sqrt{\left(\frac{\rho}{2} + \tilde{a}\right)^2 + \frac{\delta^2}{\gamma + \theta_{\mathcal{A}}}\left(q + \theta_X + \frac{\gamma\,\theta_{\mathcal{A}}}{\gamma + \theta_{\mathcal{A}}}\right)},$$

and setting $\theta_X = \theta_{\mathcal{A}} = 0$, so that $\tilde{a} = 0$, gives the individual's.

With Hayashi costs, investing at the replacement rate is free whatever the capital stock, so depreciation no longer pushes a firm back toward its steady state.

The drift δ that sat inside the square root in the formula without cross terms disappears from the individual's problem, and it returns in the industry's problem only through the price of investment goods.

Let's compare the half-lives with and without Hayashi costs, holding γ at its calibrated value.

```
def λ_cross(ρ, a, b, q_eff, γ_eff, c_eff):
    "Scalar aggregate eigenvalue with an effective cross term, by completing the␣
 ↪square."
    a_t = a - b*c_eff/γ_eff
    q_t = q_eff - c_eff**2/γ_eff
    return ρ/2 - np.sqrt((ρ/2 + a_t)**2 + b**2*q_t/γ_eff)

λ_ind_H = λ_cross(ρ_c, δ_c, δ_c, q_c + γ_c, γ_c, γ_c)
λ_agg_H = λ_cross(ρ_c, δ_c, δ_c, q_c + γ_c + θ_X_c, γ_c + θ_A_c, γ_c)

# the general solver agrees

    print(f"{label:>20}{half_life(λ_i):>12.2f}{half_life(λ_a):>10.2f}"
          f"{half_life(λ_a)/half_life(λ_i):>8.2f}")
```

```
aggregate λ: closed form -0.121690, solver -0.121690

                     individual  industry   ratio
    investment costs        3.00      4.99    1.66
       Hayashi costs        3.47      5.70    1.64
```

Hayashi costs slow both the individual firm and the industry, and leave the ratio of the two half-lives about where it was.

Exercise 131.6.1 recalibrates ϕ to restore a three-year individual half-life, and revisits the limit of constant returns to scale.

131.3.4 When the restriction fails

Alvarez and Argente [2026] point out that the restriction $\Theta_{X\alpha} = \Theta_{x\mathcal{A}}$ has no general economic justification.

Consider a country with capital k and investment i that takes world capital K and world investment I as given.

Suppose its consumption is $c = f(k, K) - i$ and its period utility is $u(c)$, with $u'' < 0$ and $f_K > 0$.

Then $\partial^2 u / \partial i \, \partial K = -u''(c) f_K > 0$, because higher world capital raises consumption and so lowers the marginal utility cost of investing.

But $\partial^2 u / \partial k \, \partial I = 0$, because world investment does not affect the return to capital.

So the two mixed interactions differ, and in the notation of (131.1), $\Theta_{X\alpha} < 0 = \Theta_{x\mathcal{A}}$.

When they differ, (131.3) is still a linear state-costate system, but the two outer factors of the Riccati equation are no longer transposes of one another, and the matrix of the system is no longer Hamiltonian.

Its eigenvalues then need not come in pairs λ and $\rho - \lambda$, and the argument that delivered at most one equilibrium in *Linear Quadratic Mean Field Games* breaks down.

Even with a single state, the two eigenvalues can both lie below $\rho/2$, giving a continuum of equilibria of the kind studied by Benhabib and Farmer [1994], or both lie above it, so that no equilibrium exists.

To see the pairing fail, we write a function for the matrix of (131.3) that allows the two mixed interactions to differ.

```
def state_costate(A, B, Q_eff, Γ_eff, ρ, C1, C2):
    """
    Matrix of the state-costate system for (w, X).  C1 = C - Θ_xA enters the
    costate equation and C2 = C - Θ_Xa enters the aggregate action.
    """
    n = A.shape[0]
    G_B = np.linalg.solve(Γ_eff, B.T)       # (Γ + Θ_A)^{-1} B'
    G_C = np.linalg.solve(Γ_eff, C2.T)      # (Γ + Θ_A)^{-1} C2'
    return np.block([[ρ*np.eye(n) + A.T - C1 @ G_B, Q_eff - C1 @ G_C],
                     [B @ G_B,                      B @ G_C - A]])
```

We apply it to the Hayashi economy, first as it is and then with a small mixed interaction of the open-economy sign, $\Theta_{X\alpha} = -0.05$ and $\Theta_{x\mathcal{A}} = 0$.

```
for label, θ_Xα, θ_xA in (('restriction holds', 0.0, 0.0),
                          ('restriction fails', -0.05, 0.0)):
    M_sc = state_costate(δ_c*one, δ_c*one, (q_c + y_c + θ_X_c)*one, (y_c + θ_A_c)*one,
                         ρ_c, (y_c - θ_xA)*one, (y_c - θ_Xα)*one)
    ev = np.sort(np.linalg.eigvals(M_sc).real)
    print(f"{label}: eigenvalues {ev.round(4)}, sum {ev.sum():.4f}, ρ = {ρ_c}")
```

```
restriction holds: eigenvalues [-0.1217  0.1717], sum 0.0500, ρ = 0.05
restriction fails: eigenvalues [-0.0889  0.1747], sum 0.0857, ρ = 0.05
```

When the restriction holds, the eigenvalues sum to ρ, so they are symmetric about $\rho/2$.

When it fails, they sum to $\rho + b(\theta_{x\mathcal{A}} - \theta_{X\alpha})/(\gamma + \theta_{\mathcal{A}})$, and the open-economy sign pushes them up, toward the case in which no equilibrium exists.

Exercise 131.6.2 finds parameters at which both eigenvalues lie on the same side of $\rho/2$.

The planner is immune to all of this, because it internalizes both mixed interactions and so sees only their sum.

131.4 Forcing processes and pass-through

The same machinery handles states that agents cannot control, such as a marginal cost.

Partition the state as $x = (x^{(1)}, x^{(2)})$, where $x^{(1)}$ is controlled and $x^{(2)}$ is a forcing process with its own law of motion,

$$A = \begin{bmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{bmatrix}, \qquad B = \begin{bmatrix} B_1 \\ 0 \end{bmatrix}.$$

Now B no longer has full row rank and $B\Gamma^{-1}B^\top$ is singular, so the Riccati equations are not of the standard full-rank kind, but they are block recursive.

Following Alvarez and Argente [2026], we keep interactions through states only, $\Theta_{\mathcal{A}} = 0$.

Proposition 131.4.1

Suppose $\Theta_{\mathcal{A}} = 0$, that $B_1\Gamma^{-1}B_1^\top$, Q_{11} and $Q_{11} + \Theta_{X,11}$ are positive definite, and that the eigenvalues of $-A_{22}$ have real parts below $\rho/2$.

Then the upper-left block of P solves the equilibrium Riccati equation of the controlled block alone,

$$P_{11}B_1\Gamma^{-1}B_1^\top P_{11} = Q_{11} + \Theta_{X,11} + \rho P_{11} + P_{11}A_{11} + A_{11}^\top P_{11},$$

the remaining blocks solve linear equations, and the eigenvalues of the aggregate closed-loop matrix are those of $B_1\Gamma^{-1}B_1^\top P_{11} - A_{11}$ together with those of $-A_{22}$.

The blocks of Q and Θ_X that involve only the forcing process affect the value of the problem but not the policy, so they can be chosen freely to keep both matrices positive definite.

Here is a pricing example in the spirit of the real rigidities of Ball and Romer [1990].

A store's log price $x^{(1)}$ has a target that puts weight $1 - \chi$ on its own log marginal cost $x^{(2)}$ and weight $\chi \in [0, 1)$ on the average price $X^{(1)}$, and the store pays a Rotemberg cost to change its price:

$$-\tfrac{q}{2}\left(x^{(1)} - (1-\chi)x^{(2)} - \chi X^{(1)}\right)^2 - \tfrac{\gamma}{2}\alpha^2, \qquad dx^{(1)} = \alpha\, dt.$$

The weight χ is the static pass-through of competitors' prices, so it measures strategic complementarity, and $\Theta_{X,11} = -q\chi$.

Terms that pair the forcing process with the average price affect neither the policy nor the dynamics, so we drop them.

Costs follow $dx^{(2)} = -a_{22}x^{(2)}dt + \sigma dW + \upsilon\, d\mathcal{J}$, where W is idiosyncratic and $\mathcal{J}$ is a common jump process.

An idiosyncratic cost shock moves a store away from the mean, so the single-agent matrix $\bar{\beta}_2$ governs its response, while a common cost shock moves the industry, which P governs.

Let's trace both responses to a permanent one percent increase in costs, $a_{22} = 0$.

```
def pricing_with_costs(χ, a_22, ρ=0.04, q=1.0, γ=1.0):
    "Aggregate and deviation drift matrices in the pricing example with cost shocks."
    A_f = np.array([[0.0, 0.0],
                    [0.0, a_22]])
    B_f = np.array([[1.0],
                    [0.0]])
    Γ_f = np.array([[γ]])
    Q_f = q*np.array([[1.0, -(1 - χ)],
                      [-(1 - χ), 2.0]])       # (2, 2) element chosen freely
    Θ_f = np.array([[-q*χ, 0.0],
                    [0.0,  0.0]])
    β2_f = mfg_riccati(A_f, B_f, Q_f, Γ_f, ρ)
    P_f = mfg_riccati(A_f, B_f, Q_f + Θ_f, Γ_f, ρ)
    return closed_loop(A_f, B_f, Γ_f, P_f), closed_loop(A_f, B_f, Γ_f, β2_f)
```

The first matrix moves the industry's average price after a common cost shock, and the second moves a store's price relative to the average after an idiosyncratic one.

```
t_f = np.linspace(0, 6, 200)
cost_shock = np.array([0.0, 1.0])

fig, axes = plt.subplots(1, 2, figsize=(11, 4.2))
for χ in (0.0, 0.5, 0.8):
    U_agg, U_dev = pricing_with_costs(χ, 0.0)
    agg = [(expm(U_agg*t) @ cost_shock)[0] for t in t_f]
    dev = [(expm(U_dev*t) @ cost_shock)[0] for t in t_f]
    axes[0].plot(t_f, agg, lw=2, label=f"$\\chi = {χ}$")
    axes[1].plot(t_f, dev, lw=2, label=f"$\\chi = {χ}$")

axes[0].set_title('average price, common cost shock')
axes[1].set_title("store's relative price, idiosyncratic cost shock")
for ax in axes:
    ax.set_xlabel('years')
    ax.set_ylabel('percent')
    ax.legend()
plt.tight_layout()
plt.show()
```

A store passes an idiosyncratic cost increase through quickly but only partially, because its competitors' prices do not move: in the long run it passes through $1 - \chi$ of it.

The industry passes an aggregate cost increase through completely, but slowly, because each store waits for the others.

Let's compare the half-lives.

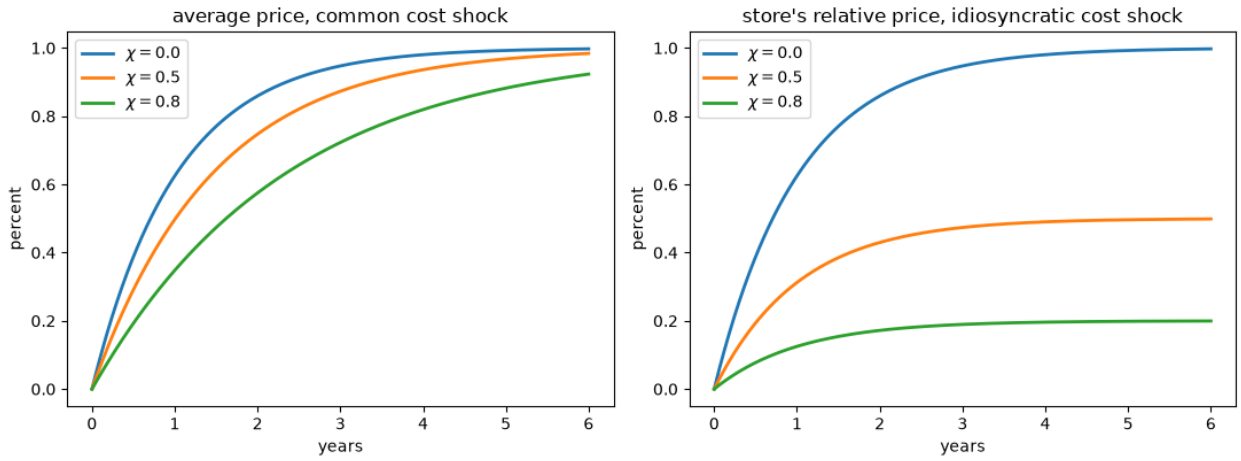

Fig. 131.1: Common and idiosyncratic cost pass-through

```
for χ in (0.0, 0.5, 0.8):
    U_agg, U_dev = pricing_with_costs(χ, 0.0)
    λ_agg_f, λ_dev_f = U_agg[0, 0], U_dev[0, 0]
    print(f"χ = {χ}: store half-life {half_life(λ_dev_f):.2f} years, "
          f"industry half-life {half_life(λ_agg_f):.2f} years")
```

```
χ = 0.0: store half-life 0.71 years, industry half-life 0.71 years
χ = 0.5: store half-life 0.71 years, industry half-life 1.01 years
χ = 0.8: store half-life 0.71 years, industry half-life 1.62 years
```

With $\chi = 0.8$ a store closes half of the gap to its new target in about 0.7 years, while the industry takes about 1.6 years.

The store's half-life is the same for every χ, because a store's deviation from the average is governed by its own curvature q alone.

So how fast stores respond to their own cost shocks reveals nothing about χ, which is the missing intercept of *Linear Quadratic Mean Field Games* in another guise.

How far they respond is a different matter: in the long run a store passes through $1 - \chi$ of its own cost shock, because χ also enters the store's own return, through the weight on its cost.

When a model ties the own curvature Q to the interaction Θ_χ in this way, micro data can be informative after all; the result of the previous lecture is that, for given Q, they are not.

Exercise 131.6.3 verifies *Proposition 131.4.1* in this example and studies transitory cost shocks.

131.5 Coupling through higher moments

So far agents have cared about the distribution of states only through its mean.

Alvarez and Argente [2026] also let payoffs depend on higher moments.

Take a scalar state and a scalar action, set $\theta_{\mathcal{A}} = 0$, and write $M_r(t) = \int x^r m(x,t)dx$ for the r-th moment of the cross-sectional distribution.

The period return is

$$-\tfrac{1}{2}qx^2 - \left(\theta_0 + \sum_{r=1}^{\bar r} \theta_r M_r\right) x - \tfrac{1}{2}\gamma\alpha^2,$$

the state follows $dx = (b\alpha - ax)dt + \sigma dW$, and the benchmark of *Linear Quadratic Mean Field Games* is the case $\bar r = 1$ and $\theta_0 = 0$.

A natural notion of strategic complementarity is that a stochastically higher distribution raises the marginal return to x, which here means that $-\sum_r \theta_r x^r$ is nondecreasing in x.

Our example below, with θ_1 and θ_3 negative and the other coefficients zero, satisfies it.

The value function is still quadratic, its curvature $\bar\beta_2$ is still that of the single-agent problem, and the individual eigenvalue

$$\lambda_{\text{ind}} \equiv \frac{b^2}{\gamma}\bar\beta_2 - a = \frac{\rho}{2} - \sqrt{\left(a + \frac{\rho}{2}\right)^2 + \frac{b^2 q}{\gamma}}$$

is unchanged.

What changes is aggregation.

The Kolmogorov forward equation implies

$$\dot M_r = r\lambda_{\text{ind}} M_r + r\frac{b^2}{\gamma}\beta_1 M_{r-1} + \frac{r(r-1)\sigma^2}{2} M_{r-2}, \qquad \dot\beta_1 = (\rho - \lambda_{\text{ind}})\beta_1 + \theta_0 + \sum_{r=1}^{\bar r} \theta_r M_r,$$

so the moments obey a finite system, but a nonlinear one, because of the products $\beta_1 M_{r-1}$.

When $\sigma > 0$, $\lambda_{\text{ind}} < 0$, and $\theta_0 = -\sum_{r \text{ even}} \theta_r \bar M_r$, there is a steady state with $\beta_1 = 0$ in which the invariant distribution is normal with mean zero and variance $v = \sigma^2/(-2\lambda_{\text{ind}})$.

Its odd moments vanish and its even moments are $\bar M_r = (r-1)!!\, v^{r/2}$; as $\sigma \to 0$ it collapses to a point mass at zero, which we include below as a limiting case.

Linearizing the system around this steady state gives $\dot y = \tilde{\mathcal{H}} y$ for $y = (\hat\beta_1, \hat M_1, \dots, \hat M_{\bar r})$, where hats denote deviations from the steady state.

Proposition 131.5.1

Let $\bar r$ be even and define

$$\bar\theta \equiv \sum_{r \text{ odd}} r\, \bar M_{r-1}\, \theta_r.$$

The eigenvalues of $\tilde{\mathcal{H}}$ are $\tilde\lambda_r = r\lambda_{\text{ind}}$ for $r = 2, \dots, \bar r$, together with

$$\tilde\lambda_1 = \frac{\rho}{2} - \sqrt{\left(a + \frac{\rho}{2}\right)^2 + \frac{b^2(q + \bar\theta)}{\gamma}}, \qquad \tilde\lambda_{\bar r + 1} = \frac{\rho}{2} + \sqrt{\left(a + \frac{\rho}{2}\right)^2 + \frac{b^2(q + \bar\theta)}{\gamma}}.$$

If $q + \bar\theta + \gamma a(a + \rho)/b^2 > 0$, the steady state is locally determinate, with one unstable and $\bar r$ stable eigenvalues.

Three features stand out.

First, the interaction coefficients enter only through $\bar\theta$, and only those on odd moments enter it, so $\bar\theta$ plays exactly the role of θ_X in the scalar formula of *Linear Quadratic Mean Field Games*.

Second, $\bar\theta$ weights $\theta_3, \theta_5, \dots$ by even moments of the invariant distribution, which grow with σ^2.

In the benchmark, the variance of idiosyncratic shocks never enters the Riccati equations, so it has no effect on aggregate dynamics; with higher moments, idiosyncratic risk affects aggregate persistence.

Third, coefficients on even moments do not affect the local eigenvalues, although they can affect transitional dynamics, as Exercise 131.6.4 shows.

Let's build $\tilde{\mathcal{H}}$ and check *Proposition 131.5.1*, using $\bar{r} = 4$ and interactions through the first and third moments.

```
def moment_system(ρ, a, b, q, γ, σ, θ):
    """
    Linearized matrix for (β̂_1, M̂_1, ..., M̂_r̄) around the zero-mean steady
    state, with θ = (θ_1, ..., θ_r̄).  Also returns the steady-state moments
    M̄_0, ..., M̄_r̄ and the individual eigenvalue.
    """
    r_bar = len(θ)
    λ_ind = ρ/2 - np.sqrt((a + ρ/2)**2 + b**2*q/γ)
    v = σ**2/(-2*λ_ind)                          # invariant variance
    M_bar = np.zeros(r_bar + 1)
    M_bar[0] = 1.0
    for r in range(2, r_bar + 1, 2):
        M_bar[r] = (r - 1)*v*M_bar[r - 2]
    H_tilde = np.zeros((r_bar + 1, r_bar + 1))
    H_tilde[0, 0] = ρ - λ_ind
    H_tilde[0, 1:] = θ
    for r in range(1, r_bar + 1):
        H_tilde[r, 0] = r*M_bar[r - 1]*b**2/γ
        H_tilde[r, r] = r*λ_ind
        if r >= 3:                               # M̂_0 is identically zero
            H_tilde[r, r - 2] = r*(r - 1)*σ**2/2
    return H_tilde, M_bar, λ_ind

ρ_m, a_m, b_m, q_m, γ_m = 0.05, 0.3, 1.0, 1.0, 1.0
θ_m = np.array([-0.3, 0.0, -0.2, 0.0])       # complementarity through M_1 and M_3

for σ in (0.0, 0.5, 1.0):
    H_m, M_bar, λ_ind = moment_system(ρ_m, a_m, b_m, q_m, γ_m, σ, θ_m)
    θ_bar = θ_m[0] + 3*M_bar[2]*θ_m[2]
    root = np.sqrt((a_m + ρ_m/2)**2 + b_m**2*(q_m + θ_bar)/γ_m)
    predicted = np.r_[ρ_m/2 - root, ρ_m/2 + root, [r*λ_ind for r in range(2, 5)]]
    print(f"σ = {σ}: eigenvalues {np.sort(np.linalg.eigvals(H_m).real).round(4)}")
    print(f"        predicted   {np.sort(predicted).round(4)}")
```

```
σ = 0.0: eigenvalues [-4.1059 -3.0795 -2.053  -0.8726  0.9226]
        predicted   [-4.1059 -3.0795 -2.053  -0.8726  0.9226]
σ = 0.5: eigenvalues [-4.1059 -3.0795 -2.053  -0.8309  0.8809]
        predicted   [-4.1059 -3.0795 -2.053  -0.8309  0.8809]
σ = 1.0: eigenvalues [-4.1059 -3.0795 -2.053  -0.6915  0.7415]
        predicted   [-4.1059 -3.0795 -2.053  -0.6915  0.7415]
```

To trace the equilibrium path we keep the $\bar{r}$ eigenvalues below $\rho/2$, express $\hat{\beta}_1$ as a linear function of the moment deviations on the stable subspace, and substitute.

That gives a law of motion for the moment deviations alone, so an initial condition specifies only those deviations, and $\hat{\beta}_1(0)$ follows from the saddle path.

```
def moment_dynamics(H_tilde, ρ):
    "Law of motion of the moment deviations on the stable subspace of H_tilde."
    ev, V = np.linalg.eig(H_tilde)
```

(continues on next page)

(continued from previous page)

```
    V_s = V[:, ev.real < ρ/2]
    s = np.real(V_s[0] @ np.linalg.inv(V_s[1:]))      # β̂₁ = s · M̂
    return H_tilde[1:, 1:] + np.outer(H_tilde[1:, 0], s)
```

As an initial condition we shift the invariant distribution to the right by Δ, which to first order raises M_1 by Δ and M_3 by $3v\Delta$ and leaves the even moments unchanged.

The next figure shows the path of the mean for several levels of idiosyncratic volatility.

```
t_m = np.linspace(0, 6, 200)
Δ = 0.1

fig, ax = plt.subplots(figsize=(8, 4.5))
for σ in (0.0, 0.6, 1.0, 1.3):
    H_m, M_bar, λ_ind = moment_system(ρ_m, a_m, b_m, q_m, γ_m, σ, θ_m)
    U_m = moment_dynamics(H_m, ρ_m)
    M_hat0 = np.array([Δ, 0.0, 3*M_bar[2]*Δ, 0.0])
    path = [(expm(U_m*t) @ M_hat0)[0] for t in t_m]
    θ_bar = θ_m[0] + 3*M_bar[2]*θ_m[2]
    λ_1 = ρ_m/2 - np.sqrt((a_m + ρ_m/2)**2 + b_m**2*(q_m + θ_bar)/γ_m)
    ax.plot(t_m, path, lw=2,
            label=f"$\\sigma = {σ}$, slowest half-life {half_life(λ_1):.2f}")
ax.set_xlabel('$t$')
ax.set_ylabel('cross-sectional mean $M_1(t)$')
ax.legend()
plt.tight_layout()
plt.show()
```

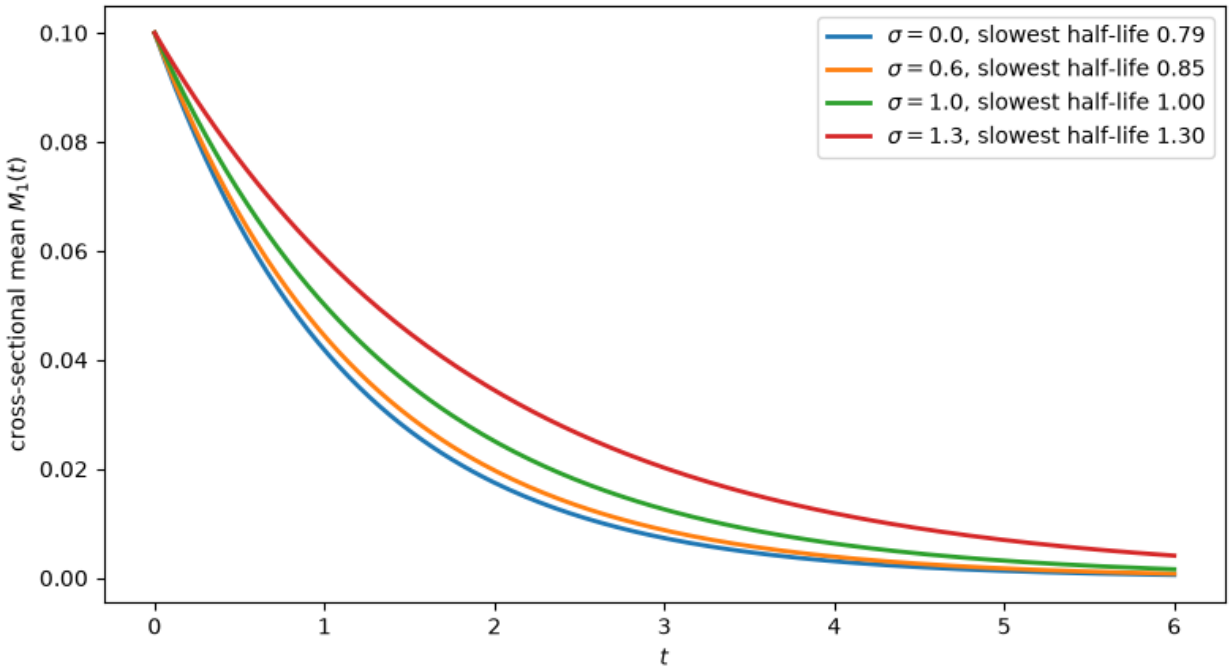

Fig. 131.2: Idiosyncratic risk and mean persistence

Greater idiosyncratic volatility makes the mean more persistent here.

A larger variance puts more weight on the third moment, through which complementarity operates, so the effective interaction $\bar{\theta}$ is stronger.

131.6 Exercises

Exercise 131.6.1

This exercise continues the Hayashi example.

1. Choose ϕ so that a firm that ignores the industry again closes half of a capital gap in three years under Hayashi costs, and recompute the industry's half-life and the ratio of the two half-lives.
2. Holding ϕ from part 1 and ε_s fixed, compute the aggregate eigenvalue in the limit of constant returns to scale, $\nu \to 1$, where $q + \theta_X \to 0$, once with no price effect and once with the calibrated supply elasticity. Explain why the answers differ from the limit $\lambda \to -\delta$ that holds without Hayashi costs.

Solution

For part 1, the individual's eigenvalue is $\rho/2 - \sqrt{\rho^2/4 + \delta^2 q/\gamma}$, so a target λ requires $\gamma = \delta^2 q/[(\rho/2-\lambda)^2 - \rho^2/4]$.

```
λ_target = -np.log(2)/3
γ_H = δ_c**2*q_c/((ρ_c/2 - λ_target)**2 - ρ_c**2/4)

λ_ind_H = λ_cross(ρ_c, δ_c, δ_c, q_c + γ_H, γ_H, γ_H)
λ_agg_H = λ_cross(ρ_c, δ_c, δ_c, q_c + γ_H + θ_X_c, γ_H + θ_A_c, γ_H)

print(f"γ = {γ_H:.4f}, so ψ = {γ_H/cap_scale(η_c, ν_c):.4f}")
print(f"individual half-life {half_life(λ_ind_H):.2f}, "
      f"industry half-life {half_life(λ_agg_H):.2f}, "
      f"ratio {half_life(λ_agg_H)/half_life(λ_ind_H):.2f}")
```

```
γ = 0.0384, so ψ = 0.1097
individual half-life 3.00, industry half-life 5.42, ratio 1.81
```

Matching the three-year individual half-life requires a cheaper installation technology than before, $\phi \approx 0.11$ instead of $1/7$.

The industry's half-life is then 5.4 years, so the gap between micro and macro adjustment widens: the ratio rises from 1.66 to 1.81.

For part 2, when $q + \theta_X = 0$ the effective state curvature in *Proposition 131.3.1* is γ, and the industry's effective return is

$$-\tfrac{1}{2}\gamma X^2 - \tfrac{1}{2}(\gamma + \theta_{\mathcal{A}})\mathcal{A}^2 + \gamma X \mathcal{A} = -\tfrac{\gamma}{2}(\mathcal{A} - X)^2 - \tfrac{\theta_{\mathcal{A}}}{2}\mathcal{A}^2.$$

In the limit $\nu \to 1$, the scale $\delta \bar{k}^{1-\nu}$ that converts ϕ and $1/\varepsilon_s$ into γ and $\theta_{\mathcal{A}}$ tends to $\delta(\eta - 1)/[\eta(\rho + \delta)]$.

Let's compute the limit with and without a price effect.

```
ψ_H = γ_H/cap_scale(η_c, ν_c)
scale_lim = cap_scale(η_c, 1.0)
γ_lim = ψ_H*scale_lim
for inv_ε in (0.0, 1/ε_s_c):
    θ_A_lim = inv_ε*scale_lim
    λ_lim = λ_cross(ρ_c, δ_c, δ_c, γ_lim, γ_lim + θ_A_lim, γ_lim)
    print(f"1/ε_s = {inv_ε:.3f}: θ_A = {θ_A_lim:.4f}, λ = {λ_lim:.5f}")
```

```
1/ε_s = 0.000: θ_A = 0.0000, λ = 0.00000
1/ε_s = 0.257: θ_A = 0.1286, λ = -0.08054
```

With $\theta_{\mathcal{A}} = 0$ the only cost is the cost of net investment, so any capital stock can be maintained for free and nothing pulls the industry back: the aggregate state has a unit root.

Without Hayashi costs, maintaining a capital stock above its steady state requires gross investment above $\bar{\imath}$, which $\psi(i)$ penalizes, so the industry lets depreciation do the work and $\lambda \to -\delta$.

With $\theta_{\mathcal{A}} > 0$ the price of investment goods penalizes gross investment away from $\bar{\imath}$, which restores some mean reversion.

Exercise 131.6.2

This exercise shows why the restriction $\Theta_{X\alpha} = \Theta_{x\mathcal{A}}$ matters, even with a single state.

Take $\rho = 0.05$, $a = 0.3$, $b = q = \gamma = 1$, $\theta_X = \theta_{\mathcal{A}} = 0$ and no own cross term, and use `state_costate` with $C_1 = -\theta_{x\mathcal{A}}$ and $C_2 = -\theta_{X\alpha}$.

1. Show that the trace of the state-costate matrix is $\rho + b(\theta_{x\mathcal{A}} - \theta_{X\alpha})/(\gamma + \theta_{\mathcal{A}})$, so that its eigenvalues can be symmetric about $\rho/2$ only when $\theta_{X\alpha} = \theta_{x\mathcal{A}}$.
2. Compute the eigenvalues for $(\theta_{X\alpha}, \theta_{x\mathcal{A}})$ equal to $(0, 0)$, $(-2, -2)$, $(-1.5, -2.5)$ and $(-2.5, -1.5)$, and count how many have real parts below $\rho/2$. What does each count imply about the number of equilibria?

Solution

For part 1, with $g = \gamma + \theta_{\mathcal{A}}$ the diagonal elements of the matrix are $\rho + a - bC_1/g$ and $bC_2/g - a$.

Their sum is $\rho + b(C_2 - C_1)/g = \rho + b(\theta_{x\mathcal{A}} - \theta_{X\alpha})/g$.

Eigenvalues symmetric about $\rho/2$ must sum to ρ, which requires $\theta_{X\alpha} = \theta_{x\mathcal{A}}$.

For part 2, we compute the eigenvalues in each case.

```
ρ_e, a_e = 0.05, 0.3

print(f"{'(θ_Xα, θ_xA)':>14}{'eigenvalues':>34}{'trace':>8}{'below ρ/2':>11}")
for θ_Xα_e, θ_xA_e in ((0.0, 0.0), (-2.0, -2.0), (-1.5, -2.5), (-2.5, -1.5)):
    M_e = state_costate(a_e*one, one, one, one, ρ_e,
                        -θ_xA_e*one, -θ_Xα_e*one)
    ev = np.linalg.eigvals(M_e)
    print(f"{str((θ_Xα_e, θ_xA_e)):>14}{str(np.round(ev, 4)):>34}"
          f"{ev.real.sum():>8.3f}{np.sum(ev.real < ρ_e/2):>11}")
```

```
  (θ_Xα, θ_xA)                      eigenvalues   trace  below ρ/2
    (0.0, 0.0)                [ 1.0765 -1.0265]   0.050          1
  (-2.0, -2.0)     [0.025+0.4409j 0.025-0.4409j]   0.050          0
  (-1.5, -2.5)                [-0.7108 -0.2392]  -0.950          2
  (-2.5, -1.5)                  [0.2892 0.7608]   1.050          0
```

With no mixed interactions there is one eigenvalue on each side of $\rho/2$ and a unique equilibrium.

At $(-2, -2)$ the restriction holds, but the sufficient condition $q - \tilde{C}^2/g > 0$ of *Proposition 131.3.1* fails, since $1 - 4 < 0$.

The eigenvalues are then complex with real part exactly $\rho/2$, so for $X(0) \neq 0$ there is no admissible path and no equilibrium.

At $(-1.5, -2.5)$ both eigenvalues are below $\rho/2$, so every initial costate $w(0)$ generates an admissible path.

Each of these paths is an equilibrium.

Given aggregate paths that grow more slowly than $e^{\rho t/2}$, the individual's costate equation has a unique admissible solution, because its own root $\rho - \lambda_{\text{ind}}$ exceeds $\rho/2$, and the w on any path of the system is that solution.

So there is a continuum of equilibria for each initial distribution.

At $(-2.5, -1.5)$ both eigenvalues are above $\rho/2$, and again no equilibrium exists for $X(0) \neq 0$.

Exercise 131.6.3

This exercise works with the pricing example of *Forcing processes and pass-through*.

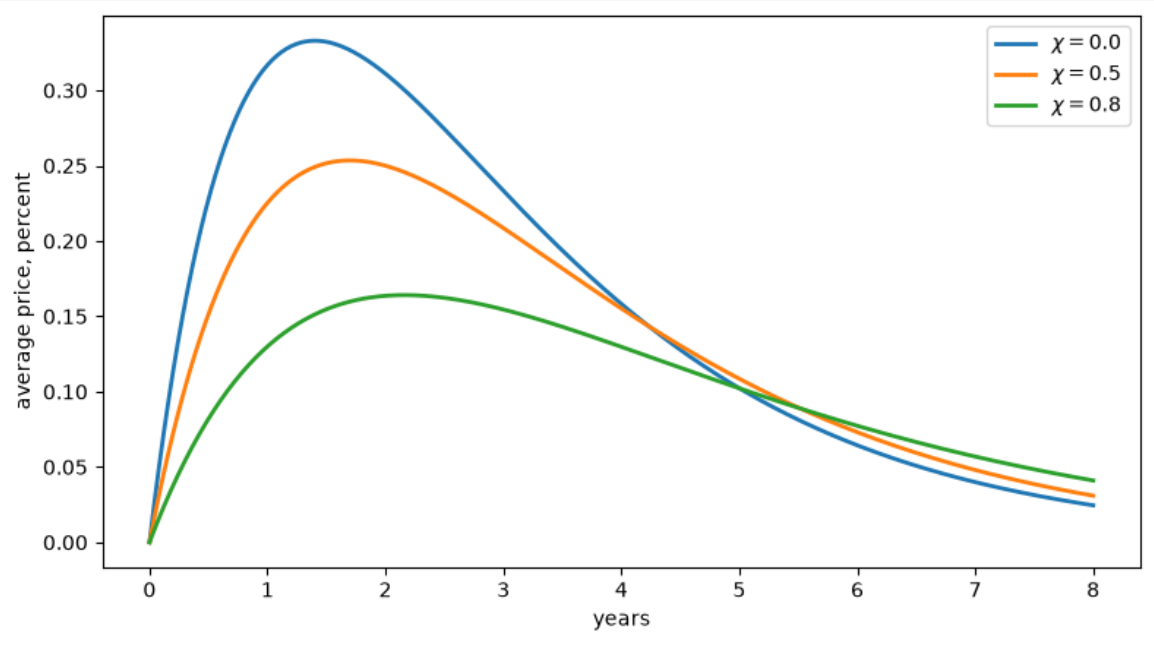
1. Take $\chi = 0.8$ and $a_{22} = 0.5$. Check that the eigenvalues of the aggregate closed-loop matrix are those of $B_1 \Gamma^{-1} B_1^\top P_{11} - A_{11}$ together with $-a_{22}$, as *Proposition 131.4.1* says. Check also that changing the $(2,2)$ elements of Q and Θ_X leaves the first row of P, and hence the pricing policy, unchanged.
2. With transitory cost shocks, $a_{22} = 0.5$, plot the industry's response to a common one percent cost increase for $\chi \in \{0, 0.5, 0.8\}$. How do the size and timing of the peak response depend on χ?

Solution

For part 1, we rebuild the example with the $(2,2)$ elements as arguments.

```
χ_e, a_22_e, ρ_f, q_f, γ_f = 0.8, 0.5, 0.04, 1.0, 1.0
A_f = np.array([[0.0, 0.0],
                [0.0, a_22_e]])
B_f = np.array([[1.0],
                [0.0]])
Γ_f = np.array([[γ_f]])

def P_forcing(q_22, θ_22):
    "Equilibrium P when the (2, 2) elements of Q and Θ_X are q_22 and θ_22."
    Q_f = q_f*np.array([[1.0, -(1 - χ_e)],
                        [-(1 - χ_e), 0.0]])
    Q_f[1, 1] = q_22
    Θ_f = np.array([[-q_f*χ_e, 0.0],
                    [0.0, θ_22]])
    return mfg_riccati(A_f, B_f, Q_f + Θ_f, Γ_f, ρ_f)



P_a, P_b = P_forcing(2.0, 0.0), P_forcing(7.0, 3.0)
λ_11 = P_a[0, 0]/γ_f          # B_1 Γ^{-1} B_1' P_11 - A_11
ev_cl = np.sort(np.linalg.eigvals(closed_loop(A_f, B_f, Γ_f, P_a)).real)
print("closed-loop eigenvalues:   ", ev_cl.round(5))
print("controlled block and -a_22:", np.sort([λ_11, -a_22_e]).round(5))
print("first row of P unchanged:", np.allclose(P_a[0], P_b[0]))
```

```
closed-loop eigenvalues:    [-0.5     -0.42766]
controlled block and -a_22: [-0.5     -0.42766]
first row of P unchanged: True
```

For part 2, we plot the response of the average price.

```
t_e = np.linspace(0, 8, 400)
fig, ax = plt.subplots(figsize=(8, 4.5))
for χ in (0.0, 0.5, 0.8):
    U_agg, _ = pricing_with_costs(χ, 0.5)
    agg = np.array([(expm(U_agg*t) @ np.array([0.0, 1.0]))[0] for t in t_e])
    k = agg.argmax()
    ax.plot(t_e, agg, lw=2, label=f"$\\chi = {χ}$")
    print(f"χ = {χ}: peak {agg[k]:.3f} percent after {t_e[k]:.2f} years")
ax.set_xlabel('years')
ax.set_ylabel('average price, percent')
ax.legend()
plt.tight_layout()
plt.show()
```

```
χ = 0.0: peak 0.333 percent after 1.40 years
χ = 0.5: peak 0.253 percent after 1.70 years
χ = 0.8: peak 0.164 percent after 2.17 years
```

Stronger complementarity makes the peak response smaller and later.

Each store raises its price more slowly because the others do, so by the time the industry's price has risen much, the cost shock has already started to fade.

Exercise 131.6.4

This exercise shows how an interaction through an even moment affects transitional dynamics without changing the local eigenvalues.

Take $\bar{r} = 2, \theta_1 = -0.3, \sigma = 1$ and the other parameters of the moment example in *Coupling through higher moments*.

1. Verify that θ_2 changes none of the eigenvalues of $\tilde{\mathcal{H}}$.

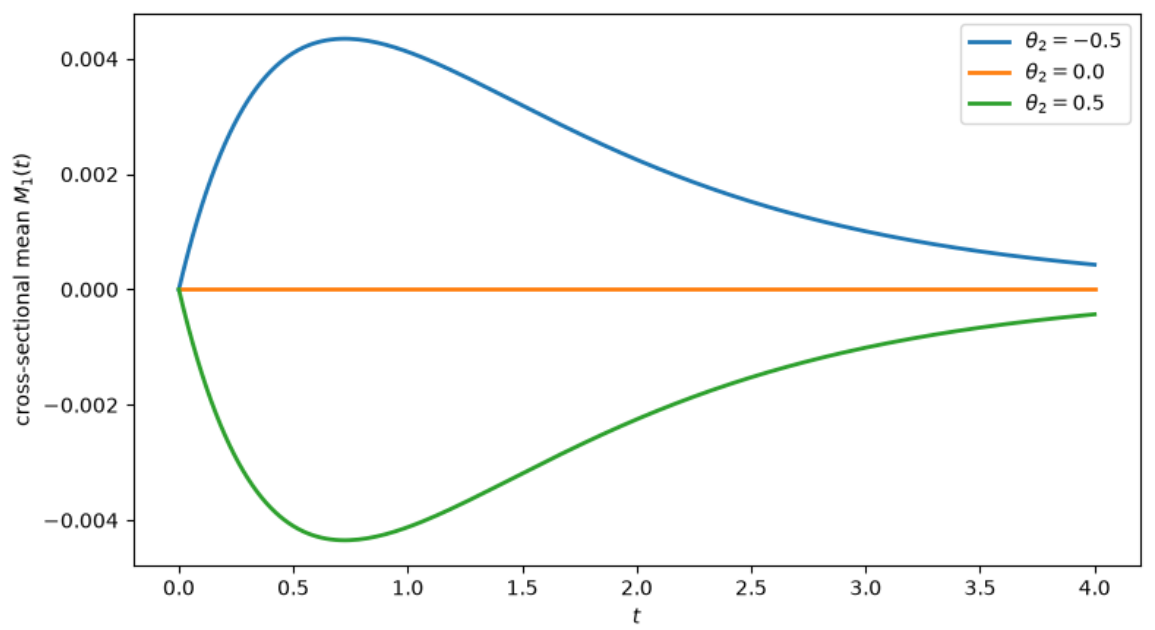
2. Suppose the cross-sectional variance rises by 0.1 while the mean stays at zero. Trace the path of the mean for $\theta_2 \in \{-0.5, 0, 0.5\}$ and explain what you see.

3. Alvarez and Argente [2026] show that along the saddle path $\dot{\hat{M}}_1 = \tilde{\lambda}_1 \hat{M}_1 + \zeta \hat{M}_2$ with $\zeta = b^2\theta_2/[\gamma(\tilde{\lambda}_1 + 2\lambda_{\text{ind}} - \rho)]$. Check this formula.

Solution

For part 1, we compute the eigenvalues for each θ_2.

```
θ_1 = -0.3
for θ_2 in (-0.5, 0.0, 0.5):
    H_2, _, _ = moment_system(ρ_m, a_m, b_m, q_m, γ_m, 1.0, np.array([θ_1, θ_2]))
    print(f"θ_2 = {θ_2:>4}: eigenvalues {np.sort(np.linalg.eigvals(H_2).real).
↪round(5)}")
```



```
θ_2 = -0.5: eigenvalues [-2.05297 -0.87257  0.92257]
θ_2 =  0.0: eigenvalues [-2.05297 -0.87257  0.92257]
θ_2 =  0.5: eigenvalues [-2.05297 -0.87257  0.92257]
```

They do not move.

At the zero-mean steady state the second moment evolves on its own, $\dot{\hat{M}}_2 = 2\lambda_{\text{ind}} \hat{M}_2$, because the term $2(b^2/\gamma)\beta_1 M_1$ in its law of motion vanishes to first order.

For part 2, we start from $\hat{M}_1 = 0$ and $\hat{M}_2 = 0.1$.

```
t_e = np.linspace(0, 4, 200)
fig, ax = plt.subplots(figsize=(8, 4.5))
for θ_2 in (-0.5, 0.0, 0.5):
    H_2, _, _ = moment_system(ρ_m, a_m, b_m, q_m, γ_m, 1.0, np.array([θ_1, θ_2]))
    U_2 = moment_dynamics(H_2, ρ_m)
    path = [(expm(U_2*t) @ np.array([0.0, 0.1]))[0] for t in t_e]
    ax.plot(t_e, path, lw=2, label=f"$\\theta_2 = {θ_2}$")
ax.set_xlabel('$t$')
ax.set_ylabel('cross-sectional mean $M_1(t)$')
ax.legend()
plt.tight_layout()
plt.show()
```

With $\theta_2 > 0$, a higher second moment lowers everybody's marginal return to x through the term $-\theta_2 M_2 x$, so agents lower x while the variance is high, and the mean dips before returning as the variance returns to its invariant level.

With $\theta_2 < 0$ the mean rises instead, and with $\theta_2 = 0$ it does not move at all.

So a shock to dispersion moves the average, even though the eigenvalues that govern local persistence are unchanged.

For part 3, we compare the coefficients of the saddle-path law of motion with the formula.

```
for θ_2 in (-0.5, 0.5):
    H_2, _, λ_ind_2 = moment_system(ρ_m, a_m, b_m, q_m, γ_m, 1.0, np.array([θ_1, θ_
↪2]))
    U_2 = moment_dynamics(H_2, ρ_m)
    λ_1 = ρ_m/2 - np.sqrt((a_m + ρ_m/2)**2 + b_m**2*(q_m + θ_1)/γ_m)
    ζ = b_m**2*θ_2/(γ_m*(λ_1 + 2*λ_ind_2 - ρ_m))
    print(f"θ_2 = {θ_2}: coefficients ({U_2[0, 0]:.5f}, {U_2[0, 1]:.5f}), "
          f"formula ({λ_1:.5f}, {ζ:.5f})")
```

```
θ_2 = -0.5: coefficients (-0.87257, 0.16804), formula (-0.87257, 0.16804)
θ_2 = 0.5: coefficients (-0.87257, -0.16804), formula (-0.87257, -0.16804)
```

131.7 Further reading

Alvarez and Argente [2026] develop the cross terms and the forcing processes in the appendices of their paper, and the coupling through higher moments in its main text.

The Hayashi and pass-through examples, and the one-state analysis of the mixed interactions in Exercise 131.6.2, are our own illustrations of their results.

> "A little knowledge of geometric series goes a long way" – Robert E. Lucas, Jr.
>
> "Asset pricing is all about covariances" – Lars Peter Hansen

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

132.1 Overview

An asset is a claim on one or more future payoffs.

The spot price of an asset depends primarily on

- the anticipated income stream
- attitudes about risk
- rates of time preference

In this lecture, we consider some standard pricing models and dividend stream specifications.

We study how prices and dividend-price ratios respond in these different scenarios.

We also look at creating and pricing *derivative* assets that repackage income streams.

Key tools for the lecture are

- Markov processses
- formulas for predicting future values of functions of a Markov state

- a formula for predicting the discounted sum of future values of a Markov state

Let's start with some imports:

```
import matplotlib.pyplot as plt
import numpy as np
import quantecon as qe
from numpy.linalg import eigvals, solve
```

132.2 Pricing Models

Let $\{d_t\}_{t \geq 0}$ be a stream of dividends

- A time-t **cum-dividend** asset is a claim to the stream $d_t, d_{t+1}, ...$
- A time-t **ex-dividend** asset is a claim to the stream $d_{t+1}, d_{t+2}, ...$

Let's look at some equations that we expect to hold for prices of assets under ex-dividend contracts (we will consider cum-dividend pricing in the exercises).

132.2.1 Risk-Neutral Pricing

Our first scenario is risk-neutral pricing.

Let $\beta = 1/(1 + \rho)$ be an intertemporal discount **factor**, where ρ is the **rate** at which agents discount the future.

The basic risk-neutral asset pricing equation for pricing one unit of an ex-dividend asset is

$$p_t = \beta \mathbb{E}_t[d_{t+1} + p_{t+1}] \tag{132.1}$$

This is a simple "cost equals expected benefit" relationship.

Here $\mathbb{E}_t[y]$ denotes the best forecast of y, conditioned on information available at time t.

More precisely, $\mathbb{E}_t[y]$ is the mathematical expectation of y conditional on information available at time t.

132.2.2 Pricing with Random Discount Factor

What happens if for some reason traders discount payouts differently depending on the state of the world?

Michael Harrison and David Kreps [Harrison and Kreps, 1979] and Lars Peter Hansen and Scott Richard [Hansen and Richard, 1987] showed that in quite general settings the price of an ex-dividend asset obeys

$$p_t = \mathbb{E}_t \left[m_{t+1} (d_{t+1} + p_{t+1}) \right] \tag{132.2}$$

for some **stochastic discount factor** m_{t+1}.

Here the fixed discount factor β in (132.1) has been replaced by the random variable m_{t+1}.

How anticipated future payoffs are evaluated now depends on statistical properties of m_{t+1}.

The stochastic discount factor can be specified to capture the idea that assets that tend to have good payoffs in bad states of the world are valued more highly than other assets whose payoffs don't behave that way.

This is because such assets pay well when funds are more urgently wanted.

We give examples of how the stochastic discount factor has been modeled below.

132.2.3 Asset Pricing and Covariances

Recall that, from the definition of a conditional covariance $\text{cov}_t(x_{t+1}, y_{t+1})$, we have

$$\mathbb{E}_t(x_{t+1}y_{t+1}) = \text{cov}_t(x_{t+1}, y_{t+1}) + \mathbb{E}_t x_{t+1}\mathbb{E}_t y_{t+1} \tag{132.3}$$

If we apply this definition to the asset pricing equation (132.2) we obtain

$$p_t = \mathbb{E}_t m_{t+1}\mathbb{E}_t(d_{t+1} + p_{t+1}) + \text{cov}_t(m_{t+1}, d_{t+1} + p_{t+1}) \tag{132.4}$$

It is useful to regard equation (132.4) as a generalization of equation (132.1)

- In equation (132.1), the stochastic discount factor $m_{t+1} = \beta$, a constant.
- In equation (132.1), the covariance term $\text{cov}_t(m_{t+1}, d_{t+1} + p_{t+1})$ is zero because $m_{t+1} = \beta$.
- In equation (132.1), $\mathbb{E}_t m_{t+1}$ can be interpreted as the reciprocal of the one-period risk-free gross interest rate.
- When m_{t+1} covaries more negatively with the payout $p_{t+1} + d_{t+1}$, the price of the asset is lower.

Equation (132.4) asserts that the covariance of the stochastic discount factor with the one period payout $d_{t+1} + p_{t+1}$ is an important determinant of the price p_t.

We give examples of some models of stochastic discount factors that have been proposed later in this lecture and also in a later lecture.

132.2.4 The Price-Dividend Ratio

Aside from prices, another quantity of interest is the **price-dividend ratio** $v_t := p_t/d_t$.

Let's write down an expression that this ratio should satisfy.

We can divide both sides of (132.2) by d_t to get

$$v_t = \mathbb{E}_t\left[m_{t+1}\frac{d_{t+1}}{d_t}(1 + v_{t+1})\right] \tag{132.5}$$

Below we'll discuss the implication of this equation.

132.3 Prices in the Risk-Neutral Case

What can we say about price dynamics on the basis of the models described above?

The answer to this question depends on

1. the process we specify for dividends
2. the stochastic discount factor and how it correlates with dividends

For now we'll study the risk-neutral case in which the stochastic discount factor is constant.

We'll focus on how an asset price depends on a dividend process.

132.3.1 Example 1: Constant Dividends

The simplest case is risk-neutral price of a constant, non-random dividend stream $d_t = d > 0$.

Removing the expectation from (132.1) and iterating forward gives

$$\begin{aligned} p_t &= \beta(d + p_{t+1}) \\ &= \beta(d + \beta(d + p_{t+2})) \\ &\quad \vdots \\ &= \beta(d + \beta d + \beta^2 d + \cdots + \beta^{k-2} d + \beta^{k-1} p_{t+k}) \end{aligned}$$

If $\lim_{k \to +\infty} \beta^{k-1} p_{t+k} = 0$, this sequence converges to

$$\bar{p} := \frac{\beta d}{1 - \beta} \tag{132.6}$$

This is the equilibrium price in the constant dividend case.

Indeed, simple algebra shows that setting $p_t = \bar{p}$ for all t satisfies the difference equation $p_t = \beta(d + p_{t+1})$.

132.3.2 Example 2: Dividends with Deterministic Growth Paths

Consider a growing, non-random dividend process $d_{t+1} = g d_t$ where $0 < g\beta < 1$.

While prices are not usually constant when dividends grow over time, a price dividend-ratio can be.

If we guess this, substituting $v_t = v$ into (132.5) as well as our other assumptions, we get $v = \beta g(1 + v)$.

Since $\beta g < 1$, we have a unique positive solution:

$$v = \frac{\beta g}{1 - \beta g}$$

The price is then

$$p_t = \frac{\beta g}{1 - \beta g} d_t$$

If, in this example, we take $g = 1 + \kappa$ and let $\rho := 1/\beta - 1$, then the price becomes

$$p_t = \frac{1 + \kappa}{\rho - \kappa} d_t$$

This is called the **Gordon formula**.

132.3.3 Example 3: Markov Growth, Risk-Neutral Pricing

Next, we consider a dividend process

$$d_{t+1} = g_{t+1} d_t \tag{132.7}$$

The stochastic growth factor $\{g_t\}$ is given by

$$g_t = g(X_t), \quad t = 1, 2, ...$$

where

1. $\{X_t\}$ is a finite Markov chain with state space S and transition probabilities

$$P(x, y) := \mathbb{P}\{X_{t+1} = y \,|\, X_t = x\} \qquad (x, y \in S)$$

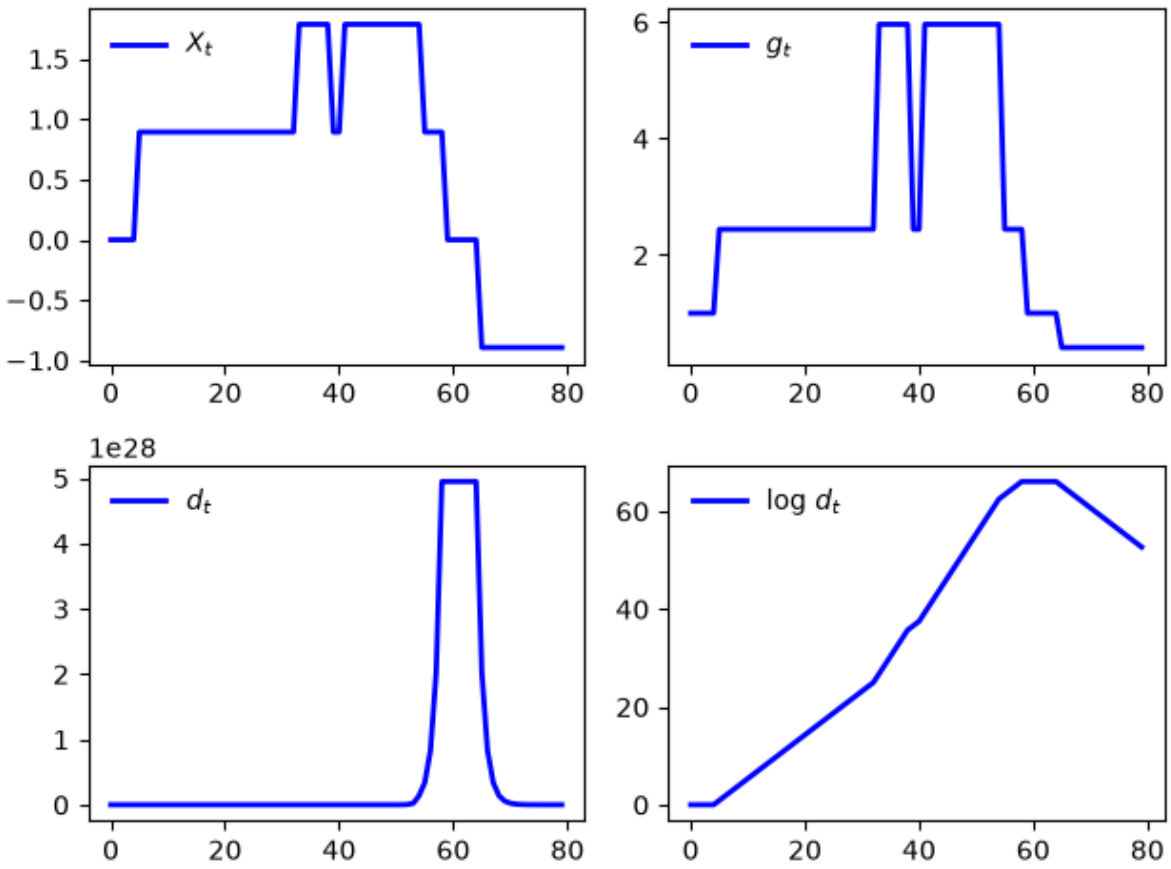
2. g is a given function on S taking nonnegative values

You can think of

- S as n possible "states of the world" and X_t as the current state.
- g as a function that maps a given state X_t into a growth of dividends factor $g_t = g(X_t)$.
- $\ln g_t = \ln(d_{t+1}/d_t)$ is the growth rate of dividends.

(For a refresher on notation and theory for finite Markov chains see *this lecture*)

The next figure shows a simulation, where



- $\{X_t\}$ evolves as a discretized AR1 process produced using *Tauchen's method*.
- $g_t = \exp(X_t)$, so that $\ln g_t = X_t$ is the growth rate.

```
n = 7
mc = qe.tauchen(n, 0.96, 0.25)
sim_length = 80

x_series = mc.simulate(sim_length, init=np.median(mc.state_values))
g_series = np.exp(x_series)
d_series = np.cumprod(g_series) # Assumes d_0 = 1

series = [x_series, g_series, d_series, np.log(d_series)]
labels = ['$X_t$', '$g_t$', '$d_t$', r'$\log \, d_t$']

fig, axes = plt.subplots(2, 2)
for ax, s, label in zip(axes.flatten(), series, labels):
    ax.plot(s, 'b-', lw=2, label=label)
    ax.legend(loc='upper left', frameon=False)
plt.tight_layout()
plt.show()
```

Pricing Formula

To obtain asset prices in this setting, let's adapt our analysis from the case of deterministic growth.

In that case, we found that v is constant.

This encourages us to guess that, in the current case, v_t is a fixed function of the state X_t.

We seek a function v such that the price-dividend ratio satisfies $v_t = v(X_t)$.

We can substitute this guess into (132.5) to get

$$v(X_t) = \beta \mathbb{E}_t[g(X_{t+1})(1 + v(X_{t+1}))]$$

If we condition on $X_t = x$, this becomes

$$v(x) = \beta \sum_{y \in S} g(y)(1 + v(y))P(x, y)$$

or

$$v(x) = \beta \sum_{y \in S} K(x, y)(1 + v(y)) \quad \text{where} \quad K(x, y) := g(y)P(x, y) \tag{132.8}$$

Suppose that there are n possible states $x_1, \ldots, x_n$.

We can then think of (132.8) as n stacked equations, one for each state, and write it in matrix form as

$$v = \beta K(\mathbb{1} + v) \tag{132.9}$$

Here

- v is understood to be the column vector $(v(x_1), \ldots, v(x_n))'$.
- K is the matrix $(K(x_i, x_j))_{1 \leq i,j \leq n}$.
- $\mathbb{1}$ is a column vector of ones.

When does equation (132.9) have a unique solution?

From the *Neumann series lemma* and Gelfand's formula, equation (132.9) has a unique solution when βK has spectral radius strictly less than one.

Thus, we require that the eigenvalues of K be strictly less than β^{-1} in modulus.

The solution is then

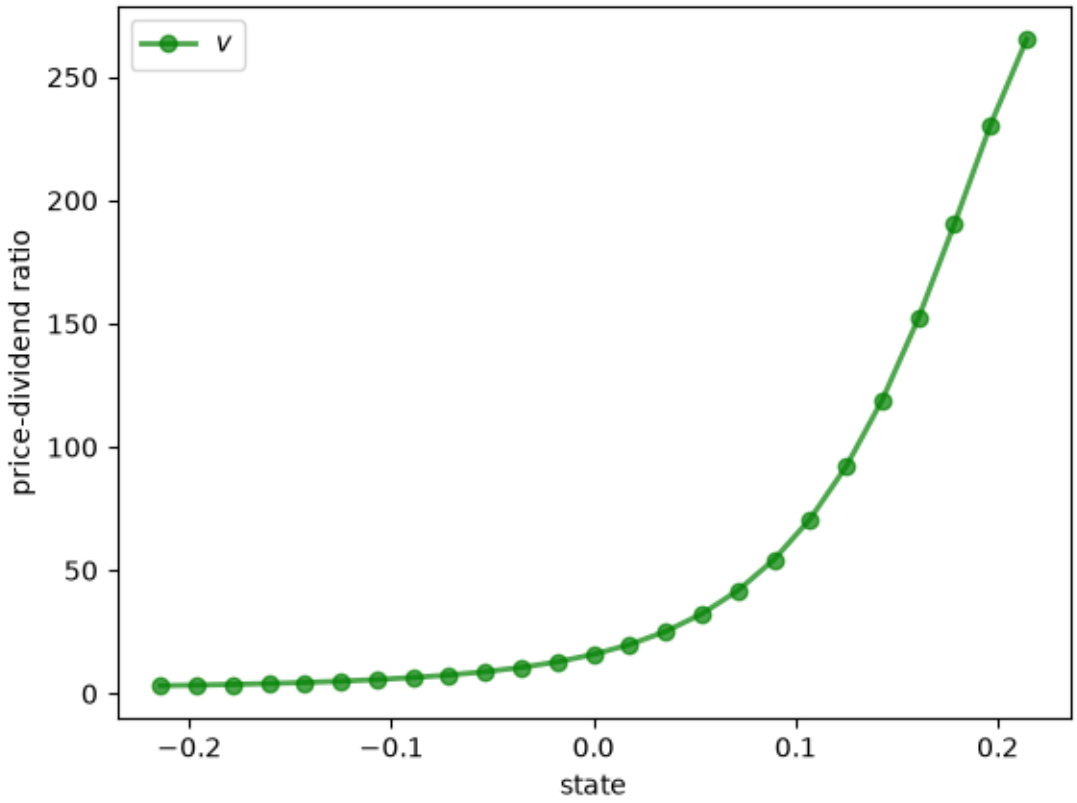
$$v = (I - \beta K)^{-1} \beta K \mathbb{1} \tag{132.10}$$

132.3.4 Code

Let's calculate and plot the price-dividend ratio at some parameters.

As before, we'll generate $\{X_t\}$ as a *discretized AR1 process* and set $g_t = \exp(X_t)$.

Here's the code, including a test of the spectral radius condition



```
n = 25  # Size of state space
β = 0.9
mc = qe.tauchen(n, 0.96, 0.02)

K = mc.P * np.exp(mc.state_values)

warning_message = "Spectral radius condition fails"
assert np.max(np.abs(eigvals(K))) < 1 / β,  warning_message

I = np.identity(n)
v = solve(I - β * K, β * K @ np.ones(n))

fig, ax = plt.subplots()
ax.plot(mc.state_values, v, 'g-o', lw=2, alpha=0.7, label='$v$')
ax.set_ylabel("price-dividend ratio")
ax.set_xlabel("state")
ax.legend(loc='upper left')
plt.show()
```

Why does the price-dividend ratio increase with the state?

The reason is that this Markov process is positively correlated, so high current states suggest high future states.

Moreover, dividend growth is increasing in the state.

The anticipation of high future dividend growth leads to a high price-dividend ratio.

132.4 Risk Aversion and Asset Prices

Now let's turn to the case where agents are risk averse.

We'll price several distinct assets, including

- An endowment stream
- A consol (a type of bond issued by the UK government in the 19th century)
- Call options on a consol

132.4.1 Pricing a Lucas Tree

Let's start with a version of the celebrated asset pricing model of Robert E. Lucas, Jr. [Lucas, 1978].

Lucas considered an abstract pure exchange economy with these features:

- a single non-storable consumption good
- a Markov process that governs the total amount of the consumption good available each period
- a single *tree* that each period yields *fruit* that equals the total amount of consumption available to the economy
- a competitive market in *shares* in the tree that entitles their owners to corresponding shares of the *dividend* stream, i.e., the *fruit* stream, yielded by the tree
- a representative consumer who in a competitive equilibrium
  - consumes the economy's entire endowment each period
  - owns 100 percent of the shares in the tree

As in [Lucas, 1978], we suppose that the stochastic discount factor takes the form

$$m_{t+1} = \beta \frac{u'(c_{t+1})}{u'(c_t)} \tag{132.11}$$

where u is a concave utility function and c_t is time t consumption of a representative consumer.

(A derivation of this expression is given in a later lecture)

Assume the existence of an endowment that follows growth process (132.7).

The asset being priced is a claim on the endowment process, i.e., the **Lucas tree** described above.

Following [Lucas, 1978], we suppose that in equilibrium the representative consumer's consumption equals the aggregate endowment, so that $d_t = c_t$ for all t.

For utility, we'll assume the **constant relative risk aversion** (CRRA) specification

$$u(c) = \frac{c^{1-\gamma}}{1-\gamma} \text{ with } \gamma > 0 \tag{132.12}$$

When $\gamma = 1$ we let $u(c) = \ln c$.

Inserting the CRRA specification into (132.11) and using $c_t = d_t$ gives

$$m_{t+1} = \beta \left(\frac{c_{t+1}}{c_t} \right)^{-\gamma} = \beta g_{t+1}^{-\gamma} \tag{132.13}$$

Substituting this into (132.5) gives the price-dividend ratio formula

$$v(X_t) = \beta \mathbb{E}_t \left[g(X_{t+1})^{1-\gamma} (1 + v(X_{t+1})) \right] \tag{132.14}$$

Conditioning on $X_t = x$, we can write this as

$$v(x) = \beta \sum_{y \in S} g(y)^{1-\gamma} (1 + v(y)) P(x, y)$$

If we let

$$J(x, y) := g(y)^{1-\gamma} P(x, y)$$

then we can rewrite equation (132.14) in vector form as

$$v = \beta J(\mathbb{1} + v)$$

Assuming that the spectral radius of J is strictly less than β^{-1}, this equation has the unique solution

$$v = (I - \beta J)^{-1} \beta J \mathbb{1} \tag{132.15}$$

We will define a function tree_price to compute v given parameters stored in the class AssetPriceModel

```
class AssetPriceModel:
    """
    A class that stores the primitives of the asset pricing model.

    Parameters
    ----------
    β : scalar, float
        Discount factor
    mc : MarkovChain
        Contains the transition matrix and set of state values for the state
        process
    γ : scalar(float)
        Coefficient of risk aversion
    g : callable
        The function mapping states to growth rates

    """
    def __init__(self, β=0.96, mc=None, γ=2.0, g=np.exp):
        self.β, self.γ = β, γ
        self.g = g

        # A default process for the Markov chain
        if mc is None:
            self.ρ = 0.9
            self.σ = 0.02
            self.mc = qe.tauchen(n, self.ρ, self.σ)
        else:
            self.mc = mc

        self.n = self.mc.P.shape[0]

    def test_stability(self, Q):
        """
        Stability test for a given matrix Q.
        """
        sr = np.max(np.abs(eigvals(Q)))
        if not sr < 1 / self.β:

    ap: AssetPriceModel
        An instance of AssetPriceModel containing primitives

    Returns
    -------
```

(continues on next page)

(continued from previous page)

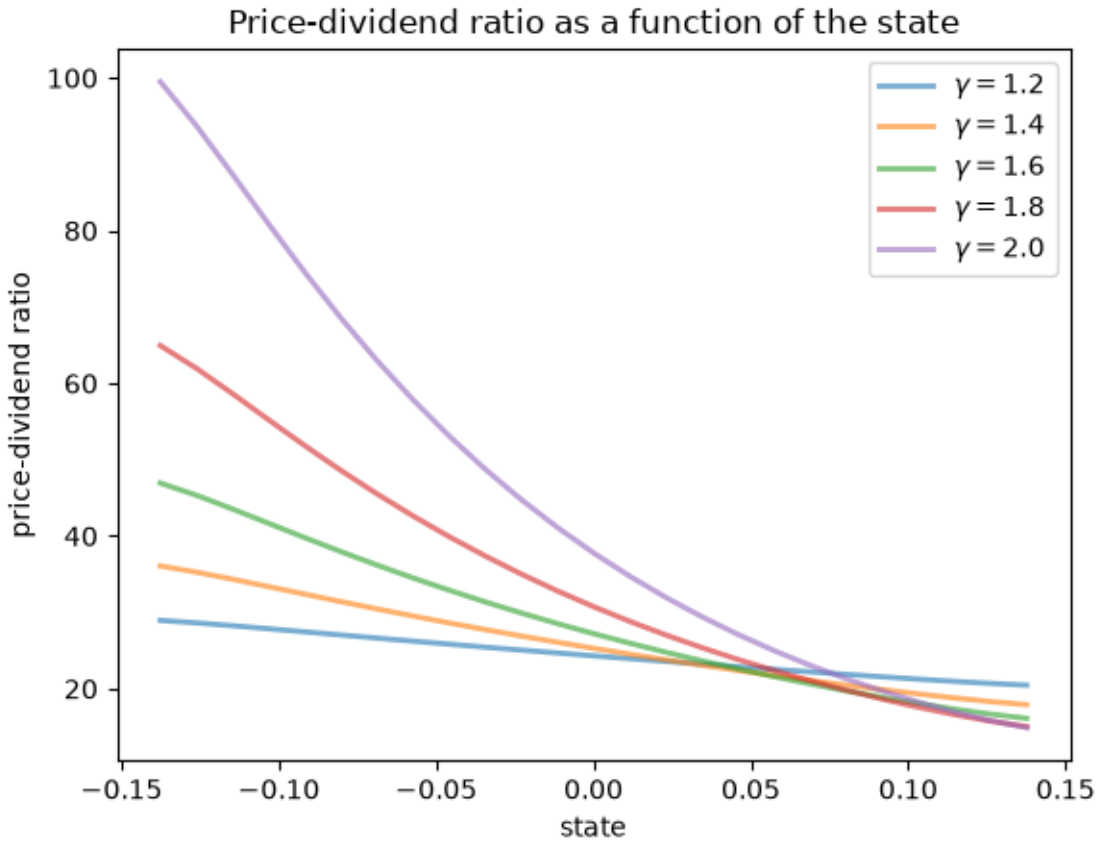
```
    v : array_like(float)
        Lucas tree price-dividend ratio

    """
    # Simplify names, set up matrices
    β, γ, P, y = ap.β, ap.γ, ap.mc.P, ap.mc.state_values
    J = P * ap.g(y)**(1 - γ)

    # Make sure that a unique solution exists
    ap.test_stability(J)

    # Compute v
    I = np.identity(ap.n)
    Ones = np.ones(ap.n)
    v = solve(I - β * J, β * J @ Ones)

    return v
```



Here's a plot of v as a function of the state for several values of γ, with a positively correlated Markov process and $g(x) = \exp(x)$

```
ys = [1.2, 1.4, 1.6, 1.8, 2.0]
ap = AssetPriceModel()
states = ap.mc.state_values

fig, ax = plt.subplots()

for γ in ys:
    ap.γ = γ
    v = tree_price(ap)
    ax.plot(states, v, lw=2, alpha=0.6, label=rf"$\gamma = {γ}$")

ax.set_title('Price-dividend ratio as a function of the state')
ax.set_ylabel("price-dividend ratio")
ax.set_xlabel("state")
ax.legend(loc='upper right')
plt.show()
```

Notice that v is decreasing in each case.

This is because, with a positively correlated state process, higher states indicate higher future consumption growth.

With the stochastic discount factor (132.13), higher growth decreases the discount factor, lowering the weight placed on future dividends.

Special Cases

In the special case $\gamma = 1$, we have $J = P$.

Recalling that $P^i \mathbb{1} = \mathbb{1}$ for all i and applying *Neumann's geometric series lemma*, we are led to

$$v = \beta(I - \beta P)^{-1} \mathbb{1} = \beta \sum_{i=0}^{\infty} \beta^i P^i \mathbb{1} = \beta \frac{1}{1-\beta} \mathbb{1}$$

Thus, with log preferences, the price-dividend ratio for a Lucas tree is constant.

Alternatively, if $\gamma = 0$, then $J = K$ and we recover the risk-neutral solution (132.10).

This is as expected, since $\gamma = 0$ implies $u(c) = c$ (and hence agents are risk-neutral).

132.4.2 A Risk-Free Consol

Consider the same pure exchange representative agent economy.

A risk-free consol promises to pay a constant amount $\zeta > 0$ each period.

Recycling notation, let p_t now be the price of an ex-coupon claim to the consol.

An ex-coupon claim to the consol entitles an owner at the end of period t to

- ζ in period $t+1$, plus
- the right to sell the claim for p_{t+1} next period

The price satisfies (132.2) with $d_t = \zeta$, or

$$p_t = \mathbb{E}_t \left[m_{t+1} (\zeta + p_{t+1}) \right]$$

With the stochastic discount factor (132.13), this becomes

$$p_t = \mathbb{E}_t \left[\beta g_{t+1}^{-\gamma} (\zeta + p_{t+1}) \right] \tag{132.16}$$

Guessing a solution of the form $p_t = p(X_t)$ and conditioning on $X_t = x$, we get

$$p(x) = \beta \sum_{y \in S} g(y)^{-\gamma} (\zeta + p(y)) P(x, y)$$

Letting $M(x, y) = P(x, y) g(y)^{-\gamma}$ and rewriting in vector notation yields the solution

$$p = (I - \beta M)^{-1} \beta M \zeta \mathbb{1} \tag{132.17}$$

The above is implemented in the function consol_price.

```
def consol_price(ap, ζ):
    """
    Computes price of a consol bond with payoff ζ

    Parameters
    ----------
    ap: AssetPriceModel
        An instance of AssetPriceModel containing primitives

    ζ : scalar(float)
        Coupon of the console

    Returns
    -------
    p : array_like(float)
        Console bond prices

    """
    # Simplify names, set up matrices
    β, γ, P, y = ap.β, ap.γ, ap.mc.P, ap.mc.state_values
    M = P * ap.g(y)**(- γ)

    # Make sure that a unique solution exists
    ap.test_stability(M)

    # Compute price
    I = np.identity(ap.n)
```

(continues on next page)

(continued from previous page)

```
    Ones = np.ones(ap.n)
    p = solve(I - β * M, β * ζ * M @ Ones)

    return p
```

132.4.3 Pricing an Option to Purchase the Consol

Let's now price options of various maturities.

We'll study an option that gives the owner the right to purchase a consol at a price p_S.

An Infinite Horizon Call Option

We want to price an **infinite horizon** option to purchase a consol at a price p_S.

The option entitles the owner at the beginning of a period either

1. to purchase the bond at price p_S now, or
2. not to exercise the option to purchase the asset now but to retain the right to exercise it later

Thus, the owner either *exercises* the option now or chooses *not to exercise* and wait until next period.

This is termed an infinite-horizon **call option** with **strike price** p_S.

The owner of the option is entitled to purchase the consol at price p_S at the beginning of any period, after the coupon has been paid to the previous owner of the bond.

The fundamentals of the economy are identical with the one above, including the stochastic discount factor and the process for consumption.

Let $w(X_t, p_S)$ be the value of the option when the time t growth state is known to be X_t but *before* the owner has decided whether to exercise the option at time t (i.e., today).

Recalling that $p(X_t)$ is the value of the consol when the initial growth state is X_t, the value of the option satisfies

$$w(X_t, p_S) = \max \left\{ \beta \, \mathbb{E}_t \frac{u'(c_{t+1})}{u'(c_t)} w(X_{t+1}, p_S), \; p(X_t) - p_S \right\}$$

The first term on the right is the value of waiting, while the second is the value of exercising now.

We can also write this as

$$w(x, p_S) = \max \left\{ \beta \sum_{y \in S} P(x, y) g(y)^{-\gamma} w(y, p_S), \; p(x) - p_S \right\} \tag{132.18}$$

With $M(x, y) = P(x, y) g(y)^{-\gamma}$ and w as the vector of values $(w(x_i), p_S)_{i=1}^n$, we can express (132.18) as the nonlinear vector equation

$$w = \max\{\beta M w, \; p - p_S \mathbb{1}\} \tag{132.19}$$

To solve (132.19), form an operator T that maps vector w into vector Tw via

$$Tw = \max\{\beta M w, \; p - p_S \mathbb{1}\}$$

Start at some initial w and iterate with T to convergence .

We can find the solution with the following function call_option

```
def call_option(ap, ζ, p_s, ϵ=1e-7):
    """
    Computes price of a call option on a consol bond.

    Parameters
    ----------
    ap: AssetPriceModel
        An instance of AssetPriceModel containing primitives

    ζ : scalar(float)
        Coupon of the console

    p_s : scalar(float)
        Strike price

    ϵ : scalar(float), optional(default=1e-8)
        Tolerance for infinite horizon problem

    Returns
    -------
    w : array_like(float)
        Infinite horizon call option prices

    """
    # Simplify names, set up matrices
    β, γ, P, y = ap.β, ap.γ, ap.mc.P, ap.mc.state_values
    M = P * ap.g(y)**(- γ)

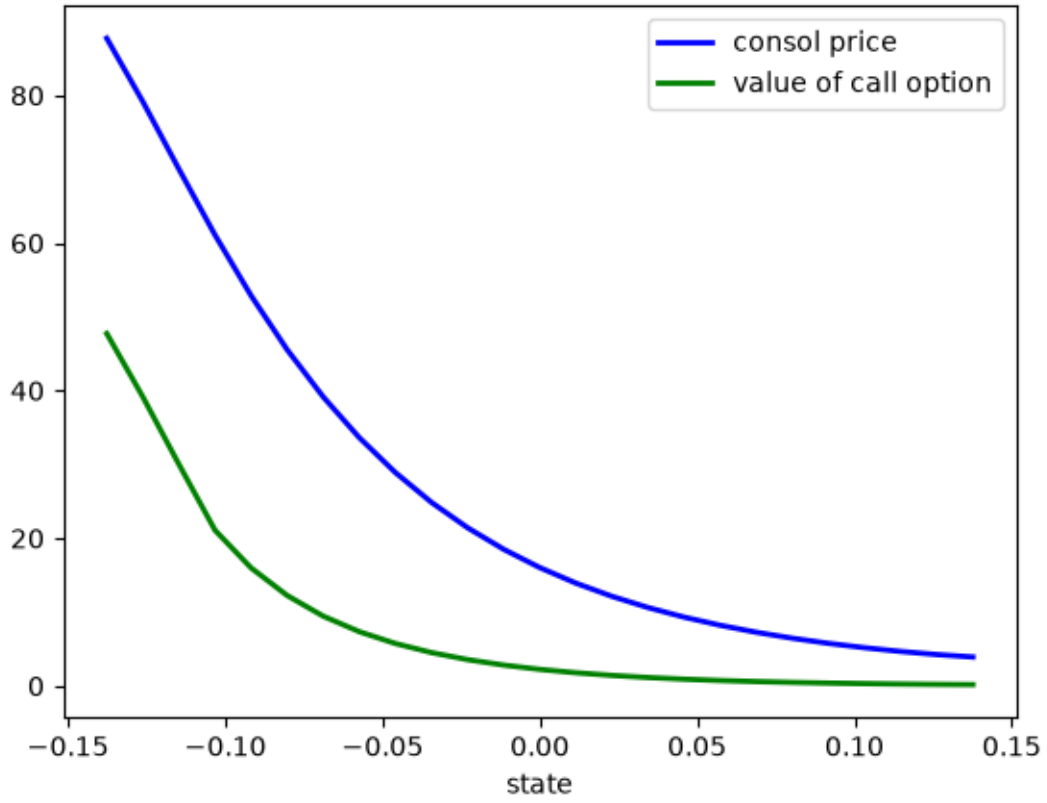
    # Make sure that a unique consol price exists
    ap.test_stability(M)

    # Compute option price
    p = consol_price(ap, ζ)
    w = np.zeros(ap.n)
    error = ϵ + 1
    while error > ϵ:
        # Maximize across columns
        w_new = np.maximum(β * M @ w, p - p_s)
        # Find maximal difference of each component and update
        error = np.amax(np.abs(w - w_new))
        w = w_new

    return w
```

Here's a plot of w compared to the consol price when $P_S = 40$

```
ap = AssetPriceModel(β=0.9)
ζ = 1.0
strike_price = 40



x = ap.mc.state_values
p = consol_price(ap, ζ)
w = call_option(ap, ζ, strike_price)

fig, ax = plt.subplots()
ax.plot(x, p, 'b-', lw=2, label='consol price')
ax.plot(x, w, 'g-', lw=2, label='value of call option')
```

(continues on next page)

(continued from previous page)

```
ax.set_xlabel("state")
ax.legend(loc='upper right')
plt.show()
```

In high values of the Markov growth state, the value of the option is close to zero.

This is despite the facts that the Markov chain is irreducible and that low states — where the consol prices are high — will be visited recurrently.

The reason for low valuations in high Markov growth states is that $\beta = 0.9$, so future payoffs are discounted substantially.

132.4.4 Risk-Free Rates

Let's look at risk-free interest rates over different periods.

The One-period Risk-free Interest Rate

As before, the stochastic discount factor is $m_{t+1} = \beta g_{t+1}^{-\gamma}$.

It follows that the reciprocal R_t^{-1} of the gross risk-free interest rate R_t in state x is

$$\mathbb{E}_t m_{t+1} = \beta \sum_{y \in S} P(x,y) g(y)^{-\gamma}$$

We can write this as

$$m_1 = \beta M \mathbb{1}$$

where the i-th element of m_1 is the reciprocal of the one-period gross risk-free interest rate in state x_i.

Other Terms

Let m_j be an $n \times 1$ vector whose i th component is the reciprocal of the j -period gross risk-free interest rate in state x_i.

Then $m_1 = \beta M$, and $m_{j+1} = M m_j$ for $j \geq 1$.

132.5 Exercises

Exercise 132.5.1

In the lecture, we considered **ex-dividend assets**.

A **cum-dividend** asset is a claim to the stream $d_t, d_{t+1}, \ldots$.

Following (132.1), find the risk-neutral asset pricing equation for one unit of a cum-dividend asset.

With a constant, non-random dividend stream $d_t = d > 0$, what is the equilibrium price of a cum-dividend asset?

With a growing, non-random dividend process $d_t = g d_t$ where $0 < g\beta < 1$, what is the equilibrium price of a cum-dividend asset?

Solution

For a cum-dividend asset, the basic risk-neutral asset pricing equation is

$$p_t = d_t + \beta \mathbb{E}_t[p_{t+1}]$$

With constant dividends, the equilibrium price is

$$p_t = \frac{1}{1-\beta} d_t$$

With a growing, non-random dividend process, the equilibrium price is

$$p_t = \frac{1}{1-\beta g} d_t$$

Exercise 132.5.2

Consider the following primitives

```
n = 5  # Size of State Space
P = np.full((n, n), 0.0125)
P[range(n), range(n)] += 1 - P.sum(1)
# State values of the Markov chain
s = np.array([0.95, 0.975, 1.0, 1.025, 1.05])
γ = 2.0
β = 0.94
```

Let g be defined by $g(x) = x$ (that is, g is the identity map).

Compute the price of the Lucas tree.

Do the same for

- the price of the risk-free consol when $\zeta = 1$
- the call option on the consol when $\zeta = 1$ and $p_S = 150.0$

Solution

First, let's enter the parameters:

```
n = 5
P = np.full((n, n), 0.0125)
P[range(n), range(n)] += 1 - P.sum(1)
s = np.array([0.95, 0.975, 1.0, 1.025, 1.05])  # State values
mc = qe.MarkovChain(P, state_values=s)

γ = 2.0
β = 0.94
ζ = 1.0
p_s = 150.0
```

Next, we'll create an instance of `AssetPriceModel` to feed into the functions

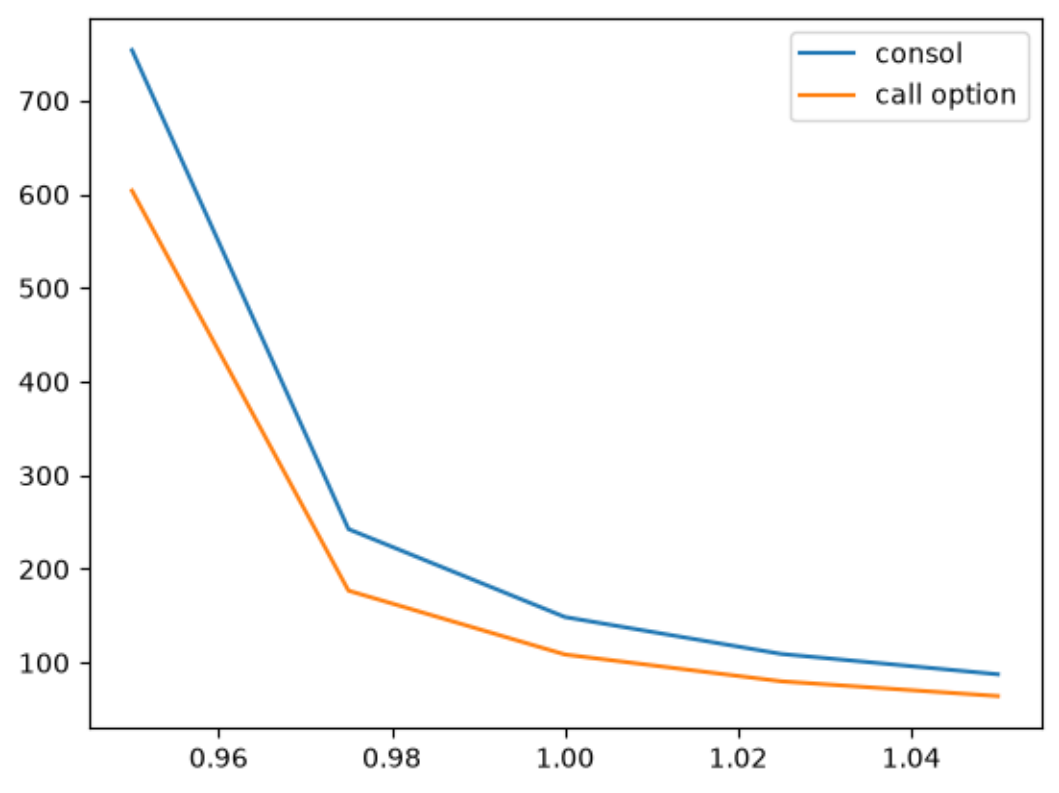
```
apm = AssetPriceModel(β=β, mc=mc, γ=γ, g=lambda x: x)
```

Now we just need to call the relevant functions on the data:

```
tree_price(apm)
```

```
array([29.47401578, 21.93570661, 17.57142236, 14.72515002, 12.72221763])
```

```
consol_price(apm, ζ)
```



```
array([753.87100476, 242.55144082, 148.67554548, 109.25108965,
       87.56860139])
```

```
call_option(apm, ζ, p_s)
```

```
array([603.87100476, 176.8393343 , 108.67734499,  80.05179254,
       64.30843748])
```

Let's show the last two functions as a plot

```
fig, ax = plt.subplots()
ax.plot(s, consol_price(apm, ζ), label='consol')
ax.plot(s, call_option(apm, ζ, p_s), label='call option')
ax.legend()
plt.show()
```

consol
call option
700
600
500
400
300
200
100
0.96
0.98
1.00
1.02
1.04

Exercise 132.5.3

Let's consider finite horizon call options, which are more common than infinite horizon ones.

Finite horizon options obey functional equations closely related to (132.18).

A k period option expires after k periods.

If we view today as date zero, a k period option gives the owner the right to exercise the option to purchase the risk-free consol at the strike price p_S at dates $0, 1, \ldots, k-1$.

The option expires at time k.

Thus, for $k = 1, 2, \ldots$, let $w(x, k)$ be the value of a k-period option.

It obeys

$$w(x,k) = \max\left\{\beta \sum_{y \in S} P(x,y) g(y)^{-\gamma} w(y, k-1),\ p(x) - p_S\right\}$$

where $w(x, 0) = 0$ for all x.

We can express this as a sequence of nonlinear vector equations

$$w_k = \max\{\beta M w_{k-1},\ p - p_S \mathbb{1}\} \quad k = 1, 2, \ldots \quad \text{with } w_0 = 0$$

Write a function that computes w_k for any given k.

Compute the value of the option with `k = 5` and `k = 25` using parameter values as in Exercise 132.5.1.

Is one higher than the other? Can you give intuition?

Solution

Here's a suitable function:

```
def finite_horizon_call_option(ap, ζ, p_s, k):
    """
    Computes k period option value.
    """
    # Simplify names, set up matrices
    β, γ, P, y = ap.β, ap.γ, ap.mc.P, ap.mc.state_values
    M = P * ap.g(y)**(- γ)

    # Make sure that a unique solution exists
    ap.test_stability(M)

    # Compute option price
    p = consol_price(ap, ζ)
    w = np.zeros(ap.n)
    for i in range(k):
        # Maximize across columns
        w = np.maximum(β * M @ w, p - p_s)

    return w
```

Now let's compute the option values at `k=5` and `k=25`

```
fig, ax = plt.subplots()
for k in [5, 25]:
    w = finite_horizon_call_option(apm, ζ, p_s, k)
    ax.plot(s, w, label=rf'$k = {k}$')
ax.legend()
plt.show()
```

Not surprisingly, options with larger k are worth more.

This is because an owner has a longer horizon over which the option can be exercised.

Evans and Honkapohja: What were the profession's most important responses to the Lucas Critique?

Sargent: There were two. The first and most optimistic response was complete rational expectations econometrics. A rational expectations equilibrium is a likelihood function. Maximize it.

– An Interview with Thomas J. Sargent [Evans and Honkapohja, 2005]

133.1 Overview

This lecture describes how Hansen and Singleton [1983] formulated a complete statistical model of asset returns and consumption growth, then estimated its parameters by the method of maximum likelihood.

They detect a defects in their model, one of which Mehra and Prescott [1985] later called the **equity premium puzzle**.

Hansen and Singleton [1983] study a consumption-based asset pricing model in which a representative consumer with CRRA preferences chooses how to allocate wealth across traded assets.

First-order conditions for asset holdings are stochastic Euler equations that connect consumption growth, asset returns, and preference parameters.

Hansen and Singleton [1983] assume that consumption growth and asset returns are *jointly lognormal*.

Then Euler equations imply a set of restrictions on a the joint distribution of asset prices and returns.

These restrict a linear time-series model for logarithms of consumption growth and returns in which predictable movements in log returns are proportional to predictable movements in log consumption growth.

Hansen and Singleton estimated their model by *Maximum Likelihood Estimation*.

The empirical findings of Hansen and Singleton [1983] constitute what Mehra and Prescott [1985] would later call the **equity premium puzzle**.

To keep lecture this lecture narrowly focused, we estimate one return at a time (either a market proxy or a T-bill) rather than the full multi-asset systems studied by Hansen and Singleton [1983].

- we use only monthly nondurable consumption (`ND`).

133.2 Euler equation

Consider a single-good economy of identical consumers whose utility functions are in the CRRA form

$$U(c_t) = c_t^\gamma / \gamma, \quad \gamma < 1, \tag{133.1}$$

where c_t is aggregate real per capita consumption and $U(\cdot)$ is the period utility function.

The representative consumer chooses a stochastic consumption plan to maximize the expected value of a time-additive utility function,

$$E_0 \sum_{t=0}^{\infty} \beta^t U(c_t), \quad 0 < \beta < 1. \tag{133.2}$$

Consumers substitute present for future consumption by trading the ownership rights of N financial and capital assets.

Let $\mathbf{w}_t$ denote the holdings of the N assets at date t, $\mathbf{q}_t$ the vector of asset prices, $\mathbf{d}_t$ the vector of dividends, and y_t real labor income.

A feasible consumption and investment plan $\{c_t, \mathbf{w}_t\}$ must satisfy the sequence of budget constraints

$$c_t + \mathbf{q}_t \cdot \mathbf{w}_{t+1} \leq (\mathbf{q}_t + \mathbf{d}_t) \cdot \mathbf{w}_t + y_t, \tag{133.3}$$

where $(\mathbf{q}_t + \mathbf{d}_t) \cdot \mathbf{w}_t$ is the cum-dividend value of the portfolio carried into period t.

To derive the first-order conditions, attach a Lagrange multiplier λ_t to the budget constraint (133.3) at each date t and form the Lagrangian

$$\mathcal{L} = E_0 \sum_{t=0}^{\infty} \beta^t \left\{ U(c_t) + \lambda_t \left[(\mathbf{q}_t + \mathbf{d}_t) \cdot \mathbf{w}_t + y_t - c_t - \mathbf{q}_t \cdot \mathbf{w}_{t+1} \right] \right\}. \tag{133.4}$$

Differentiating $\mathcal{L}$ with respect to c_t gives

$$\frac{\partial \mathcal{L}}{\partial c_t} = 0 \implies \lambda_t = U'(c_t).$$

Differentiating with respect to $w_{i,t+1}$, the holdings of asset i carried from date t into date $t+1$, collects two terms: $w_{i,t+1}$ appears in the date-t budget constraint as well as in the date-$(t+1)$ constraint:

$$\frac{\partial \mathcal{L}}{\partial w_{i,t+1}} = 0 \implies E_0 \left[\beta^t \left(-\lambda_t \, q_{it} + \beta \, \lambda_{t+1} (q_{i,t+1} + d_{i,t+1}) \right) \right] = 0.$$

By the law of iterated expectations, this becomes

$$E_0 \left[\beta^t \, E_t \left(-\lambda_t \, q_{it} + \beta \, \lambda_{t+1} (q_{i,t+1} + d_{i,t+1}) \right) \right] = 0.$$

Hence,

$$\lambda_t \, q_{it} = \beta \, E_t \left[\lambda_{t+1} (q_{i,t+1} + d_{i,t+1}) \right].$$

Substituting $\lambda_t = U'(c_t)$ and $\lambda_{t+1} = U'(c_{t+1})$ yields

$$q_{it} \, U'(c_t) = \beta \, E_t \left[U'(c_{t+1}) (q_{i,t+1} + d_{i,t+1}) \right].$$

Dividing both sides by q_{it} and defining the gross return $r_{it+1} := (q_{i,t+1} + d_{i,t+1})/q_{it}$ yields the stochastic Euler equation:

$$U'(c_t) = \beta E_t [U'(c_{t+1}) \, r_{it+1}], \quad i = 1, \ldots, N, \tag{133.5}$$

where r_{it+1} is the gross real return on asset i.

Substituting the CRRA marginal utility $U'(c_t) = c_t^{\gamma - 1} = c_t^{\alpha}$ with $\alpha := \gamma - 1$ into (133.5) and rearranging gives

$$E_t \left[\beta \left(\frac{c_{t+1}}{c_t} \right)^{\alpha} r_{it+1} \right] = 1, \quad i = 1, \ldots, N. \tag{133.6}$$

The coefficient of relative risk aversion is $-\alpha$.

133.3 The Euler equation under lognormality

Using the Euler equation (133.6) derived above, we now impose the distributional assumptions of Hansen and Singleton [1983].

Let $x_t = c_t / c_{t-1}$ denote the consumption ratio, and define $u_{it} = x_t^{\alpha} r_{it}$ where r_{it} is the gross real return on asset i.

The Euler equation (133.6) states $E_{t-1}[u_{it}] = 1/\beta$.

Define log variables $X_t = \log x_t$, $R_{it} = \log r_{it}$, and $U_{it} = \log u_{it}$, so that

$$U_{i,t} = \alpha X_t + R_{i,t}. \tag{133.7}$$

Assume the vector process $\{Y_t\} = \{(X_t, R_{1t}, \dots, R_{nt})^\top\}$ is jointly stationary and Gaussian.

Under this assumption, U_{it} conditional on the information set ψ_{t-1} is normal with constant variance σ_i^2 and a conditional mean $\mu_{i,t-1}$ that is a linear function of past Y's.

Because $u_{it} = \exp(U_{it})$ is conditionally lognormal,

$$E_{t-1}[u_{it}] = \exp\left(\mu_{i,t-1} + \tfrac{1}{2}\sigma_i^2\right). \tag{133.8}$$

Setting $E_{t-1}[u_{it}] = 1/\beta$ and taking logs gives $\mu_{i,t-1} + \sigma_i^2/2 = -\log\beta$.

Now define the innovation

$$V_{i,t} := U_{i,t} - \mu_{i,t-1} = \alpha X_t + R_{i,t} + \log\beta + \frac{\sigma_i^2}{2}, \quad i = 1, \dots, N. \tag{133.9}$$

Then $E_{t-1}[V_{i,t}] = 0$, where $\sigma_i^2 = \mathrm{Var}_{t-1}(\alpha X_t + R_{it})$ is constant under the stationarity and Gaussian assumptions.

Setting $E_{t-1}[V_{i,t}] = 0$ gives the conditional mean restriction

$$E_{t-1}[R_{i,t}] = -\alpha\, E_{t-1}[X_t] - \log\beta - \frac{\sigma_i^2}{2}. \tag{133.10}$$

Equation (133.10) is the central result of Hansen and Singleton [1983].

The predictable component of each asset's log return is proportional to the predictable component of log consumption growth, with proportionality factor $-\alpha$.

The intercept absorbs the discount factor β and the lognormal variance term $\sigma_i^2/2$.

Let's consider three special cases to better understand the implications of (133.10):

- Risk neutrality ($\alpha = 0$): Each asset's log return equals a constant plus a serially uncorrelated error, so returns are serially uncorrelated.
- Log utility ($\alpha = -1$): The difference $R_{it} - X_t$ has no time-varying predictable component, so returns and consumption growth share the same predictable component.
- Risk aversion ($\alpha < 0$): The time-varying part of $E_{t-1}[R_{it}]$ equals $-\alpha$ times $E_{t-1}[X_t]$, so a larger $|\alpha|$ amplifies the sensitivity of expected returns to expected consumption growth.

For a given consumption–return covariance structure, higher relative risk aversion ($-\alpha$) widens the gap between risky-asset returns and the risk-free return.

The equity premium puzzle arises because the observed spread is large but estimated $|\alpha|$ is small as we will see soon in our estimation.

133.4 The restricted system and its likelihood

To build a likelihood, we need to parameterize the conditional expectation $E_{t-1}[X_t]$.

In the single-return case, write $\mathbf{Y}_t = (X_t, R_t)^\top$ and assume that the predictable component of X_t is a finite-order linear function of past observations:

$$E(X_t \mid \psi_{t-1}) = \mathbf{a}(L)^\top \mathbf{Y}_{t-1} + \mu_x, \tag{133.11}$$

where $\mathbf{a}(L)$ is a vector of lag polynomial coefficients in past (X, R) and μ_x is a constant.

The consumption-growth equation is unrestricted, so X_t depends freely on its own lags and on lagged returns.

The return equation, however, is restricted by the Euler equation.

Combining (133.10) with (133.11) forces the predictable part of R_t to be $-\alpha$ times the predictable part of X_t, plus a constant.

This gives the restricted system

$$\mathbf{A}_0 \mathbf{Y}_t = \mathbf{A}_1(L)\mathbf{Y}_{t-1} + \mu + \mathbf{V}_t, \tag{133.12}$$

with

$$\mathbf{A}_0 = \begin{bmatrix} 1 & 0 \\ \alpha & 1 \end{bmatrix}, \quad \mathbf{A}_1(L) = \begin{bmatrix} \mathbf{a}(L)^\top \\ 0 \end{bmatrix}, \quad \mu = \begin{bmatrix} \mu_x \\ -\log\beta - \sigma_U^2/2 \end{bmatrix}, \tag{133.13}$$

where $\sigma_U^2 := \mathrm{Var}_{t-1}(\alpha X_t + R_t) = \alpha^2\sigma_{XX} + \sigma_{RR} + 2\alpha\sigma_{XR}$ under conditional homoskedasticity.

The sign in the second element of μ follows directly from (133.10).

The innovations $\mathbf{V}_t$ are assumed to be Gaussian with density $f_V(\mathbf{v})$.

Since $\mathbf{V}_t = \mathbf{A}_0\mathbf{Y}_t - \mathbf{A}_1(L)\mathbf{Y}_{t-1} - \mu$, the observables $\mathbf{Y}_t$ are a linear transformation of $\mathbf{V}_t$ with $\mathbf{Y}_t = \mathbf{A}_0^{-1}(\mathbf{V}_t + \mathbf{A}_1(L)\mathbf{Y}_{t-1} + \mu)$.

The change-of-variables formula for densities gives

$$f_Y(\mathbf{y}_t \mid \mathbf{Y}_{t-1}) = f_V(\mathbf{A}_0\mathbf{y}_t - \mathbf{A}_1(L)\mathbf{Y}_{t-1} - \mu) \left|\det\left(\frac{\partial \mathbf{V}_t}{\partial \mathbf{Y}_t}\right)\right| = f_V(\mathbf{v}_t) \,|\det(\mathbf{A}_0)|.$$

Because $\mathbf{A}_0$ is unit lower triangular, $\det(\mathbf{A}_0) = 1$, so the Jacobian term disappears and the log-likelihood of $\mathbf{Y}_t$ equals the log-likelihood of $\mathbf{V}_t$ evaluated at the residuals.

Since the Jacobian is unity, the conditional density of $\mathbf{Y}_t$ is the Gaussian density of $\mathbf{V}_t$ evaluated at $\mathbf{v}_t = \mathbf{A}_0\mathbf{Y}_t - \mathbf{A}_1(L)\mathbf{Y}_{t-1} - \mu$.

For a single observation, $\mathbf{V}_t \sim N(\mathbf{0}, \Sigma)$ has density

$$f_V(\mathbf{v}_t) = (2\pi)^{-1}|\Sigma|^{-1/2} \exp\!\left(-\tfrac{1}{2}\,\mathbf{v}_t^\top \Sigma^{-1}\mathbf{v}_t\right).$$

Taking logarithms gives

$$\ell_t(\theta) = -\log(2\pi) - \tfrac{1}{2}\log|\Sigma| - \tfrac{1}{2}\,\mathbf{v}_t^\top\Sigma^{-1}\,\mathbf{v}_t.$$

Summing over T observations and dropping the constant $-T\log(2\pi)$ yields the log-likelihood function

$$L(\theta) = -\frac{T}{2}\log|\Sigma| - \frac{1}{2}\sum_{t=1}^{T}(\mathbf{A}_0\mathbf{Y}_t - \mathbf{A}_1(L)\mathbf{Y}_{t-1} - \mu)^\top\Sigma^{-1}(\mathbf{A}_0\mathbf{Y}_t - \mathbf{A}_1(L)\mathbf{Y}_{t-1} - \mu), \tag{133.14}$$

where Σ is the covariance matrix of the innovation $\mathbf{V}_t$ and θ collects all free parameters including α, β, the covariance parameters, the first-row intercept μ_x, and the first-row lag coefficients.

The restrictions imposed by (133.6) enter (133.14) through the structure of $\mathbf{A}_0$, $\mathbf{A}_1(L)$, and μ in (133.13).

The second row of (133.12) has no free lag coefficients and its intercept is determined by α, β, and Σ.

An alternative unrestricted bivariate VAR(p) would estimate both rows of (133.12) freely.

Each row has 1 intercept plus $2p$ lag coefficients (p lags $\times$ 2 variables), giving $2(1 + 2p)$ mean parameters.

Adding 3 free covariance parameters ($\sigma_{XX}, \sigma_{RR}, \sigma_{XR}$) gives a total of $5 + 4p$.

The restricted system (133.12) has only $6 + 2p$ free parameters: the first row contributes $1 + 2p$ (its intercept μ_x and $2p$ lag coefficients), plus α, β, and the 3 covariance parameters.

The second row adds nothing because its lag structure and intercept are pinned down by α, β, and Σ via (133.10).

The difference $(5 + 4p) - (6 + 2p) = 2p - 1$ gives the degrees of freedom for the likelihood ratio tests we will perform soon.

133.5 Likelihood implementation

Now let's implement the likelihood (133.14).

The building blocks are:

- a function to construct lagged data matrices $(\mathbf{Y}_t, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_{t-p})$,
- a function to map the parameter vector into the matrices $\mathbf{A}_0$, $\mathbf{A}_1$, μ, Σ,
- a function to compute the restricted-system residuals $\mathbf{V}_t = \mathbf{A}_0 \mathbf{Y}_t - \mathbf{A}_1(L)\mathbf{Y}_{t-1} - \mu$, and
- the Gaussian log-likelihood itself.

Since we are working with log-transformed data, we define a helper for the transformation below

```
def to_mle_array(data):
    valid = (data[:, 0] > 0.0) & (data[:, 1] > 0.0)
    return np.column_stack(
        [np.log(data[valid, 1]), np.log(data[valid, 0])])
```

First we build the lagged data matrices, which are the inputs to the likelihood function

```
def build_lagged_data(data, n_lags):
    """
    Build Y_t and lag stacks [Y_{t-1}, ..., Y_{t-p}] for bivariate data.
    """
    if data.ndim != 2 or data.shape[1] != 2:
        raise ValueError("data must be T x 2.")
    if data.shape[0] <= n_lags:
        raise ValueError("Sample size must exceed n_lags.")

    t_obs = data.shape[0]
    n_obs = t_obs - n_lags
    y_t = data[n_lags:, :]
    y_lag = np.empty((n_obs, 2 * n_lags))

    for lag in range(1, n_lags + 1):
        y_lag[:, 2 * (lag - 1) : 2 * lag] = data[n_lags - lag : t_obs - lag, :]

    return y_t, y_lag
```

Next, we validate and unpack the parameter vector while enforcing feasibility conditions

```
def unpack_parameters(params, n_lags):
    """
    Validate and unpack parameter vector.
    """
    if len(params) != 6 + 2 * n_lags:
        return None
```

(continues on next page)

(continued from previous page)

```
    α, β, σ_x, σ_r, cov_xr, μ_x = params[:6]
    a_lags = params[6:]

    tol = 1e-8
    if not np.isfinite(α):
        return None
    if not (tol < β):
        return None
    if not (σ_x > tol and σ_r > tol):
        return None

    Σ = np.array(
        [
            [σ_x ** 2, cov_xr],
            [cov_xr, σ_r ** 2],
        ]
    )

    try:
        cholesky(Σ, lower=True)
    except (LinAlgError, ValueError):
        return None

    return {
        "α": np.array(α),
        "β": np.array(β),
        "σ_x": np.array(σ_x),
        "σ_r": np.array(σ_r),
        "cov_xr": np.array(cov_xr),
        "μ_x": np.array(μ_x),
        "a_lags": a_lags,
    }
```

The next step maps parameters and lagged data into restricted-system residuals

```
def restricted_residuals(
    params,
    y_t,
    y_lag,
    n_lags,
):
    """
    Compute V_t implied by A0 Y_t - A1 Y_{t-1} - mu.
    """
    parsed = unpack_parameters(params, n_lags)
    if parsed is None:
        return None

    α = float(parsed["α"])
    β = float(parsed["β"])
    σ_x = float(parsed["σ_x"])
    σ_r = float(parsed["σ_r"])
    cov_xr = float(parsed["cov_xr"])
    μ_x = float(parsed["μ_x"])
    a_lags = np.asarray(parsed["a_lags"])
```

(continues on next page)

(continued from previous page)

```
    A0 = np.array([[1.0, 0.0], [α, 1.0]])
    A1 = np.zeros((2, 2 * n_lags))
    A1[0, :] = a_lags
    σ_u2 = α ** 2 * σ_x ** 2 + σ_r ** 2 + 2.0 * α * cov_xr
    μ = np.array([μ_x, -np.log(β) - 0.5 * σ_u2])

    resid = y_t @ A0.T - y_lag @ A1.T - μ[None, :]
    if np.any(np.abs(resid) > 1e10):
        return None
    return resid
```

The recursive structure also lets us simulate data from the model.

We can generate data from the model by drawing innovations $\mathbf{V}_t \sim N(\mathbf{0}, \Sigma)$ and compute $\mathbf{Y}_t = \mathbf{A}_0^{-1}(\mathbf{A}_1(L)\mathbf{Y}_{t-1} + \mu + \mathbf{V}_t)$ forward in time.

This is useful for checking the likelihood implementation through Monte Carlo

```
def simulate_restricted_var(
    params,
    n_obs,
    n_lags,
    burn_in=200,
    seed=0,
):
    """
    Simulate [log consumption growth, log return] from the restricted model.
    """
    rng = np.random.default_rng(seed)

    if len(params) != 6 + 2 * n_lags:
        raise ValueError("Parameter vector length must be 6 + 2 * n_lags.")

    α, β, σ_x, σ_r, cov_xr, μ_x = params[:6]
    a_lags = params[6:]

    Σ_e = np.array(
        [
            [σ_x ** 2, cov_xr],
            [cov_xr, σ_r ** 2],
        ]
    )

    A0 = np.array([[1.0, 0.0], [α, 1.0]])
    Σ_v = A0 @ Σ_e @ A0.T

    eigvals = np.linalg.eigvals(Σ_v)
    if np.min(eigvals) <= 0.0:
        Σ_v += np.eye(2) * 1e-6

    A1 = np.zeros((2, 2 * n_lags))
    A1[0, :] = a_lags
    σ_u2 = α ** 2 * σ_x ** 2 + σ_r ** 2 + 2.0 * α * cov_xr
    μ = np.array([μ_x, -np.log(β) - 0.5 * σ_u2])

    total_n = n_obs + burn_in
    y = np.zeros((total_n, 2))
```

(continues on next page)

(continued from previous page)

```
    for t in range(n_lags, total_n):
        lag_stack = []
        for lag in range(1, n_lags + 1):
            lag_stack.append(y[t - lag, :])

133.5.1 Simulation

Before applying the likelihood to real data, we verify that it recovers known parameters from simulated data generated by the restricted system.

For `n_lags = 1`, the parameter vector is

$$\theta = (\alpha,\ \beta,\ \sigma_x,\ \sigma_r,\ \sigma_{xr},\ \mu_x,\ a_{x,1},\ a_{r,1}),$$

where the last two entries are the coefficients on X_{t-1} and R_{t-1} in the first-row regression for X_t.

More generally, for `n_lags = p` we pack `a_lags` in the order $[a_{x,1}, a_{r,1}, \dots, a_{x,p}, a_{r,p}]$, so the full parameter vector has length $6 + 2p$.

The covariance parameters $(\sigma_x, \sigma_r, \sigma_{xr})$ describe the reduced-form shocks to (X_t, R_t): if $\varepsilon_t = (\varepsilon_{x,t}, \varepsilon_{r,t})^\top \sim N(0, \Sigma_\varepsilon)$, then $\Sigma_\varepsilon = \begin{bmatrix} \sigma_x^2 & \sigma_{xr} \\ \sigma_{xr} & \sigma_r^2 \end{bmatrix}$.

The restricted-system innovation is $\mathbf{V}_t = \mathbf{A}_0 \varepsilon_t$, so its covariance is $\Sigma_V = \mathbf{A}_0 \Sigma_\varepsilon \mathbf{A}_0^\top$, which is what enters the likelihood.

In the simulation recursion we draw $\mathbf{V}_t \sim N(0, \Sigma_V)$ and compute $\mathbf{Y}_t = \mathbf{A}_0^{-1}(\mathbf{A}_1(L)\mathbf{Y}_{t-1} + \mu + \mathbf{V}_t)$ forward.

The following table compares the true parameters to the MLE estimates from a large simulated sample

```
α_true = -1.00
β_true = 0.993
σ_x_true = 0.015
σ_r_true = 0.020
cov_xr_true = 0.0001
μ_x_true = 0.002
a_x1_true = 0.40
a_r1_true = 0.10

true_params = np.array(
    [
        α_true,
        β_true,
        σ_x_true,
        σ_r_true,
        cov_xr_true,
        μ_x_true,
        a_x1_true,
        a_r1_true,
    ]
)

sim_mle_data = simulate_restricted_var(
    params=true_params,
    n_obs=50000,
```

(continues on next page)

(continued from previous page)

```
    n_lags=1,
    burn_in=5000,
    seed=0,
)

fit_sim = estimate_mle(sim_mle_data, n_lags=1, verbose=False)
```

	true	estimate	se	t (H_0: true)
α	-1.0000	-0.9757	0.011291	2.15
β	0.9930	0.9929	0.000107	-0.78

The point estimates are close to the true parameters, and the t-statistics for the null hypothesis that the true value is correct are small in magnitude, consistent with sampling variation.

133.6 Preference parameters and likelihood ratio tests

The restricted system embeds preference parameters through cross-equation restrictions.

The parameter α links predictable variation in returns to predictable variation in consumption growth.

Under the model, the return equation's dependence on lagged variables is entirely determined by $-\alpha$ times the consumption equation's lag coefficients.

The parameter β shifts the return-equation intercept through $-\log\beta - \sigma_U^2/2$.

Hansen and Singleton [1983] test these restrictions by comparing the restricted system to an unrestricted bivariate VAR estimated on the same sample.

If the restrictions imposed by the Euler-equation are correct, the restricted model should fit nearly as well as the unrestricted model.

The standard test is the likelihood ratio statistic

$$LR = 2(\ell_u - \ell_r) \Rightarrow \chi^2_d, \tag{133.15}$$

where ℓ_u and ℓ_r are the maximized log-likelihoods of the unrestricted and restricted models, and d is the difference in the number of free parameters.

Both likelihoods must be evaluated on the same effective sample for the LR distribution to be valid.

Hansen and Singleton [1983] report that for the value-weighted aggregate stock return, the χ^2 test statistics provide little evidence against the model.

In the tables below we report both `chi2.cdf(LR, df)` (corresponding to what HS report in parentheses) and the usual right-tail `p(LR) = 1 - chi2.cdf`

```
def likelihood_ratio_test(
    fit_restricted,
    fit_unrestricted,
    df_diff,
):
    """
    Compare nested specifications with an LR test.
    """
    if not (fit_restricted["converged"] and fit_unrestricted["converged"]):
```

(continues on next page)

(continued from previous page)

```
        return {"lr_stat": np.nan, "p_value": np.nan, "chi2_cdf": np.nan}
    if fit_restricted.get("n_obs") != fit_unrestricted.get("n_obs"):
        return {"lr_stat": np.nan, "p_value": np.nan, "chi2_cdf": np.nan}

    lr_stat = 2.0 * (fit_unrestricted["loglike"] - fit_restricted["loglike"])
    chi2_cdf = stats.chi2.cdf(lr_stat, df=df_diff)
    p_value = 1.0 - chi2_cdf
    return {
        "lr_stat": float(lr_stat),
        "p_value": float(p_value),
        "chi2_cdf": float(chi2_cdf),
    }
```

The unrestricted benchmark is a Gaussian VAR for $\mathbf{Y}_t = (X_t, R_t)^\top$ with free coefficients on all lags in both equations.

```

```

133.7 Predictability and the R-squared restriction

Section II of Hansen and Singleton [1983] emphasizes an implication of the restricted system for return predictability.

From (133.10) and (133.11), the predictable component of the log return is

$$E(R_t \mid \psi_{t-1}) = -\alpha\, E(X_t \mid \psi_{t-1}) - \log\beta - \frac{\sigma_U^2}{2}. \tag{133.16}$$

Since the predictable return is a linear function of the predictable consumption growth, the variance of the predictable return component is exactly α^2 times the variance of the predictable consumption-growth component:

$$\operatorname{Var}[E(R_t \mid \psi_{t-1})] = \alpha^2 \operatorname{Var}[E(X_t \mid \psi_{t-1})]. \tag{133.17}$$

Hansen and Singleton [1983] derive the implied R^2 of the return projection onto ψ_{t-1}:

$$R_R^2 = \frac{\alpha^2 \operatorname{Var}[E(X_t \mid \psi_{t-1})]}{\operatorname{Var}(R_t \mid \psi_{t-1}) + \alpha^2 \operatorname{Var}[E(X_t \mid \psi_{t-1})]}. \tag{133.18}$$

If $\alpha = 0$ (risk neutrality), then $R_R^2 = 0$ and asset returns are unpredictable.

If $\alpha = -1$ (log utility), then $R_t - X_t$ is unpredictable, so returns and consumption growth share the same predictable component.

More generally, the R_R^2 for returns will be small whenever the variance of the unpredictable return component $\operatorname{Var}(R_t \mid \psi_{t-1})$ is large relative to the predictable variance, which is the case for stock returns.

The function below reports:

- restriction-side predictable-variance terms implied by the Euler equation, and
- R_X^2 and R_R^2 from the unrestricted VAR.

```
def predictability_metrics(data, restricted_fit, unrestricted_fit, n_lags):
    """
    Compute predictable-component metrics and unrestricted VAR R^2 values.
    """
    y_t, y_lag = build_lagged_data(data, n_lags)
    parsed = unpack_parameters(restricted_fit["params"], n_lags)
    α = float(parsed["α"])
    β = float(parsed["β"])
    σ_x = float(parsed["σ_x"])
    σ_r = float(parsed["σ_r"])
    cov_xr = float(parsed["cov_xr"])
    μ_x = float(parsed["μ_x"])

        "T": int(y_t.shape[0]),
    }
```

133.8 Return-difference tests

Hansen and Singleton [1983] also propose tests based on differences in log returns across assets.

From (133.10), the conditional mean of asset i's log return is $E_{t-1}[R_{it}] = -\alpha\, E_{t-1}[X_t] - \log\beta - \sigma_i^2/2$.

The term $-\alpha\, E_{t-1}[X_t] - \log\beta$ is common to all assets, so it cancels in the difference:

$$E_{t-1}[R_{it} - R_{jt}] = \frac{\sigma_j^2 - \sigma_i^2}{2},$$

which is a constant that does not depend on time-$(t-1)$ information.

Return differences should therefore be unpredictable if the model is correct, regardless of the values of α and β.

These tests avoid the need to measure consumption, at the cost of losing the ability to identify α and β.

Hansen and Singleton [1983] report that the return-difference restrictions are strongly rejected for models with multiple stock returns, providing substantial evidence against the CRRA-lognormal specification even when consumption measurement problems are eliminated.

The code below is an illustration of this logic on simulated data.

Reproducing the paper's empirical return-difference tables requires estimating multi-asset systems that are outside this lecture's scope

```
def simulate_multi_asset_nominal_returns(
    n_obs,
    n_assets=3,
    α_true=-1.0,
    β_true=0.993,
```

(continues on next page)

(continued from previous page)

```

We run `return_difference_test` on simulated data with $m = 3$ assets, giving $\binom{3}{2} = 3$ pairs.

For each pair, the function regresses the return spread on a constant and `n_lags` lags of all asset returns, then tests whether the slope coefficients are jointly zero using a Wald χ^2 statistic

```
_, sim_log_returns = simulate_multi_asset_nominal_returns(
    n_obs=1500,
    n_assets=3,
    α_true=-1.0,
    β_true=0.993,
    seed=0,
)

spread_test = return_difference_test(sim_log_returns, n_lags=2)
spread_pretty = spread_test.rename(columns={
    "wald_chi2": r"\chi^2", "p_value": "p", "mean_spread": r"\overline{\Delta R}",
})
display_table(spread_pretty, fmt={
    r"\chi^2": "{:.3f}",
    "p": "{:.3f}",
    r"\overline{\Delta R}": "{:.5f}",
})
```

pair	χ^2	p	$\overline{\Delta R}$
$1-2$	9.445	0.150	0.00132
$1-3$	8.338	0.214	0.00154
$2-3$	4.272	0.640	0.00023

Large p-values confirm that return differences are unpredictable in this simulation, exactly as the model predicts when $\alpha = -1$.

133.9 Empirical MLE estimation

We now apply the maximum likelihood estimator of Hansen and Singleton [1983] to real data.

133.9.1 Data

Both this lecture and the companion lecture *Estimating Euler Equations by Generalized Method of Moments* use the same data construction.

Hansen and Singleton [1982] and Hansen and Singleton [1983] use monthly data on real per capita consumption (nondurables) and stock returns from CRSP for the period 1959:2 through 1978:12.

To align with the paper, we set the default sample to 1959:2–1978:12.

You can pass different `start` and `end` dates to study later periods.

This lecture pulls stock-market and one-month bill returns from the Ken French data library (`F-F_Research_Data_Factors`) and constructs gross nominal returns as `1 + (Mkt-RF + RF)/100` for the market and `1 + RF/100` for T-bills.

`Mkt-RF` is the value-weighted return on all CRSP firms minus the risk-free rate, and `RF` is the one-month Treasury bill return (see here for details).

While Hansen-Singleton use CRSP value-weighted NYSE returns, we use the Ken French market factor as the closest open-access alternative.

The consumption series is constructed from consumption of nondurables (`ND`) with the nondurables deflator.

The hidden cell below loads a monthly dataset of returns and consumption series from QuantEcon/data-lectures. The data are built from the FRED and Ken French data libraries by the maintenance script at `builders/hansen_singleton_1983_data.py` and read here directly from GitHub.

133.9.2 MLE estimation and predictability summaries

With the data in hand, we can run the MLE estimation and compute the predictability summaries.

Lognormality makes the MLE tractable when the assumption is correct.

As Hansen and Singleton [1983] stress, however, α is estimated with relatively large standard errors, and precise inference on risk aversion cannot be expected from aggregate monthly data alone.

```
lags = (2, 4, 6)

emp_frame, emp_data = get_estimation_data()
```

The following table reports the restricted MLE estimates of $\hat{\alpha}$ and $\hat{\beta}$ by lag length

```
emp_log_data = to_mle_array(emp_data)
mle_table, mle_fits = run_mle_by_lag(
    emp_log_data, lags=lags, verbose=False
)
mle_pretty = mle_table.rename(columns={
    "α_hat": r"\hat{\alpha}", "se_α": r"\mathrm{se}(\hat{\alpha})",
    "β_hat": r"\hat{\beta}", "se_β": r"\mathrm{se}(\hat{\beta})",
    "loglike": "logL", "n_obs": "T",
})
display_table(mle_pretty, fmt={
    r"\hat{\alpha}": "{:.4f}", r"\mathrm{se}(\hat{\alpha})": "{:.4f}",
    r"\hat{\beta}": "{:.4f}", r"\mathrm{se}(\hat{\beta})": "{:.4f}",
    "logL": "{:.1f}", "T": "{:.0f}",
})
```

NLAG	$\hat{\alpha}$	se($\hat{\alpha}$)	$\hat{\beta}$	se($\hat{\beta}$)	logL	T
2	−0.3228	0.7916	0.9976	0.0030	1209.3	237
4	−0.6402	0.6902	0.9980	0.0028	1206.4	235
6	−0.6155	0.6448	0.9979	0.0028	1199.2	233

The table reports $\hat{\alpha}$ and $\hat{\beta}$ by lag length for the sample used in the code cell above.

For comparison, Hansen and Singleton [1983] report $\hat{\alpha}$ values of -0.32 to -1.25 (standard errors 0.65 to 0.83) for the value-weighted return with nondurables consumption.

Our numbers fall into those ranges.

In risk-aversion units, this corresponds to $-\hat{\alpha}$ between 0.32 and 1.25.

We now compute the predictability summaries

```
unres_table, unres_fits = run_unrestricted_var_by_lag(
    emp_log_data,
    lags=lags,
)
```

NLAG	$\hat{\alpha}$	$\mathrm{Var}(\hat{E}[X_t \mid \psi_{t-1}])$	$\mathrm{Var}(\hat{E}[R_t \mid \psi_{t-1}])$	$\hat{\alpha}^2\,\mathrm{Var}(\hat{E}[X_t \mid \psi_{t-1}])$	R^2_X	R^2_R	T
2	−0.3228	0.000014	0.000001	0.000001	0.1630	0.0246	237
4	−0.6402	0.000016	0.000007	0.000007	0.1966	0.0459	235
6	−0.6155	0.000018	0.000007	0.000007	0.2270	0.0602	233

The column $\hat{\alpha}^2\,\mathrm{Var}(\hat{E}[X_t \mid \psi_{t-1}])$ should equal $\mathrm{Var}(\hat{E}[R_t \mid \psi_{t-1}])$ if the restriction (133.17) holds.

The columns R^2_X and R^2_R match the paper convention of reporting the values from the unrestricted VAR projections.

In Hansen and Singleton [1983], R^2_R is small (0.02 to 0.06) even when R^2_X is nontrivial: most stock-return variation is unpredictable.

Our estimates show the same pattern.

We now test the Euler-equation restrictions by comparing the restricted system to an unrestricted VAR.

```
lr_hs83 = restricted_vs_unrestricted_lr(mle_fits, unres_fits, lags=lags)
lr_pretty = lr_hs83.rename(columns={
    "lr_stat": "LR",
    "chi2_cdf": "chi2.cdf(LR,df)",
    "p_value": "p(LR)",
    "df": "df",
    "T": "T",
})
display_table(lr_pretty, fmt={
    "LR": "{:.3f}",
    "chi2.cdf(LR,df)": "{:.3f}",
    "p(LR)": "{:.3f}",
    "df": "{:.0f}",
    "T": "{:.0f}",
})

sig_level = 0.05
rejected_lags = [int(lag) for lag in lr_hs83.index if lr_hs83.loc[lag, "p_value"] <␣
↪sig_level]
not_rejected_lags = [int(lag) for lag in lr_hs83.index if lr_hs83.loc[lag, "p_value"]␣
↪>= sig_level]
print(f"Not rejected at 5%: {not_rejected_lags if not_rejected_lags else 'none'}")
```

NLAG	LR	p(LR)	chi2.cdf(LR,df)	df	T
2	5.977	0.113	0.887	3	237
4	10.023	0.187	0.813	7	235
6	12.519	0.326	0.674	11	233

```
Not rejected at 5%: [2, 4, 6]
```

The LR test does not reject the model for the value-weighted return, consistent with Hansen and Singleton [1983].

133.9.3 Treasury bill estimation

We now repeat the estimation using the 1-month Treasury bill return in place of the stock return.

Hansen and Singleton [1983] find that the model is strongly rejected for Treasury bills (Table 4 of their paper).

Because the nominally risk-free T-bill return is much more predictable than stock returns, the proportionality restriction has more bite, and the LR test has greater power to detect violations

```
tbill_frame, tbill_data = get_tbill_estimation_data()
```

The following table reports the restricted MLE estimates for Treasury bill returns by lag length.

```
tbill_log_data = to_mle_array(tbill_data)
tbill_mle_table, tbill_mle_fits = run_mle_by_lag(
    tbill_log_data, lags=lags, verbose=False
)
```

NLAG	$\hat{\alpha}$	se($\hat{\alpha}$)	$\hat{\beta}$	se($\hat{\beta}$)	logL	T
2	−0.3060	0.0600	0.9996	0.0003	1817.5	237
4	−0.2882	0.0612	0.9996	0.0003	1804.9	235
6	−0.1991	0.0571	0.9996	0.0003	1791.4	233

The LR test below remains the main specification check in the paper

```
tbill_unres_table, tbill_unres_fits = run_unrestricted_var_by_lag(
    tbill_log_data,
    lags=lags,
)

tbill_unres_pretty = tbill_unres_table.rename(columns={"loglike": "logL", "n_obs": "T
↪"})
display_table(tbill_unres_pretty, fmt={
    "logL": "{:.1f}", "T": "{:.0f}",
})
```

NLAG	logL	T
2	1838.8	237
4	1828.2	235
6	1824.8	233

NLAG	$\hat{\alpha}$	Var($\hat{E}[X_t \mid \psi_{t-1}]$)	Var($\hat{E}[R_t \mid \psi_{t-1}]$)	$\hat{\alpha}^2$ Var($\hat{E}[X_t \mid \psi_{t-1}]$)	R^2_X	R^2_R	T
2	−0.3060	0.000019	0.000002	0.000002	0.2309	0.1618	237
4	−0.2882	0.000018	0.000001	0.000001	0.2223	0.1870	235
6	−0.1991	0.000019	0.000001	0.000001	0.2333	0.2560	233

The following table reports the likelihood ratio tests for the Treasury bill model.

```
tbill_lr = restricted_vs_unrestricted_lr(tbill_mle_fits, tbill_unres_fits, lags=lags)
```

NLAG	LR	p(LR)	chi2.cdf(LR,df)	df	T
2	42.503	0.000	1.000	3	237
4	46.617	0.000	1.000	7	235
6	66.656	0.000	1.000	11	233

```
T-bill model rejected at 5% for lags: [2, 4, 6]
```

Hansen and Singleton [1983] find the same qualitative pattern in their 1959–1978 sample: the Treasury bill model is rejected much more strongly than the value-weighted stock-return model.

Why does the LR test not reject the model for stocks?

As we hinted earlier, one reason may be limited test power when return predictability is small (as reflected in the low R_R^2 for stocks).

When aggregate stock returns are nearly unpredictable, there is almost no predictable variation to constrain.

133.10 Residual diagnostics

As a final check, let's inspect the residual paths, histograms, and diagnostic statistics from the restricted model to assess whether the normality and serial independence assumptions hold.

```
diag_lag = 2
diag_fit = mle_fits[diag_lag]
resid = diag_fit["residuals"]

if diag_fit["converged"] and resid is not None:
    fig, axes = plt.subplots(2, 2, figsize=(12, 8))
    axes[0, 0].plot(resid[:, 0], lw=2)
    axes[0, 0].axhline(0.0, color="black", lw=2)
    axes[0, 0].set_ylabel("consumption residual")
    axes[0, 0].set_xlabel("observation")

    axes[0, 1].plot(resid[:, 1], lw=2)
    axes[0, 1].axhline(0.0, color="black", lw=2)
    axes[0, 1].set_ylabel("return residual")
    axes[0, 1].set_xlabel("observation")

    axes[1, 0].hist(resid[:, 0], bins=30, edgecolor="white")
    axes[1, 0].set_xlabel("consumption residual")
    axes[1, 0].set_ylabel("count")

    axes[1, 1].hist(resid[:, 1], bins=30, edgecolor="white")
    axes[1, 1].set_xlabel("return residual")
    axes[1, 1].set_ylabel("count")
    plt.tight_layout()
    plt.show()
```

The following table reports Jarque-Bera normality tests and Durbin-Watson serial correlation statistics for the restricted-model residuals.

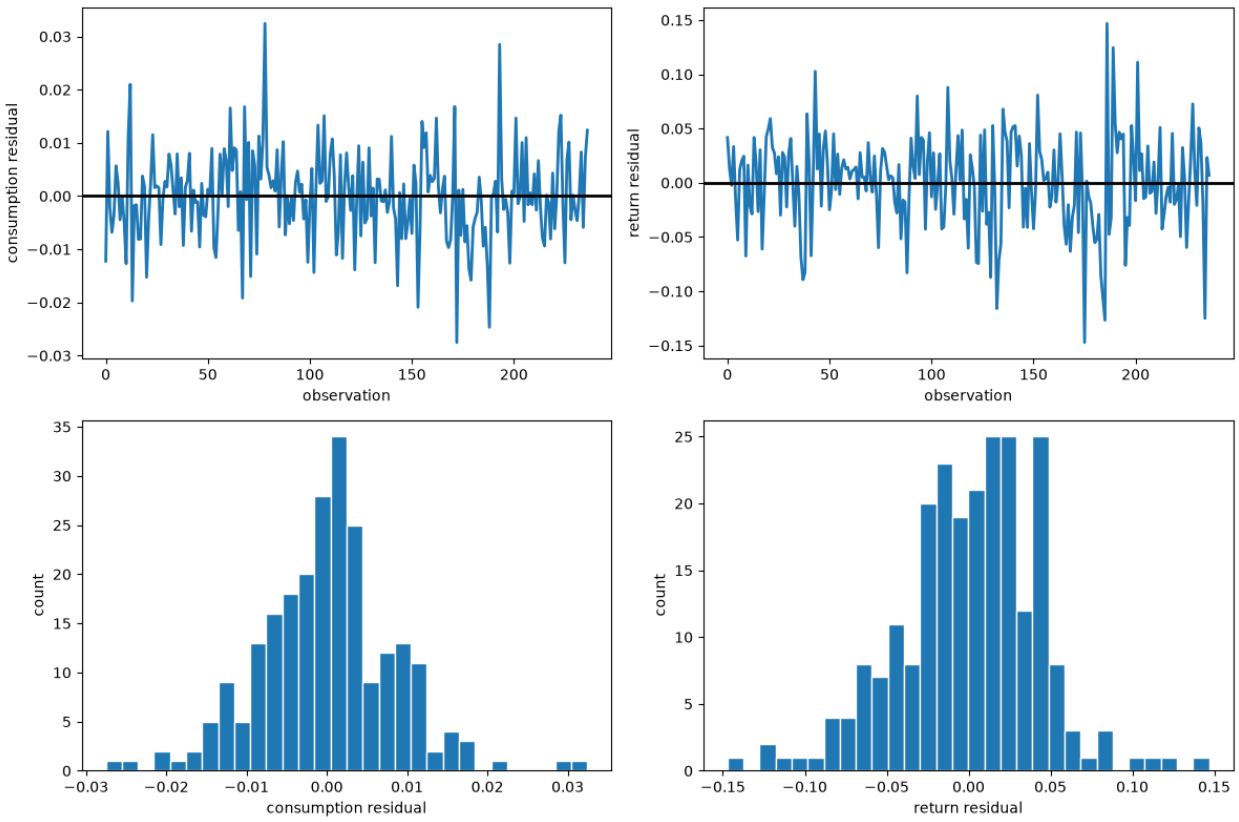

Fig. 133.1: Restricted-model residual diagnostics

```
if diag_fit["converged"] and resid is not None:
    diag = residual_diagnostics(resid)
    diag_df = pd.DataFrame({
        "JB stat": [diag["consumption_jb_stat"], diag["return_jb_stat"]],
        "JB p-val": [diag["consumption_jb_pval"], diag["return_jb_pval"]],
        "DW": [diag["consumption_dw"], diag["return_dw"]],
    }, index=pd.Index(["consumption", "return"], name="series"))
    display_table(diag_df, fmt={
        "JB stat": "{:.2f}", "JB p-val": "{:.4f}", "DW": "{:.3f}",
    })
```

series	JB stat	JB p-val	DW
consumption	18.16	0.0001	1.969
return	13.27	0.0013	1.766

The residual time-series plots reveal periods of volatility clustering, while the histograms show departures from bell curve with fatter tails.

The Jarque-Bera statistics are large for both series, rejecting the normality assumption that underlies the likelihood.

The Durbin-Watson statistics are close to 2 for both series, so serial correlation is not a concern.

This motivates the companion lecture *Estimating Euler Equations by Generalized Method of Moments* where we discuss how GMM avoids the normality assumption.

133.11 Connection to the equity premium puzzle

Our estimates reproduce the pattern that Mehra and Prescott [1985] later called the **equity premium puzzle**.

- *Low estimated risk aversion:* The estimated $\hat{\alpha}$ values (and thus risk aversion $-\hat{\alpha}$) from the table above are similar to those in Hansen and Singleton [1983], who report $\hat{\alpha}$ between -0.32 and -1.25.
- *Tiny return predictability:* The unrestricted-VAR R^2_R values are comparable to the 0.02 to 0.06 range in Hansen and Singleton [1983] – the predictable component of stock returns is small relative to the unpredictable component.
- *Strong rejection for Treasury bills:* The Euler-equation restrictions are decisively rejected for the nominally risk-free Treasury bill return, just as in Table 4 of Hansen and Singleton [1983].

The restrictions have more bite when the return series is more predictable (the unrestricted-VAR R^2_R for bills is much larger than for stocks), a precursor to what Weil [1989] would later call the **risk-free rate puzzle**.

Mehra and Prescott [1985] presented closely related findings.

In a calibrated version of the consumption-based model with CRRA utility, they showed that for relative risk aversion γ_{MP} in the range of 0 to 10, the model could not simultaneously match:

1. the average annual equity premium of about 6%,
2. the average annual risk-free rate of about 1%.

Matching the equity premium requires γ_{MP} well above 10, while matching the risk-free rate requires low γ_{MP}.

The same difficulty appears in our estimates: the implied risk aversion $-\hat{\alpha}$ is too low to generate a large equity premium.

133.12 Another approach

A companion lecture *Estimating Euler Equations by Generalized Method of Moments* describes a closely related paper in which Hansen and Singleton specified less about the joint distribution of returns and consumption growth.

They formulated an incomplete probability model that stops short of specifying a likelihood function.

To proceed, they used a generalized methods of moments (GMM) estimator to estimate key parameters that appear in the Euler equation.

134.1 Overview

This lecture implements the generalized instrumental variables estimator of Hansen and Singleton [1982] for nonlinear rational expectations models.

The preceding lecture *Stochastic Consumption, Risk Aversion, and the Temporal Behavior of Asset Returns* derives the consumption Euler equation from the representative consumer's problem with CRRA preferences and estimates it by maximum likelihood under normality assumptions.

That approach requires specifying the joint distribution of consumption and returns, and its validity depends on lognormality being correct.

However, as we saw in *Stochastic Consumption, Risk Aversion, and the Temporal Behavior of Asset Returns*, the lognormal model is rejected by the data.

Moreover, outside of linear-quadratic environments, closed-form solutions for equilibrium typically require strong assumptions about the stochastic properties of forcing variables, the nature of preferences, or the production technology.

Hansen and Singleton [1982] propose an estimation strategy that circumvents this requirement.

The key idea is that the Euler equations from economic agents' optimization problems imply a set of population orthogonality conditions that depend on observable variables and unknown preference parameters.

By making sample counterparts of these orthogonality conditions close to zero, the parameters can be estimated without explicitly solving for the stochastic equilibrium and without specifying the distribution of the observable variables.

Though maximum likelihood estimators (such as the MLE in *Stochastic Consumption, Risk Aversion, and the Temporal Behavior of Asset Returns*) will be asymptotically more efficient when the distributional assumptions are correctly specified.

Relative to the full paper, we only estimate one return at a time (value-weighted stock returns), using only monthly nondurable consumption (`ND`), and omitting their maximum-likelihood comparison (Table II) and multi-return systems (Table III).

```
import matplotlib.pyplot as plt
import numpy as np

from statsmodels.sandbox.regression import gmm
from statsmodels.tsa.stattools import acf
```

We also define a helper to display DataFrames as LaTeX arrays in the hidden cell below

134.2 The economic model

We consider a single-good economy with a representative consumer whose preferences are of the CRRA type, following Hansen and Singleton [1982] and Hansen and Singleton [1983].

Note

The following discussion is very close to the setup in *Stochastic Consumption, Risk Aversion, and the Temporal Behavior of Asset Returns*, but it is more general in that it allows for multiple assets with different maturities and does not assume lognormality.

The representative consumer chooses stochastic consumption and investment plans to maximize

$$\max E_0 \sum_{t=0}^{\infty} \beta^t u(C_t) \tag{134.1}$$

where C_t is consumption in period t, $\beta \in (0,1)$ is a subjective discount factor, and $u(\cdot)$ is a strictly concave period utility function.

The consumer trades N assets with potentially different maturities.

Let Q_{jt} denote the quantity of asset j held at the end of date t, P_{jt} its price at date t, and R_{jt} the date-t payoff from holding one unit of an M_j-period asset purchased at date $t - M_j$.

Feasible consumption and investment plans must satisfy the sequence of budget constraints

$$C_t + \sum_{j=1}^{N} P_{jt} Q_{jt} \leq \sum_{j=1}^{N} R_{jt} Q_{jt-M_j} + W_t, \tag{134.2}$$

where W_t is real labor income at date t.

We specialize to CRRA preferences

$$u(C_t) = \frac{C_t^{1-\gamma}}{1-\gamma}, \quad \gamma > 0, \tag{134.3}$$

where γ is the coefficient of relative risk aversion.

The maximization of (134.1) subject to (134.2) gives the first-order necessary conditions (see Lucas [1978], Brock [1982], Prescott and Mehra [1980], and *Stochastic Consumption, Risk Aversion, and the Temporal Behavior of Asset Returns*):

$$P_{jt} u'(C_t) = \beta^{M_j} E_t \left[R_{jt+M_j} u'(C_{t+M_j}) \right], \quad j = 1, \ldots, N. \tag{134.4}$$

When asset j is a one-period stock ($M_j = 1$) with payoff $R_{jt+1} = P_{jt+1} + D_{jt+1}$ where D_{jt} is the dividend, the **gross real return** is $R^i_{t+1} = (P_{i,t+1} + D_{i,t+1})/P_{i,t}$.

Substituting the CRRA marginal utility into (134.4) and dividing both sides by $P_{jt} u'(C_t)$ yields the Euler equation

$$E_t \left[\beta \left(\frac{C_{t+1}}{C_t} \right)^{-\gamma} R^i_{t+1} \right] = 1, \tag{134.5}$$

where R^i_{t+1} is the gross real return on asset i.

We define the **stochastic discount factor** $M_{t+1}(\theta) = \beta (C_{t+1}/C_t)^{-\gamma}$ with parameter vector $\theta = (\gamma, \beta)$.

In this notation the Euler equation becomes $E_t[M_{t+1}(\theta) R^i_{t+1} - 1] = 0$.

As we have seen and will see, equation (134.5) is the central object of both *Stochastic Consumption, Risk Aversion, and the Temporal Behavior of Asset Returns* and this lecture.

It holds for every traded asset for which the agent's optimality conditions apply (interior solution, no binding portfolio constraints or transaction costs).

It depends on observable quantities (consumption growth and returns) and unknown preference parameters (γ and β).

The challenge that Hansen and Singleton [1982] address is how to estimate θ from (134.5) without specifying the rest of the economic environment.

134.3 From conditional to unconditional moments

A natural approach to estimating θ from (134.5) would be to specify the entire economic environment, solve for equilibrium, and apply maximum likelihood.

Just like what we did together in *Stochastic Consumption, Risk Aversion, and the Temporal Behavior of Asset Returns*,

Hansen and Singleton [1982] argue that this is impractical for most nonlinear models because it requires strong assumptions about the stochastic properties of "forcing variables" and the production technology.

Their alternative is to work directly with the Euler equation's implications for observable moments.

The Euler equation (134.5) states that $E_t[M_{t+1}(\theta_0) R^i_{t+1} - 1] = 0$.

Let z_t denote any q-dimensional vector of variables that are in the agent's time-t information set and observed by the econometrician.

Because z_t is known at date t,

$$E[(M_{t+1}(\theta_0) R^i_{t+1} - 1) \otimes z_t] = E\left[z_t \otimes \underbrace{E_t[M_{t+1}(\theta_0) R^i_{t+1} - 1]}_{=0 \text{ by the Euler equation}} \right] = 0.$$

This yields the moment restriction

$$E\left[(M_{t+1}(\theta_0)R^i_{t+1} - 1) \otimes z_t\right] = 0, \tag{134.6}$$

where $\otimes$ denotes the Kronecker product.

The vector z_t plays the role of **instruments**.

The conditional Euler equation $E_t[M_{t+1}R^i_{t+1} - 1] = 0$ says that the pricing error is unpredictable given *everything* in the agent's time-t information set.

That is a very strong restriction – it says the pricing error is orthogonal to every time-t measurable random variable.

We cannot use the entire information set in practice, but we can pick any finite collection of time-t observable variables z_t and the orthogonality must still hold.

Each variable we include in z_t gives us one sample moment condition $\frac{1}{T}\sum_t (M_{t+1}R^i_{t+1} - 1)\, z_{kt} \approx 0$ that we can compute from data.

More instruments means more orthogonality conditions to match, which can improve efficiency and provides more overidentifying restrictions to test the model against.

With q instruments and m Euler equations we obtain mq moment restrictions for estimating the parameter vector θ.

For one return and p lags of instruments, Hansen and Singleton [1982] use

$$z_t = \left[1, R_t, g_t, R_{t-1}, g_{t-1}, \ldots, R_{t-p+1}, g_{t-p+1}\right]^\top, \tag{134.7}$$

where $g_t = C_t / C_{t-1}$ is gross consumption growth.

Note

Hansen and Singleton [1982] describe z_t as "lagged values of x_{t+1}" where $x_{t+1} = (R_{t+1}, g_{t+1})$.

The constant 1 is not stated explicitly but is implied by the degrees of freedom reported in their Table I.

More generally, Hansen and Singleton [1982] write the first-order condition as $E_t[h(x_{t+n}, b_0)] = 0$, where x_{t+n} is a vector of observables dated $t+n$ and b_0 is the true parameter vector.

The disturbance $u_{t+1} = h(x_{t+1}, b_0)$ is serially uncorrelated in the one-period stock case.

Stacking moment conditions via the Kronecker product gives $f(x_{t+n}, z_t, b) = h(x_{t+n}, b) \otimes z_t$, a vector of dimension mq.

The resulting unconditional restriction $E[f(x_{t+n}, z_t, b_0)] = 0$ nests both the single-return one-period Euler equation and the multi-maturity asset pricing restrictions.

The orthogonality condition and lagged instrument vector follow equations (134.6) and (134.7)

```

        instruments[:, left:right] = data[n_lags - 1 - j : t_obs - 1 - j, :]

    return endog, exog, instruments
```

When the asset has maturity $n > 1$, the Euler equation involves n-period compounded returns and consumption growth.

For CRRA preferences, the n-period Euler restriction is

$$E_t\left[\beta^n \left(\frac{C_{t+n}}{C_t}\right)^{-\gamma} R^i_{t,t+n}\right] = 1. \tag{134.8}$$

For estimation, the n-period exog can either use directly observed n-period returns/payoffs, or be constructed by compounding one-period returns and consumption growth over n consecutive periods.

Again, a key requirement from Hansen and Singleton [1982] is that instruments z_t must lie in the agent's time-t information set $\mathcal{I}_t$.

For the multi-period case, instruments must be measurable with respect to $\mathcal{I}_t$.

In particular, one should avoid any lagged multi-period aggregates that still include periods after t, since these would embed realizations not in $\mathcal{I}_t$.

The n-period exog is constructed by compounding one-period data, and instruments are timed to lie in $\mathcal{I}_t$.

```
def build_gmm_arrays_horizon(one_period_data, n_lags, horizon):
    """
    Build endog, exog, and instruments for multi-period GMM.

    Exog contains n-period compounded returns and consumption growth.
    """

        exog[i, 1] = np.prod(window[:, 1])    # n-period consumption growth
        for j in range(n_lags):
            instruments[
                i, 2 * j + 1 : 2 * j + 3] = one_period_data[t - 1 - j, :]

    endog = np.zeros(n_obs)
    return endog, exog, instruments
```

When $n > 1$, the Euler equation involves variables dated $t + n$, and the disturbance $u_{t+n} = h(x_{t+n}, b_0)$ will generally be serially correlated.

As Hansen and Singleton [1982] note, if the m assets are all one-period stocks, then u is serially uncorrelated because observations on x_{t-s}, $s \geq 0$, are in the agent's time-t information set and $E_t[h(x_{t+1}, b_0)] = 0$.

But if $n_j > 1$ for some asset j, the condition $E_t[h(x_{t+n}, b_0)] = 0$ does not preclude serial correlation in u, since x_{t+n-1} is not necessarily in I_t when $n > 1$.

The number of population autocovariances in the long-run covariance S_0 is determined by n, the order of the moving average disturbance term u_t.

We implement this directly as a finite-order covariance estimator

```
def finite_ma_covariance(moment_series, ma_order):
    """
    Estimate
    S = Gamma_0 + sum_{j=1}^{ma_order}(Gamma_j + Gamma_j.T) for moment vectors.
    """
    if ma_order < 0:
        raise ValueError("ma_order must be nonnegative.")
    if moment_series.ndim != 2:
        raise ValueError("moment_series must be 2D.")

    t_obs, n_mom = moment_series.shape
    if t_obs <= ma_order:
        raise ValueError("Need more observations than ma_order.")

    # Use the *uncentered* cross products
    # T^{-1} sum_t f_t f_{t-j}' and then add the symmetric lag terms.
    s_hat = moment_series.T @ moment_series / t_obs

    for j in range(1, ma_order + 1):
        gamma_j = moment_series[j:, :].T @ moment_series[:-j, :] / t_obs
        s_hat += gamma_j + gamma_j.T

    ridge = 1e-8 * np.eye(n_mom)
    return s_hat + ridge
```

The estimation procedure in Hansen and Singleton [1982] is a two-step generalized instrumental variables procedure.

In the first step, we minimize the GMM criterion with a suboptimal weighting matrix (the identity) to obtain a consistent preliminary estimate b_T.

In the second step, we use b_T to estimate the covariance matrix of the sample moment conditions and invert it to form the optimal weighting matrix, then re-minimize the criterion.

Let's implement this algorithm

```
def two_step_gmm(data, n_lags, ma_order=0, horizon=1, start_params=None):
    """
    Two-step GMM with finite-order covariance.

    The Euler error uses β**horizon.
    """

```

134.4 GMM criterion and asymptotic theory

We now formalize the estimation procedure.

Let $m_t(\theta) = (M_{t+1}(\theta) R^i_{t+1} - 1) \otimes z_t$ denote the vector of moment conditions at date t, and define the sample mean

$$g_T(\theta) = \frac{1}{T} \sum_{t=1}^{T} m_t(\theta). \tag{134.9}$$

If the model is correctly specified, $g_T(\theta_0)$ should be close to zero for large T.

We estimate θ by choosing the parameter vector that makes g_T as close to zero as possible, measured by a quadratic form:

$$\hat{\theta} = \arg\min_{\theta} g_T(\theta)^\top W_T g_T(\theta) \tag{134.10}$$

where W_T is a symmetric positive-definite weighting matrix.

Under regularity conditions given in Hansen [1982], the GMM estimator is consistent, asymptotically normal, and has the sandwich covariance matrix

$$\sqrt{T}(\hat{\theta} - \theta_0) \Rightarrow N\left(0, (D^\top W D)^{-1} D^\top W S W D (D^\top W D)^{-1}\right), \tag{134.11}$$

where $D = E[\partial m_t(\theta_0)/\partial\theta^\top]$ is the Jacobian of the moment conditions, S is the long-run covariance matrix of $m_t(\theta_0)$, and W is the probability limit of W_T.

Hansen [1982] shows that the optimal weighting matrix is $W^* = S^{-1}$, which yields the smallest asymptotic covariance matrix among all choices of W.

Under $W = S^{-1}$ the sandwich simplifies to $(D^\top S^{-1} D)^{-1}$.

When the number of moment conditions r (e.g., $r = mq$ for m Euler equations and q instruments) exceeds the number of parameters k, the model is overidentified and we can test whether the data are consistent with the maintained restrictions.

Hansen and Singleton [1982] test the overidentifying restrictions using a result from Hansen [1982]:

$$J_T = T\, g_T(\hat{\theta})^\top \hat{S}^{-1} g_T(\hat{\theta}) \Rightarrow \chi^2_{r-k}, \tag{134.12}$$

where $\hat{S}$ is a consistent estimator of S.

A large J_T relative to χ^2_{r-k} critical values leads to rejection of the model's overidentifying restrictions.

For the multi-period case ($n > 1$), the disturbance is at most MA($n-1$) as discussed above, so Hansen and Singleton [1982] obtain the optimal weighting matrix by setting $W_0 = S_0^{-1}$ where

$$S_0 = \sum_{j=-n+1}^{n-1} E\left[f(x_{t+n}, z_t, b_0)\, f(x_{t+n-j}, z_{t-j}, b_0)^\top\right]. \tag{134.13}$$

134.5 Covariance estimation and the choice of instruments

For the one-period Euler equation ($n = 1$), the disturbance $u_{t+1} = M_{t+1}(\theta_0) R_{t+1} - 1$ is a martingale difference sequence.

In this case the moment vector $m_t(\theta_0) = u_{t+1} \otimes z_t$ is serially uncorrelated, and the long-run covariance S equals the contemporaneous variance $E[m_t m_t^\top]$.

The covariance estimator therefore requires no kernel or bandwidth choice.

We simply use the sample analogue $\hat{S} = T^{-1} \sum_t m_t m_t^\top$.

In our implementation below, we use a HAC (heteroskedasticity and autocorrelation consistent) estimator against possible mild serial dependence from time aggregation or measurement timing.

This is a modern precaution, not part of the original Hansen and Singleton [1982] procedure, which exploits the known MA order directly as in (134.13).

The number of instrument lags p determines how many orthogonality conditions we use and hence the power of the J test.

Hansen and Singleton [1982] report results for NLAG $= 1, 2, 4, 6$ and note (footnote 12) that using more orthogonality conditions may lead to estimators with less desirable small-sample properties.

Below we implement the estimation procedure and allow the user to choose the number of lags and whether to use a HAC estimator for the covariance matrix

```
def estimate_gmm(
    data,
    n_lags,
    start_params=None,
    use_hac=True,
    hac_maxlag=None,
    maxiter=2,
```

(continues on next page)

(continued from previous page)

```
):
    """
    Estimate Euler-equation parameters with nonlinear IV-GMM.
    """
    if start_params is None:
        start_params = np.array([1.0, 0.99])

    endog, exog, instruments = build_gmm_arrays(data, n_lags)
    model = gmm.NonlinearIVGMM(endog, exog, instruments, euler_error)

    if use_hac:
        if hac_maxlag is None:
            hac_maxlag = max(
                1, int(
                    np.floor(4.0 * (endog.shape[0] / 100.0) ** (2.0 / 9.0))))
        result = model.fit(
            start_params=start_params,
            maxiter=maxiter,
            optim_method="bfgs",
            optim_args={"disp": False},
            weights_method="hac",
            wargs={"maxlag": hac_maxlag},
        )
    else:
        result = model.fit(
            start_params=start_params,
            maxiter=maxiter,
            optim_method="bfgs",
            optim_args={"disp": False},
        )

    return result
```

Next we include a helper to run GMM estimation across lag lengths and summarize results in a table

```
def run_gmm_by_lag(
    data,
    lags=(1, 2, 4, 6),
    use_hac=True,

        )
    return pd.DataFrame(rows).set_index("NLAG")
```

134.5.1 Simulation

Before applying the estimator to real data, we verify that GMM recovers known parameters from simulated data.

We build a simulator that generates synthetic return-growth pairs satisfying the Euler equation by construction.

We generate log consumption growth from a stationary AR(1), compute the stochastic discount factor at known true parameters, and construct gross returns as $R_{t+1} = \xi_{t+1}/M_{t+1}(\theta_0)$ where ξ_{t+1} is an iid lognormal shock with mean one.

```
@njit
def _ar1_simulate(mu_c, phi_c, sigma_c, shocks_c, total_n):
    """
    Simulate AR(1) log consumption growth.
    """
    delta_c = np.empty(total_n)
    delta_c[0] = mu_c
    for t in range(1, total_n):
        delta_c[t] = mu_c * (1.0 - phi_c) + phi_c * delta_c[t - 1] + sigma_c * shocks_
↪c[t]
    return delta_c

def simulate_euler_sample(
    n_obs,
    γ_true=0.8,
    β_true=0.993,
    seed=0,
):
    """
    Simulate [gross real return, gross consumption growth].
    """
    rng = np.random.default_rng(seed)
    mu_c = 0.0015
    sigma_c = 0.006
    phi_c = 0.4
    sigma_eta = 0.02
    burn_in = 200

    total_n = n_obs + burn_in
    shocks_c = rng.standard_normal(total_n)
    delta_c = _ar1_simulate(mu_c, phi_c, sigma_c, shocks_c, total_n)

    cons_growth = np.exp(delta_c[burn_in:])
    sdf = β_true * cons_growth ** (-γ_true)

    # Positive mean-one return shock: E[ξ]=1 so E[M R]=1 by construction.
    eps = rng.standard_normal(n_obs)
    xi = np.exp(sigma_eta * eps - 0.5 * sigma_eta**2)
    gross_return = xi / sdf

    return np.column_stack([gross_return, cons_growth])
```

We set $\gamma = 2$ and $\beta = 0.995$ as the true parameters and generate 700 monthly observations from the Euler-consistent DGP.

```
γ_true = 2.0
β_true = 0.995
sim_data = simulate_euler_sample(
```

(continues on next page)

(continued from previous page)

```
    n_obs=5000,
    γ_true=γ_true,
    β_true=β_true,
    seed=0,
)

print(f"Simulation sample size: {sim_data.shape[0]}")
print(f"True γ: {γ_true:.3f}")
print(f"True β: {β_true:.3f}")
```

```
Simulation sample size: 5000
True γ: 2.000
True β: 0.995
```

We now estimate GMM across lag lengths, following the format of Table I in Hansen and Singleton [1982].

```
sim_table = run_two_step_by_lag(sim_data, lags=(1, 2, 4, 6), horizon=1)
```

6	2.0991	0.1443	0.9949	0.0004	8.125	11	0.298

GMM recovers the true γ and β across lag specifications pretty closely.

For hypothesis testing, the right-tail p value is $1 - \text{Prob}(J)$.

The large standard errors visible in both papers' tables suggest that the preference parameters γ and β can be weakly identified.

To visualize this, we plot the GMM criterion over a (γ, β) grid using the simulated data

```
def gmm_objective_surface(
    data,
    n_lags=2,
    γ_grid=None,
    β_grid=None,
):
    """
    Compute identity-weighted GMM objective on a parameter grid.
    """
    _, exog, instruments = build_gmm_arrays(data, n_lags)

    if γ_grid is None:
        γ_grid = np.linspace(-1.0, 8.0, 70)
    if β_grid is None:
        β_grid = np.linspace(0.96, 1.02, 70)

    objective = np.empty((len(β_grid), len(γ_grid)))

    for i, β_val in enumerate(β_grid):
        for j, γ_val in enumerate(γ_grid):
            err = euler_error(np.array([γ_val, β_val]), exog)
            moments = (err[:, None] * instruments).mean(axis=0)
```

(continues on next page)

(continued from previous page)

```
            objective[i, j] = moments @ moments

    return γ_grid, β_grid, objective
```

```
γ_grid, β_grid, objective = gmm_objective_surface(sim_data, n_lags=2)
log_obj = np.log10(objective + 1e-12)

fig, ax = plt.subplots()
contours = ax.contourf(γ_grid, β_grid, log_obj, levels=30, cmap="viridis")
ax.set_xlabel(r"$\gamma$")
ax.set_ylabel(r"$\beta$")
ax.plot(γ_true, β_true, "k*", ms=12, lw=2, label="true values")
ax.legend()
plt.colorbar(contours, ax=ax)
plt.tight_layout()
plt.show()
```

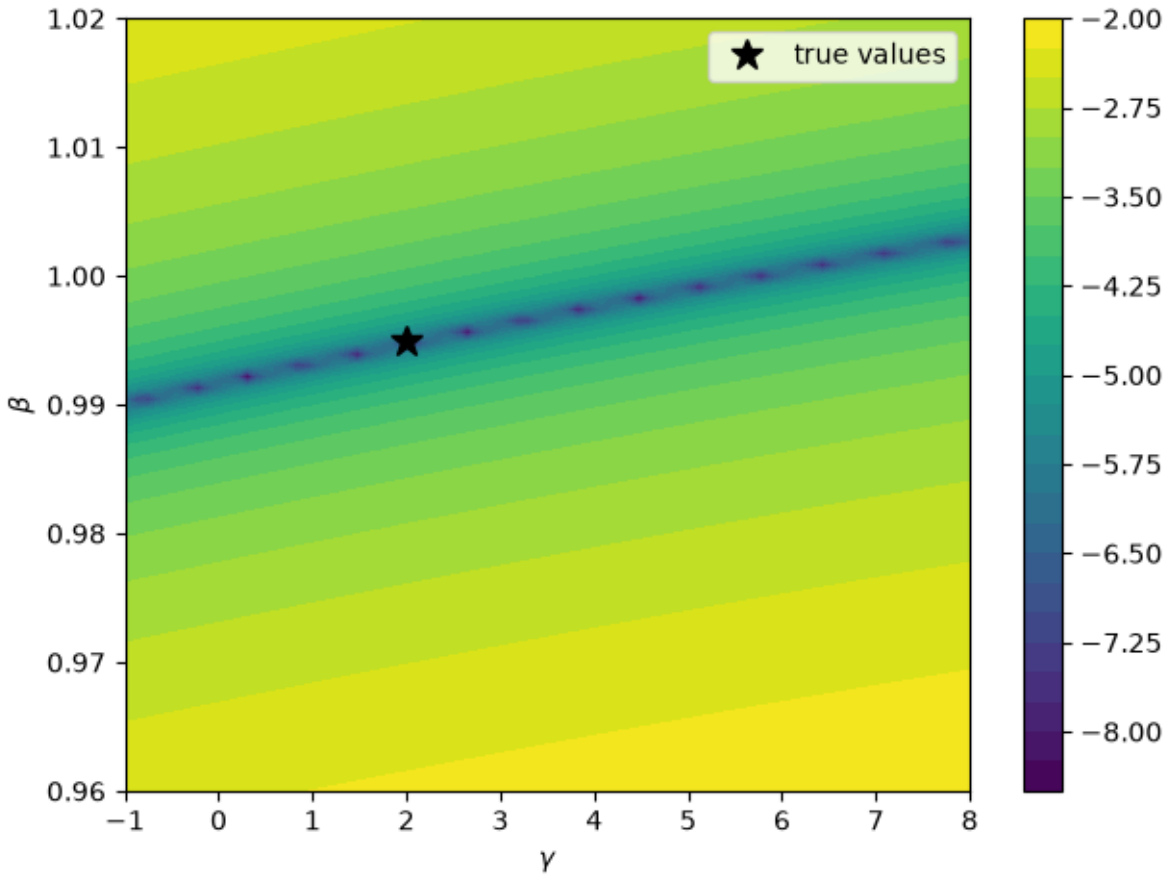

Fig. 134.1: GMM objective contour surface (simulated data)

The criterion surface may have elongated valleys where many parameter combinations fit the moments nearly equally well.

To illustrate the multi-period case from Section 2 of Hansen and Singleton [1982], we estimate the three-period Euler

restriction using overlapping-horizon returns and consumption growth, with instruments formed from one-period data dated t or earlier and the finite-order covariance appropriate for MA(2) disturbances.

```
horizon_n = 3
two_step = two_step_gmm(
    sim_data,
    n_lags=2,
    ma_order=horizon_n - 1,
    horizon=horizon_n,
)

print(f"Horizon n: {horizon_n}")
print(f"Step-2 converged: {two_step['success']}")
print(f"Step-2 gamma: {two_step['params_step2'][0]:.4f}")
print(f"Step-2 beta (one-period): {two_step['params_step2'][1]:.4f}")
print(
    f"J({two_step['j_df']}): {two_step['j_stat']:.3f}, "
    f"Prob={two_step['j_prob']:.3f}, p={two_step['j_pval']:.3f}"
)

_, exog_n, _ = build_gmm_arrays_horizon(sim_data, n_lags=2, horizon=horizon_n)
acf_n = acf(
    euler_error_horizon(two_step["params_step2"], exog_n, horizon=horizon_n),
    nlags=6,
    fft=True,
)
print("Euler-error ACF lags 1-3:", ", ".join([f"{v:.3f}" for v in acf_n[1:4]]))
```

```
Horizon n: 3
Step-2 converged: True
Step-2 gamma: 2.1095
Step-2 beta (one-period): 0.9949
J(3): 2.518, Prob=0.528, p=0.472
Euler-error ACF lags 1-3: 0.678, 0.356, 0.023
```

The low-lag ACF is consistent with the MA(2) dependence implied by the 3-period horizon.

We now run a Monte Carlo exercise with 500 replications to visualize the finite-sample distribution of $\hat{\gamma}$, $\hat{\beta}$, and the J statistic and verify that the asymptotic theory from Section 3 of Hansen and Singleton [1982] provides a reasonable approximation.

```
n_rep = 500
estimates = []
j_stats = []

for rep in range(n_rep):
    rep_data = simulate_euler_sample(
        n_obs=900,
        γ_true=γ_true,
        β_true=β_true,
        seed=rep,
    )
    rep_res = estimate_gmm(rep_data, n_lags=2, use_hac=True, maxiter=2)
    estimates.append(rep_res.params)
    j_stats.append(rep_res.jval)

estimates = np.asarray(estimates)
j_stats = np.asarray(j_stats)
```

(continues on next page)

(continued from previous page)

```
fig, axes = plt.subplots(1, 3, figsize=(15, 4))
axes[0].hist(estimates[:, 0], bins=20, edgecolor="white")
axes[0].axvline(γ_true, color="red", ls="--", lw=2)
axes[0].set_xlabel(r"$\hat{\gamma}$")
axes[1].hist(estimates[:, 1], bins=20, edgecolor="white")
axes[1].axvline(β_true, color="red", ls="--", lw=2)
axes[1].set_xlabel(r"$\hat{\beta}$")

df_j = 2 * 2 + 1 - 2
axes[2].hist(j_stats, bins=20, density=True, edgecolor="white")
grid = np.linspace(0.0, max(j_stats.max(), 1.0), 200)
axes[2].plot(grid, stats.chi2.pdf(grid, df_j), "r-", lw=2)
axes[2].set_xlabel("j-statistic")
plt.tight_layout()
plt.show()
```

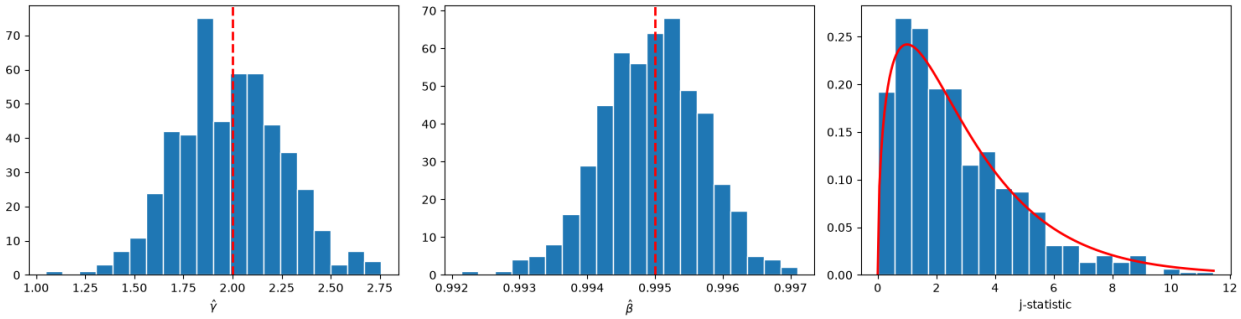

Fig. 134.2: Monte Carlo GMM sampling distributions

Both $\hat{\gamma}$ and $\hat{\beta}$ are centered near their true values, and the J histogram tracks the χ^2 density, supporting the asymptotic approximation at this sample size.

134.6 Empirical GMM estimation

We now apply GMM to observed data, following the empirical strategy of Section 5 in Hansen and Singleton [1982].

Hansen and Singleton [1982] use monthly per capita consumption of nondurables (ND) and nondurables plus services (NDS) paired with the equally-weighted (EWR) and value-weighted (VWR) aggregate stock returns from CRSP, for 1959:2 through 1978:12.

We focus on their ND+VWR specification using FRED nondurables consumption and the Ken French value-weighted market return as a proxy for CRSP, on the same 1959:2–1978:12 sample period.

Because the Ken French return is not identical to the original CRSP NYSE value-weighted return, we only want to match the paper qualitatively.

Both this lecture and the companion lecture *Stochastic Consumption, Risk Aversion, and the Temporal Behavior of Asset Returns* use the same data construction.

The hidden cell below loads a monthly dataset of gross real returns and gross consumption growth from QuantEcon/data-lectures. The data are built from the FRED and Ken French data libraries by the maintenance script at `builders/hansen_singleton_1982_data.py` and read here directly from GitHub.

We first examine the raw data moments.

```
LAGS = (1, 2, 4, 6)

emp_frame, emp_data = get_estimation_data()

print(f"Mean net real return: {(emp_data[:, 0].mean() - 1.0) * 100:.3f}%")
print(f"Std net real return: {emp_data[:, 0].std() * 100:.3f}%")
print(f"Mean net consumption growth: {(emp_data[:, 1].mean() - 1.0) * 100:.3f}%")
print(f"Std net consumption growth: {emp_data[:, 1].std() * 100:.3f}%")
print(f"Std log consumption growth: {np.log(emp_data[:, 1]).std() * 100:.3f}%")
```

```
Mean net real return: 0.308%
Std net real return: 4.335%
Mean net consumption growth: 0.093%
Std net consumption growth: 0.915%
Std log consumption growth: 0.915%
```

One feature of these data is the large gap between the volatility of returns and the volatility of consumption growth.

This is again an empirical fact underlying the equity premium puzzle of Mehra and Prescott [1985]: matching the observed equity premium with CRRA preferences requires implausibly high risk aversion.

We now estimate the Euler equation using the two-step generalized instrumental variables (GIV) / GMM procedure in Hansen and Singleton [1982].

For the one-period stock-return Euler equation ($n = 1$), the disturbance is a martingale difference sequence, so the optimal weighting matrix uses the contemporaneous covariance $S_0 = E[m_t m_t^\top]$.

To match Table I, we report the paper's exponent parameter α in $E_t[\beta(C_{t+1}/C_t)^\alpha R_{t+1} - 1] = 0$.

The two-step GMM estimates of $\hat{\alpha}$ and $\hat{\beta}$ by lag length are

```
gmm_raw = run_two_step_by_lag(emp_data, lags=LAGS, horizon=1)
gmm_raw.index.name = "NLAG"

table_i = pd.DataFrame(index=gmm_raw.index)
table_i.index.name = "NLAG"
table_i[r"\hat{\alpha}"] = -gmm_raw["γ_hat"]
table_i[r"SE(\hat{\alpha})"] = gmm_raw["se_γ"]
table_i[r"\beta"] = gmm_raw["β_hat"]
table_i[r"\mathrm{SE}(\beta)"] = gmm_raw["se_β"]
table_i[r"\chi^2"] = gmm_raw["j_stat"]
table_i["DF"] = gmm_raw["j_df"]
table_i["Prob"] = gmm_raw["j_prob"]

display_table(
    table_i,
    fmt={
        r"\hat{\alpha}": "{:.4f}",
        r"SE(\hat{\alpha})": "{:.4f}",
        r"\beta": "{:.4f}",
        r"\mathrm{SE}(\beta)": "{:.4f}",
        r"\chi^2": "{:.4f}",
        "DF": "{:.0f}",
        "Prob": "{:.4f}",
    },
)
```

NLAG	$\hat{\alpha}$	$SE(\hat{\alpha})$	β	SE(β)	χ^2	DF	Prob
1	−1.1974	0.8428	0.9966	0.0026	1.7644	1	0.8159
2	−0.5494	0.7844	0.9969	0.0026	6.6667	3	0.9167
4	−0.5441	0.7040	0.9968	0.0026	9.0237	7	0.7490
6	−0.8718	0.6457	0.9973	0.0026	11.0602	11	0.5618

For comparison, Table I of Hansen and Singleton [1982] (as corrected in the 1984 *Econometrica* errata) reports the following ND+VWR values for 1959:2–1978:12:

NLAG	α	$SE(\alpha)$	β	SE(β)	χ^2	DF	Prob
1	−1.2028	0.7789	0.9976	0.0027	1.4570	1	0.7726
2	−0.5761	0.7067	0.9975	0.0027	5.8190	3	0.8792
4	−0.6565	0.6896	0.9978	0.0027	7.9230	7	0.6606
6	−0.9638	0.6425	0.9985	0.0027	10.5220	11	0.5159

They are very close to our estimates.

134.7 Summary

The GMM estimator requires only the orthogonality conditions implied by the Euler equation and a set of conditioning variables.

It does not require assumptions about the joint distribution of consumption and returns, the production technology, or any other part of the economic environment beyond the representative agent's first-order conditions.

So GMM is provides a way to estimate some objects of interest while not estimating all of the parameters that Hansen and Singleton [1983] estimated in their loglinear model of consumption growth and returns.

- If the complete model of Hansen and Singleton [1983] is correctly specified, then their maximum likelihood estimators promise to be more efficient that are the GMM estimators described in this lecture.
- The theme of estimating *something* while not estimating *everything* runs through much of Lars Peter Hansen's work. See Hansen [2014]

135.1 Overview

This lecture presents Python code for experimenting with competitive equilibria of an infinite-horizon pure exchange economy with

- heterogeneous agents,
- endowments of a single consumption good that are person-specific functions of a common Markov state,
- complete markets in one-period Arrow state-contingent securities,
- discounted expected utility preferences of a kind often used in macroeconomics and finance,
- identical preferences across agents, with a common discount factor and a constant relative risk aversion (CRRA) one-period utility function, and

- common beliefs among agents.

Differences in their endowments make individuals want to reallocate consumption goods across time and Markov states.

Identical CRRA preferences imply that equilibrium consumption shares are constant, so we can compute equilibrium prices from the aggregate endowment *before* we compute the equilibrium distribution of wealth.

We impose restrictions that allow us to **Bellmanize** competitive equilibrium prices and quantities.

We use Bellman equations to describe

- asset prices,
- continuation wealth levels for each person, and
- state-by-state natural debt limits for each person.

In the course of presenting the model we shall encounter these important ideas:

- a **resolvent operator** widely used in this class of models,
- the absence of **borrowing limits** in finite-horizon economies,
- state-by-state **borrowing limits** required in infinite-horizon economies,
- a counterpart of the **law of iterated expectations** known as a **law of iterated values**, and
- a **state variable degeneracy** that prevails within a competitive equilibrium and that opens the way to various appearances of resolvent operators.

The lecture implements a Python version of the model presented in section 9.3.3 of [Ljungqvist and Sargent, 2018].

The material is older than it might appear.

Both the sequential trading arrangement studied here and the time 0 arrangement with a complete set of history-contingent claims, as well as the proof that the two support the same allocation, appear in a paper that Kenneth Arrow read in Paris in May 1952 and published in French in 1953 [Arrow, 1964].

Arrow's sequential arrangement deserves a second name as well.

Because a household that trades securities today must act on a forecast of the prices at which goods will trade tomorrow, and because the equivalence of the two arrangements holds only when markets confirm that forecast, Arrow's sequential equilibrium is a **rational expectations** equilibrium in the sense that Muth [1961] gave the term almost a decade later.

We develop this reading, which we learned from Kihlstrom [2019], in the section on *A rational expectations equilibrium* below.

Readers will find it helpful to know the finite-state Markov asset pricing formulas of *Asset Pricing: Finite State Models* and the Markov chain concepts of *Finite Markov Chains*.

Let's start with some imports.

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.optimize import root

np.set_printoptions(suppress=True)
```

135.2 The setting

135.2.1 Preferences and endowments

In each period $t \geq 0$, a stochastic event $s_t \in \mathbf{S}$ is realized.

Let the history of events up until time t be denoted $s^t = [s_0, s_1, \ldots, s_{t-1}, s_t]$.

The unconditional probability of observing a particular sequence of events s^t is given by a probability measure $\pi_t(s^t)$.

For $t > \tau$, we write the probability of observing s^t conditional on the realization of s^τ as $\pi_t(s^t \mid s^\tau)$.

We assume that trading occurs after observing s_0, which we capture by setting $\pi_0(s_0) = 1$ for the initially given value of s_0.

In this lecture we follow much of macroeconomics and econometrics and assume that $\pi_t(s^t)$ is induced by a Markov process.

There are K consumers named $k = 1, \ldots, K$.

Consumer k owns a stochastic endowment of one good $y_t^k(s^t)$ that depends on the history s^t.

The history s^t is publicly observable.

Consumer k purchases a history-dependent consumption plan $c^k = \{c_t^k(s^t)\}_{t=0}^\infty$.

All consumers order consumption plans by

$$U(c^k) = \sum_{t=0}^{\infty} \sum_{s^t} \beta^t u[c_t^k(s^t)] \pi_t(s^t),$$

where $0 < \beta < 1$.

The right side equals $E_0 \sum_{t=0}^\infty \beta^t u(c_t^k)$, where E_0 is the mathematical expectation operator conditioned on s_0.

Here $u(c)$ is an increasing, twice continuously differentiable, strictly concave function of consumption $c \geq 0$ of one good.

The utility function satisfies the Inada condition

$$\lim_{c \downarrow 0} u'(c) = +\infty.$$

This condition implies that each agent chooses strictly positive consumption for every date-history pair (t, s^t) whenever the present value of its endowment is positive.

Those interior solutions allow us to confine our analysis to Euler equations that hold with equality, and they guarantee that **natural debt limits** don't bind in economies like ours with sequential trading of Arrow securities.

We adopt the assumption, routinely employed in much of macroeconomics, that consumers share probabilities $\pi_t(s^t)$ for all t and s^t.

A **feasible allocation** satisfies

$$\sum_{k=1}^{K} c_t^k(s^t) \leq \sum_{k=1}^{K} y_t^k(s^t)$$

for all t and for all s^t.

Until we reach the section on computing an equilibrium, u need only satisfy the properties listed above.

From then on we specialize to CRRA utility.

135.3 Markov asset prices

Before setting up the equilibrium, we summarize formulas for computing asset prices in a Markov setting.

These formulas are developed at greater length in *Asset Pricing: Finite State Models*.

The setup assumes the following infrastructure:

- Markov states $s \in \mathbf{S} = \{\bar{s}_1, \ldots, \bar{s}_n\}$ governed by an n-state Markov chain with transition probability
$$P_{ij} = \Pr\left\{s_{t+1} = \bar{s}_j \mid s_t = \bar{s}_i\right\};$$
- a collection $h = 1, \ldots, H$ of assets, where asset h pays $d^h(s)$ in state s, so that d^h is an $n \times 1$ vector; and
- an $n \times n$ pricing kernel Q for one-period Arrow securities, where Q_{ij} is the price at time t in state $s_t = \bar{s}_i$ of one unit of consumption delivered at time $t+1$ if $s_{t+1} = \bar{s}_j$.

The price in state $\bar{s}_i$ of a one-period risk-free bond that pays one unit of consumption in every state is $\sum_j Q_{ij}$.

The gross rate of return on that bond is therefore

$$R_i = \Big(\sum_j Q_{ij}\Big)^{-1}.$$

135.3.1 An exogenous pricing kernel

For now we take the pricing kernel Q as exogenous, that is, determined outside the model.

Two examples are

- $Q = \beta P$, where $\beta \in (0, 1)$, and
- $Q_{ij} = m_{ij} P_{ij}$, where $m_{ij} > 0$ is the value of a **stochastic discount factor** when the Markov state moves from $\bar{s}_i$ to $\bar{s}_j$.

The second example multiplies P element by element, not as a matrix product.

We now describe the prices of two types of assets.

The first is a **cum-dividend** stock that entitles its owner to the time t dividend and to the option to sell the asset at time $t+1$.

Its price satisfies $p^h(\bar{s}_i) = d^h(\bar{s}_i) + \sum_j Q_{ij} p^h(\bar{s}_j)$, so the vector p^h satisfies $p^h = d^h + Q p^h$.

Provided every eigenvalue of Q has modulus less than one, this implies

$$p^h = (I - Q)^{-1} d^h.$$

The second is an **ex-dividend** stock purchased at the end of time t, which entitles its owner to the time $t+1$ dividend and to the option to sell the stock at time $t+1$.

Its price is

$$p^h = (I - Q)^{-1} Q d^h.$$

> **Note**
>
> The matrix geometric sum $(I - Q)^{-1} = I + Q + Q^2 + \cdots$ is an example of a **resolvent operator**.
>
> It converges when the spectral radius of Q is less than one.

Below we describe an equilibrium model with trading of one-period Arrow securities in which the pricing kernel is endogenous.

In constructing that model, we'll repeatedly encounter formulas that remind us of these asset pricing formulas.

135.3.2 Multi-step transition probabilities and pricing kernels

The (i, j) component of the j-step-ahead transition matrix P^j is

$$\Pr(s_{t+j} = \bar{s}_{j'} \mid s_t = \bar{s}_i) = (P^j)_{ij'}.$$

To keep the notation light below, we write $P_j(s_{t+j} \mid s_t)$ for these j-step transition probabilities, so that P_j is represented by the matrix P^j.

In the same way, the price at time t in state s_t of one unit of consumption delivered at time $t + j$ in state s_{t+j} is $Q_j(s_{t+j} \mid s_t)$, represented by the matrix Q^j.

We'll use these objects to state a useful property of asset pricing theory.

135.3.3 Laws of iterated expectations and iterated values

A **law of iterated values** has a mathematical structure that parallels a **law of iterated expectations**.

We can describe its structure readily in the Markov setting of this lecture.

Recall the following recursion satisfied by j-step-ahead transition probabilities for our finite-state Markov chain:

$$P_j(s_{t+j} \mid s_t) = \sum_{s_{t+1}} P_{j-1}(s_{t+j} \mid s_{t+1}) P(s_{t+1} \mid s_t).$$

We can use this recursion to verify the law of iterated expectations applied to the conditional expectation of a random variable $d(s_{t+j})$ conditioned on s_t:

$$\begin{aligned}
E[E[d(s_{t+j}) \mid s_{t+1}] \mid s_t] &= \sum_{s_{t+1}} \left[\sum_{s_{t+j}} d(s_{t+j}) P_{j-1}(s_{t+j} \mid s_{t+1}) \right] P(s_{t+1} \mid s_t) \\
&= \sum_{s_{t+j}} d(s_{t+j}) \left[\sum_{s_{t+1}} P_{j-1}(s_{t+j} \mid s_{t+1}) P(s_{t+1} \mid s_t) \right] \\
&= \sum_{s_{t+j}} d(s_{t+j}) P_j(s_{t+j} \mid s_t) \\
&= E[d(s_{t+j}) \mid s_t].
\end{aligned}$$

The pricing kernel for j-step-ahead Arrow securities satisfies the recursion

$$Q_j(s_{t+j} \mid s_t) = \sum_{s_{t+1}} Q_{j-1}(s_{t+j} \mid s_{t+1}) Q(s_{t+1} \mid s_t).$$

The time t **value** in Markov state s_t of a time $t + j$ payout $d(s_{t+j})$ is

$$W[d(s_{t+j}) \mid s_t] = \sum_{s_{t+j}} d(s_{t+j}) Q_j(s_{t+j} \mid s_t).$$

The **law of iterated values** states that

$$W[W[d(s_{t+j}) \mid s_{t+1}] \mid s_t] = W[d(s_{t+j}) \mid s_t].$$

We verify it with a string of equalities that are counterparts to those we used to verify the law of iterated expectations:

$$\begin{aligned} W[W[d(s_{t+j}) \mid s_{t+1}] \mid s_t] &= \sum_{s_{t+1}} \left[\sum_{s_{t+j}} d(s_{t+j}) Q_{j-1}(s_{t+j} \mid s_{t+1}) \right] Q(s_{t+1} \mid s_t) \\ &= \sum_{s_{t+j}} d(s_{t+j}) \left[\sum_{s_{t+1}} Q_{j-1}(s_{t+j} \mid s_{t+1}) Q(s_{t+1} \mid s_t) \right] \\ &= \sum_{s_{t+j}} d(s_{t+j}) Q_j(s_{t+j} \mid s_t) \\ &= W[d(s_{t+j}) \mid s_t]. \end{aligned}$$

135.4 Recursive formulation

Following section 9.3.3 of [Ljungqvist and Sargent, 2018], we now set up a competitive equilibrium of a pure exchange economy with complete markets in one-period Arrow securities.

When endowments $y^k(s)$ are all functions of a common Markov state s, the pricing kernel takes the form $Q(s' \mid s)$, the price of one unit of consumption in state s' at date $t+1$ when the Markov state at date t is s.

This lets us formulate a consumer's optimization problem recursively.

Consumer k's state at time t is its financial wealth a_t^k and the Markov state s_t.

Let $v^k(a, s)$ be the optimal value of consumer k's problem starting from state (a, s).

Thus $v^k(a, s)$ is the maximum expected discounted utility that consumer k with current financial wealth a can attain in Markov state s.

The optimal value function satisfies the Bellman equation

$$v^k(a, s) = \max_{c, \hat{a}(s')} \left\{ u(c) + \beta \sum_{s'} v^k[\hat{a}(s'), s'] \pi(s' \mid s) \right\},$$

where the maximization is subject to the budget constraint

$$c + \sum_{s'} \hat{a}(s') Q(s' \mid s) \leq y^k(s) + a$$

and the constraints

$$\begin{aligned} c &\geq 0, \\ -\hat{a}(s') &\leq \bar{A}^k(s'), \quad \forall s' \in \mathbf{S}. \end{aligned}$$

The second set of constraints is a collection of state-by-state debt limits.

The value function and decision rule that solve the Bellman equation depend on the pricing kernel $Q(\cdot \mid \cdot)$ because it appears in the budget constraint.

The first-order conditions for the problem on the right of the Bellman equation, together with a Benveniste–Scheinkman formula, imply

$$Q(s_{t+1} \mid s_t) = \frac{\beta u'(c_{t+1}^k) \pi(s_{t+1} \mid s_t)}{u'(c_t^k)},$$

where it is understood that $c_t^k = c^k(s_t)$ and $c_{t+1}^k = c^k(s_{t+1})$.

135.4.1 Recursive competitive equilibrium

A **recursive competitive equilibrium** is an initial distribution of wealth $\vec{a}_0$, a set of borrowing limits $\{\bar{A}^k(s)\}_{k=1}^K$, a pricing kernel $Q(s' \mid s)$, sets of value functions $\{v^k(a,s)\}_{k=1}^K$, and decision rules $\{c^k(s), \hat{a}^k(s)\}_{k=1}^K$ such that

1. the state-by-state borrowing limits satisfy the recursion
$$\bar{A}^k(s) = y^k(s) + \sum_{s'} Q(s' \mid s)\bar{A}^k(s');$$
2. for all k, given a_0^k, $\bar{A}^k(s)$, and the pricing kernel, the value functions and decision rules solve the consumers' problems;
3. for all realizations of $\{s_t\}_{t=0}^\infty$, the consumption and asset portfolios $\{\{c_t^k, \{\hat{a}_{t+1}^k(s')\}_{s'}\}_k\}_t$ satisfy $\sum_k c_t^k = \sum_k y^k(s_t)$ and $\sum_k \hat{a}_{t+1}^k(s') = 0$ for all t and s'; and
4. the initial financial wealth vector $\vec{a}_0$ satisfies $\sum_{k=1}^K a_0^k = 0$.

The third condition asserts that goods markets clear and that there are zero net aggregate claims in all Markov states.

The fourth condition asserts that the economy is closed and starts from a situation in which there are zero net aggregate claims.

135.5 A rational expectations equilibrium

The equilibrium that we have just defined asks each consumer to choose a portfolio $\hat{a}(s')$ of claims today while knowing the pricing kernel $Q(s' \mid s)$ at which those claims trade.

But the value of a portfolio to a consumer depends on what goods will cost tomorrow.

So an equilibrium of this kind embeds a forecast, and it is an equilibrium only when markets confirm that forecast.

That is what Radner [1972] later formalized as an equilibrium of plans, prices, and price expectations.

135.5.1 What a single good conceals

In our economy the only price that a sequential trader must forecast is the one-period pricing kernel $Q(s' \mid s)$.

Within a date and Markov state there are no relative prices left to forecast, because one good is the numeraire by default.

In Arrow's economy with $C > 1$ goods, a household choosing a portfolio must forecast the entire vector of spot prices $\bar{p}_s = (\bar{p}_{s1}, \ldots, \bar{p}_{sC})$ that will prevail in each state s, because only those prices tell it what a dollar delivered in state s will be worth.

The equivalence of the two trading arrangements then holds *if and only if those forecasts are correct*, state by state.

That is the precise sense in which Arrow's sequential equilibrium is a rational expectations equilibrium, and it is a requirement that our one-good formulation satisfies vacuously.

Exercise 135.13.4 asks you to verify the equivalence in a two-period economy with several goods, where the requirement has content.

135.5.2 Securities denominated in a unit of account

That Arrow's equivalence turns *only* on the correctness of those forecasts is itself a consequence of his having denominated securities in a unit of account.

Because a unit of security s pays one dollar if state s occurs, the set of state-contingent wealth distributions that a portfolio can deliver is settled before any forecast is made.

Hart [1975] asked what happens when securities instead pay *goods*.

If security f delivers the bundle $a_f(s)$ in state s, its payoff in dollars is $\bar{p}_s \cdot a_f(s)$, so the forecast $\bar{p}$ determines the span of the asset market, the span determines consumers' budget sets, and those budget sets determine the prices being forecast.

Completeness becomes an equilibrium object rather than an assumption.

Two things can then go wrong that cannot go wrong in our one-good economy.

There can be several equilibria, all of them with correct forecasts, that differ in which markets are *effectively* open and that are strictly Pareto ranked.

And there can be no equilibrium at all, even with strictly concave utility functions, strictly positive endowments, and no transaction costs.

Exercise 135.13.5 works through Hart's examples of both.

Note

Hart [1975] also delimits when things go right.

An equilibrium of the kind defined by Radner [1972] is Pareto optimal when the market structure is complete, and it is Pareto optimal relative to the set of such equilibria when there is one good and the market structure is complete up to the next-to-last date, which generalizes a result of Diamond [1967].

Outside those two cases, utility functions and endowments can generally be chosen so that an equilibrium fails even that weaker test.

Both of Hart's examples are knife edge, so small perturbations of preferences, endowments, or dividends destroy them.

135.5.3 Beliefs about nature versus expectations of prices

Arrow drew a distinction here that is worth preserving.

His consumers act on *subjective* probabilities that are allowed to differ across people, and nothing in his theorems requires agreement about how likely the states are.

What his sequential arrangement does require is that consumers agree, and be right, about something else: the prices that will rule in each state.

Beliefs about exogenous nature may be heterogeneous; expectations about endogenous prices may not.

This lecture imposes the stronger assumption of common beliefs, which lets us write a single probability $\pi(s' \mid s)$ in each consumer's Euler equation.

Heterogeneous Beliefs and Bubbles and *Heterogeneous Beliefs and Financial Markets* relax that assumption while keeping the expectations of prices correct.

135.5.4 Economizing on markets

Arrow observed that the sequential arrangement *permits economizing on markets*.

In our infinite-horizon economy, time 0 trading requires a market in a claim for every date and every history, while sequential trading requires only n one-period markets at each date.

In the two-period, S-state, C-good economy of Exercise 135.13.4, time 0 trading requires SC contingent claims markets, while the sequential arrangement requires S security markets followed by C spot markets in whichever state occurs.

No counting of markets, however, would reveal the extra assumption that the sequential arrangement needs, which is that the forecasts of spot prices are correct.

Note

Kihlstrom [2019] remarks that when Arrow presented this material in 1952, the dynamic programming machinery that makes the equivalence transparent did not yet exist, because Bellman was in the midst of creating it.

The step that decomposes a household's once-and-for-all problem into a portfolio choice followed by a sequence of within-period problems is exactly the argument that we used to Bellmanize the equilibrium above.

135.6 State variable degeneracy

[Ljungqvist and Sargent, 2018] and *Cass-Koopmans Competitive Equilibrium* describe a different timing protocol, in which there is a complete menu of history-contingent claims on consumption at all dates and all trades occur once and for all at time 0.

For the allocation and pricing kernel of a recursive competitive equilibrium to coincide with those of that time 0 arrangement, we must impose $a_0^k = 0$ for $k = 1, \ldots, K$.

That initial condition ensures that at time 0 the present value of each consumer's consumption equals the present value of its endowment stream, which is the single budget constraint of the time 0 arrangement.

Starting the system with $a_0^k = 0$ for all k has a striking implication that we call **state variable degeneracy**.

Although two state variables a and s appear in the value function $v^k(a, s)$, within a recursive competitive equilibrium that starts from $a_0^k = 0$ for all k at initial Markov state s_0, two outcomes prevail:

- financial wealth a_t^k is an exact function of the Markov state s_t, which we compute below, and
- $a_t^k = 0$ for all k whenever the Markov state s_t returns to s_0.

The first finding asserts that within a competitive equilibrium the exogenous Markov state is all we require to track an individual, because financial wealth is redundant.

The second finding asserts that each household returns to the zero financial wealth with which it began life whenever the Markov state returns to its initial value.

That happens infinitely often if s_0 is a recurrent state of the Markov chain, but it need not happen at all if s_0 is transient; see *Finite Markov Chains*.

This outcome depends critically on there being complete markets in Arrow securities.

For example, it does not prevail in the incomplete markets setting of *The Aiyagari Model*, where a household's wealth depends on its whole history of shocks.

135.7 Computing a competitive equilibrium

Now we are ready to do some fun calculations.

We find it useful to think in terms of analytical **inputs** into and **outputs** from our general equilibrium theorizing.

135.7.1 Inputs and outputs

The inputs are

- Markov states $s \in \mathbf{S} = \{\bar{s}_1, \ldots, \bar{s}_n\}$ governed by an n-state Markov chain with transition matrix P;
- K vectors of individual endowments y^k, each of dimension $n \times 1$ with components $y^k(\bar{s}_i)$;
- the $n \times 1$ vector of aggregate endowments $y(s) \equiv \sum_{k=1}^K y^k(s)$; and
- preferences given by the common utility functional $E_0 \sum_{t=0}^\infty \beta^t u(c_t^k)$ with discount factor $\beta \in (0,1)$ and CRRA one-period utility function

$$u(c) = \frac{c^{1-\gamma}}{1-\gamma}, \qquad u'(c) = c^{-\gamma}.$$

Feasibility requires

$$c(s) = \sum_{k=1}^K c^k(s) \leq y(s).$$

The outputs are

- an $n \times n$ pricing kernel Q for one-period Arrow securities;
- the aggregate allocation, which in a pure exchange economy is $c(s) = y(s)$;
- a $K \times 1$ distribution of wealth α with $\alpha_k \geq 0$ and $\sum_{k=1}^K \alpha_k = 1$; and
- K vectors of individual consumptions c^k, each of dimension $n \times 1$.

135.7.2 The pricing kernel

For any agent $k \in \{1, \ldots, K\}$, at the equilibrium allocation, the one-period Arrow securities pricing kernel satisfies

$$Q_{ij} = \beta \left(\frac{c^k(\bar{s}_j)}{c^k(\bar{s}_i)} \right)^{-\gamma} P_{ij}.$$

This follows from agent k's first-order necessary conditions.

Because all agents face the same pricing kernel, the Euler equations of any two agents k and m imply

$$\left(\frac{c^k(\bar{s}_j)}{c^k(\bar{s}_i)} \right)^{-\gamma} = \left(\frac{c^m(\bar{s}_j)}{c^m(\bar{s}_i)} \right)^{-\gamma} \quad \text{whenever } P_{ij} > 0.$$

So the ratio $c^k(s)/c^m(s)$ is the same in any two states connected by a positive transition probability, and hence in every state reachable from s_0.

Consumption shares are therefore constant, and feasibility gives

$$c^k(s) = \alpha_k c(s) = \alpha_k y(s)$$

for a **distribution of wealth** α that satisfies $\alpha_k \geq 0$ and $\sum_{k=1}^{K} \alpha_k = 1$.

> **Note**
>
> Identical CRRA preferences also satisfy the conditions for **Gorman aggregation**, since Engel curves are linear with a common slope, so a representative consumer exists.
>
> The constancy of consumption shares, however, follows directly from the Euler equations above.

This means that we can compute the pricing kernel from

$$Q_{ij} = \beta \left(\frac{y_j}{y_i} \right)^{-\gamma} P_{ij}. \tag{135.1}$$

This is the pricing kernel of the Lucas tree economy studied in *Asset Pricing: Finite State Models*, in which a representative consumer eats the aggregate endowment.

The pricing kernel Q does not depend on the vector α.

Key finding: We can compute competitive equilibrium **prices** prior to computing a **distribution of wealth**.

The wealth distribution α is not arbitrary.

It is pinned down by the initial condition $a_0^k = 0$, as we show below.

Formula (135.1) has a useful matrix form.

Let $D = \text{diag}(u'(y_1), \ldots, u'(y_n))$.

Then $Q = \beta D^{-1} P D$, so Q is similar to βP.

Its eigenvalues are β times those of P, and because P is a stochastic matrix, the spectral radius of Q equals $\beta < 1$.

This guarantees that the resolvent $(I - Q)^{-1}$ used below exists.

The factorization is an instance of the **transition independence** structure exploited in *The Recovery Theorem*, a connection we pursue in Exercise 135.13.2.

135.7.3 Natural debt limits

Having computed an equilibrium pricing kernel Q, we can compute several **values** that are required to pose or represent the solution of an individual household's optimization problem.

For each individual k, let $\bar{A}^k$ be the $n \times 1$ vector with components $\bar{A}^k(\bar{s}_i)$.

The recursion in the definition of equilibrium implies

$$\bar{A}^k = [I - Q]^{-1} y^k. \tag{135.2}$$

In a competitive equilibrium of an **infinite-horizon** economy with sequential trading of one-period Arrow securities, $\bar{A}^k(s)$ is a state-by-state limit on the quantity of one-period Arrow securities paying off in state s at time $t+1$ that individual k can issue at time t.

These are often called **natural debt limits**.

They equal the maximum amount that individual k can repay in state s even if it consumes nothing forevermore.

Note

If utility satisfies an Inada condition at zero consumption, or if consumption is simply required to be nonnegative, then a **finite-horizon** economy with sequential trading of one-period Arrow securities needs no natural debt limits.

See the section on a finite-horizon economy below.

135.7.4 Continuation wealth and optimal portfolios

Continuation wealth plays an important role in Bellmanizing a competitive equilibrium with sequential trading of a complete set of one-period Arrow securities.

For each individual k, let ψ^k be the $n \times 1$ vector with components $\psi^k(\bar{s}_i)$, the financial wealth that consumer k holds when the Markov state is $\bar{s}_i$.

Continuation wealth satisfies

$$\psi^k = [I - Q]^{-1} [\alpha_k y - y^k] . \tag{135.3}$$

To see why, note that with consumption $c^k = \alpha_k y$ and a portfolio $\hat{a}^k(s') = \psi^k(s')$, the budget constraint holds with equality in every state exactly when $\psi^k = \alpha_k y - y^k + Q\psi^k$.

Summing over k shows that $\sum_{k=1}^K \psi^k = 0_{n\times 1}$, so Arrow security markets clear.

A nifty feature of the model is that an optimal portfolio of a type k agent equals the continuation wealth that we just computed.

Thus, agent k's purchases of Arrow securities that pay off next period depend only on next period's Markov state and equal

$$\hat{a}^k(s) = \psi^k(s), \quad s \in \{\bar{s}_1, \ldots, \bar{s}_n\}. \tag{135.4}$$

135.7.5 The equilibrium wealth distribution

With the initial state being a particular state $s_0 \in \{\bar{s}_1, \ldots, \bar{s}_n\}$, we must have

$$\psi^k(s_0) = 0, \quad k = 1, \ldots, K,$$

so that every agent starts debt-free and holding no financial assets.

This means that the equilibrium distribution of wealth satisfies

$$\alpha_k = \frac{V_z y^k}{V_z y}, \tag{135.5}$$

where $V \equiv [I - Q]^{-1}$ and V_z is the row of V corresponding to the initial state s_0.

Since $\sum_{k=1}^K V_z y^k = V_z y$, we have $\sum_{k=1}^K \alpha_k = 1$.

Comparing (135.5) with (135.2) gives a revealing interpretation,

$$\alpha_k = \frac{\bar{A}^k(s_0)}{\sum_{m=1}^K \bar{A}^m(s_0)}.$$

Each consumer's share of aggregate consumption equals its share of the value, in the initial state, of the aggregate endowment.

Because α depends on s_0 through V_z, the same economy started in different Markov states delivers different wealth distributions.

135.7.6 Value functions

We can also compute optimal value functions in a competitive equilibrium with trades in a complete set of one-period state-contingent Arrow securities.

Call the optimal value function of consumer k the $n \times 1$ vector J^k.

For the infinite-horizon economy now under study,

$$J^k = (I - \beta P)^{-1} u(\alpha_k y),$$

where $u(\alpha_k y)$ is the $n \times 1$ vector with components $u(\alpha_k y_i)$.

135.7.7 Summary of the algorithm

Here is the logical flow of an algorithm to compute a competitive equilibrium:

1. compute Q from the aggregate endowment using formula (135.1);
2. compute the distribution of wealth α from formula (135.5);
3. using α, assign each consumer k the share α_k of the aggregate endowment in each state;
4. compute continuation wealths from the α-dependent formula (135.3);
5. set agent k's portfolio equal to its continuation wealth state by state, as in (135.4); and
6. compute value functions J^k.

135.8 Finite horizon

We now describe a finite-horizon version of the economy that operates for $T+1$ periods $t \in \mathbf{T} = \{0, 1, \ldots, T\}$.

We'll want time-dependent counterparts of the objects described above, with one important exception: we won't need **borrowing limits**.

- Borrowing limits aren't required in a finite-horizon economy in which the one-period utility function $u(c)$ satisfies an Inada condition that sends the marginal utility of consumption to infinity as consumption approaches zero.
- Nonnegativity of consumption at all $t \in \mathbf{T}$ automatically limits borrowing, because no one can end period T in debt.

For each individual k and date t, let ψ_t^k be the $n \times 1$ vector of continuation wealths.

At the terminal date there is no future to finance, so $\psi_T^k = \alpha_k y - y^k$.

Working backward with the budget constraint $\psi_t^k = \alpha_k y - y^k + Q\psi_{t+1}^k$ gives

$$\psi_t^k = \left[I + Q + Q^2 + \cdots + Q^{T-t}\right]\left[\alpha_k y - y^k\right], \quad t = 0, 1, \ldots, T. \tag{135.6}$$

As before, $\sum_{k=1}^K \psi_t^k = 0_{n\times 1}$ for all $t \in \mathbf{T}$.

With the initial state being a particular state s_0, we must have

$$\psi_0^k(s_0) = 0, \quad k = 1, \ldots, K,$$

which means the equilibrium distribution of wealth satisfies

$$\alpha_k = \frac{V_z y^k}{V_z y}, \tag{135.7}$$

where now

$$V = [I + Q + Q^2 + \cdots + Q^T] \tag{135.8}$$

and V_z is the row of V corresponding to the initial state s_0.

Note

In the finite-horizon economy, continuation wealth depends on calendar time as well as on the Markov state.

The initial condition sets $\psi_0^k(s_0) = 0$, but when the Markov state returns to s_0 at a later date t, fewer periods remain, the geometric sum in (135.6) is truncated sooner, and in general $\psi_t^k(s_0) \neq 0$.

The strong form of state variable degeneracy, in which wealth is a function of the Markov state alone, is special to the infinite horizon.

Exercise 135.13.3 explores this.

To compute a competitive equilibrium with Arrow securities in the finite-horizon Markov economy,

1. compute Q from the aggregate endowment using formula (135.1);
2. compute the distribution of wealth α from formulas (135.7) and (135.8);
3. using α, assign each consumer k the share α_k of the aggregate endowment in each state;
4. compute continuation wealths from formula (135.6); and
5. set agent k's portfolio equal to its continuation wealth state by state.

The value function of consumer k at time t is

$$J_t^k = [I + \beta P + \cdots + (\beta P)^{T-t}]\, u(\alpha_k y).$$

135.9 Python code

We now create a Python class to compute the objects that comprise a competitive equilibrium with sequential trading of one-period Arrow securities.

The class handles both infinite-horizon economies and finite-horizon economies indexed by horizon T.

Every geometric sum in the lecture has the form $I + M + \cdots$, with $M = Q$ for prices and wealth and $M = \beta P$ for values, so a single helper method computes them all.

In the finite-horizon case the helper works backward with the recursion $S_t = I + MS_{t+1}$, starting from $S_T = I$.

With $M = Q$, this recursion is the law of iterated values at work: the time t value of payouts from t through T is the payout at t plus the time t value of the time $t + 1$ value of the remaining payouts.

With $M = \beta P$, it is the law of iterated expectations applied to discounted utility.

The class also has a method that prices an asset with dividend vector d by applying these sums, which delivers the cum-dividend price $p = d + Qd + Q^2 d + \cdots$ and the ex-dividend price $p - d$.

In the finite-horizon case, arrays that depend on time are ordered from $t = 0$ to $t = T$, so that `ψ[t]` is ψ_t and `J[t]` is J_t.

In the infinite-horizon case they have a single leading element.

```
class RecurCompetitive:

```

135.10 Examples

We'll use our code to construct equilibrium objects in several example economies.

Our first several examples are infinite-horizon economies.

Our final example is a finite-horizon economy.

Unless we say otherwise, examples use the default parameter values $\gamma = 0.5$ and $\beta = 0.98$.

135.10.1 Example 1: a constant aggregate endowment

Two agents have perfectly negatively correlated endowments, so the aggregate endowment is constant.

```
s = np.array([0, 1])
P = np.array([[.5, .5],
              [.5, .5]])

ys = np.empty((2, 2))
ys[:, 0] = 1 - s        # agent 1
ys[:, 1] = s            # agent 2

ex1 = RecurCompetitive(s, P, ys)
```

```
print("aggregate endowment y =", ex1.y)
print("pricing kernel Q = \n", ex1.Q)
print("risk-free rate R =", ex1.R)
print("natural debt limits A = \n", ex1.A)
```

```
aggregate endowment y = [1. 1.]
pricing kernel Q =
 [[0.49 0.49]
 [0.49 0.49]]
risk-free rate R = [1.02040816 1.02040816]
natural debt limits A =
 [[25.5 24.5]
 [24.5 25.5]]
```

Because the aggregate endowment is constant, marginal utility is constant, so $Q = \beta P$ and the risk-free rate is β^{-1} in both states.

```
# initial state is state 1
print(f'α = {ex1.wealth_distribution(s0_idx=0)}')
print(f'ψ = \n{ex1.continuation_wealths()}')
print(f'J = \n{ex1.value_functions()}')
print(f'share of natural debt limits in s0: {ex1.A[0] / ex1.A[0].sum()}')
```

```
α = [0.51 0.49]
ψ =
[[-0.  0.]
  [ 1. -1.]]]
J =
[[[71.41428429 70.        ]
  [71.41428429 70.        ]]]
share of natural debt limits in s0: [0.51 0.49]
```

When the economy starts in state 1, agent 1 receives slightly more than half of aggregate consumption.

Its endowment arrives in the initial period, and consumption received sooner is discounted less.

As the last line confirms, each agent's consumption share equals its share of the natural debt limits in the initial state.

In state 2, where agent 1 has no endowment, agent 1 holds financial wealth of one unit, which finances its consumption, and agent 2 owes exactly that amount.

```
# initial state is state 2
print(f'α = {ex1.wealth_distribution(s0_idx=1)}')
```

(continues on next page)

(continued from previous page)

```
print(f'ψ = \n{ex1.continuation_wealths()}')
print(f'J = \n{ex1.value_functions()}')
```

```
α = [0.49 0.51]
ψ =
[[[-1.  1.]
  [ 0. -0.]]]
J =
[[[70.         71.41428429]
  [70.         71.41428429]]]
```

Starting in state 2 simply swaps the roles of the two agents.

135.10.2 Example 2: a fluctuating aggregate endowment

Now agent 1 has a constant endowment while agent 2's endowment fluctuates, so the aggregate endowment fluctuates.

```
s = np.array([1, 2])
P = np.array([[.5, .5],
              [.5, .5]])

ys = np.empty((2, 2))
ys[:, 0] = 1.5          # agent 1
ys[:, 1] = s            # agent 2

ex2 = RecurCompetitive(s, P, ys)

print("aggregate endowment y =", ex2.y)
print("pricing kernel Q = \n", ex2.Q)
print("risk-free rate R =", ex2.R)
print("natural debt limits A = \n", ex2.A)
```

```
aggregate endowment y = [2.5 3.5]
pricing kernel Q =
 [[0.49       0.41412558]
 [0.57977582 0.49      ]]
risk-free rate R = [1.10604104 0.93477529]
natural debt limits A =
 [[69.30941886 66.91255848]
 [81.73318641 79.98879094]]
```

The pricing kernels in examples 1 and 2 differ because the aggregate endowment is constant in example 1 but differs across states in example 2.

We can check two off-diagonal entries of Q directly against formula (135.1).

```
print(ex2.β * ex2.u_prime(3.5) / ex2.u_prime(2.5) * ex2.P[0, 1], ex2.Q[0, 1])
print(ex2.β * ex2.u_prime(2.5) / ex2.u_prime(3.5) * ex2.P[1, 0], ex2.Q[1, 0])
```

```
0.4141255848169731 0.4141255848169731
0.5797758187437624 0.5797758187437624
```

A claim to consumption in the high-endowment state is cheap, because marginal utility is low there.

The risk-free rate is high in the low-endowment state, where consumption is expected to rise, and low in the high-endowment state, where consumption is expected to fall.

Now let's price some risky assets with the formulas $p^h = (I - Q)^{-1} d^h$ and $p^h = (I - Q)^{-1} Q d^h$ from the section on Markov asset prices.

We price a Lucas tree, which pays the aggregate endowment as its dividend, and claims to each agent's endowment stream.

```
p_tree = ex2.asset_price(ex2.y)
p_tree_ex = ex2.asset_price(ex2.y, ex_dividend=True)

print("cum-dividend tree price     p =", p_tree)
print("ex-dividend tree price      p =", p_tree_ex)
print("price-dividend ratio (ex)     =", p_tree_ex / ex2.y)
print("Bellman residual |p - d - Qp| =",
      np.abs(p_tree - ex2.y - ex2.Q @ p_tree).max())
print("claims to endowments = \n", ex2.asset_price(ex2.ys))
```

```
cum-dividend tree price     p = [136.22197734 161.72197734]
ex-dividend tree price      p = [133.72197734 158.22197734]
price-dividend ratio (ex)     = [53.48879094 45.20627924]
Bellman residual |p - d - Qp| = 0.0
claims to endowments =
 [[69.30941886 66.91255848]
 [81.73318641 79.98879094]]
```

The cum-dividend price satisfies the one-step Bellman equation $p = d + Qp$ to machine precision.

The ex-dividend price-dividend ratio is higher in the low-endowment state, where the current dividend is low relative to expected future dividends.

The last array reproduces the natural debt limits computed above: agent k's natural debt limit in state s is the cum-dividend price of a claim to agent k's own endowment stream.

That is why an agent can always repay a debt no larger than $\bar{A}^k(s)$: it could sell the claim to its endowment and consume nothing forever.

```
# initial state is state 1
print(f'α = {ex2.wealth_distribution(s0_idx=0)}')
print(f'ψ = \n{ex2.continuation_wealths()}')
print(f'J = \n{ex2.value_functions()}')
```

```
α = [0.50879763 0.49120237]
ψ =
[[[ 0.          0.        ]
  [ 0.55057195 -0.55057195]]]
J =
[[[122.907875   120.76397493]
  [123.32114686 121.17003803]]]
```

```
# initial state is state 2
print(f'α = {ex2.wealth_distribution(s0_idx=1)}')
print(f'ψ = \n{ex2.continuation_wealths()}')
print(f'J = \n{ex2.value_functions()}')
```

```
α = [0.50539319 0.49460681]
ψ =
[[[-0.46375886  0.46375886]
  [-0.         -0.        ]]]
J =
```

(continues on next page)

(continued from previous page)

```
[[[122.49598809 121.18174895]
  [122.907875   121.58921679]]]
```

135.10.3 Example 3: an absorbing state

In this example state 2 is absorbing, so state 1 is transient.

```
s = np.array([1, 2])

λ = 0.9
P = np.array([[1-λ, λ],
              [0, 1]])

ys = np.empty((2, 2))
ys[:, 0] = [1, 0]      # agent 1
ys[:, 1] = [0, 1]      # agent 2

ex3 = RecurCompetitive(s, P, ys)

print("pricing kernel Q = \n", ex3.Q)
print("natural debt limits A = \n", ex3.A)
```

```
pricing kernel Q =
 [[0.098 0.882]
 [0.    0.98 ]]
natural debt limits A =
 [[ 1.10864745 48.89135255]
 [ 0.         50.        ]]
```

The natural debt limit for agent 1 in state 2 is 0.

Once the economy enters the absorbing state, agent 1 never receives another unit of endowment, so it cannot credibly promise to repay anything.

```
# initial state is state 1
print(f'α = {ex3.wealth_distribution(s0_idx=0)}')
print(f'ψ = \n{ex3.continuation_wealths()}')
print(f'J = \n{ex3.value_functions()}')
```

```
α = [0.02217295 0.97782705]
ψ =
[[[ 0.         -0.        ]
  [ 1.10864745 -1.10864745]]]
J =
[[[14.89058394 98.88513796]
  [14.89058394 98.88513796]]]
```

Starting in state 1, agent 1 receives only a small share of aggregate consumption, because its endowment arrives only while the economy remains in the transient state.

Because state 1 is transient, the economy eventually leaves it for good, and agents' wealths do not recurrently return to zero.

```
# initial state is state 2
print(f'α = {ex3.wealth_distribution(s0_idx=1)}')
print(f'ψ = \n{ex3.continuation_wealths()}')
print(f'J = \n{ex3.value_functions()}')
```

```
α = [0. 1.]
ψ =
[[-1.10864745  1.10864745]
  [ 0.          0.        ]]]
J =
[[[  0. 100.]
  [  0. 100.]]]
```

Starting in the absorbing state, agent 1 owns nothing of value, so $\alpha_1 = 0$ and agent 1 consumes nothing forever.

This corner is consistent with the discussion of the Inada condition above, which guarantees interior consumption only for agents whose endowments have positive value.

For the specification of the Markov chain in example 3, let's see how the equilibrium wealth distribution varies with the transition probability λ.

```
λ_seq = np.linspace(0, 0.99, 100)

# prepare containers
αs0_seq = np.empty((len(λ_seq), 2))
αs1_seq = np.empty((len(λ_seq), 2))

for i, λ in enumerate(λ_seq):
    P_λ = np.array([[1-λ, λ],
                    [0, 1]])
    ex3_λ = RecurCompetitive(s, P_λ, ys)

    # initial state s0 = 1
    αs0_seq[i, :] = ex3_λ.wealth_distribution(s0_idx=0)

    # initial state s0 = 2
    αs1_seq[i, :] = ex3_λ.wealth_distribution(s0_idx=1)
```

```
fig, axs = plt.subplots(1, 2, figsize=(12, 4))

for i, αs_seq in enumerate([αs0_seq, αs1_seq]):
    for j in range(2):
        axs[i].plot(λ_seq, αs_seq[:, j], label=f'$\\alpha_{j+1}$')
    axs[i].set_xlabel(r'$\lambda$')
    axs[i].set_title(f'initial state $s_0 = {s[i]}$')
    axs[i].legend()

plt.show()
```

When the economy starts in state 1, a higher probability λ of leaving that state for good shortens the expected duration of agent 1's endowment and lowers its wealth share.

When the economy starts in the absorbing state 2, λ is irrelevant and agent 2 owns everything.

135.10.4 Example 4: prosperity, a moderate state, and recession

Our last infinite-horizon example has three Markov states, which we interpret as prosperity, a moderate state, and recession.

```
s = np.array([1, 2, 3])

λ = .9
μ = .9
δ = .05

# prosperous, moderate, and recession states
P = np.array([[1-λ, λ, 0],
              [(1-μ)/2, μ, (1-μ)/2],
              [(1-δ)/2, (1-δ)/2, δ]])

ys = np.empty((3, 2))
ys[:, 0] = [.25, .75, .2]       # agent 1
ys[:, 1] = [1.25, .25, .2]      # agent 2

ex4 = RecurCompetitive(s, P, ys)

print("rows of P sum to", P.sum(axis=1))
print("aggregate endowment y =", ex4.y)
print("pricing kernel Q = \n", ex4.Q)
print("risk-free rate R =", ex4.R)
print("natural debt limits A = \n", ex4.A)
```

```
rows of P sum to [1. 1. 1.]
aggregate endowment y = [1.5 1.  0.4]
pricing kernel Q =
 [[0.098      1.08022498 0.        ]
 [0.04000833 0.882      0.0774758 ]
 [0.24038317 0.29440805 0.049     ]]
```

(continues on next page)

(continued from previous page)

```
risk-free rate R = [0.84873434 1.00051613 1.71294115]
natural debt limits A =
 [[41.66943407 19.83317897]
 [34.56301265 15.40376106]
 [21.44296495  9.99216994]]
```

The moderate state is highly persistent, and the economy moves out of recession quickly.

The gross risk-free rate is below one in prosperity, where aggregate consumption is expected to fall, and well above one in recession, where it is expected to recover.

```
for i in range(3):
    print(f"initial state is state {i+1}")
    print(f'α = {ex4.wealth_distribution(s0_idx=i)}')
    print(f'ψ = \n{ex4.continuation_wealths()}')
    print(f'J = \n{ex4.value_functions()}\n')
```

```

Agent 1, whose endowment is concentrated in the persistent moderate state, receives about two thirds of aggregate consumption whichever state the economy starts in.

135.10.5 A finite-horizon example

We now revisit the economy defined in example 1, but set the time horizon to $T = 10$.

```
s = np.array([0, 1])
P = np.array([[.5, .5],
              [.5, .5]])

ys = np.empty((2, 2))
ys[:, 0] = 1 - s        # agent 1
ys[:, 1] = s            # agent 2

ex1_finite = RecurCompetitive(s, P, ys, T=10)
```

```
# I + Q + Q^2 + ... + Q^T
ex1_finite.V[0]
```

```
array([[5.48171623, 4.48171623],
       [4.48171623, 5.48171623]])
```

In the finite-horizon case, ψ and $\mathcal{J}$ are returned as sequences ordered from $t = 0$ to $t = T$.

```
# initial state is state 1
print(f'α = {ex1_finite.wealth_distribution(s0_idx=0)}')
print(f'ψ = \n{ex1_finite.continuation_wealths()}\n')
print(f'J = \n{ex1_finite.value_functions()}')
```

```

The wealth distribution is further from equal than in example 1, because with a short horizon the endowment received in the initial period is a larger fraction of the total value of an agent's endowment.

Let's check why this economy needs no borrowing limits.

At date t, the most that agent k could ever repay from its own endowment is the value of its remaining endowment stream, $[I + Q + \cdots + Q^{T-t}]\, y^k$.

Unlike in the infinite-horizon economy, these bounds need not be imposed.

At date T no securities are traded, so an agent cannot roll debt over, and nonnegative consumption at T limits what it can owe to $y^k(s_T)$.

Working backward, nonnegative consumption at each earlier date implies the bound for that date.

The distance between an agent's bound and its debt, $\psi_t^k + [I + Q + \cdots + Q^{T-t}]\, y^k$, equals $[I + Q + \cdots + Q^{T-t}]\, \alpha_k y$, the value of the agent's remaining consumption.

That value is positive because consumption is positive, so the implied bounds never bind.

The following code computes the bounds for every date and state and confirms this.

```
ex1_finite.wealth_distribution(s0_idx=0)
ψ_finite = ex1_finite.continuation_wealths()
bounds = ex1_finite.V @ ex1_finite.ys      # bounds[t] = (I + ... + Q^(T-t)) y^k

print("implied bounds at t = T (rows: states, columns: agents):\n", bounds[-1])
print("smallest slack ψ_t + bound over all t, states, agents:",
      (ψ_finite + bounds).min().round(4))
```

```
implied bounds at t = T (rows: states, columns: agents):
 [[1. 0.]
 [0. 1.]]
smallest slack ψ_t + bound over all t, states, agents: 0.4498
```

At $t = T$, the bounds are just current endowments, and the slack is smallest there because only one period of consumption remains to be valued.

In the infinite-horizon economy there is no last date at which debts must be settled, so without explicit limits an agent could roll over ever larger debts forever, and the natural debt limits (135.2) must be imposed.

We can check that as $T \to \infty$ the finite-horizon results converge to those of the infinite-horizon economy.

Both economies below start in state 2, and we compare time-0 objects.

```
ex1_large = RecurCompetitive(s, P, ys, T=10000)
ex1.wealth_distribution(s0_idx=1)
ex1_large.wealth_distribution(s0_idx=1)

print("V:", np.abs(ex1.V[0] - ex1_large.V[0]).max())
print("ψ:", np.abs(ex1.continuation_wealths()[0]
                   - ex1_large.continuation_wealths()[0]).max())
print("J:", np.abs(ex1.value_functions()[0]
                   - ex1_large.value_functions()[0]).max())
```

```
V: 8.526512829121202e-14
ψ: 1.1857181902996411e-15
J: 2.2737367544323206e-13
```

The maximum absolute differences are negligible.

135.11 Concluding remarks

We began by promising a computable account of competitive equilibrium in an infinite-horizon exchange economy with heterogeneous endowments, complete markets in one-period Arrow securities, identical CRRA preferences, and common beliefs.

Here is how the lecture delivered on that promise.

135.11.1 Prices before the wealth distribution

Because all agents face the same pricing kernel, their Euler equations force consumption shares to be constant, so that $c^k(s) = \alpha_k y(s)$.

The pricing kernel (135.1) therefore depends only on the aggregate endowment, and it coincides with the kernel of a representative-agent Lucas tree economy.

The wealth distribution α comes second, pinned down by the requirement that every agent start with zero financial wealth, which makes α_k equal to agent k's share of the value of aggregate endowments in the initial state.

135.11.2 Bellmanizing the equilibrium

Each object that the overview promised to describe with a Bellman equation satisfies a one-step recursion of the form $x = b + Qx$:

- asset prices satisfy $p^h = d^h + Qp^h$, as we verified for a Lucas tree in example 2;
- natural debt limits satisfy $\bar{A}^k = y^k + Q\bar{A}^k$, which makes them the prices of claims to agents' endowment streams; and
- continuation wealth satisfies $\psi^k = (\alpha_k y - y^k) + Q\psi^k$.

Value functions satisfy the analogous recursion $J^k = u(\alpha_k y) + \beta P J^k$, with βP in place of Q.

These recursions are what let a single Python class, `RecurCompetitive`, compute an entire equilibrium from a few matrix operations.

135.11.3 The five ideas

- **Resolvent operators.** Solving each recursion gives $(I - Q)^{-1}$ or $(I - \beta P)^{-1}$, and the similarity $Q = \beta D^{-1} P D$ guarantees that the spectral radius of Q is $\beta < 1$, so these resolvents exist.
- **State-by-state borrowing limits in infinite horizons.** Natural debt limits $\bar{A}^k = (I - Q)^{-1} y^k$ are the largest debts that agent k could repay from its own endowment, and example 3 showed that they can be zero in states where an agent's future endowment is worthless.
- **No borrowing limits in finite horizons.** When the economy ends at T, no one can roll debt over past the last date, and nonnegative consumption implies bounds $[I + Q + \cdots + Q^{T-t}]\, y^k$ that we computed and showed never bind, so no separate debt limits need to be imposed.
- **The law of iterated values.** Multi-period Arrow prices compound as Q^j in the same way that multi-period transition probabilities compound as P^j, and the backward recursion $S_t = I + QS_{t+1}$ used in `RecurCompetitive` values payouts one period at a time.
- **State variable degeneracy.** Starting from zero financial wealth, each agent's wealth is a function of the Markov state alone and returns to zero whenever the state returns to s_0, as Exercise 135.13.1 verified along a simulated path;

Exercise 135.13.3 showed that this strong form of degeneracy fails in finite horizons, where wealth also depends on calendar time.

135.11.4 What the assumptions bought

Complete markets, identical CRRA preferences, and common beliefs together are what make prices independent of the wealth distribution and make wealth a function of the current state alone.

Relaxing any of them breaks at least one of these properties, which is the subject of several of the lectures listed below.

135.11.5 How old this is

Before leaving the model, it is worth recording how much of it was in place at the start.

Both trading arrangements, the proof that they support the same allocation, and the observation that the sequential one presumes correct forecasts of future spot prices all appear in the paper that Arrow read in 1952, nine years before Muth [1961] named the hypothesis that such forecasts embody.

Arrow did not use the term, and the dynamic programming arguments that make the equivalence transparent were not yet available to him.

His argument also has a knife edge that his unit of account conceals and that Hart [1975] exposed: when securities pay goods rather than dollars, consumers' forecasts determine which risks the asset market can carry, and correct forecasts no longer pin down a unique, or even an existing, equilibrium.

The single good per date and history that we assumed throughout is exactly the case in which the forecasting requirement has no bite.

135.12 Related lectures

This lecture assumes that all agents share beliefs about nature, and that their expectations of prices are correct.

Arrow's distinction between those two uses of probability organizes the first two entries below.

- *Heterogeneous Beliefs and Bubbles* studies an economy in which agents disagree about probabilities and short sales are constrained.
- *Heterogeneous Beliefs and Financial Markets* studies complete markets when agents hold different beliefs, in which case wealth shares drift with likelihood ratios instead of staying constant at α.
- *Consumption Smoothing with Incomplete and Complete Markets* shows, in a linear-quadratic setting, how complete markets in Arrow securities deliver a time-invariant cross-section distribution of consumption.
- *The Recovery Theorem* and *Long-term Risk: An Operator Approach* study what the Perron–Frobenius eigenvalue and eigenvector of a pricing kernel like Q reveal.
- *Stochastic Consumption, Risk Aversion, and the Temporal Behavior of Asset Returns* confronts Euler equations like those used here with data.

135.13 Exercises

Exercise 135.13.1

This exercise verifies that the objects computed by `RecurCompetitive` constitute a recursive competitive equilibrium.

Use example 4 and start the economy in state 1.

1. Check that every agent's Euler equation holds at the allocation $c^k(s) = \alpha_k y(s)$ and the pricing kernel Q.
2. Check that agent k's budget constraint $c^k(s) + \sum_{s'} Q(s' \mid s)\,\psi^k(s') = y^k(s) + \psi^k(s)$ holds in every state when the agent holds the portfolio $\hat{a}^k(s') = \psi^k(s')$.
3. Check that Arrow security markets clear, $\sum_k \psi^k(s) = 0$, and that no natural debt limit binds.
4. Simulate 200 periods of the Markov chain and confirm that each agent's financial wealth is exactly zero at every visit to the initial state.

Solution

Here is one solution.

```
ex = RecurCompetitive(ex4.s, ex4.P, ex4.ys)

α = ex.wealth_distribution(s0_idx=0)
ψ = ex.continuation_wealths()[0]
c = np.outer(ex.y, α)

euler = max(np.abs(ex.Q - ex.β * ex.P * ex.u_prime(c[:, k])[None, :]
                   / ex.u_prime(c[:, k])[:, None]).max()
            for k in range(ex.K))
budget = np.abs(c + ex.Q @ ψ - ex.ys - ψ).max()

print(f"largest Euler equation residual    {euler:.1e}")
print(f"largest budget constraint residual {budget:.1e}")
print(f"largest net supply of any security {np.abs(ψ.sum(axis=1)).max():.1e}")
print(f"all natural debt limits slack:     {np.all(ψ + ex.A > 0)}")
```

```
largest Euler equation residual    2.2e-16
largest budget constraint residual 3.1e-16
largest net supply of any security 6.5e-15
all natural debt limits slack:     True
```

```
rng = np.random.default_rng(0)
T_sim = 200
states = np.empty(T_sim, dtype=int)
states[0] = 0
for t in range(T_sim - 1):
    states[t+1] = rng.choice(ex.n, p=ex.P[states[t]])

a = ψ[states]            # financial wealth of each agent along the path
print(f"visits to the initial state: {np.sum(states == 0)}")
print(f"largest |wealth| at those visits: {np.abs(a[states == 0]).max():.1e}")
```

```
visits to the initial state: 16
largest |wealth| at those visits: 5.9e-15
```

All four conditions hold to machine precision.

The last check is **state variable degeneracy** in action: financial wealth is a function of the Markov state alone, so it returns to its initial value of zero whenever the state does.

Exercise 135.13.2

This exercise connects the lecture to *The Recovery Theorem*.

An outside observer sees the equilibrium pricing kernel Q and the aggregate endowment y, but not β, γ, or the transition matrix P.

1. Show that the vector with components $y(\bar{s}_j)^\gamma$ is a right eigenvector of Q with eigenvalue β.
2. Using example 4, compute the Perron–Frobenius eigenvalue and eigenvector of Q, and use them to recover β, γ, and P.

Solution

Here is one solution.

Let $v_j = y_j^\gamma$.

Using (135.1),

$$\sum_j Q_{ij} v_j = \sum_j \beta \left(\frac{y_j}{y_i}\right)^{-\gamma} P_{ij}\, y_j^\gamma = \beta\, y_i^\gamma \sum_j P_{ij} = \beta\, v_i,$$

because the rows of P sum to one.

Since v is strictly positive, it is the Perron–Frobenius eigenvector of the nonnegative matrix Q, and β is its largest eigenvalue.

Given β and v, the transition matrix is $P_{ij} = Q_{ij} v_j / (\beta v_i)$, and γ is the slope of $\log v$ on $\log y$.

```
eigvals, eigvecs = np.linalg.eig(ex4.Q)
i = np.argmax(eigvals.real)
β_hat = eigvals[i].real
v = np.abs(eigvecs[:, i].real)

γ_hat = np.polyfit(np.log(ex4.y), np.log(v), 1)[0]
P_hat = ex4.Q * v[None, :] / (β_hat * v[:, None])

print(f"recovered β = {β_hat:.6f}   (true {ex4.β})")
print(f"recovered γ = {γ_hat:.6f}   (true {ex4.γ})")
print(f"max |P_hat - P| = {np.abs(P_hat - ex4.P).max():.1e}")
```

```
recovered β = 0.980000   (true 0.98)
recovered γ = 0.500000   (true 0.5)
max |P_hat - P| = 3.3e-16
```

Recovery is exact because the equilibrium kernel has precisely the **transition independence** structure studied in *The Recovery Theorem*: $Q = \beta D^{-1} P D$, with D built from the marginal utility of the aggregate endowment.

Exercise 135.13.3

In the infinite-horizon economy, continuation wealth depends only on the Markov state.

This exercise shows that in the finite-horizon economy it depends on calendar time as well.

1. For the finite-horizon version of example 1 with $T = 10$ and initial state 1, report $\psi_t^1(\bar{s}_1)$ for $t = 0, 1, \ldots, 10$.
2. Explain why agent 1's wealth does not return to zero when the Markov state returns to $\bar{s}_1$.
3. Compute the wealth distribution α for horizons $T = 1, \ldots, 300$ and show that it converges to the infinite-horizon distribution at a geometric rate close to β.

Solution

Here is one solution.

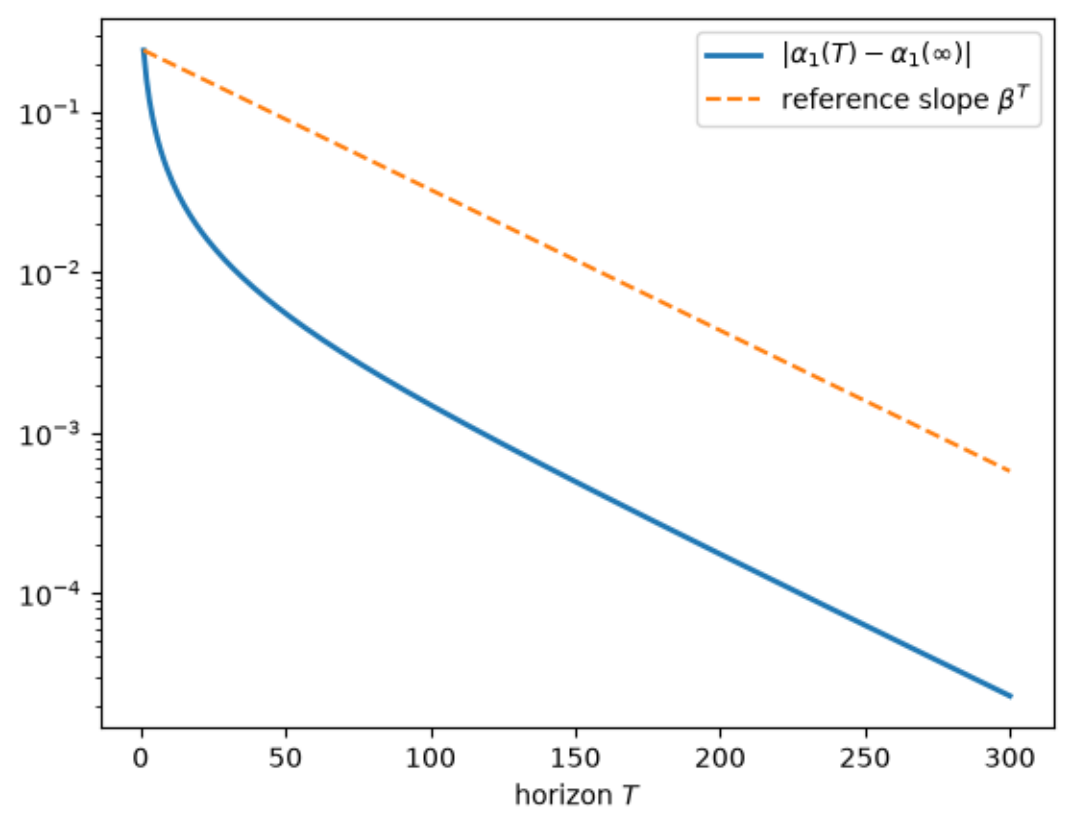
```
s = np.array([0, 1])
P = np.array([[.5, .5],
              [.5, .5]])
ys = np.array([[1., 0.],
               [0., 1.]])

ex_T = RecurCompetitive(s, P, ys, T=10)
ex_T.wealth_distribution(s0_idx=0)
ψ_T = ex_T.continuation_wealths()

print("ψ_t^1(s_1), t = 0,...,10:", ψ_T[:, 0, 0].round(4))
```

```
ψ_t^1(s_1), t = 0,...,10: [ 0.     -0.041  -0.0828 -0.1255 -0.1691 -0.2136 -0.
↪2589 -0.3052 -0.3524
 -0.4006 -0.4498]
```

From (135.6), $\psi_t^k = [I + Q + \cdots + Q^{T-t}][\alpha_k y - y^k]$.



The initial condition pins $\psi_0^k(\bar{s}_1) = 0$, but at a later date t fewer periods remain, so the geometric sum is truncated sooner and $\psi_t^k(\bar{s}_1) \neq 0$.

In the infinite horizon the sum is never truncated, which is why wealth there depends on the state alone.

```
α_inf = RecurCompetitive(s, P, ys).wealth_distribution(s0_idx=0)[0]

T_grid = np.arange(1, 301)
gaps = np.array([abs(RecurCompetitive(s, P, ys, T=T).wealth_distribution(s0_
↪idx=0)[0]
                     - α_inf)
                 for T in T_grid])

fig, ax = plt.subplots()
ax.semilogy(T_grid, gaps, lw=2, label=r'$|\alpha_1(T) - \alpha_1(\infty)|$')
ax.semilogy(T_grid, gaps[0] * ex_T.β ** (T_grid - 1), '--', lw=1.5,
            label=r'reference slope $\beta^{T}$')
ax.set_xlabel('horizon $T$')
ax.legend()
plt.show()
```

The gap shrinks geometrically, at a rate governed by the spectral radius of Q, which equals β.

Exercise 135.13.4

This exercise asks you to verify, in a setting with more than one good, the equivalence that *A rational expectations equilibrium* describes for our one-good economy.

Following Arrow [1964], consider a two-period pure exchange economy with n consumers, S states, and C goods.

Consumer i is endowed with the state-contingent vector $\omega_i = (\omega_{i1}, \ldots, \omega_{iS})$ and ranks state-contingent consumption plans x_i by

$$U_i(x_i) = \sum_{s=1}^{S} u_i(x_{is})\,\pi_s, \qquad u_i(x) = a_{i1}\sqrt{x_1} + a_{i2}\sqrt{x_2}$$

In a **contingent claims equilibrium**, a price vector p^* for claims to goods in states and an allocation $\{x_i^*\}$ are such that each consumer maximizes U_i subject to $p^* \cdot x_i = p^* \cdot \omega_i$ and all SC markets clear.

In the **sequential** arrangement, consumer i enters a securities market with an endowment M_i of dollars, a unit of security s pays one dollar if state s occurs and sells for q_s, and after the state is realized goods trade on spot markets at prices $\bar{p}_s$.

1. Show that consumer i's spot problem has indirect utility $V_i(y, \bar{p}_s) = \sqrt{y}\, G_i(\bar{p}_s)$ with $G_i(\bar{p}_s) = \left(\sum_c a_{ic}^2 / \bar{p}_{sc}\right)^{1/2}$, and derive the within-state demands. At which point does the definition of a **rational expectations equilibrium** require consumers to forecast $\bar{p}_s$ correctly?

2. Compute the contingent claims equilibrium of the two-state, two-good, two-consumer economy specified in the solution below.
3. Define

$$M_i = p^* \cdot \omega_i, \qquad q_s^* = \frac{\sum_i p_s^* \cdot x_{is}^*}{\sum_\sigma \sum_i p_\sigma^* \cdot x_{i\sigma}^*}, \qquad \bar{p}_s = \frac{p_s^*}{q_s^*}, \qquad y_{is}^* = \bar{p}_s \cdot x_{is}^*$$

and verify that $\{y_i^*, x_i^*\}, q^*, \bar{p}$ is a rational expectations equilibrium: check that $\sum_s q_s^* y_{is}^* = M_i$, that $\sum_i y_{is}^* = \sum_i M_i$ for every s, that the spot demands reproduce x_i^*, and that the portfolio satisfies its own first-order conditions.

4. Verify that $\sum_s q_s^* = 1$, and explain why a consumer who could hold cash instead of securities would arbitrage against any price system that violated this equality.
5. Going the other way, define $p_s^* = q_s^* \bar{p}_s$ and verify that you recover the contingent claims equilibrium.
6. Finally, show that an incorrect forecast is not an equilibrium: perturb the forecast of relative prices in state 1, recompute portfolios, and compare the spot prices that then clear the goods markets with the forecast.

Solution

Part 1. With $u_i(x) = \sum_c a_{ic}\sqrt{x_c}$ and a spot budget $\bar{p}_s \cdot x = y$, the first-order conditions give $x_c \propto a_{ic}^2/\bar{p}_{sc}^2$, so

$$x_c = \frac{a_{ic}^2/\bar{p}_{sc}^2}{\sum_{c'} a_{ic'}^2/\bar{p}_{sc'}}\, y, \qquad V_i(y, \bar{p}_s) = \sqrt{y}\left(\sum_c a_{ic}^2/\bar{p}_{sc}\right)^{1/2}$$

The portfolio problem is max $\sum_s \pi_s V_i(y_{is}, \bar{p}_s)$ subject to $\sum_s q_s y_{is} = M_i$.

The forecast $\bar{p}_s$ enters here, through $G_i(\bar{p}_s)$, before any state is realized.

The definition of equilibrium requires the forecast used in this portfolio problem to be the price vector that later clears the spot market in state s.

Since V_i is increasing in y and concave, and G_i depends on $\bar{p}_s$, a consumer who misforecasts relative prices chooses a portfolio that is optimal for prices that never materialize.

Parts 2 to 5.

```
π = np.array([0.4, 0.6])                  # probabilities of the two states
A = np.array([[2.0, 1.0],                 # taste parameters a_{ic}
              [1.0, 3.0]])
ω = np.array([[[2.0, 0.5], [0.5, 1.5]],   # consumer 1, by state
              [[1.0, 1.5], [1.0, 1.0]]]) # consumer 2, by state
Ω = ω.sum(axis=0)                         # aggregate endowment by state
S, C = Ω.shape

def spot_demand(p_s, y, a):
    "Within-state demands given spot prices p_s and spending y."
    w = a**2 / p_s**2
    return w * y / (w * p_s).sum()

def G(p_s, a):
    "Indirect utility coefficient: V = sqrt(y) G(p_s)."
    return np.sqrt((a**2 / p_s).sum())

def spending_shares(p, a):
    "Shares of time 0 wealth spent in each state."
    g = np.array([π[s] * G(p[s], a) for s in range(S)])
    return g**2 / (g**2).sum()
```

```
def cc_excess_demand(p_flat):
    "Excess demand in the SC contingent claims markets."
    p = p_flat.reshape((S, C))
    exc = np.zeros((S, C))
    for i in range(len(A)):
        M_i = (p * ω[i]).sum()
        share = spending_shares(p, A[i])
        for s in range(S):
            exc[s] += spot_demand(p[s], share[s] * M_i, A[i])
    return (exc - Ω).ravel()

sol = root(cc_excess_demand, np.ones(S * C), tol=1e-13)
p_star = sol.x.reshape((S, C))
p_star = p_star / p_star[0, 0]           # numeraire: good 1 in state 1

M = np.array([(p_star * ω[i]).sum() for i in range(len(A))])
x_star = np.array([[spot_demand(p_star[s], spending_shares(p_star, A[i])[s] * M[i],
                                A[i]) for s in range(S)] for i in range(len(A))])

print("p* =\n", p_star.round(5))
print("largest excess demand:", np.abs(cc_excess_demand(p_star.ravel())).max())
print("M =", M.round(5))
print("x1* =\n", x_star[0].round(5), "\nx2* =\n", x_star[1].round(5))
```

```
p* =
 [[1.      1.42351]
 [2.12132 1.90983]]
largest excess demand: 1.3322676295501878e-15
M = [6.63716 7.16641]
x1* =
 [[2.62254 0.32355]

          for i in range(len(A)) for s in range(S)))

# portfolio first-order condition: sqrt(y_is) q_s / (π_s G_i) is constant across s
for i in range(len(A)):
    ratio = np.sqrt(y_star[i]) * q / np.array([π[s] * G(p_bar[s], A[i])
                                               for s in range(S)])
    print(f"consumer {i+1} portfolio FOC, across states:", ratio.round(8))

print("\nq*_s p_bar_s recovers p*:", np.allclose(q[:, None] * p_bar, p_star))
```

```
q* = [0.42359 0.57641]  and Σ_s q*_s = 1.0
p_bar =
 [[2.36079 3.3606 ]
 [3.68021 3.31331]]
y* =
 [[7.27861 6.16579]
 [6.52497 7.63779]]

Σ_s q*_s y*_is = M_i:           True
Σ_i y*_is = Σ_i M_i for each s: True
spot demands reproduce x*:      True
consumer 1 portfolio FOC, across states: [2.02428387 2.02428387]
consumer 2 portfolio FOC, across states: [1.53593595 1.53593595]

q*_s p_bar_s recovers p*: True
```

The securities prices sum to one because a unit of each security, bought in equal numbers, pays one dollar for sure.

A portfolio of one unit of every security is therefore a riskless claim to one dollar, so it must cost one dollar.

If $\sum_s q_s < 1$, a consumer could buy that bundle and hold a sure dollar for less than a dollar; if $\sum_s q_s > 1$, selling the bundle and holding cash would do the same in reverse.

Part 6.

```
def realized_spot_prices(y):
    "Spot prices that clear each state's goods markets given dollar wealth y."
    out = np.zeros((S, C))
    for s in range(S):
        def excess(p_s):
            return sum(spot_demand(p_s, y[i, s], A[i])
                       for i in range(len(A))) - Ω[s]
        out[s] = root(excess, np.ones(C), tol=1e-13).x
    return out

def portfolios(forecast):
    "Optimal portfolios when consumers forecast the spot prices in forecast."
    y = np.zeros((len(A), S))
    for i in range(len(A)):
        g = np.array([π[s] * G(forecast[s], A[i]) for s in range(S)])
        y[i] = M[i] * (g / q)**2 / ((g / q)**2 * q).sum()
    return y

print("correct forecast reproduces itself:",
      np.allclose(realized_spot_prices(y_star), p_bar))

p_wrong = p_bar.copy()
p_wrong[0] = p_bar[0] * np.array([1.5, 1.0])     # misforecast relative prices
p_realized = realized_spot_prices(portfolios(p_wrong))

print(f"\nforecast relative price in state 1: "
      f"{p_wrong[0, 0] / p_wrong[0, 1]:.4f}")
print(f"realized relative price in state 1: "
      f"{p_realized[0, 0] / p_realized[0, 1]:.4f}")
```

```
correct forecast reproduces itself: True

forecast relative price in state 1: 1.0537
realized relative price in state 1: 0.6496
```

With the correct forecast, the prices that clear the spot markets are the prices that consumers used when choosing portfolios, so the forecast is confirmed and the sequential allocation is the contingent claims allocation.

With the incorrect forecast, consumers carry the wrong dollar wealth into each state, and the prices that then clear the spot markets are not the prices they forecast.

The plans are feasible and the securities market clears, but the economy is not in a rational expectations equilibrium.

Note that only *relative* prices within a state need to be forecast correctly.

Scaling all of state s's spot prices by a constant is absorbed by the security price q_s, which is why the normalization of $\bar{p}_s$ is harmless.

Exercise 135.13.5

In Exercise 135.13.4 the securities pay dollars, so the set of state-contingent wealth distributions that a portfolio can deliver does not depend on what consumers forecast.

This exercise, which follows Hart [1975], asks what happens when securities pay *goods* instead.

There are two dates.

Securities trade at the first date; at the second date a state $s \in \{1, 2\}$ is realized and $C = 2$ goods trade on spot markets.

Two consumers care only about consumption at the second date and assign probability $1/2$ to each state, with

$$u^1(x) = 2^{2.5}\sqrt{x_1} + 2\sqrt{x_2}, \qquad u^2(x) = 2\sqrt{x_1} + 2^{2.5}\sqrt{x_2}$$

and endowments

$$\omega_{11} = \left(\tfrac{5}{2}, \tfrac{50}{21}\right), \quad \omega_{21} = \left(\tfrac{1}{2}, \tfrac{13}{21}\right), \quad \omega_{12} = \left(\tfrac{13}{21}, \tfrac{1}{2}\right), \quad \omega_{22} = \left(\tfrac{50}{21}, \tfrac{5}{2}\right)$$

where ω_{is} is consumer i's endowment in state s.

The aggregate endowment of each good is 3 in each state, so all risk is idiosyncratic, and the two consumers and the two states are mirror images of each other.

1. Suppose first that no securities are available. Compute the spot market equilibrium in each state.
2. Now let two securities trade at the first date. A unit of security 1 delivers one unit of good 1 if state 1 occurs and two units of good 1 if state 2 occurs; a unit of security 2 delivers two units of good 2 if state 1 occurs and one unit of good 2 if state 2 occurs. Show that if consumers forecast the spot prices of part 1, the two securities become perfect substitutes, so that no portfolio of them can move wealth between states. Conclude that this is a rational expectations equilibrium, and compute each consumer's expected utility.
3. Show that the forecast $\hat{p}_1 = \hat{p}_2 = (1, 1)$ instead makes the two securities span, so that the equilibrium allocation is the contingent claims allocation $x_{1s} = (8/3, 1/3)$, $x_{2s} = (1/3, 8/3)$. Verify that this forecast is also confirmed, compute expected utilities, and find the portfolio that consumer 1 uses.
4. Compare the two equilibria, and explain why no market force selects the better one.
5. Change only the dividends: let security 1 deliver one unit of good 1 in *both* states and security 2 one unit of good 2 in both states. Show that now no rational expectations equilibrium exists.

Solution

Part 1.

```
a = np.array([[2**2.5, 2.0],       # consumer 1
              [2.0, 2**2.5]])      # consumer 2
ω_h = np.array([[[5 / 2, 50 / 21], [13 / 21, 1 / 2]],      # consumer 1, by state
                [[1 / 2, 13 / 21], [50 / 21, 5 / 2]]])     # consumer 2, by state
Ω_h = ω_h.sum(axis=0)
def u(x, a_i):
    "Expected utility of the bundle x for a consumer with tastes a_i."
    return a_i @ np.sqrt(x)

print("aggregate endowment by state:\n", Ω_h.round(6))

p_hat = np.array([[2.0, 1.0], [1.0, 2.0]])      # conjectured spot prices
x_auto = np.array([[spot_demand(p_hat[s], p_hat[s] @ ω_h[i, s], a[i])
                    for s in range(2)] for i in range(2)])

print("\nno securities, state by state:")
for s in range(2):
    print(f"  state {s+1}: p = {p_hat[s]}, "
          f"x_1 = {(21 * x_auto[0, s]).round(4)}/21, "
          f"x_2 = {(21 * x_auto[1, s]).round(4)}/21, "
          f"markets clear: {np.allclose(x_auto[:, s].sum(axis=0), Ω_h[s])}")
```

```
aggregate endowment by state:
 [[3. 3.]
 [3. 3.]]

no securities, state by state:
  state 1: p = [2. 1.], x_1 = [62. 31.]/21, x_2 = [ 1. 32.]/21, markets clear:␣
↪True
  state 2: p = [1. 2.], x_1 = [32.  1.]/21, x_2 = [31. 62.]/21, markets clear:␣
↪True
```

The spot equilibrium in state 1 has prices proportional to $(2, 1)$ and in state 2 proportional to $(1, 2)$.

Each consumer eats mostly the good that it likes more.

In each state the good favored by the richer consumer is the expensive one, because the aggregate endowment is the same in both states and only the distribution of wealth differs.

Part 2. The dollar payoff of a security is the forecast price of the good it delivers, times the quantity delivered.

```
def payoff_matrix(forecast, dividends):
    """
    Dollar payoffs of securities, given forecast spot prices.

    dividends[f, s] is the bundle that security f delivers in state s.
    """
    return np.array([[forecast[s] @ dividends[f, s] for s in range(2)]
                     for f in range(2)])

div_b = np.array([[[1.0, 0.0], [2.0, 0.0]],     # security 1: good 1, 1 then 2␣
↪units
                  [[0.0, 2.0], [0.0, 1.0]]])    # security 2: good 2, 2 then 1 unit

Z = payoff_matrix(p_hat, div_b)
print("payoff matrix with the part 1 forecast:\n", Z)
print("rank:", np.linalg.matrix_rank(Z))

EU_auto = [sum(0.5 * u(x_auto[i, s], a[i]) for s in range(2)) for i in range(2)]
```

```
print(f"\nexpected utilities with no risk sharing: {EU_auto[0]:.4f}, {EU_auto[1]:.
 ↪4f}")
```

```
payoff matrix with the part 1 forecast:
 [[2. 2.]
 [2. 2.]]
rank: 1

expected utilities with no risk sharing: 9.7846, 9.7846
```

Both securities pay $(2, 2)$, so they are perfect substitutes and must bear the same price.

No portfolio of them can move wealth between the two states, so no securities trade, the realized spot prices are those of part 1, and the forecast is confirmed.

This is a rational expectations equilibrium in which the asset market is effectively incomplete.

Part 3.

```
p_span = np.array([[1.0, 1.0], [1.0, 1.0]])
Z_span = payoff_matrix(p_span, div_b)
print("payoff matrix with the forecast (1,1):\n", Z_span)
print("rank:", np.linalg.matrix_rank(Z_span))

x_cm = np.array([[8 / 3, 1 / 3], [1 / 3, 8 / 3]])    # complete markets allocation
print("\nallocation clears:", np.allclose(x_cm.sum(axis=0), ω_h[0]))
for i in range(2):
    ratio = x_cm[i, 1] / x_cm[i, 0]
    print(f"  consumer {i+1}: x_2/x_1 = {ratio:.4f}, "
          f"(a_2/a_1)^2 = {(a[i, 1] / a[i, 0])**2:.4f}")

EU_cm = [u(x_cm[i], a[i]) for i in range(2)]
print(f"\nexpected utilities with complete markets: {EU_cm[0]:.4f}, {EU_cm[1]:.4f}
 ↪")

wealth = np.array([p_span[s] @ ω_h[0, s] for s in range(2)])
z1 = np.linalg.solve(Z_span.T, p_span[0] @ x_cm[0] - wealth)
print(f"\nconsumer 1 state-contingent wealth: {(42 * wealth).round(3)}/42")
print(f"consumer 1 portfolio: {(42 * z1).round(3)}/42")
```

```
payoff matrix with the forecast (1,1):
 [[1. 2.]
 [2. 1.]]
rank: 2

allocation clears: True
  consumer 1: x_2/x_1 = 0.1250, (a_2/a_1)^2 = 0.1250
  consumer 2: x_2/x_1 = 8.0000, (a_2/a_1)^2 = 8.0000

expected utilities with complete markets: 10.3923, 10.3923

consumer 1 state-contingent wealth: [205.  47.]/42
consumer 1 portfolio: [ 79. -79.]/42
```

With this forecast the payoff vectors $(1, 2)$ and $(2, 1)$ are linearly independent, so the securities span and the allocation must be the contingent claims allocation.

Because each consumer's demands satisfy $x_2/x_1 = (a_2/a_1)^2$ at prices proportional to $(1, 1)$, those are indeed the spot prices that clear the markets, so this forecast is confirmed too.

Consumer 1 reaches the allocation by buying $79/42$ units of security 1 and selling $79/42$ units of security 2, a swap that costs nothing because the two securities bear the same price, and that converts its state-contingent wealth of

$(205/42, 47/42)$ into $(3, 3)$.

Consumer 2 holds the mirror-image portfolio.

Part 4.

```
print(f"{'':12}{'no risk sharing':>18}{'complete markets':>19}")
for i in range(2):
    print(f"consumer {i+1}: {EU_auto[i]:>17.4f}{EU_cm[i]:>19.4f}")
```

```
                no risk sharing   complete markets
consumer 1:             9.7846            10.3923
consumer 2:             9.7846            10.3923
```

Both consumers strictly prefer the second equilibrium, so it Pareto dominates the first.

Yet both are rational expectations equilibria: in each, consumers forecast correctly and markets clear.

Hart's point is that no market force selects the better one, because the trading opportunities available to a consumer depend on forecasts of spot prices, and a competitive consumer takes those forecasts as given.

A consumer cannot unilaterally make the two securities span, since spanning is a property of prices that no individual chooses.

Part 5.

```
div_e = np.array([[[1.0, 0.0], [1.0, 0.0]],     # security 1: one unit of good 1
                  [[0.0, 1.0], [0.0, 1.0]]])    # security 2: one unit of good 2

# each candidate forecast implies a span, the span implies an allocation,
# and the allocation implies the spot prices that actually clear markets
for name, forecast, implied in [
    ("(2,1) and (1,2)", p_hat,  p_span),
    ("(1,1) and (1,1)", p_span, p_hat),
]:
    Z_e = payoff_matrix(forecast, div_e)
    rank = np.linalg.matrix_rank(Z_e)
    spans = "spans" if rank == 2 else "does not span"
    allocation = "complete markets" if rank == 2 else "no risk sharing"
    print(f"forecast {name}: rank {rank}, {spans}")
    print(f"  implied allocation: {allocation}")
    print(f"  spot prices it implies: {implied[0]} and {implied[1]}")
    print(f"  forecast confirmed: {np.allclose(forecast, implied)}\n")
```

```
forecast (2,1) and (1,2): rank 2, spans
  implied allocation: complete markets
  spot prices it implies: [1. 1.] and [1. 1.]
  forecast confirmed: False

forecast (1,1) and (1,1): rank 1, does not span
  implied allocation: no risk sharing
  spot prices it implies: [2. 1.] and [1. 2.]
  forecast confirmed: False
```

With these dividends the payoff vectors are $(\hat{p}_{11}, \hat{p}_{21})$ and $(\hat{p}_{12}, \hat{p}_{22})$, so the securities span if and only if the two states' price vectors are not proportional.

Suppose a forecast makes them proportional.

Then no risk can be traded, so the realized spot prices are those of part 1, which are *not* proportional, and the forecast is wrong.

Suppose instead that a forecast makes them non-proportional.

Then the securities span, so the allocation is the complete markets allocation of part 3, whose spot prices *are* proportional, and again the forecast is wrong.

So no rational expectations equilibrium exists, even though preferences are strictly concave, endowments are strictly positive, and there are no transaction costs.

Nothing like parts 2 to 5 can happen in the sequential economy of this lecture, where there is one good per date and history and the one-period Arrow securities are denominated in that good.

There the span of the asset market is n-dimensional whatever consumers forecast, and the only forecast that matters is of the pricing kernel Q itself.

  - *Structure of the model*
  - *Solving the model*
  - *Exercises*

In addition to what's in Anaconda, this lecture uses following libraries:

```
!pip install quantecon
```

136.1 Overview

This lecture describes a version of a model of Harrison and Kreps [Harrison and Kreps, 1978].

The model determines the price of a dividend-yielding asset that is traded by two types of self-interested investors.

The model features

- heterogeneous beliefs
- incomplete markets
- short sales constraints, and possibly ...
- (leverage) limits on an investor's ability to borrow in order to finance purchases of a risky asset

Let's start with some standard imports:

```
import numpy as np
import quantecon as qe
import scipy.linalg as la
```

136.1.1 References

Prior to reading the following, you might like to review our lectures on

- *Markov chains*
- *Asset pricing with finite state space*

136.1.2 Bubbles

Economists differ in how they define a *bubble*.

The Harrison-Kreps model illustrates the following notion of a bubble that attracts many economists:

> *A component of an asset price can be interpreted as a bubble when all investors agree that the current price of the asset exceeds what they believe the asset's underlying dividend stream justifies*.

136.2 Structure of the model

The model simplifies things by ignoring alterations in the distribution of wealth among investors who have hard-wired different beliefs about the fundamentals that determine asset payouts.

There is a fixed number A of shares of an asset.

Each share entitles its owner to a stream of dividends $\{d_t\}$ governed by a Markov chain defined on a state space $S \in \{0, 1\}$.

The dividend obeys

$$d_t = \begin{cases} 0 & \text{if } s_t = 0 \\ 1 & \text{if } s_t = 1 \end{cases}$$

An owner of a share at the end of time t and the beginning of time $t+1$ is entitled to the dividend paid at time $t+1$.

Thus, the stock is traded **ex dividend**.

An owner of a share at the beginning of time $t+1$ is also entitled to sell the share to another investor during time $t+1$.

Two types $h = a, b$ of investors differ only in their beliefs about a Markov transition matrix P with typical element

$$P(i,j) = \mathbb{P}\{s_{t+1} = j \mid s_t = i\}$$

Investors of type a believe the transition matrix

$$P_a = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} \\ \frac{2}{3} & \frac{1}{3} \end{bmatrix}$$

Investors of type b think the transition matrix is

$$P_b = \begin{bmatrix} \frac{2}{3} & \frac{1}{3} \\ \frac{1}{4} & \frac{3}{4} \end{bmatrix}$$

Thus, in state 0, a type a investor is more optimistic about next period's dividend than is investor b.

But in state 1, a type a investor is more pessimistic about next period's dividend than is investor b.

The stationary (i.e., invariant) distributions of these two matrices can be calculated as follows:

```
qa = np.array([[1/2, 1/2], [2/3, 1/3]])
qb = np.array([[2/3, 1/3], [1/4, 3/4]])
mca = qe.MarkovChain(qa)
mcb = qe.MarkovChain(qb)
mca.stationary_distributions
```

```
array([[0.57142857, 0.42857143]])
```

```
mcb.stationary_distributions
```

```
array([[0.42857143, 0.57142857]])
```

The stationary distribution of P_a is approximately $\pi_a = \begin{bmatrix} .57 & .43 \end{bmatrix}$.

The stationary distribution of P_b is approximately $\pi_b = \begin{bmatrix} .43 & .57 \end{bmatrix}$.

Thus, a type a investor is more pessimistic on average.

136.2.1 Ownership rights

An owner of the asset at the end of time t is entitled to the dividend at time $t+1$ and also has the right to sell the asset at time $t+1$.

Both types of investors are risk-neutral and both have the same fixed discount factor $\beta \in (0, 1)$.

In our numerical example, we'll set $\beta = .75$, just as Harrison and Kreps [Harrison and Kreps, 1978] did.

We'll eventually study the consequences of two alternative assumptions about the number of shares A relative to the resources that our two types of investors can invest in the stock.

1. Both types of investors have enough resources (either wealth or the capacity to borrow) so that they can purchase the entire available stock of the asset[1].
2. No single type of investor has sufficient resources to purchase the entire stock.

Case 1 is the case studied in Harrison and Kreps.

In case 2, both types of investors always hold at least some of the asset.

136.2.2 Short sales prohibited

No short sales are allowed.

This matters because it limits how pessimists can express their opinions.

- They *can* express themselves by selling their shares.
- They *cannot* express themselves more loudly by artificially "manufacturing shares" – that is, they cannot borrow shares from more optimistic investors and then immediately sell them.

[1] By assuming that both types of agents always have "deep enough pockets" to purchase all of the asset, the model takes wealth dynamics off the table. The Harrison-Kreps model generates high trading volume when the state changes either from 0 to 1 or from 1 to 0.

136.2.3 Optimism and pessimism

The above specifications of the perceived transition matrices P_a and P_b, taken directly from Harrison and Kreps, build in stochastically alternating temporary optimism and pessimism.

Remember that state 1 is the high dividend state.

- In state 0, a type a agent is more optimistic about next period's dividend than a type b agent.
- In state 1, a type b agent is more optimistic about next period's dividend than a type a agent is.

However, the stationary distributions $\pi_a = \begin{bmatrix} .57 & .43 \end{bmatrix}$ and $\pi_b = \begin{bmatrix} .43 & .57 \end{bmatrix}$ tell us that a type b person is more optimistic about the dividend process in the long run than is a type a person.

136.2.4 Information

Investors know a price function mapping the state s_t at t into the equilibrium price $p(s_t)$ that prevails in that state.

This price function is endogenous and to be determined below.

When investors choose whether to purchase or sell the asset at t, they also know s_t.

136.3 Solving the model

Now let's turn to solving the model.

We'll determine equilibrium prices under a particular specification of beliefs and constraints on trading selected from one of the specifications described above.

We shall compare equilibrium price functions under the following alternative assumptions about beliefs:

1. There is only one type of agent, either a or b.
2. There are two types of agents differentiated only by their beliefs. Each type of agent has sufficient resources to purchase all of the asset (Harrison and Kreps's setting).
3. There are two types of agents with different beliefs, but because of limited wealth and/or limited leverage, both types of investors hold the asset each period.

136.3.1 Summary table

The following table gives a summary of the findings obtained in the remainder of the lecture (in an exercise you will be asked to recreate the table and also reinterpret parts of it).

The table reports implications of Harrison and Kreps's specifications of P_a, P_b, β.

s_t	0	1
p_a	1.33	1.22
p_b	1.45	1.91
p_o	1.85	2.08
p_p	1	1
$\hat{p}_a$	1.85	1.69
$\hat{p}_b$	1.69	2.08

Here

- p_a is the equilibrium price function under homogeneous beliefs P_a
- p_b is the equilibrium price function under homogeneous beliefs P_b
- p_o is the equilibrium price function under heterogeneous beliefs with optimistic marginal investors
- p_p is the equilibrium price function under heterogeneous beliefs with pessimistic marginal investors
- $\hat{p}_a$ is the amount type a investors are willing to pay for the asset
- $\hat{p}_b$ is the amount type b investors are willing to pay for the asset

We'll explain these values and how they are calculated one row at a time.

The row corresponding to p_o applies when both types of investor have enough resources to purchase the entire stock of the asset and strict short sales constraints prevail so that temporarily optimistic investors always price the asset.

The row corresponding to p_p would apply if neither type of investor has enough resources to purchase the entire stock of the asset and both types must hold the asset.

The row corresponding to p_p would also apply if both types have enough resources to buy the entire stock of the asset but short sales are also possible so that temporarily pessimistic investors price the asset.

136.3.2 Single belief prices

We'll start by pricing the asset under homogeneous beliefs.

(This is the case treated in *the lecture* on asset pricing with finite Markov states)

Suppose that there is only one type of investor, either of type a or b, and that this investor always "prices the asset".

Let $p_h = \begin{bmatrix} p_h(0) \\ p_h(1) \end{bmatrix}$ be the equilibrium price vector when all investors are of type h.

The price today equals the expected discounted value of tomorrow's dividend and tomorrow's price of the asset:

$$p_h(s) = \beta \left(P_h(s,0)(0 + p_h(0)) + P_h(s,1)(1 + p_h(1)) \right), \quad s = 0, 1 \tag{136.1}$$

These equations imply that the equilibrium price vector is

$$\begin{bmatrix} p_h(0) \\ p_h(1) \end{bmatrix} = \beta [I - \beta P_h]^{-1} P_h \begin{bmatrix} 0 \\ 1 \end{bmatrix} \tag{136.2}$$

The first two rows of the table report $p_a(s)$ and $p_b(s)$.

Here's a function that can be used to compute these values

```
def price_single_beliefs(transition, dividend_payoff, β=.75):
    """
    Function to Solve Single Beliefs
    """
    # First compute (I - βQ)
    A = np.eye(transition.shape[0]) - β * transition

    # Next compute βQd
    b = β * (transition @ dividend_payoff)

    # Solve linear system
    prices = la.solve(A, b)

    return prices
```

Single belief prices as benchmarks

These equilibrium prices under homogeneous beliefs are important benchmarks for the subsequent analysis.

- $p_h(s)$ tells what a type h investor thinks is the "fundamental value" of the asset.
- Here "fundamental value" means the expected discounted present value of future dividends.

We will compare these fundamental values of the asset with equilibrium values when traders have different beliefs.

136.3.3 Pricing under heterogeneous beliefs

There are several cases to consider.

The first is when both types of agents have sufficient wealth to purchase all of the asset themselves.

In this case, the marginal investor who prices the asset is the more optimistic type so that the equilibrium price $\bar{p}$ satisfies Harrison and Kreps's key equation:

$$\bar{p}(s) = \beta \max \left\{ P_a(s,0)\bar{p}(0) + P_a(s,1)(1+\bar{p}(1)),\ P_b(s,0)\bar{p}(0) + P_b(s,1)(1+\bar{p}(1)) \right\} \tag{136.3}$$

for $s = 0, 1$.

In the above equation, the max on the right side is over the two prospective values of next period's payout from owning the asset.

The marginal investor who prices the asset in state s is of type a if

$$P_a(s,0)\bar{p}(0) + P_a(s,1)(1+\bar{p}(1)) > P_b(s,0)\bar{p}(0) + P_b(s,1)(1+\bar{p}(1))$$

The marginal investor is of type b if

$$P_a(s,0)\bar{p}(0) + P_a(s,1)(1+\bar{p}(1)) < P_b(s,0)\bar{p}(0) + P_b(s,1)(1+\bar{p}(1))$$

Thus the marginal investor is the (temporarily) optimistic type.

Equation (136.3) is a functional equation that, like a Bellman equation, can be solved by

- starting with a guess for the price vector $\bar{p}$ and
- iterating to convergence on the operator that maps a guess $\bar{p}^j$ into an updated guess $\bar{p}^{j+1}$ defined by the right side of (136.3), namely

$$\bar{p}^{j+1}(s) = \beta \max \left\{ P_a(s,0)\bar{p}^j(0) + P_a(s,1)(1+\bar{p}^j(1)),\ P_b(s,0)\bar{p}^j(0) + P_b(s,1)(1+\bar{p}^j(1)) \right\} \tag{136.4}$$

for $s = 0, 1$.

The third row of the table labeled p_o reports equilibrium prices that solve the functional equation when $\beta = .75$.

Here the type that is optimistic about s_{t+1} prices the asset in state s_t.

It is instructive to compare these prices with the equilibrium prices for the homogeneous belief economies that solve under beliefs P_a and P_b reported in the rows labeled p_a and p_b, respectively.

Equilibrium prices p_o in the heterogeneous beliefs economy evidently exceed what any prospective investor regards as the fundamental value of the asset in each possible state.

Nevertheless, the economy recurrently visits a state that makes each investor want to purchase the asset for more than he believes its future dividends are worth.

An investor is willing to pay more than what he believes is warranted by fundamental value of the prospective dividend stream because he expects to have the option later to sell the asset to another investor who will value the asset more highly than he will then.

- Investors of type a are willing to pay the following price for the asset

$$\hat{p}_a(s) = \begin{cases} \bar{p}(0) & \text{if } s_t = 0 \\ \beta(P_a(1,0)\bar{p}(0) + P_a(1,1)(1+\bar{p}(1))) & \text{if } s_t = 1 \end{cases}$$

- Investors of type b are willing to pay the following price for the asset

$$\hat{p}_b(s) = \begin{cases} \beta(P_b(0,0)\bar{p}(0) + P_b(0,1)(1+\bar{p}(1))) & \text{if } s_t = 0 \\ \bar{p}(1) & \text{if } s_t = 1 \end{cases}$$

Evidently, $\hat{p}_a(1) < \bar{p}(1)$ and $\hat{p}_b(0) < \bar{p}(0)$.

Investors of type a want to sell the asset in state 1 while investors of type b want to sell it in state 0.

- The asset changes hands whenever the state changes from 0 to 1 or from 1 to 0.
- The valuations $\hat{p}_a(s)$ and $\hat{p}_b(s)$ are displayed in the fourth and fifth rows of the table.
- Even pessimistic investors who don't buy the asset think that it is worth more than they think future dividends are worth.

Here's code to solve for $\bar{p}$, $\hat{p}_a$ and $\hat{p}_b$ using the iterative method described above

```
def price_optimistic_beliefs(transitions, dividend_payoff, β=.75,
                             max_iter=50000, tol=1e-16):
    """
    Function to Solve Optimistic Beliefs
    """
    # We will guess an initial price vector of [0, 0]
    p_new = np.array([[0], [0]])
    p_old = np.array([[10.], [10.]])

    # We know this is a contraction mapping, so we can iterate to conv
    for i in range(max_iter):
        p_old = p_new
        p_new = β * np.max([q @ p_old
                            + q @ dividend_payoff for q in transitions],
                            axis=0)

        # If we succeed in converging, break out of for loop
        if np.max(np.sqrt((p_new - p_old)**2)) < tol:
            break

    ptwiddle = β * np.min([q @ p_old
                           + q @ dividend_payoff for q in transitions],
                           axis=0)

    phat_a = np.array([p_new[0], ptwiddle[1]])
    phat_b = np.array([ptwiddle[0], p_new[1]])

    return p_new, phat_a, phat_b
```

136.3.4 Insufficient funds

Outcomes differ when the more optimistic type of investor has insufficient wealth — or insufficient ability to borrow enough — to hold the entire stock of the asset.

In this case, the asset price must adjust to attract pessimistic investors.

Instead of equation (136.3), the equilibrium price satisfies

$$\check{p}(s) = \beta \min \{P_a(s,0)\check{p}(0) + P_a(s,1)(1+\check{p}(1)),\ P_b(s,0)\check{p}(0) + P_b(s,1)(1+\check{p}(1))\} \tag{136.5}$$

and the marginal investor who prices the asset is always the one that values it *less* highly than does the other type.

Now the marginal investor is always the (temporarily) pessimistic type.

Notice from the sixth row of that the pessimistic price p_o is lower than the homogeneous belief prices p_a and p_b in both states.

When pessimistic investors price the asset according to (136.5), optimistic investors think that the asset is underpriced.

If they could, optimistic investors would willingly borrow at a one-period risk-free gross interest rate β^{-1} to purchase more of the asset.

Implicit constraints on leverage prohibit them from doing so.

When optimistic investors price the asset as in equation (136.3), pessimistic investors think that the asset is overpriced and would like to sell the asset short.

Constraints on short sales prevent that.

Here's code to solve for $\check{p}$ using iteration

```
def price_pessimistic_beliefs(transitions, dividend_payoff, β=.75,
                              max_iter=50000, tol=1e-16):
    """
    Function to Solve Pessimistic Beliefs
    """
    # We will guess an initial price vector of [0, 0]
    p_new = np.array([[0], [0]])
    p_old = np.array([[10.], [10.]])

    # We know this is a contraction mapping, so we can iterate to conv
    for i in range(max_iter):
        p_old = p_new
        p_new = β * np.min([q @ p_old
                            + q @ dividend_payoff for q in transitions],
                           axis=0)

        # If we succeed in converging, break out of for loop
        if np.max(np.sqrt((p_new - p_old)**2)) < tol:
            break

    return p_new
```

136.3.5 Further interpretation

Jose Scheinkman [Scheinkman, 2014] interprets the Harrison-Kreps model as a model of a bubble — a situation in which an asset price exceeds what every investor thinks is merited by his or her beliefs about the value of the asset's underlying dividend stream.

Scheinkman stresses these features of the Harrison-Kreps model:

- High volume occurs when the Harrison-Kreps pricing formula (136.3) prevails.
- Type a investors sell the entire stock of the asset to type b investors every time the state switches from $s_t = 0$ to $s_t = 1$.
- Type b investors sell the asset to type a investors every time the state switches from $s_t = 1$ to $s_t = 0$.

Scheinkman takes this as a strength of the model because he observes high volume during *famous bubbles*.

- If the *supply* of the asset is increased sufficiently either physically (more "houses" are built) or artificially (ways are invented to short sell "houses"), bubbles end when the asset supply has grown enough to outstrip optimistic investors' resources for purchasing the asset.
- If optimistic investors finance their purchases by borrowing, tightening leverage constraints can extinguish a bubble.

Scheinkman extracts insights about the effects of financial regulations on bubbles.

He emphasizes how limiting short sales and limiting leverage have opposite effects.

136.4 Exercises

Exercise 136.4.1

This exercise invites you to recreate the summary table using the functions we have built above.

s_t	0	1
p_a	1.33	1.22
p_b	1.45	1.91
p_o	1.85	2.08
p_p	1	1
$\hat{p}_a$	1.85	1.69
$\hat{p}_b$	1.69	2.08

You will want first to define the transition matrices and dividend payoff vector.

In addition, below we'll add an interpretation of the row corresponding to p_o by inventing two additional types of agents, one of whom is **permanently optimistic**, the other who is **permanently pessimistic**.

We construct subjective transition probability matrices for our permanently optimistic and permanently pessimistic investors as follows.

The permanently optimistic investors(i.e., the investor with the most optimistic beliefs in each state) believes the transition matrix

$$P_o = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} \\ \frac{1}{4} & \frac{3}{4} \end{bmatrix}$$

The permanently pessimistic investor believes the transition matrix

$$P_p = \begin{bmatrix} \frac{2}{3} & \frac{1}{3} \\ \frac{2}{3} & \frac{1}{3} \end{bmatrix}$$

We'll use these transition matrices when we present our solution of exercise 1 below.

Solution

First, we will obtain equilibrium price vectors with homogeneous beliefs, including when all investors are optimistic or pessimistic.

```
qa = np.array([[1/2, 1/2], [2/3, 1/3]])     # Type a transition matrix
qb = np.array([[2/3, 1/3], [1/4, 3/4]])     # Type b transition matrix
# Optimistic investor transition matrix
qopt = np.array([[1/2, 1/2], [1/4, 3/4]])
# Pessimistic investor transition matrix
qpess = np.array([[2/3, 1/3], [2/3, 1/3]])

dividendreturn = np.array([[0], [1]])

transitions = [qa, qb, qopt, qpess]
labels = ['p_a', 'p_b', 'p_optimistic', 'p_pessimistic']

for transition, label in zip(transitions, labels):
    print(label)
    print("=" * 20)
    s0, s1 = np.round(price_single_beliefs(transition, dividendreturn), 2)
    print(f"State 0: {s0}")
    print(f"State 1: {s1}")
    print("-" * 20)
```

```
p_a
====================
State 0: [1.33]
State 1: [1.22]
--------------------
p_b
====================
State 0: [1.45]
State 1: [1.91]
--------------------
p_optimistic
====================
State 0: [1.85]
State 1: [2.08]
--------------------
p_pessimistic
====================
State 0: [1.]
State 1: [1.]
--------------------
```

We will use the price_optimistic_beliefs function to find the price under heterogeneous beliefs.

```
opt_beliefs = price_optimistic_beliefs([qa, qb], dividendreturn)
labels = ['p_optimistic', 'p_hat_a', 'p_hat_b']

for p, label in zip(opt_beliefs, labels):
    print(label)
    print("=" * 20)
    s0, s1 = np.round(p, 2)
    print(f"State 0: {s0}")
    print(f"State 1: {s1}")
    print("-" * 20)
```

```
p_optimistic
====================
State 0: [1.85]
State 1: [2.08]
--------------------
p_hat_a
====================
State 0: [1.85]
State 1: [1.69]
--------------------
p_hat_b
====================
State 0: [1.69]
State 1: [2.08]
--------------------
```

Notice that the equilibrium price with heterogeneous beliefs is equal to the price under single beliefs with **permanently optimistic** investors - this is due to the marginal investor in the heterogeneous beliefs equilibrium always being the type who is temporarily optimistic.

137.1 Overview

This lecture describes how Morris [1996] extended the Harrison–Kreps model [Harrison and Kreps, 1978] of speculative asset pricing.

Like Harrison and Kreps's model, Morris's model determines the price of a dividend-yielding asset that is traded by risk-neutral investors who have heterogeneous beliefs.

The Harrison-Kreps model assumes that the traders have dogmatic, hard-wired beliefs about the asset's dividend stream.

Morris replaced Harrison and Kreps's traders with hard-wired beliefs about the dividend stream with traders who use Bayes' Law to update their beliefs about prospective dividends as new dividend data arrive.

Note

Morris's traders don't use data on past prices of the asset to update their beliefs about the dividend process.

Key features of the environment in Morris's model include:

- All traders share a set of statistical models for prospective dividends

- A single parameter indexes the set of statistical models
- All traders observe the same dividend history
- All traders use Bayes' Law to update beliefs
- Traders have different initial *prior distributions* over the parameter
- Traders' *posterior distributions* over the parameter eventually merge
- Before their posterior distributions merge, traders disagree about the predictive density over prospective dividends
  - therefore they disagree about the value of the asset

Just as in the hard-wired beliefs model of Harrison and Kreps, those differences of opinion induce investors to engage in *speculative behavior* in the following sense:

- sometimes they are willing to pay more for the asset than what they think is its "fundamental" value, i.e., the expected discounted value of its prospective dividend stream

Prior to reading this lecture, you might want to review the following quantecon lectures:

- *Harrison-Kreps model*
- *Likelihood ratio processes*
- *Bayesian versus frequentist statistics*

Let's start with some standard imports:

```
import numpy as np
import matplotlib.pyplot as plt
```

137.2 Structure of the model

There is a fixed supply of shares of an asset.

Each share entitles its owner to a stream of *binary* i.i.d. dividends $\{d_t\}$ where

$$d_{t+1} \in \{0, 1\}$$

The dividend at time t equals 1 with unknown probability $\theta \in (0, 1)$ and equals 0 with probability $1 - \theta$.

Unlike [Harrison and Kreps, 1978] where traders have hard-wired beliefs about a Markov transition matrix, in Morris's model:

- The true dividend probability θ is unknown
- Traders have *prior beliefs* about θ
- Traders observe dividend realizations and update beliefs via Bayes' Law

There is a finite set $\mathcal{I}$ of *risk-neutral* traders.

All traders have the same discount factor $\beta \in (0, 1)$.

- You can think of β as being related to a net risk-free interest rate r by $\beta = 1/(1 + r)$.

Owning the asset at the end of period t entitles the owner to dividends at time $t + 1, t + 2, \ldots$.

Because the dividend process is i.i.d., trader i thinks that the fundamental value of the asset is the capitalized value of the dividend stream, namely, $\sum_{j=1}^{\infty} \beta^j \hat{\theta}_i = \frac{\hat{\theta}_i}{r}$, where $\hat{\theta}_i$ is the mean of the trader's posterior distribution over θ.

137.2.1 Possible trades

Traders buy and sell the risky asset in competitive markets each period $t = 0, 1, 2, ...$ after dividends are paid.

As in Harrison-Kreps:

- The asset is traded *ex dividend*
- An owner of a share at the end of time t is entitled to the dividend at time $t + 1$
- An owner of a share at the end of period t also has the right to sell the share at time $t + 1$ after having received the dividend at time $t + 1$.

Short sales are prohibited.

This matters because it limits how pessimists can express their opinions:

- They *can* express themselves by selling their shares
- They *cannot* express themselves more emphatically by borrowing shares and immediately selling them

All traders have sufficient wealth to purchase the risky asset.

137.3 Information and beliefs

At time $t \geq 1$, all traders observe $(d_1, d_2, ..., d_t)$.

All traders update their subjective distribution over θ by applying Bayes' rule.

Traders have *heterogeneous priors* over the unknown dividend probability θ.

This heterogeneity in priors produces heterogeneous posterior beliefs.

137.4 Source of heterogeneous priors

Imputing different statistical models to agents inside a model is controversial.

Many game theorists and rational expectations applied economists think it is a bad idea.

While these economists often construct models in which agents have different *information*, they prefer to assume that all of the agents inside their model always share the same statistical model – i.e., the same joint probability distribution over the random process being modeled.

For a statistician or an economic theorist, a statistical model is a joint probability distribution that is characterized by a known parameter vector.

When working with a *set* of statistical models swept out by parameters, say θ in a known set Θ, economic theorists reduce the set of models to a single model by imputing to all agents inside the model the same prior probability distribution over θ.

Note

A set of statistical models that has a particular geometric structure is called a manifold of statistical models. Morris endows traders with a shared manifold of statistical models.

Proceeding in this way adheres to the *Harsanyi Common Priors Doctrine*.

[Harsanyi, 1967], [Harsanyi, 1968], [Harsanyi, 1968] argued that if two rational agents have the same information and the same reasoning capabilities, they will have the same joint probability distribution over outcomes of interest.

Harsanyi interpreted disagreements about prospective outcomes as arising from differences in agents' information sets, not differences in their statistical models.

Evidently, [Harrison and Kreps, 1978] departed from the Harsanyi common statistical model assumption when they hard-wired dogmatic disparate beliefs.

Morris [1996] abandons the Harsanyi doctrine less completely than Harrison and Kreps had.

- Morris does assume that agents share the same set of statistical models, but ...
- Morris assumes that they have different initial prior distributions over the parameter that indexes the models

Morris's agents express their initial ignorance about the parameter differently – they have different priors.

Morris defends his assumption by alluding to the apparent "mispricing" of initial public offerings presented by [Miller, 1977].

Miller described a situation in which agents have access to little or no data about a new enterprise.

Morris wanted his traders to be open to changing their opinions as information about the parameter arrives.

Knowledgeable statisticians have been known to disagree about an appropriate prior.

For example, Morris described *different* respectable ways to express "maximal ignorance" about the parameter of a Bernoulli distribution

- a uniform distribution on $[0, 1]$
- a Jeffreys prior [Jeffreys, 1946] that is invariant to reparameterization; in the present situation, the Jeffreys prior takes the form of a Beta distribution with parameters $.5, .5$

Is one of these priors more "rational" than the other?

Morris thinks not.

137.5 Beta priors

For tractability, assume trader i has a Beta prior over the dividend probability

$$\theta \sim \text{Beta}(a_i, b_i)$$

where $a_i, b_i > 0$ are the prior parameters.

Note

The Beta distribution also appears in these quantecon lectures *Statistical Divergence Measures*, *Likelihood Ratio Processes*, *Job Search IX: Search with Learning*.

Suppose trader i observes a history of t periods in which a total of s dividends are paid (i.e., s successes with dividend and $t - s$ failures without dividend).

By Bayes' rule, the posterior density over θ is:

$$\pi_i(\theta \mid s, t) = \frac{\theta^s (1-\theta)^{t-s} \pi_i(\theta)}{\int_0^1 \theta^s (1-\theta)^{t-s} \pi_i(\theta) d\theta}$$

where $\pi_i(\theta)$ is trader i's prior density.

Note

The Beta distribution is the conjugate prior for the Binomial likelihood. This means that when the prior is Beta(a_i, b_i) and we observe s successes in t trials, the posterior is Beta$(a_i + s, b_i + t - s)$.

The posterior mean (or expected dividend probability) is:

$$\mu_i(s,t) = \int_0^1 \theta \pi_i(\theta \mid s,t) d\theta = \mathbb{E}[\text{Beta}(a_i + s, b_i + t - s)] = \frac{a_i + s}{a_i + b_i + t}$$

Morris refers to $\mu_i(s,t)$ as trader i's **fundamental valuation** of the asset after history (s,t).

This is the probability trader i assigns to receiving a dividend next period.

It embeds trader i's updated belief about θ.

137.6 Market prices with learning

Fundamental valuations equal expected present values of dividends that our heterogeneous traders attach to the option of holding the asset *forever*.

The equilibrium price process is determined by the condition that the asset is held at time t by the trader who attaches the highest valuation to the asset at time t.

An owner of the asset has the option to sell it after receiving that period's dividend.

Traders take that into account.

That opens the possibility that a trader will be willing to pay more for the asset than that trader's fundamental valuation.

Definition 137.6.1 (Most Optimistic Valuation)

After history (s,t), the *most optimistic fundamental valuation* is:

$$\mu^*(s,t) = \max_{i \in \mathcal{I}} \mu_i(s,t)$$

Definition 137.6.2 (Equilibrium Asset Price)

Write $\tilde{p}(s,t,r)$ for the competitive equilibrium price of the risky asset (in current dollars) after history (s,t) when the interest rate is r.

The equilibrium price satisfies:

$$\tilde{p}(s,t,r) = \frac{1}{1+r}\Big[\mu^*(s,t)\{1 + \tilde{p}(s+1,t+1,r)\} + (1 - \mu^*(s,t))\tilde{p}(s,t+1,r)\Big]$$

The equilibrium price equals the highest expected discounted return among all traders from holding the asset to the next period.

Definition 137.6.3 (Normalized Price)

Define the normalized price as:

$$p(s,t,r) = r\tilde{p}(s,t,r)$$

Since the current "dollar" price of the riskless asset is $1/r$, this represents the price of the risky asset in terms of the riskless asset.

Substituting the preceding formula into the equilibrium condition gives:

$$p(s,t,r) = \frac{r}{1+r}\mu^*(s,t) + \frac{1}{1+r}\Big[\mu^*(s,t)p(s+1,t+1,r) + (1-\mu^*(s,t))p(s,t+1,r)\Big]$$

or equivalently:

$$p(s,t,r) = \mu^*(s,t) + \frac{r}{1+r}\Big[\mu^*(s,t)p(s+1,t+1,r) + (1-\mu^*(s,t))p(s,t+1,r) - \mu^*(s,t)\Big]$$

A price function that satisfies the equilibrium condition can be computed recursively.

Set $p^0(s,t,r) = 0$ for all (s,t,r), and define $p^{n+1}(s,t,r)$ by:

$$p^{n+1}(s,t,r) = \frac{r}{1+r}\mu^*(s,t) + \frac{1}{1+r}\Big[\mu^*(s,t)p^n(s+1,t+1,r) + (1-\mu^*(s,t))p^n(s,t+1,r)\Big]$$

The sequence $\{p^n(s,t,r)\}$ converges to the equilibrium price $p(s,t,r)$.

Definition 137.6.4 (Speculative Premium)

When the identity of the most optimistic trader can switch with future dividend realizations, the market price exceeds *every* trader's fundamental valuation.

In normalized units:

$$p(s,t,r) > \mu_i(s,t) \quad \text{for all } i \in \mathcal{J}$$

Define the **speculative premium** as:

$$p(s,t,r) - \mu^*(s,t) > 0$$

137.7 Two Traders

We now focus on an example with two traders with Beta priors with parameters (a_1, b_1) and (a_2, b_2).

Definition 137.7.1 (Rate Dominance (Beta Priors))

Trader 1 **rate-dominates** trader 2 if:

$$a_1 \geq a_2 \quad \text{and} \quad b_1 \leq b_2$$

Theorem 137.7.1 (Global Optimist (Two Traders))

For two traders with Beta priors:

1. If trader 1 rate-dominates trader 2, then trader 1 is a **global optimist**: $\mu_1(s,t) \geq \mu_2(s,t)$ for all histories (s,t)
2. In this case where $p(s,t,r) = \mu_1(s,t)$ for all (s,t,r), there is *no speculative premium*.

When neither trader rate-dominates the other, the identity of the most optimistic trader can switch as dividends accrue.

Along a history in which perpetual switching occurs, the price of the asset strictly exceeds both traders' fundamental valuations so long as traders continue to disagree:

$$p(s,t,r) > \max\{\mu_1(s,t), \mu_2(s,t)\}$$

Thus, along such a history, there is a persistent speculative premium.

137.7.1 Implementation

For computational tractability, let's work with a finite horizon T and solve by backward induction.

Note

On page 1122, Morris [1996] provides an argument that the limit as $T \to +\infty$ of such finite-horizon economies provides a useful selection algorithm that excludes additional equilibria that involve a Ponzi-scheme price component that Morris dismisses as fragile.

Following *Definition 137.6.2*, we use the discount factor parameterization $\beta = 1/(1+r)$ and compute dollar prices $\tilde{p}(s,t)$ via:

$$\tilde{p}(s,t) = \beta \max_{i \in \{1,2\}} \Big[\mu_i(s,t)\{1 + \tilde{p}(s+1,t+1)\} + (1-\mu_i(s,t))\tilde{p}(s,t+1)\Big]$$

We set the terminal price $\tilde{p}(s,T)$ equal to the perpetuity value under the most optimistic belief.

```
def posterior_mean(a, b, s, t):
    """
    Compute posterior mean μ_i(s,t) for Beta(a, b) prior.
    """
    return (a + s) / (a + b + t)

def perpetuity_value(a, b, s, t, β=.75):
    """
    Compute perpetuity value (β/(1-β)) * μ_i(s,t).
    """
    return (β / (1 - β)) * posterior_mean(a, b, s, t)

def price_learning_two_agents(prior1, prior2, β=.75, T=200):
    """
    Compute \tilde p(s,t) for two Beta-prior traders via backward induction.
    """
    a1, b1 = prior1
    a2, b2 = prior2
    price_array = np.zeros((T+1, T+1))
```

(continues on next page)

(continued from previous page)

```
    # Terminal condition: set to perpetuity value under max belief
    for s in range(T+1):
        perp1 = perpetuity_value(a1, b1, s, T, β)
        perp2 = perpetuity_value(a2, b2, s, T, β)
        price_array[s, T] = max(perp1, perp2)

    # Backward induction
    for t in range(T-1, -1, -1):
        for s in range(t, -1, -1):
            μ1 = posterior_mean(a1, b1, s, t)
            μ2 = posterior_mean(a2, b2, s, t)

            # One-step continuation values under each trader's beliefs
            cont1 = μ1 * (1.0 + price_array[s+1, t+1]) \
                    + (1.0 - μ1) * price_array[s, t+1]
            cont2 = μ2 * (1.0 + price_array[s+1, t+1]) \
                    + (1.0 - μ2) * price_array[s, t+1]
            price_array[s, t] = β * max(cont1, cont2)

    def μ1_fun(s, t):
        return posterior_mean(a1, b1, s, t)
    def μ2_fun(s, t):
        return posterior_mean(a2, b2, s, t)

    return price_array, μ1_fun, μ2_fun
```

137.7.2 Case A: global optimist (no premium)

Pick priors with rate dominance, e.g., trader 1: Beta$(a_1, b_1) = (2, 1)$ and trader 2: $(a_2, b_2) = (1, 2)$.

Trader 1 is the global optimist, so the normalized price equals trader 1's fundamental valuation: $p(s, t, r) = \mu_1(s, t)$.

```
β = 0.75
price_go, μ1_go, μ2_go = price_learning_two_agents(
        (2,1), (1,2), β=β, T=200)

perpetuity_1 = (β / (1 - β)) * μ1_go(0, 0)
perpetuity_2 = (β / (1 - β)) * μ2_go(0, 0)

print("Price at (0, 0) =", price_go[0,0])
print("Valuation of trader 1 at (0, 0) =", perpetuity_1)
print("Valuation of trader 2 at (0, 0) =", perpetuity_2)
```

```
Price at (0, 0) = 2.0
Valuation of trader 1 at (0, 0) = 2.0
Valuation of trader 2 at (0, 0) = 1.0
```

The price equals trader 1's perpetuity value.

137.7.3 Case B: perpetual switching (positive premium)

Now assume trader 1 has Beta$(1, 1)$, trader 2 has Beta$(1/2, 1/2)$.

These produce crossing posteriors, so there is no global optimist and the price exceeds both fundamentals early on.

```
price_ps, μ1_ps, μ2_ps = price_learning_two_agents(
                                (1,1), (0.5,0.5), β=β, T=200)

price_00 = price_ps[0,0]
μ1_00 = μ1_ps(0,0)
μ2_00 = μ2_ps(0,0)

perpetuity_1 = (β / (1 - β)) * μ1_ps(0, 0)
perpetuity_2 = (β / (1 - β)) * μ2_ps(0, 0)

print("Price at (0, 0) =", np.round(price_00, 6))
print("Valuation of trader 1 at (0, 0) =", perpetuity_1)
print("Valuation of trader 2 at (0, 0) =", perpetuity_2)
```

```
Price at (0, 0) = 1.599322
Valuation of trader 1 at (0, 0) = 1.5
Valuation of trader 2 at (0, 0) = 1.5
```

The resulting premium reflects the option value of reselling to whichever trader becomes temporarily more optimistic as dividends arrive sequentially.

Within this setting, we can reproduce two key figures reported in Morris [1996]

```
def normalized_price_two_agents(prior1, prior2, r, T=250):
    """Return p(s,t,r) = r \tilde p(s,t,r) for two traders."""
    β = 1.0 / (1.0 + r)
    price_array, *_ = price_learning_two_agents(prior1, prior2, β=β, T=T)
    return r * price_array

# Figure I: p*(0,0,r) as a function of r
r_grid = np.linspace(1e-3, 5.0, 200)
priors = ((1,1), (0.5,0.5))
p00 = np.array([normalized_price_two_agents(
                priors[0], priors[1], r, T=300)[0,0]
                for r in r_grid])

fig, ax = plt.subplots()
ax.plot(r_grid, p00, lw=2)
ax.set_xlabel(r'$r$')
ax.set_ylabel(r'$p^*(0,0,r)$')
ax.axhline(0.5, color='C1', linestyle='--')
plt.show()
```

In the first figure, notice that:

- The resale option pushes the normalized price $p^*(0, 0, r)$ above fundamentals (0.5) for any finite r.
- As r increases (β decreases), the option value fades and $p^*(0, 0, r) \to 0.5$.
- At $r = 0.05$ the premium is about 8–9%, consistent with Morris (1996, Section IV).

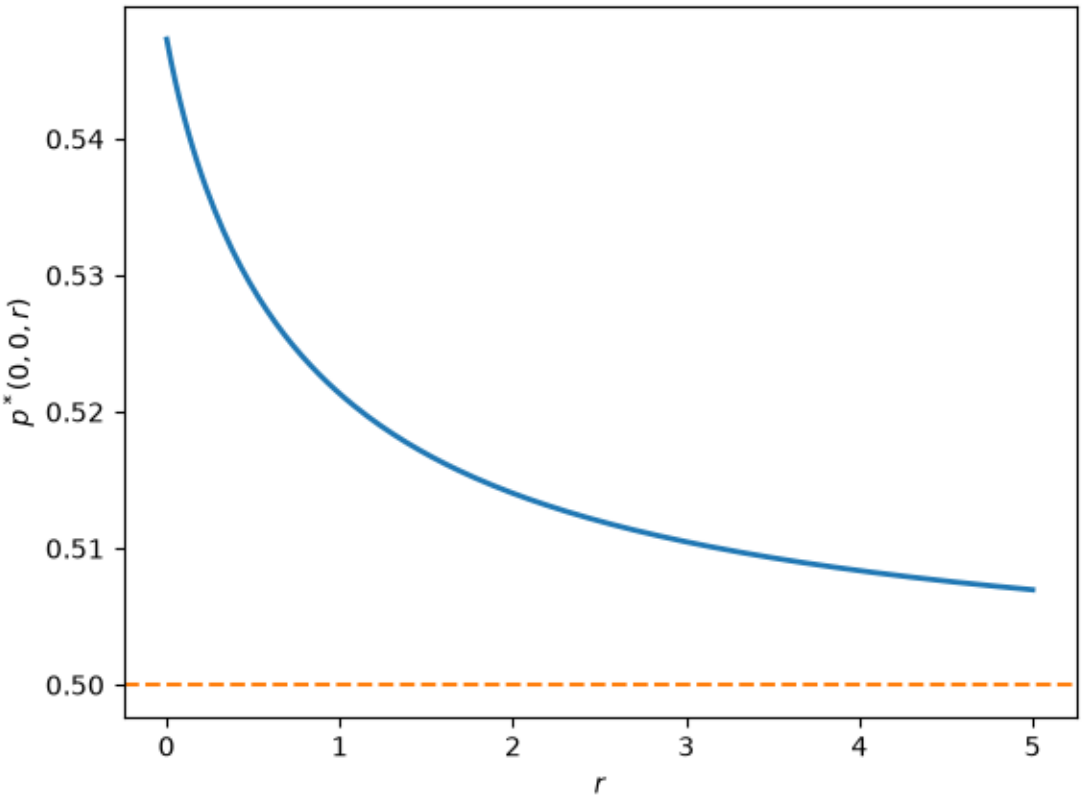

Fig. 137.1: Normalized price against interest rate

```
# Figure II: p*(t/2,t,0.05) as a function of t
r = 0.05
T = 60
p_mat = normalized_price_two_agents(priors[0], priors[1], r, T=T)
t_vals = np.arange(0, 54, 2)
s_vals = t_vals // 2
y = np.array([p_mat[s, t] for s, t in zip(s_vals, t_vals)])

fig, ax = plt.subplots()
ax.plot(t_vals, y, lw=2)
ax.set_xlabel(r'$t$')
ax.set_ylabel(r'$p^*(t/2,t,0.05)$')
ax.axhline(0.5, color='C1', linestyle='--')
plt.show()

p0 = p_mat[0,0]
μ0 = 0.5
print("Initial normalized premium at r=0.05 (%):",
      np.round(100 * (p0 / μ0 - 1.0), 2))
```

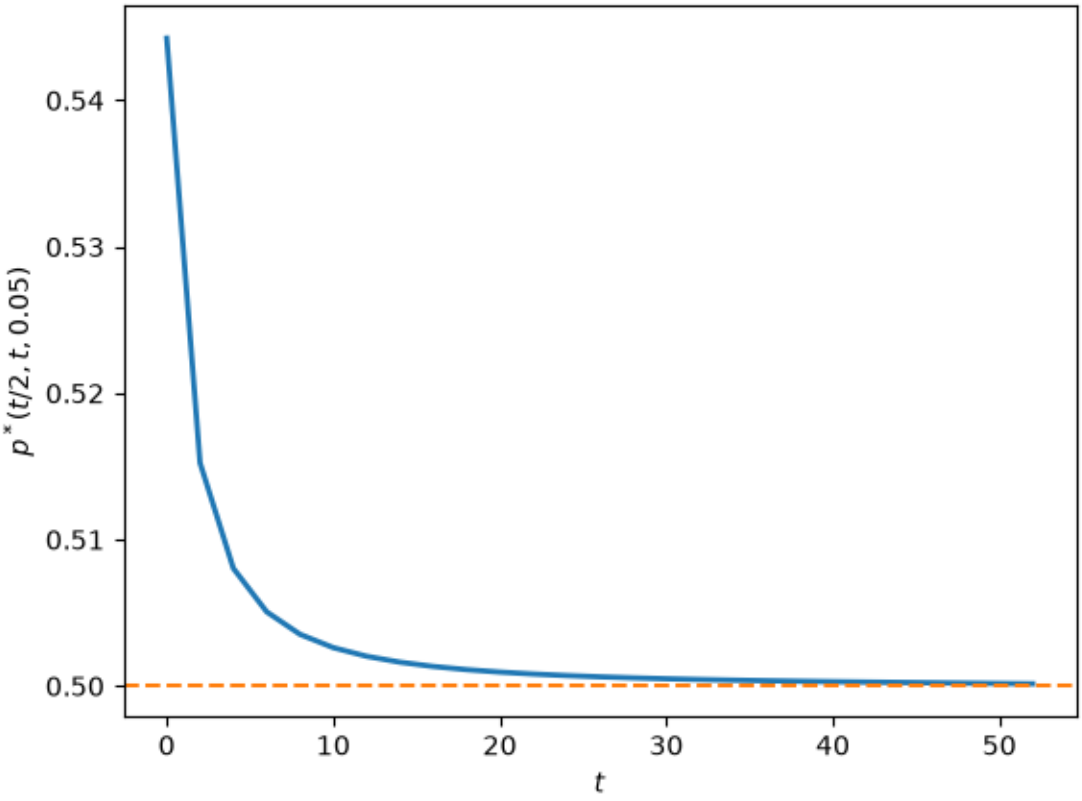

Fig. 137.2: Normalized price against time

```
Initial normalized premium at r=0.05 (%): 8.85
```

In the second figure, notice that:

- Along the symmetric path $s = t/2$, both traders' fundamental valuations equal 0.5 at every t, yet the price starts above 0.5 and declines toward 0.5 as learning reduces disagreement and the resale option loses value.

137.7.4 General N-trader extension

The same recursion extends to any finite set of Beta priors $\{(a_i, b_i)\}_{i=1}^N$ by taking a max over i each period.

```
def price_learning(priors, β=0.75, T=200):
    """
    N-trader version with heterogeneous Beta priors.
    """
    price_array = np.zeros((T+1, T+1))

    def perp_i(i, s, t):
        a, b = priors[i]
        return perpetuity_value(a, b, s, t, β)

    # Terminal condition
    for s in range(T+1):
        price_array[s, T] = max(
            perp_i(i, s, T) for i in range(len(priors)))

    # Backward induction
    for t in range(T-1, -1, -1):
        for s in range(t, -1, -1):
            conts = []
            for (a, b) in priors:
                μ = posterior_mean(a, b, s, t)
                conts.append(μ *
                (1.0 + price_array[s+1, t+1])
                     + (1.0 - μ) * price_array[s, t+1])
            price_array[s, t] = β * max(conts)

    return price_array

β = 0.75
priors = [(1,1), (0.5,0.5), (3,2)]
price_N = price_learning(priors, β=β, T=150)

# Compute valuations for each trader at (0,0)
μ_vals = [posterior_mean(a, b, 0, 0) for a, b in priors]
perp_vals = [(β / (1 - β)) * μ for μ in μ_vals]

print("Three-trader example at (s,t)=(0,0):")
print(f"Price at (0,0) = {np.round(price_N[0,0], 6)}")
print(f"\nTrader valuations:")
for i, (μ, perp) in enumerate(zip(μ_vals, perp_vals), 1):
    print(f"  Trader {i} = {np.round(perp, 6)}")
```

```
Three-trader example at (s,t)=(0,0):
Price at (0,0) = 1.937972

Trader valuations:
  Trader 1 = 1.5
  Trader 2 = 1.5
  Trader 3 = 1.8
```

Note that the asset price is above all traders' valuations.

Morris tells us that no rate dominance exists in this case.

Let's verify this using the code below

```
dominant = None
for i in range(len(priors)):
    is_dom = all(
        priors[i][0] >= priors[j][0] and priors[i][1] <= priors[j][1]
                for j in range(len(priors)) if i != j)
    if is_dom:
        dominant = i
        break

if dominant is not None:
    print(f"\nTrader {dominant+1} is the global optimist (rate-dominant)")
else:
    print(f"\nNo global optimist and speculative premium exists")
```

```
No global optimist and speculative premium exists
```

Indeed, there is no global optimist and a speculative premium exists.

137.8 Concluding remarks

Morris [1996] uses his model to interpret a "hot issue" anomaly described by [Miller, 1977] according to which opening market prices of initial public offerings seem higher than values prices that emerge later.

137.9 Exercise

Exercise 137.9.1

Morris [Morris, 1996] provides a sharp characterization of when speculative bubbles arise.

The key condition is that there is no *global optimist*.

In this exercise, you will verify this condition for the following sets of traders with Beta priors:

1. Trader 1: Beta$(2,1)$, Trader 2: Beta$(1,2)$
2. Trader 1: Beta$(1,1)$, Trader 2: Beta$(1/2,1/2)$
3. Trader 1: Beta$(3,1)$, Trader 2: Beta$(2,1)$, Trader 3: Beta$(1,2)$
4. Trader 1: Beta$(1,1)$, Trader 2: Beta$(1/2,1/2)$, Trader 3: Beta$(3/2,3/2)$

Solution

Here is one solution:

```
def check_rate_dominance(priors):
    """
    Check if any trader rate-dominates all others.
    """
    N = len(priors)

    for i in range(N):
        a_i, b_i = priors[i]
```

```
        is_dominant = True

        for j in range(N):
            if i == j:
                continue
            a_j, b_j = priors[j]

            # Check rate dominance condition
            if not (a_i >= a_j and b_i <= b_j):
                is_dominant = False
                break

        if is_dominant:
            return i

    return None

# Test cases
test_cases = [
    ([(2, 1), (1, 2)], "Global optimist exists"),
    ([(1, 1), (0.5, 0.5)], "Perpetual switching"),
    ([(3, 1), (2, 1), (1, 2)], "Three traders with dominant"),
    ([(1, 1), (0.5, 0.5), (1.5, 1.5)], "Three traders, no dominant")
]

for priors, description in test_cases:
    dominant = check_rate_dominance(priors)

    print(f"\n{description}")
    print(f"Priors: {priors}")
    print("=="*8)
    if dominant is not None:
        print(f"Trader {dominant+1} is the global optimist (rate-dominant)")
    else:
        print(f"No global optimist exists")
    print("=="*8 + "\n")
```

138.1 Overview

This lecture explores an important question in economic theory: what can agents learn inside a rational expectations equilibrium?

This question is related to, but distinct from, the adaptive-learning question of whether a rational expectations equilibrium can be justified as a dynamic attractor.

The starting point is Bray and Kreps [1987], which gives a rigorous model of Bayesian learning inside a rational expectations equilibrium.

In a rational expectations equilibrium, agents use market prices to make inferences about other agents' private information.

Each agent knows the *statistical relationship* between prices and the underlying payoff-relevant variables and that relationship is *correct* given the equilibrium.

But this raises a question: where does that knowledge come from?

Their **rational learning** approach answers a narrower question.

Agents are uncertain about structural parameters, and the state space is enlarged to include, for each candidate value, the associated equilibrium price and allocation maps.

Agents then use Bayes' rule to update over those possibilities as prices and returns are observed.

This lecture develops that Bayesian formulation through an asset-market model.

The aim is to see what rational learning can explain, and where its limits appear, before turning to the computational illustration.

The discussion also connects to earlier work by Bray [1982], Bray and Savin [1986], and the rational expectations literature of Radner [1979], Grossman [1976], and Jordan [1982].

Let's start with the following imports

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.optimize import brentq
```

138.2 The economy

The model is a simple asset market built around the recurring information model of Grossman and Stiglitz [1980], repeated across infinitely many dates.

138.2.1 Agents and assets

Each date is economically disconnected from the others, so agents start each period afresh.

There are two types of agents and two assets:

- A **safe asset** with net return normalized to zero.
- A **risky asset** endowed one unit per agent and traded at date t at spot price p_t.

At each date $t = 0, 1, 2, \ldots$ the risky asset yields a gross return r_t at date $t + 1/2$.

An informed signal s_t satisfies

$$r_t = s_t + \epsilon_t, \qquad s_t \sim N(\mu_s, \tau^2), \qquad \epsilon_t \sim N(0, \sigma^2),$$

where $\{s_t\}$ and $\{\epsilon_t\}$ are IID normal sequences and are mutually independent.

Common knowledge of the prior moments (μ_s, τ^2) is what makes the price observation informative about θ^I, as we will see.

There are two representative agents:

- **Agent I (informed)** observes s_t before trading at date t.
- **Agent U (uninformed)** observes the equilibrium price p_t but not s_t before trading.

Both agents observe the previous return before current trading.

138.2.2 Preferences

Agent $n \in \{I, U\}$ has constant absolute risk tolerance θ^n.

If agent n holds x^n units of the risky asset and y^n units of the safe asset between dates t and $t + 1/2$, period utility is

$$-\exp\left[-\frac{x^n r_t + y^n}{\theta^n}\right].$$

Thus $1/\theta^n$ is the coefficient of absolute risk aversion.

Given the signal s_t, the informed agent's demand is

$$x_t^I = \frac{\theta^I}{\sigma^2}(s_t - p_t). \tag{138.1}$$

Because each of the two agents is endowed with one unit of the risky asset, market clearing is

$$x_t^I + x_t^U = 2.$$

138.2.3 Rational expectations equilibrium

If all agents knew s_t, agent n would demand

$$x_t^n = \frac{\theta^n}{\sigma^2}(s_t - p_t).$$

With N agents and total risky-asset supply N, market clearing gives the **full communication equilibrium price**

$$p_t = s_t - \frac{N\sigma^2}{\sum_{n=1}^N \theta^n}. \tag{138.2}$$

Thus if $\sum_n \theta^n$ is known, the price fully reveals s_t.

Following Radner [1979], this is called a full communication rational expectations equilibrium.

Suppose now that θ^I is unknown to agent U.

Following Bray and Kreps [1987], we treat this uncertainty by *expanding the state space*: we let the unknown parameter θ^I become a coordinate of the state, alongside the per-period shocks (s_t, ϵ_t).

Formally, the state space is $\Omega = \Theta \times \Phi^\infty$, where $\Theta = [a, b]$ supports the unknown θ^I and Φ supports each (s_t, ϵ_t).

Agent U knows σ^2 and θ^U, and starts with a prior density over θ^I on $[a, b]$.

This expansion is what turns the learning problem into Bayesian inference inside a single rational expectations equilibrium on Ω.

At a date when agent U has posterior density f over θ^I, his own trade reveals $x_t^I = 2 - x_t^U$ through market clearing.

Combining this inferred x_t^I with (138.1), each candidate θ^I implies

$$s_t = p_t + \frac{\sigma^2 x_t^I}{\theta^I}. \tag{138.3}$$

After trading, agent U observes r_t.

Bayes' rule then updates the posterior over θ^I using the normal density of the signal implied by (138.3) conditional on the realized return.

This is the main object learned in the two-agent example.

Even in this simple case, the equilibrium can be defined recursively but closed-form prices are unavailable.

138.3 The rational learning equilibrium

The model has two pieces that interact at each date.

The first is the within-period equilibrium given the uninformed agent's current posterior on θ^I.

The second is the Bayesian update of that posterior after the period closes.

138.3.1 Uninformed demand given beliefs

Suppose at date t agent U has posterior density f_t on θ^I, supported on $[a, b]$.

Suppose the equilibrium price is p and the equilibrium informed trade $X^I = 2 - x^U$ has been inferred from market clearing.

Conditional on θ, equation (138.3) pins down the signal as $s_t(\theta) = \sigma^2 X^I/\theta + p$.

Two sources of information about θ are therefore present at the start of date t trading: the carried-over posterior $f_t(\theta)$ and the Gaussian prior $\phi_s(\cdot; \mu_s, \tau^2)$ on s_t that values some implied signals as more plausible than others.

Bayes' rule combines them into the *intra-period* posterior

$$f_t^{(p,X^I)}(\theta) \propto f_t(\theta)\, \phi_s\left(\frac{\sigma^2 X^I}{\theta} + p\,;\, \mu_s, \tau^2\right), \tag{138.4}$$

which is the posterior on θ^I that the agent actually uses to forecast r_t before r_t is observed.

Conditional on a candidate value θ, the excess payoff on one unit of the risky asset is

$$r_t - p = \frac{\sigma^2 X^I}{\theta} + \epsilon_t, \qquad \epsilon_t \sim N(0, \sigma^2).$$

Because CARA preferences have no wealth effects, agent U's problem reduces to

$$\max_{x^U} \mathbb{E}[u^U(x^U, r_t, p)], \qquad u^U(x^U, r_t, p) = -\exp\left(-\frac{x^U(r_t - p)}{\theta^U}\right),$$

where the expectation integrates over $\theta^I \sim f_t^{(p,X^I)}$ and ϵ_t.

Substituting the conditional excess payoff and using the normal moment-generating formula gives

$$\mathbb{E}[u^U] = -\exp\left(\frac{(x^U)^2\sigma^2}{2(\theta^U)^2}\right) \int_a^b f_t(\theta)\, \phi_s\left(\tfrac{\sigma^2 X^I}{\theta} + p; \mu_s, \tau^2\right) \exp\left(-\tfrac{x^U \sigma^2 X^I}{\theta\, \theta^U}\right) d\theta,$$

up to a θ-independent constant absorbed in normalisation.

Define the tilted weight

$$w(\theta;\, p, X^I, x^U) = f_t(\theta)\, \phi_s\left(\tfrac{\sigma^2 X^I}{\theta} + p; \mu_s, \tau^2\right) \exp\left(-\tfrac{x^U \sigma^2 X^I}{\theta\, \theta^U}\right). \tag{138.5}$$

The first-order condition rearranges to

$$\frac{x^U}{\theta^U} = X^I\, \frac{\int_a^b \theta^{-1}\, w(\theta;\, p, X^I, x^U)\, d\theta}{\int_a^b w(\theta;\, p, X^I, x^U)\, d\theta}. \tag{138.6}$$

The right-hand side is X^I multiplied by a tilted expectation of $1/\theta^I$ under the weighting in (138.5).

Equation (138.6) implicitly defines $x^U(p, X^I; f_t)$, the uninformed agent's optimal demand at observed price p, conjectured informed trade X^I, and prior posterior f_t.

Dependence on p enters through the prior weight ϕ_s: at higher prices, candidate values of θ that imply s_t above the prior mean become less plausible, so the agent's demand schedule slopes downward in p as expected.

138.3.2 Market clearing

Equilibrium requires that the informed and uninformed demands sum to the total endowment.

Substituting (138.1) and the implicit function $x^U(p, X^I; f_t)$, the equilibrium (p_t, X_t^I) satisfies the two equations

$$X_t^I = \frac{\theta^I}{\sigma^2}(s_t - p_t), \qquad X_t^I + x^U(p_t, X_t^I; f_t) = 2. \tag{138.7}$$

Eliminating X_t^I between the two leaves a single root-finding problem for p_t.

Combining the two equations, the equilibrium price has the form

$$p_t = s_t - \frac{\sigma^2 X_t^I}{\theta^I}. \tag{138.8}$$

When f_t collapses to a point mass at the true θ^I, equation (138.6) simplifies to $x^U/\theta^U = X^I/\theta^I$, and market clearing gives the full-communication allocation

$$X_t^I = \frac{2\theta^I}{\theta^I + \theta^U}, \qquad x_t^U = \frac{2\theta^U}{\theta^I + \theta^U}. \tag{138.9}$$

This is the full-communication allocation we will use to check the simulation.

138.3.3 Bayesian update

After trading, agent U observes (p_t, x_t^U, r_t).

Market clearing gives $X_t^I = 2 - x_t^U$, and equation (138.3) assigns a candidate $s_t(\theta) = \sigma^2 X_t^I/\theta + p_t$ to each θ.

Since $s_t \sim N(\mu_s, \tau^2)$ independently of $\epsilon_t \sim N(0, \sigma^2)$, the conditional density of s_t given r_t is Gaussian:

$$g(s \mid r) = \phi\left(s;\, \frac{\sigma^2\mu_s + \tau^2 r}{\sigma^2 + \tau^2},\, \frac{\sigma^2\tau^2}{\sigma^2 + \tau^2}\right),$$

where $\phi(\cdot; m, v)$ denotes the Normal density with mean m and variance v.

Bayes' rule then produces the posterior update

$$f_{t+1}(\theta) \propto f_t(\theta)\; g\left(\frac{\sigma^2 X_t^I}{\theta} + p_t \,\middle|\, r_t\right). \tag{138.10}$$

This is the rule we simulate below.

138.4 Computing the equilibrium

We discretise the support $[a, b]$ of θ^I on a fine grid and represent f_t as a vector of density values.

The three computational primitives are:

- `uninformed_demand` solves the FOC in (138.6) for $x^U(p, X^I; f)$ by root-finding.
- `equilibrium_price` solves the market-clearing system (138.7) for p_t.
- `bayes_update` applies (138.10) and renormalises.

```
def uninformed_demand(p, XI, f, θ_grid, θ_U, σ2, μ_s, τ2):
    """
    Solve the FOC for x^U(p, X^I; f), the uninformed
    agent's optimal demand given observed price p, conjectured
    informed trade XI, and carried-over posterior density f.
    """
    with np.errstate(divide='ignore'):
        log_f = np.log(f)
    s_implied = σ2 * XI / θ_grid + p
    log_phi_s = -0.5 * (s_implied - μ_s)**2 / τ2  # prior weight on s_t

    def foc(xU):
        z = xU * σ2 * XI / (θ_grid * θ_U)
        log_w = log_f + log_phi_s - z
        M = log_w.max()
        w = np.exp(log_w - M)
        num = np.sum(w / θ_grid)
        den = np.sum(w)
        return xU / θ_U - XI * num / den

    return brentq(foc, -50.0, 50.0, xtol=1e-10)
```

```
def equilibrium_price(s_t, θ_I_true, f, θ_grid, θ_U, σ2, μ_s, τ2):
    """

    snapshots = {0: f.copy()}

    for t in range(T):
        p_t = equilibrium_price(
            s_seq[t], θ_I_true, f, θ_grid, θ_U, σ2, μ_s, τ2
        )
        XI = θ_I_true * (s_seq[t] - p_t) / σ2
        xU = 2.0 - XI
        r_t = s_seq[t] + eps_seq[t]
        f = bayes_update(f, θ_grid, p_t, xU, r_t, σ2, τ2, μ_s)

        XI_path[t] = XI
        p_path[t] = p_t
        r_path[t] = r_t
        post_mean[t + 1] = np.sum(θ_grid * f) * dθ
        post_var[t + 1] = np.sum(
            (θ_grid - post_mean[t + 1])**2 * f
        ) * dθ
        if (t + 1) in snap_times:
            snapshots[t + 1] = f.copy()

    return dict(
        θ_grid=θ_grid,
        snapshots=snapshots,
        XI_path=XI_path,
        p_path=p_path,
        r_path=r_path,
        post_mean=post_mean,
        post_var=post_var,
    )
```

138.5 Posterior concentration

We run the simulation with a uniform prior on $[0.5, 4]$ and true $\theta^I = 2$.

```
params = dict(
    θ_I_true=2.0,
    θ_U=1.0,
    σ2=1.0,
    μ_s=1.0,
    τ2=1.0,
    a=0.5,
    b=4.0,
    n_grid=300,
    T=200,
    seed=42,
)

res = simulate(**params)
```

The first picture shows snapshots of the posterior density at selected dates.

```
fig, ax = plt.subplots(figsize=(10, 5))
for t, ft in sorted(res['snapshots'].items()):
    ax.plot(res['θ_grid'], ft, lw=2, label=f't = {t}')
ax.axvline(params['θ_I_true'], color='black', ls='--', lw=1.5,
           label=r'$\theta^I_{\rm true}$')
ax.set_xlabel(r'$\theta^I$')
ax.set_ylabel('posterior density')
ax.legend()
plt.tight_layout()
plt.show()
```

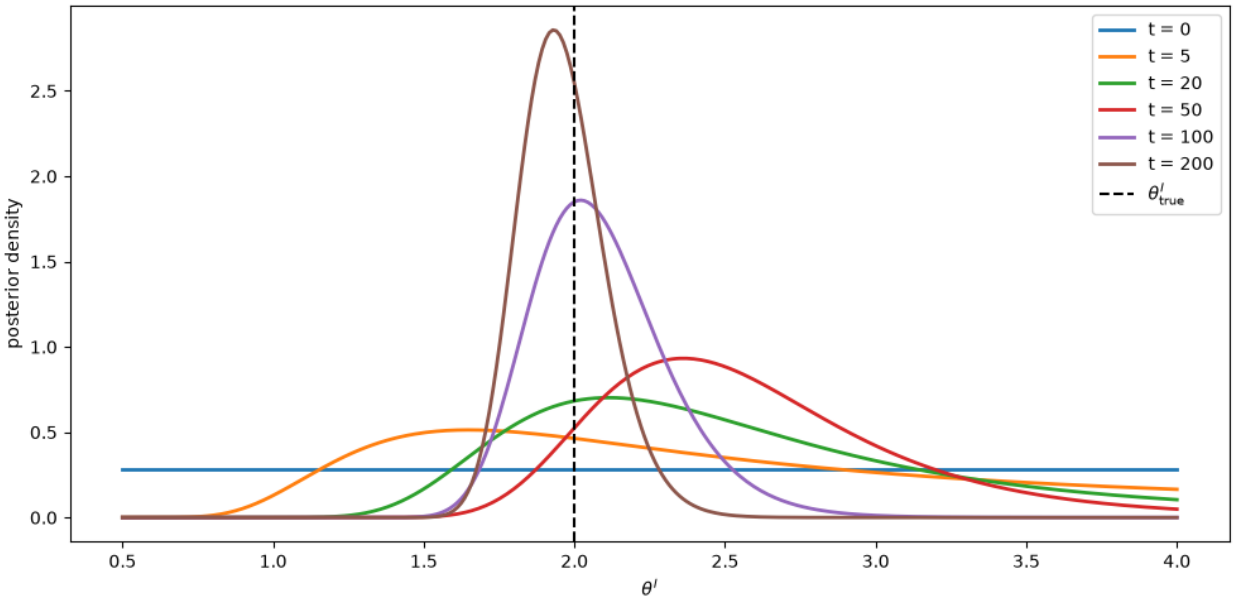

Fig. 138.1: posterior density over θ^I at selected dates

The posterior tightens around $\theta^I_{\text{true}} = 2$ as price and return data accumulate.

The next picture tracks the posterior mean and variance.

```
fig, axes = plt.subplots(1, 2, figsize=(13, 5))

ax = axes[0]
ax.plot(np.arange(params['T'] + 1), res['post_mean'], lw=2)
ax.axhline(params['θ_I_true'], color='red', ls='--', lw=2,
           label=r'$\theta^I_{\rm true}$')
ax.set_xlabel('$t$')
ax.set_ylabel(r'$E_t[\theta^I]$')
ax.legend()

ax = axes[1]
ax.plot(np.arange(params['T'] + 1), res['post_var'], lw=2)
ax.set_xlabel('$t$')
ax.set_ylabel(r'${\rm Var}_t[\theta^I]$')

plt.tight_layout()
plt.show()
```

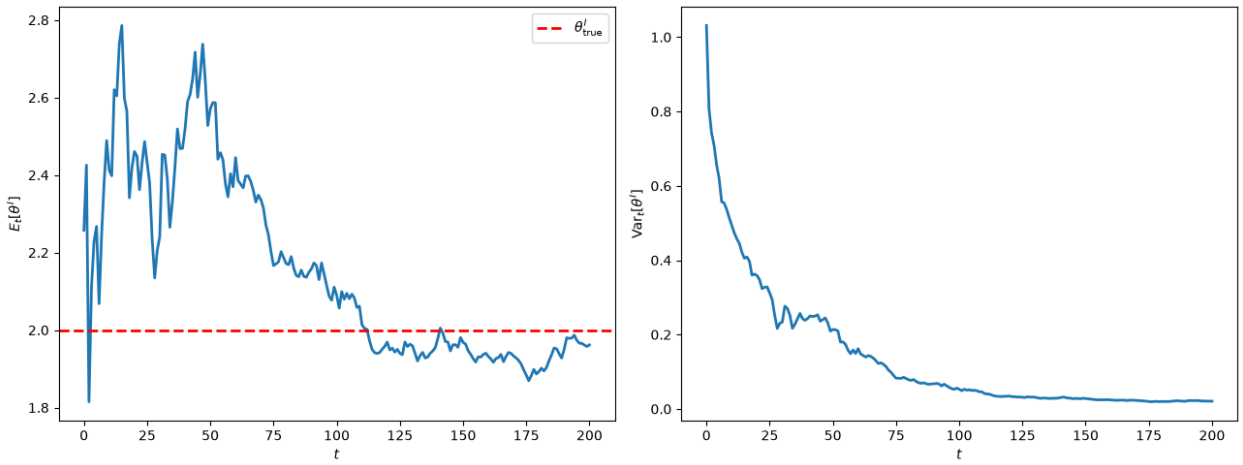

Fig. 138.2: posterior mean and variance over time

The posterior mean converges to the truth and the posterior variance vanishes.

This is the concrete manifestation of weak convergence of posteriors to a point mass at θ^I_{true}, which we describe in general terms below.

138.6 Equilibrium trades and prices

The equilibrium informed trade X_t^I depends on the current signal s_t, on θ_{true}^I, and on the carried-over posterior f_t, all through the market-clearing system (138.7).

As f_t tightens around θ_{true}^I, the average X_t^I approaches the full-communication allocation in (138.9).

```
XI_full = 2 * params['θ_I_true'] / (params['θ_I_true'] + params['θ_U'])
p_mean_full = params['μ_s'] - params['σ2'] * XI_full / params['θ_I_true']

fig, axes = plt.subplots(1, 2, figsize=(13, 5))

ax = axes[0]
ax.plot(res['XI_path'], lw=2, label='$X^I_t$ (learning)')
ax.axhline(XI_full, color='red', ls='--', lw=2,
           label='$X^I$ (full info)')
ax.set_xlabel('$t$')
ax.set_ylabel('$X^I_t$')
ax.legend()

ax = axes[1]
ax.plot(res['p_path'], lw=1.5, alpha=0.7, label='$p_t$ (learning)')
ax.axhline(p_mean_full, color='red', ls='--', lw=2,
           label='$E[p_t]$ (full info)')
ax.set_xlabel('$t$')
ax.set_ylabel('$p_t$')
ax.legend()

plt.tight_layout()
plt.show()
```

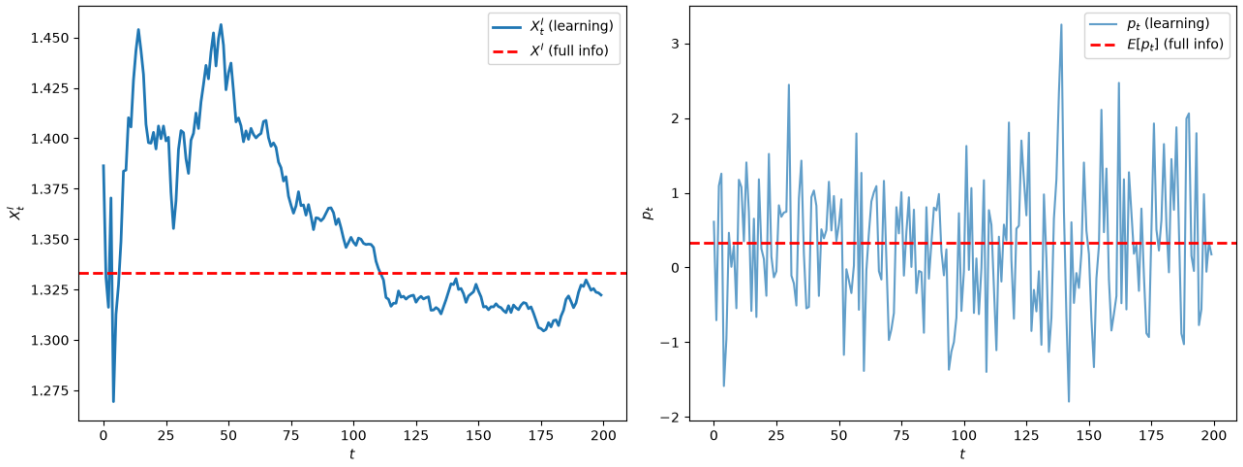

Fig. 138.3: equilibrium trade and prices over time

The left panel shows X_t^I approaching the full-information allocation as beliefs concentrate.

The right panel shows the price path, which fluctuates because p_t inherits the variation in s_t.

The simulation illustrates three features of this equilibrium.

The posterior density on θ^I concentrates around the true value, the posterior variance vanishes, and the equilibrium informed trade X_t^I converges to its full-information benchmark.

The next sections identify the theorems behind these outcomes and the assumptions they require.

We first state the two convergence results of Bray and Kreps [1987] for the abstract model, then specialize to the two-agent example to pin down the hypotheses that drive concentration on the true θ^I, and finally explain when those hypotheses can fail.

138.7 Convergence of posterior assessments

Let $(\Omega, \mathcal{F})$ be a measurable space carrying the equilibrium.

In the two-agent example, $\Omega = \Theta \times \Phi^\infty$, where $\Theta = [a, b] \times \{\theta^U\}$ collects the structural parameters, Φ collects the per-period shocks (s_t, ϵ_t), and $\mathcal{F}$ is the product Borel σ-field.

Agent n enters date 0 with a prior probability measure P^n on $(\Omega, \mathcal{F})$.

Let $G_t^n \subseteq \mathcal{F}$ denote the σ-field generated by agent n's private information through date t, and let

$$H_t^n(p) = G_t^n \vee \sigma(p_0, p_1, \dots, p_t)$$

be the σ-field that adds observation of equilibrium prices through date t.

The tail σ-field is

$$H_\infty^n(p) = \bigvee_{t \geq 0} H_t^n(p).$$

The first result, due to Bray and Kreps [1987], states that the conditional probability of any event converges almost surely.

Proposition 138.7.1

Fix an agent n and an event $A \in \mathcal{F}$.

The process $M_t = \mathbb{E}^n[\mathbf{1}_A \mid H_t^n(p)]$ is a P^n-bounded martingale with respect to $(H_t^n(p))_{t \geq 0}$, and

$$\lim_{t \to \infty} \mathbb{E}^n[\mathbf{1}_A \mid H_t^n(p)] = \mathbb{E}^n[\mathbf{1}_A \mid H_\infty^n(p)], \qquad P^n\text{-a.s.}$$

The proof is the bounded martingale convergence theorem, with $M_t \in [0, 1]$ supplying the uniform integrability needed for the limit identification.

Proposition 138.7.1 is convergence of posterior assessments, not convergence to "correct" beliefs.

Two qualifications are worth stating.

The "a.s." statement is relative to agent n's own prior P^n, so if two priors P^n and $P^{n'}$ are mutually singular, the conclusion need not hold simultaneously on a common P-positive event.

If the priors share a common null collection, simultaneous convergence holds outside a common null set.

The second result in Bray and Kreps [1987] sharpens convergence from individual events to the entire posterior measure on the parameter space, given a topological assumption on Θ.

Assumption 138.7.1

The parameter space Θ is a complete separable metric (Polish) space, and the Borel σ-field on Θ generated by its open sets makes $(\Theta, \mathcal{B}(\Theta))$ a Borel space.

In the two-agent example $\Theta = [a, b]$ trivially satisfies this assumption.

Under *Assumption 138.7.1* one can fix regular versions of the conditional probabilities: maps

$$P_t^n : \Omega \to \mathcal{P}(\Theta), \qquad \omega \mapsto P_t^n(\omega),$$

such that for each measurable $A \subseteq \Theta$, $\omega \mapsto P_t^n(\omega)(A)$ is a version of $\mathbb{E}^n[\mathbf{1}_{A \times \Phi^\infty} \mid H_t^n(p)](\omega)$, and $P_t^n(\omega) \in \mathcal{P}(\Theta)$ is a probability measure P^n-a.s.

The sharpened convergence result says these regular versions converge weakly almost surely.

Proposition 138.7.2

Under *Assumption 138.7.1*, the regular versions P_t^n converge weakly to a regular version P_∞^n, P^n-a.s.

Equivalently, for P^n-a.e. ω and every bounded continuous $f : \Theta \to \mathbb{R}$,

$$\int_\Theta f \, dP_t^n(\omega) \xrightarrow[t \to \infty]{} \int_\Theta f \, dP_\infty^n(\omega).$$

The proof in Bray and Kreps [1987] applies *Proposition 138.7.1* to a countable disjoint partition of Θ by $1/k$-balls, which exists because Θ is Polish, and then invokes the Portmanteau characterisation of weak convergence on bounded continuous functions.

Rational Bayesian learning therefore always produces a limiting posterior measure.

But *Proposition 138.7.2* alone does not pin down what that limit is, and additional structure is needed before the limit assesses the truth correctly.

138.8 Sharpening the convergence result

We now return to the two-agent example and identify hypotheses under which P_∞^U is a point mass at the true θ^I.

Write F_t for the CDF of agent U's posterior on θ^I at date t after observing $(r_{t-1}, p_{t-1}, x_{t-1}^U)$ and all earlier data.

Proposition 138.7.2 yields a random CDF F_∞ such that F_t converges weakly to F_∞, P^U-a.s.

Three ingredients sharpen this to concentration on the truth, corresponding to the three steps in Bray and Kreps [1987].

Assumption 138.8.1

The equilibrium uninformed demand $x^U(p, F)$ is continuous in F with respect to weak convergence, uniformly in p on a P^U-full-measure set of prices.

Assumption 138.8.2

For fixed θ^U and limiting posterior F_∞, the map

$$\theta^I \mapsto \mathcal{L}\{p_\infty(s; F_\infty, \theta^I, \theta^U)\}$$

is injective, where s is drawn from its marginal distribution.

A sufficient condition is strict stochastic monotonicity of this marginal price distribution in θ^I.

In the lecture's CARA-Normal setup, these assumptions are plausible under the maintained uniqueness and regularity of the implicit demand and price equations.

Continuity requires continuous dependence of the FOC root in (138.6) on F, not just pointwise continuity of the integrals.

Identification also uses the full equilibrium map: the equation $p_t = s_t - \sigma^2 X_t^I/\theta^I$ is informative, but X_t^I itself depends on θ^I, F_t, and the equilibrium fixed point.

The IID assumption on $\{s_t\}$, already part of the model, supplies the ergodicity used in step 2 below.

Under these three assumptions and the IID signal sequence, the limiting posterior in the two-agent example concentrates on the truth.

Proposition 138.8.1

Suppose $\theta^I_{\text{true}} \in [a, b]$ and the prior f_0 puts positive density in every neighbourhood of θ^I_{true}.

Under *Assumption 138.7.1*, *Assumption 138.8.1*, and *Assumption 138.8.2*, and given the IID signal sequence $\{s_t\}$, the limiting posterior on θ^I satisfies

$$F_\infty = \delta_{\theta^I_{\text{true}}} \qquad P^U\text{-a.s.}$$

The proof has three steps.

Step 1: price functional convergence.

Assumption 138.8.1 and the weak convergence $F_t \Rightarrow F_\infty$ from *Proposition 138.7.2* imply that equilibrium demands $x^U(p, F_t)$ converge to $x^U(p, F_\infty)$.

Combining with market clearing and the price equation (138.8) gives $p_t - p_\infty(s_t; F_\infty, \theta^I, \theta^U) \to 0$ on a P^U-full-measure set.

Step 2: the limit price distribution is observable.

Since the deviation $p_t - p_\infty(s_t; F_\infty, \theta^I, \theta^U) \to 0$ almost surely and $\{s_t\}$ is IID, the empirical distribution of observed prices has the same limit as the empirical distribution of the limiting price functional.

The latter equals the distribution of $p_\infty(s; F_\infty, \theta^I, \theta^U)$ for $s \sim N(\mu_s, \tau^2)$, and that limit is $H^U_\infty(p)$-measurable as a long-run frequency of an observable sequence.

Step 3: identification.

Assumption 138.8.2 makes the marginal distribution of p_∞ identify θ^I given (F_∞, θ^U).

Combined with step 2, this means θ^I is itself $H^U_\infty(p)$-measurable, so for any subinterval $[c, d] \subseteq [a, b]$ the limiting posterior satisfies $P^U_\infty(\theta^I \in [c, d]) = \mathbf{1}_{\{\theta^I_{\text{true}} \in [c,d]\}}$.

Combining steps 1, 2, and 3 yields $F_\infty = \delta_{\theta^I_{\text{true}}}$.

The numerical simulation above is consistent with this result.

The posterior density on θ^I collapses to a spike at $\theta^I_{\text{true}} = 2$, and the equilibrium informed trade X^I_t converges to the full-information value $2\theta^I_{\text{true}}/(\theta^I_{\text{true}} + \theta^U)$.

Hence, the path connecting *Proposition 138.7.1* (martingale convergence) to *Proposition 138.8.1* (concentration on the truth) depends on three model-specific ingredients: continuity, ergodicity, and identification.

138.9 Obstacles to convergence

It is natural to ask when these ingredients can fail, and what the consequences are for learning.

138.9.1 Obstacle 1: failure of continuity

If *Assumption 138.8.1* fails, step 1 of the proof breaks.

When the equilibrium price functional is discontinuous in F, small changes in beliefs can produce large changes in the information content of prices, and weak convergence of beliefs need not imply convergence of prices.

Bray and Kreps [1987] flag this as the most delicate step in their argument.

Continuity of $x^U(p, F)$ in F is plausible in this lecture's regular CARA-Normal case, but it also requires uniqueness of the FOC solution and continuous dependence of that solution on F.

Verifying the same property in richer market structures often requires non-trivial regularity arguments.

138.9.2 Obstacle 2: failure of identification

If *Assumption 138.8.2* fails, step 3 breaks even when steps 1 and 2 succeed.

Consider a variant with two informed agents and risk tolerances θ^{I1}, θ^{I2} both unknown to the uninformed agent.

With three agents each endowed with one unit of the risky asset, the full-communication formula (138.2) gives

$$p_t = s_t - \frac{3\sigma^2}{\theta^{I1} + \theta^{I2} + \theta^U},$$

which depends on $(\theta^{I1}, \theta^{I2})$ only through the sum $\theta^{I1} + \theta^{I2}$.

Proposition 138.7.2 still applies, but F_∞ is supported on the level set

$$\{(\theta_1, \theta_2) \in [a, b]^2 : \theta_1 + \theta_2 = \theta^{I1}_{\text{true}} + \theta^{I2}_{\text{true}}\},$$

not on the singleton $\{(\theta^{I1}_{\text{true}}, \theta^{I2}_{\text{true}})\}$.

Convergence occurs, but to a manifold of observationally equivalent parameter values rather than to the truth.

138.9.3 Obstacle 3: misspecification

A separate obstacle arises if the true pricing relation lies outside the agent's prior support.

Blume and Easley [1982] give a stylised version of this obstacle, and *Heterogeneous Beliefs and Financial Markets* develops the Blume-Easley heterogeneous-beliefs model in this lecture series.

Each agent entertains competing conditional likelihoods for other agents' information given his own information and the price.

An equilibrium can exist in which agents assign asymptotic probability one to an incorrect model that gives the observed events positive likelihood, while the true stable price relation receives zero posterior probability because that relation was absent from the prior model class.

In strict rational learning the prior already covers the truth: it is supported on Bayesian-consistent models in the expanded state space, and positive weight is placed on the true parameter.

Bayes' rule can only reweight that initial model class, so a pricing relation with zero prior probability stays at zero no matter what data accumulate.

138.10 Learning within versus learning about a rational expectations equilibrium

The framework above points to an important conceptual distinction in Bray and Kreps [1987].

138.10.1 The distinction

Learning *within* a rational expectations equilibrium is the topic of this lecture.

It is Bayesian inference inside a correctly specified model: *Assumption 138.7.1*, *Assumption 138.8.1*, and *Assumption 138.8.2* all hold, and the prior puts positive weight on the truth.

Agent U is uncertain about θ^I, but for every candidate value he already knows the equilibrium price and allocation maps.

The expanded-state-space formulation $\Omega = \Theta \times \Phi^\infty$ embeds a rational expectations equilibrium on the larger space, and inference reduces to conditional probability over Θ.

Learning *about* a rational expectations equilibrium is a fundamentally different exercise.

The agent does not begin with the equilibrium map embedded in his probability model.

Instead he must infer the price-state relation from data generated while his own beliefs and behavior co-evolve with the data.

138.10.2 The trade-off

The two notions sit on opposite sides of a precise trade-off.

A correctly-specified Bayesian learner enjoys the convergence guarantees in *Proposition 138.7.1* and *Proposition 138.7.2*, but only because the equilibrium has been built into the prior from date zero.

An adaptive learner who treats the price-state relation as something to be estimated can hope to discover it from data, but the estimator he uses cannot be derived from Bayes' rule applied to a correctly specified model.

Bayesian rational learning can update among equilibrium maps already included in the agent's prior, but it does not explain how agents come to obtain those maps in the first place.

The literature on learning *about* rational expectations equilibria, beginning with Bray [1982] and Bray and Savin [1986] and extended by Marcet and Sargent [1989], takes the second side of the trade-off and replaces Bayes' rule with **ordinary least squares** or related recursive estimators.

The companion lecture *Least Squares Learning in Self-Referential Models* develops this least-squares-learning framework in self-referential models and traces the resulting dynamics through the associated ordinary differential equation.

Those rules are computationally tractable and converge in important examples, but they are not the Bayesian update implied by the fully specified rational-learning equilibrium prior.

138.11 Summary

This lecture implemented the rational-learning equilibrium of Bray and Kreps [1987].

Posterior assessments converge by bounded martingale convergence (*Proposition 138.7.1*), and posterior measures converge weakly under a Polish-Borel assumption (*Proposition 138.7.2*).

Concentration on the truth additionally requires continuity (*Assumption 138.8.1*), ergodicity, and identification (*Assumption 138.8.2*); each obstacle above is a failure of one of these.

The simulation illustrates both conclusions: the posterior on θ^I collapses toward θ^I_{true} and the equilibrium informed trade approaches its full-information value.

Rational learning describes the limits of Bayesian inference *given* the equilibrium structure; adaptive learning, in *Least Squares Learning in Self-Referential Models*, describes how that structure can be learned in the first place.

138.12 Exercises

Exercise 138.12.1

Off-center prior

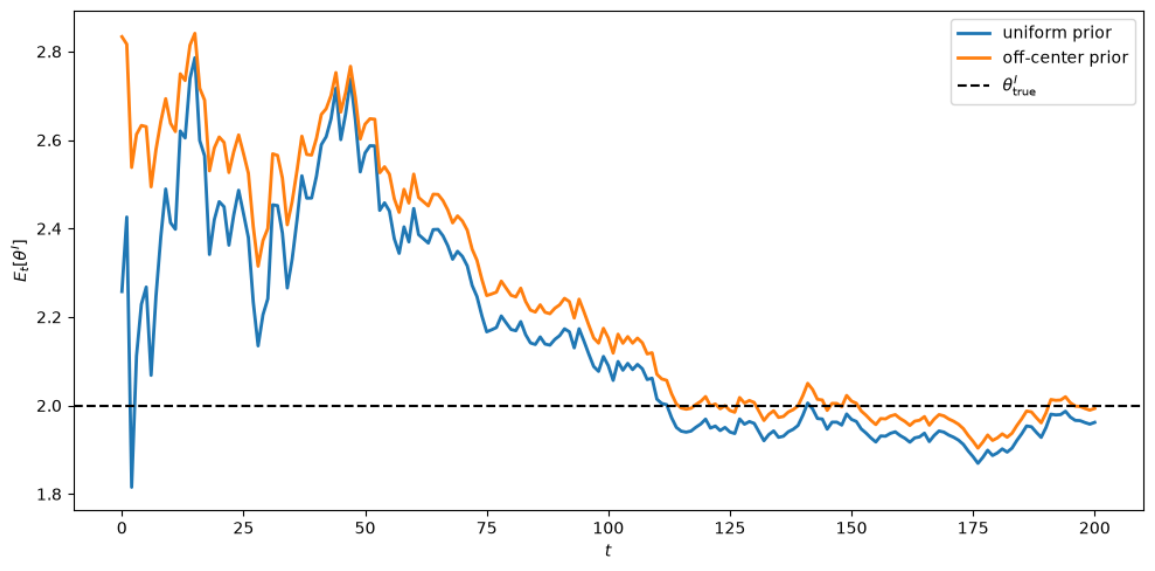
The baseline simulation uses a uniform prior on $\theta^I \in [0.5, 4]$.

1. Re-run the simulation with a prior whose mass sits *above* the true value, for example

```
prior = lambda θ: (θ - 0.5)**3 * (4 - θ)
```

which peaks near $\theta = 3.1$.

2. Plot the posterior mean over time alongside the uniform-prior baseline.
3. Does the posterior eventually concentrate on θ^I_{true}, and how does the speed compare?



Solution

Here is one solution:

```
res_uniform = simulate(**params)

params_biased = dict(params)
params_biased['prior'] = lambda θ: (θ - 0.5)**3 * (4 - θ)
res_biased = simulate(**params_biased)

fig, ax = plt.subplots(figsize=(10, 5))
ax.plot(res_uniform['post_mean'], lw=2, label='uniform prior')
ax.plot(res_biased['post_mean'], lw=2, label='off-center prior')
ax.axhline(params['θ_I_true'], color='black', ls='--',
           label=r'$\theta^I_{\rm true}$')
ax.set_xlabel('$t$')
ax.set_ylabel(r'$E_t[\theta^I]$')
ax.legend()
plt.tight_layout()
plt.show()
```

The off-center prior starts the posterior mean well above $\theta^I_{\text{true}} = 2$, but Bayesian updating drives it down to the truth.

This is the rational-learning convergence result in action: any prior that puts positive density on θ^I_{true} eventually concentrates around it.

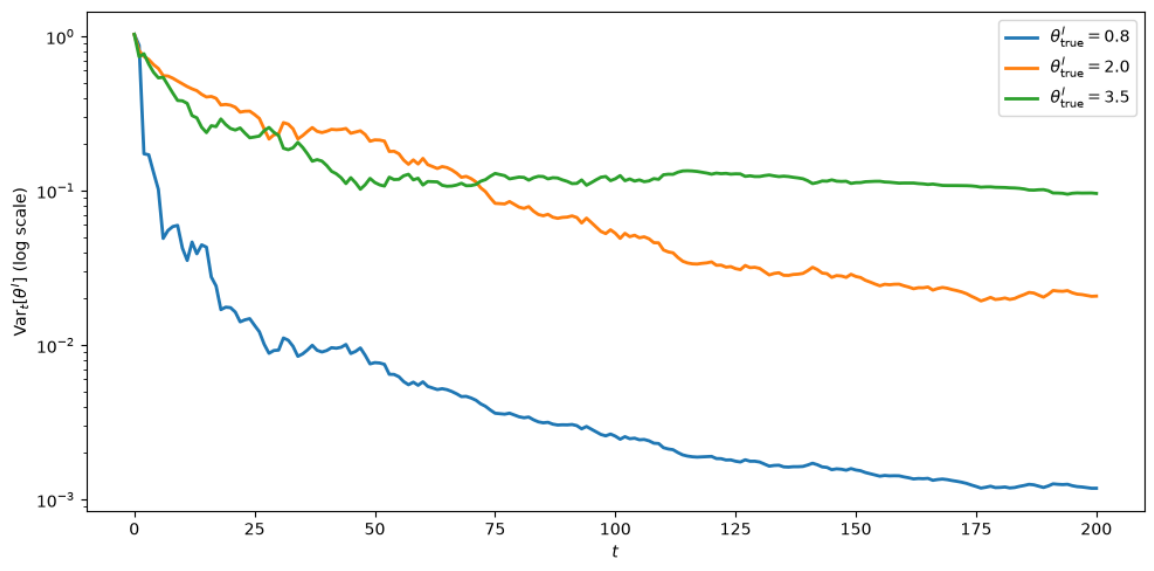
Exercise 138.12.2

Speed of learning across θ^I

Information from one period about θ^I comes through the implied signal

$$s_t(\theta) = \frac{\sigma^2 X_t^I}{\theta} + p_t.$$

The sensitivity $|\partial s_t / \partial \theta| = \sigma^2 X_t^I / \theta^2$ depends on the level of θ^I_{true} through X_t^I and θ^{-2}.



1. Run the simulation for $\theta^I_{\text{true}} \in \{0.8, 2.0, 3.5\}$, holding everything else at the baseline.
2. Plot the posterior variance on a log scale for each case.
3. Which value of θ^I_{true} yields the fastest concentration, and does the result match the sensitivity formula above?

Solution

Here is one solution:

```
fig, ax = plt.subplots(figsize=(10, 5))
for θ_val in [0.8, 2.0, 3.5]:
    params_θ = dict(params)
    params_θ['θ_I_true'] = θ_val
    res_θ = simulate(**params_θ)
    ax.semilogy(res_θ['post_var'], lw=2,
                label=fr'$\theta^I_{{\rm true}} = {θ_val}$')
ax.set_xlabel('$t$')
ax.set_ylabel(r'${\rm Var}_t[\theta^I]$ (log scale)')
ax.legend()
```

```
plt.tight_layout()
plt.show()
```

The smallest θ^I_{true} produces the steepest decline in posterior variance.

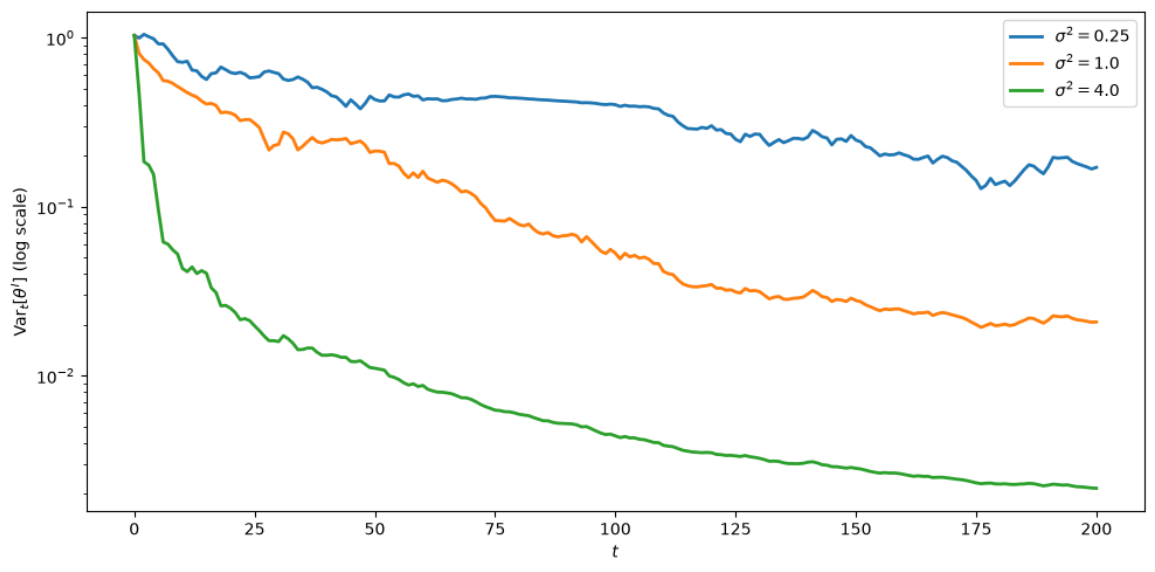
The reason is that the sensitivity $\sigma^2 X_t^I / \theta^2$ scales as θ^{-2} for fixed X_t^I, so the same noise level conveys much more information about θ^I when θ^I is small.

Exercise 138.12.3

Effect of return noise

Larger σ^2 widens the conditional density of s_t given r_t, which one might guess slows learning.

But σ^2 also scales the price intercept in (138.8), so price dispersion across candidate θ grows with σ^2.



1. Run the simulation with $\sigma^2 \in \{0.25, 1.0, 4.0\}$, keeping $\tau^2 = 1$ fixed.
2. Plot the posterior variance on a log scale for each σ^2.
3. Explain which effect dominates in terms of the signal-to-noise ratio for inferring θ^I from the price.

Solution

Here is one solution:

```
fig, ax = plt.subplots(figsize=(10, 5))
for σ2_val in [0.25, 1.0, 4.0]:
    params_σ = dict(params)
    params_σ['σ2'] = σ2_val
    res_σ = simulate(**params_σ)
    ax.semilogy(res_σ['post_var'], lw=2,
                label=fr'$\sigma^2 = {σ2_val}$')
ax.set_xlabel('$t$')
ax.set_ylabel(r'${\rm Var}_t[\theta^I]$ (log scale)')
ax.legend()
plt.tight_layout()
```

```
plt.show()
```

The posterior variance falls *faster* for larger σ^2.

To see why, write $\nu = \sigma^2$ and hold the realized trade X_t^I fixed.

Two nearby values of θ imply signals separated by approximately

$$\left| \frac{\partial s_t(\theta)}{\partial \theta} \right| = \frac{\nu |X_t^I|}{\theta^2}.$$

The likelihood compares these implied signals using $g(s \mid r_t)$, whose conditional variance is

$$\mathrm{Var}(s_t \mid r_t) = \frac{\nu \tau^2}{\nu + \tau^2}.$$

Thus the local signal-to-noise ratio for distinguishing nearby θ values is proportional to

$$\frac{\nu |X_t^I| / \theta^2}{\sqrt{\nu \tau^2 / (\nu + \tau^2)}} = \frac{|X_t^I|}{\theta^2} \sqrt{\frac{\nu(\nu + \tau^2)}{\tau^2}},$$

This ratio rises with ν when τ^2 is fixed.

The price-revelation effect therefore dominates the extra return noise in this experiment.

139.1 Overview

This lecture is a companion to *Rational Learning and Rational Expectations*, which presents the Bray-Kreps perspective on rational learning.

We examine the related but distinct question of whether *least squares* learning converges to a rational expectations equilibrium in self-referential models.

We present the framework of Marcet and Sargent [1989] for studying **least squares learning** in a class of **self-referential** linear stochastic models.

A self-referential model is one where the *actual* law of motion for the economy depends on the *perceived* law of motion of agents within it.

In a rational expectations equilibrium (REE) the two coincide: the perceived and actual laws of motion are the same.

But if agents start away from equilibrium and update their beliefs by running least squares regressions, will they converge to the REE?

Marcet and Sargent [1989] answer this question by using a powerful technique from systems-control engineering: the differential equation approach of Ljung [1977].

The key insight is that the stochastic difference equation of belief evolution can be approximated by a deterministic ordinary differential equation (ODE) in the limit.

Almost-sure convergence can be studied through the stability of that ODE.

Local stability of the small ODE is closely related to local convergence, while global almost-sure convergence also requires boundedness and domain-of-attraction conditions.

The framework unifies and extends earlier work by Bray [1982] and Bray and Savin [1986] and connects naturally to the distinction between learning *within* a rational expectations equilibrium (Bayesian updating inside a correctly specified model) and learning *about* one (adapting an OLS estimator whose data-generating process shifts with beliefs) discussed in Bray and Kreps [1987].

Let's begin with the imports we'll use throughout.

```
import numpy as np
import matplotlib.pyplot as plt
from numpy import linalg as la
from scipy.integrate import solve_ivp
from scipy.optimize import fsolve
```

Before simulating anything, we describe the object being learned.

139.2 The self-referential structure

139.2.1 Perceived and actual laws of motion

At each date t, agents hold a **perceived law of motion** summarized by a parameter matrix β_t.

They believe that the variable z_{1t} they care about evolves according to

$$z_{1t} = \beta_t z_{2,t-1} + \eta_t, \tag{139.1}$$

where z_{2t} is a vector of variables agents use to forecast $z_{1,t+1}$, and η_t is orthogonal to all past z_2's.

Because agents optimize (or behave) on the basis of this belief, their actions feed back into the economy.

To write the actual law of motion for the full state vector $z_t = (z_{1t}, z_{1t}^c)^\top$, partition $A(\beta_t)$ conformably with $(z_{2,t-1}^c, z_{2,t-1})$ as $A(\beta_t) = [A_c(\beta_t)\ A_2(\beta_t)]$.

$$z_t = \begin{bmatrix} 0 & T(\beta_t) \\ A_c(\beta_t) & A_2(\beta_t) \end{bmatrix} \begin{bmatrix} z_{2,t-1}^c \\ z_{2,t-1} \end{bmatrix} + \begin{bmatrix} V(\beta_t) \\ B(\beta_t) \end{bmatrix} u_t, \tag{139.2}$$

where u_t is IID white noise with covariance Σ.

The mapping T is the key object, as it maps the *perceived* coefficient β to the coefficient that *actually* governs z_{1t} in equilibrium.

A **rational expectations equilibrium** is a fixed point $\beta_f = T(\beta_f)$.

139.2.2 The learning scheme

Agents update β_t each period using **recursive least squares** (RLS).

Define R_t as a running estimate of the second-moment matrix $Ez_{2t}z_{2t}^\top$.

Updating equations are

$$\beta_t^\top = \beta_{t-1}^\top + \frac{\alpha_t}{t} R_{t-1}^{-1} \left\{ z_{2,t-2} z_{2,t-2}^\top [T(\beta_{t-1}) - \beta_{t-1}]^\top + z_{2,t-2} u_{t-1}^\top V(\beta_{t-1})^\top \right\}, \tag{139.3}$$

$$R_t = R_{t-1} + \frac{\alpha_t}{t} [z_{2,t-1} z_{2,t-1}^\top - R_{t-1}/\alpha_t], \tag{139.4}$$

where $\{\alpha_t\}$ is a positive, non-decreasing sequence with $\alpha_t \to 1$ as $t \to \infty$.

When $\alpha_t = 1$ for all t, equations (139.3)-(139.4) reduce to **ordinary least squares** updated recursively.

139.2.3 Lagged and contemporaneous data

The recursion above is written with *lagged information*, so the estimate β_t uses observations available through date $t-1$.

Marcet and Sargent [1989] also treat a *contemporaneous-data* version in which agents update using z_{1t} and $z_{2,t-1}$ at date t.

That timing creates simultaneous determination, because z_t depends on the same estimate β_t that is being updated from z_t.

An extra requirement is that the date-t system must have a unique solution (β_t, R_t, z_t) for each history.

If this uniqueness condition holds, and if the regularity and boundedness conditions used below also hold, convergence is still governed by the same full ODE (139.6) and small ODE (139.5).

Note

As Bray and Savin [1986] and Bray and Kreps [1987] emphasize, the RLS algorithm cannot be derived from Bayes' rule applied to a correctly specified model, because during the learning transition the data-generating process is non-stationary — beliefs shift the equilibrium, which shifts the data.

The algorithm is *"irrational"* in the sense that it acts as if the environment were stationary, when it is not.

Thus, any state variable that matters for the actual law of motion must appear among the regressors in the perceived law.

139.3 Why a differential equation governs the limit

The RLS recursion (139.3)-(139.4) is a *stochastic difference equation* with two key features.

First, the *step size* in front of each update is α_t/t, which shrinks to zero as t grows.

Second, the bracketed expression on the right-hand side of (139.3) is, at the long-run average values of the regressors and noise, just the discrepancy $T(\beta_{t-1}) - \beta_{t-1}$ that measures how far perceived beliefs are from the law of motion they actually generate.

Combine these two facts and a clear picture emerges.

The recursion makes only small adjustments to β_t each period and those adjustments average out, by the law of large numbers, to the deterministic drift $T(\beta) - \beta$.

As the gain α_t/t vanishes, the time-rescaled trajectory β_t looks more and more like a solution to the continuous-time differential equation

$$\frac{d\beta}{dt} = T(\beta) - \beta. \tag{139.5}$$

To compare the ODE with RLS after t observations, evaluate the ODE at $\tau_t = \sum_{s=1}^{t} \alpha_s/s$, the total step size accumulated by the learning algorithm.

When $\alpha_t = 1$, this accumulated step size is $\tau_t = \sum_{s=1}^{t} 1/s \approx \log t$.

This idea, due to Ljung [1977], is what lets Marcet and Sargent [1989] reduce the analysis of a noisy adaptive learning rule to the much easier study of a deterministic ODE.

The rest of this section makes the connection precise.

139.4 The governing ODE

139.4.1 Small and full ODEs

The *small ODE* (139.5) keeps only the drift in β, holding the variance estimator R at its long-run value.

Its rest points are precisely the rational expectations equilibria of the model: $\dot\beta = 0$ if and only if $T(\beta) = \beta$.

The *full ODE* tracks both β and R jointly:

$$\frac{d}{dt}\begin{bmatrix}\beta^\top \\ R\end{bmatrix} = \begin{bmatrix} R^{-1} M_{z_2}(\beta)\,[T(\beta) - \beta]^\top \\ M_{z_2}(\beta) - R \end{bmatrix}, \tag{139.6}$$

where $M_{z_2}(\beta) = \mathbb{E}[z_{2t} z_{2t}^\top]$ is computed at the stationary distribution of z_{2t} that prevails when agents believe the perceived law has constant parameter β.

The fixed point of (139.6) is (β_f, R_f) with $R_f = M_{z_2}(\beta_f)$ — the same β_f as the small ODE, paired with the second-moment matrix consistent with it.

139.4.2 Regularity assumptions

Marcet and Sargent [1989] distinguish two groups of assumptions, with quite different roles.

The first five are standard regularity conditions on the operator T, the shocks u_t, and the gain sequence; they are usually easy to check in applications.

Let $D_s \subset \mathbb{R}^{n_1 \times n_2}$ be the set on which $T(\beta)$, $A(\beta)$, $B(\beta)$, $V(\beta)$ are well defined and the eigenvalues of

$$\begin{bmatrix} 0 & T(\beta) \\ A_c(\beta) & A_2(\beta) \end{bmatrix}$$

are less than one in modulus, so that the state process induced by belief β is covariance-stationary.

Assumption 139.4.1 (Unique REE)

The operator T has a unique fixed point $\beta_f = T(\beta_f)$ with $\beta_f \in D_s$.

Assumption 139.4.2 (Smoothness of T, A, B, V)

T is twice differentiable and A, B, V each have one derivative in D_s.

Assumption 139.4.3 (Nonsingular limit covariance)

The covariance matrix $M_{z_2}(\beta_f)$ is nonsingular.

Assumption 139.4.4 (Gain sequence)

For all t, $\alpha_t > 0$; α_t is non-decreasing in t; $\alpha_t \to 1$ as $t \to \infty$; and $\limsup_{t\to\infty} t\,|\alpha_t - \alpha_{t-1}| < \infty$.

Assumption 139.4.5 (Shock moments)

The vector u_t is serially independent, and $E|u_{it}|^p < \infty$ for all $p > 1$ and all $i = 1, \ldots, m$.

These five say: there is a unique target, the model is smooth around it, the regression has a well-defined precision matrix in the limit, the gain shrinks at the right speed, and the shocks have enough moments for laws of large numbers to work.

The remaining two are *boundedness* conditions.

They are needed because Ljung's theorem requires the relevant sample path to return to a bounded region infinitely often.

In this model that includes the regressor process z_{2t} and the covariance estimate R_t.

Assumption 139.4.6 (Boundedness along a subsequence)

There exist a set Ω_0 with $\mathbb{P}(\Omega_0) = 1$, random variables $C_1(\omega)$ and $C_2(\omega)$, and a subsequence $\{t_k(\omega)\}$ such that

$$|z_{2t_k}(\omega)| < C_1(\omega) \quad \text{and} \quad |R_{t_k}(\omega)| < C_2(\omega)$$

for all $\omega \in \Omega_0$ and all $k = 1, 2, \ldots$.

Assumption 139.4.7 (Sample path stays in a workable domain)

Either the compact-state version or the projection-set version holds.

- *Compact-state version.*
  - $D_1 = D_2 = \mathbb{R}^{n_1 \times (n_2)^3}$.
  - There exists a compact $D' \subset D_s$ that contains $\beta_{t_k}(\omega)$ for all k and all $\omega \in \Omega_0$.
  - For every initial condition $(\beta(0), R(0))$ with $\beta(0) \in D'$ and $R(0)$ bounded as in *Assumption 139.4.6*, the β-component of the trajectory of (139.6) remains in a closed subset of D_s.
- *Projection-set version.*
  - D_2 is closed.

- D_1 is open and bounded.
- $\beta \in D_s$ for every $(\beta, R) \in D_1$.
- Trajectories of (139.6) with initial conditions in D_2 never leave a closed subset of D_1.

Assumption 139.4.6 is automatic when the regressors z_{2t} are *exogenous* and ergodic, but it can be delicate when z_{2t} contains endogenous variables.

Assumption 139.4.7 is satisfied in the compact-state version when the model has a natural bounded domain on which T is well-defined; otherwise the projection-set version corresponds to using the projection facility described below.

Let D_A denote the domain of attraction of the unique equilibrium (β_f, R_f) of (139.6).

139.4.3 Convergence of least squares

Proposition 139.4.1 (Least-squares convergence)

Assume *Assumption 139.4.1*, *Assumption 139.4.2*, *Assumption 139.4.3*, *Assumption 139.4.4*, *Assumption 139.4.5*, and *Assumption 139.4.6*.

If either

- the compact-state version of *Assumption 139.4.7* is satisfied and $D' \subset D_A$, or
- the projection-set version of *Assumption 139.4.7* is satisfied and $D_1 \subset D_A$,

then $\beta_t \to \beta_f$ almost surely as $t \to \infty$.

Proposition 139.4.1 reduces the problem of almost-sure convergence of recursive least squares to checking the *stability* of the ODE (139.6) at (β_f, R_f) and guaranteeing the boundedness of the sample path.

139.4.4 Stability governs convergence

Let $\mathcal{M}$ be the Jacobian matrix of $T(\beta) - \beta$ evaluated at the REE β_f:

$$\mathcal{M} = \frac{d\ \mathrm{col}(T(\beta) - \beta)}{d\ \mathrm{col}(\beta)^\top}\bigg|_{\beta=\beta_f}, \tag{139.7}$$

and let $h(\beta, R)$ denote the Jacobian of the right-hand side of the full ODE (139.6) after stacking $(\beta^\top, R)$ into a column vector.

Proposition 139.4.2 (Jacobian reduction)

The matrix $h(\beta_f, R_f)$ has $(n_2)^2$ repeated eigenvalues equal to -1; its remaining $n_1 \times n_2$ eigenvalues coincide with the eigenvalues of $\mathcal{M}$.

Consequently:

- If all eigenvalues of $\mathcal{M}$ have *strictly negative real parts*, both (139.5) and (139.6) are locally stable.
- Under the boundedness and domain-of-attraction conditions in *Proposition 139.4.1*, this local stability can be used to obtain almost-sure convergence of β_t to β_f.

- If any eigenvalue of $\mathcal{M}$ has *positive real part*, then the next proposition shows that convergence is impossible.

Proposition 139.4.3 (Necessity)

Assume *Assumption 139.4.1*, *Assumption 139.4.2*, *Assumption 139.4.3*, *Assumption 139.4.4*, and *Assumption 139.4.5*.

1. Let $\hat{\beta} \neq \beta_f$ and suppose $M_{z_2}(\hat{\beta})$ is positive definite and $\hat{\beta} \in \text{int}(D_2)$.

   Then $\mathbb{P}(\beta_t \to \hat{\beta}) = 0$.

2. If $h(\beta_f, R_f)$ has at least one eigenvalue with strictly positive real part, then $\mathbb{P}(\beta_t \to \beta_f) = 0$.

The first part says that recursive least squares cannot settle on a non-equilibrium belief in the interior of the admissible domain.

If learning has a limit, that limit must be a fixed point of T.

The second part says that local instability is not just slow convergence.

If the REE is unstable for the learning ODE, convergence to that REE has probability zero.

The stability condition $\text{Re}(\lambda_i(\mathcal{M})) < 0$ for all i is what is called **E-stability** (See Evans [1985]): the REE is a stable rest point of the expectational dynamics $\dot{\beta} = T(\beta) - \beta$.

E-stability plays the role here that prior support plays in Bayesian learning: it tells us when the learning process can find its way to the equilibrium.

139.4.5 The projection facility

E-stability is the local condition that makes the REE attractive for the learning ODE.

By itself, it is not an almost-sure convergence theorem.

The stochastic recursion must also remain in a bounded region where the ODE approximation is valid.

Conversely, a strictly positive eigenvalue rules out convergence to the REE, while boundary cases with zero real parts are not covered by the theorem.

Ljung's theorem requires the learning process and the relevant regressors to return to bounded regions with probability one.

The **projection facility** is a procedure that enforces boundedness of the estimated coefficients and covariance matrix.

What the projection facility does

The full learning algorithm augments the plain RLS update with a constraint set $D_1 \supset D_2$ in (β, R)-space.

After each unconstrained RLS step produces a candidate $(\tilde{\beta}_t, \tilde{R}_t)$, the projection facility enforces:

$$(\beta_t, R_t) = \begin{cases} (\tilde{\beta}_t,\ \tilde{R}_t) & \text{if } (\tilde{\beta}_t, \tilde{R}_t) \in D_1, \\ \text{some point in } D_2 & \text{otherwise.} \end{cases} \tag{139.8}$$

The set D_1 is chosen so that the model remains well-defined (e.g., R_t stays positive definite; β_t stays in a region where $T(\beta)$ is well-defined and the state process is covariance-stationary).

The set $D_2 \subset D_1$ is a slightly smaller "safe" region to which the algorithm is retracted whenever it threatens to leave D_1.

Without the projection facility, the stochastic path (β_t, R_t) might temporarily wander to regions where the system (139.2) is non-stationary (e.g., an explosive VAR).

The projection facility keeps (β_t, R_t) inside a chosen admissible region.

When regressors include endogenous variables, the separate boundedness condition *Assumption 139.4.6* still has to control z_{2t} along a subsequence.

Formally, Marcet and Sargent [1989] require that trajectories of the full ODE (139.6) originating in D_1 do not leave D_1.

This is often checked by verifying that the full vector field points toward the interior at the boundary ∂D_1.

Corollary 139.4.1

Assume *Assumption 139.4.1*, *Assumption 139.4.2*, *Assumption 139.4.3*, *Assumption 139.4.4*, *Assumption 139.4.5*, and *Assumption 139.4.6*.

Suppose also that $(\beta, R) \in D_1$ implies $\beta \in D_s$, and that D_1 is open and bounded with $D_1 \subset D_A$.

Then for some subsequence $\{t_k(\omega)\}$,

$$\mathbb{P}(\beta_t \to \beta_f) + \mathbb{P}(\beta_{t_k} \to (D_1 \setminus D_2)) = 1.$$

The second event has probability zero whenever the ODE trajectories point inward at ∂D_1, in which case *Corollary 139.4.1* reduces to $\beta_t \to \beta_f$ almost surely.

The exogenous-regressor case

When the regressors z_{2t} are *exogenous*, so that $E(z_{2t} z_{2t}^\top) = M_{z_2}(\beta) \equiv M$ does not depend on β, the verification of the boundary condition becomes routine.

Let $H(\beta)$ be the mean-value slope of T, i.e. the matrix satisfying

$$\operatorname{col}\{T(\beta) - T(\beta_f)\} = H(\beta) \operatorname{col}(\beta - \beta_f). \tag{139.9}$$

Corollary 139.4.2

Consider the algorithm defined by (139.3)-(139.4) with projection rule (139.8).

Choose $0 < K' < K < \infty$ and assume

1. *Assumption 139.4.1*, *Assumption 139.4.2*, *Assumption 139.4.3*, *Assumption 139.4.4*, and *Assumption 139.4.5* hold;
2. z_{2t} is exogenous, so that $E(z_{2t} z_{2t}^\top) = M_{z_2}(\beta) \equiv M$;
3. the small ODE $\dot\beta = T(\beta) - \beta$ is globally stable in $\mathbb{R}^{n_1 \times n_2}$;
4. there exists $\bar\varepsilon > 0$ such that for all $0 < \varepsilon \le \bar\varepsilon$ and all β with $|\beta - \beta_f| = K$, every eigenvalue of $[I(1-\varepsilon) + \varepsilon H(\beta)]^\top [I(1-\varepsilon) + \varepsilon H(\beta)]$ has modulus less than α^2 with $\alpha < 1$.

Take $D_1 = \{(\beta, R) : |\beta - \beta_f| < K\}$ and $D_2 = \{(\beta, R) : |\beta - \beta_f| \le K'\}$, and let the projection rule retract β_t to any value with $|\beta - \beta_f| \le K'$, while leaving $R_t = \tilde R_t$.

Then $\beta_t \to \beta_f$ almost surely.

For the scalar linear examples below, condition (4) reduces to checking that the feedback slope of T is not too strong.

For the first four examples below, T is linear and M_{z_2} is independent of β, so *Corollary 139.4.2* uses D_1 and D_2 only to justify the projection argument and leaves the examples with the scalar ODE stability checks.

D_1 and D_2 are therefore not economic primitives in the examples below.

They are proof devices for the projected learning algorithm: D_1 is the outer admissible region where the model and ODE remain well defined, and D_2 is the smaller region used to reset the estimates if an update tries to leave D_1.

Once the corollary says suitable sets can be chosen, the examples no longer need to display them and can focus on T, β_f, and the local stability slope.

139.5 Five examples

We now work through five examples from Marcet and Sargent [1989].

Each substantive learning example follows the same template.

1. Write down the economic equations that determine the equilibrium.
2. Substitute the perceived law of motion for any expectational variables to obtain the actual law of motion as a function of β.
3. Read off the operator T and the REE $\beta_f = T(\beta_f)$.
4. Check E-stability by computing $\mathcal{M} = dT/d\beta - I$ at β_f.
5. Plot the RLS paths, the small ODE evaluated at cumulative-gain time, and the drift $T(\beta) - \beta$.

In each case, β_t is the law of motion agents currently use when making decisions, while $T(\beta_t)$ is the law of motion their decisions actually produce.

Least-squares learning asks whether repeated observations move β_t toward a fixed point of this map.

The first example is the control case with no self-referential feedback.

For the remaining scalar examples, the simulation figure appears immediately after the model description.

139.6 Example 1: Ordinary linear stochastic difference equations

The first example has no self-referential component.

Let the actual law of motion be fixed, with $T(\beta) = \Gamma$ for a stable matrix Γ and with $V(\beta) = I$.

Economically, this is the control case.

Agents are estimating a stable, exogenous data-generating process.

Their beliefs do not feed back into prices, quantities, or future data.

The REE is $\beta_f = \Gamma$.

Since T is constant, $H(\beta) = 0$ in (139.9).

The small-ODE Jacobian is $\mathcal{M} = -I$, so the small ODE is globally stable.

Corollary 139.4.2 then implies that recursive least squares converges almost surely to the true law of motion.

In this no-feedback benchmark, the Marcet-Sargent result reduces to the standard consistency of least squares for stable linear stochastic difference equations.

139.7 Example 2: Bray's cobweb model

Bray [1982] studied a simple cobweb economy in which the equilibrium price satisfies

$$p_t = a + b\beta_t + \tilde{u}_t, \tag{139.10}$$

where β_t is agents' OLS estimate of the price (their point forecast of p_t), and $\tilde{u}_t$ is IID noise with mean zero and variance σ_u^2.

Here the forecast itself is a state variable for the economy.

If producers expect a high price, their current supply decisions alter the market-clearing price.

The parameter b measures the strength of this expectational feedback.

When $b < 1$, the actual price response is weaker than the forecast error, so least squares has a force pushing beliefs back toward the fixed point.

When $b > 1$, the feedback is too strong and the same learning rule moves beliefs away from the REE.

The mapping T is simply $T(\beta) = a + b\beta$.

The REE is

$$\beta_f = \frac{a}{1-b}, \quad b \neq 1. \tag{139.11}$$

The small ODE is

$$\dot{\beta} = T(\beta) - \beta = a + b\beta - \beta = a - (1-b)\beta, \tag{139.12}$$

which has the unique fixed point $\beta_f = a/(1-b)$.

Its Jacobian is $\mathcal{M} = b - 1 < 0$ when $b < 1$.

Under the boundedness and domain conditions above, RLS then converges almost surely.

When $b > 1$, $\mathcal{M} > 0$ and convergence fails.

The code below sets $a = 1$ and $b = 0.6$.

The rational expectations price forecast is then $\beta_f = 2.5$.

The three panels show the noisy RLS paths, the small-ODE approximation, and the learning drift $T(\beta) - \beta$.

The next cell sets up the simulator and plotting helpers used in the Bray figures.

```
REE: β_f = a/(1-b) = 2.5000
Jacobian M = b - 1 = -0.4000  (< 0: E-stable)
```

The stochastic paths are noisy because prices contain $\tilde{u}_t$.

The average path and the ODE paths remove most of that noise and reveal the mean learning direction.

139.8 Counterexample: Unstable Bray feedback

To see what happens when E-stability is violated, repeat Bray's model with $b > 1$.

It represents an economy where expectations affect actual prices more than one-for-one.

If agents start with a forecast that is too high, the market outcome induced by that forecast is higher still, so least squares raises the forecast.

The same logic works in reverse below the REE.

The REE exists, but it is not learnable by this adaptive rule.

The same three diagnostic panels now show how beliefs are pushed away from the REE rather than toward it, and the drift panel shows that the learning force points away from the fixed point on both sides.

139.9 Example 3: Bray-Savin supply-shifter model

Bray and Savin [1986] studied a model where

$$p_t = x_t^\top (m + a\beta_{t-1}) + \tilde{u}_t, \quad p_t^e = x_t^\top \beta_{t-1}, \tag{139.13}$$

with x_t an exogenous supply-shifter, a a scalar feedback parameter, and agents running an OLS regression of p on x.

This is the same learning problem with one extra economic ingredient: expectations are conditional on an observed shifter.

Agents do not merely forecast the average price.

They estimate how price responds to x_t.

The actual coefficient on x_t is $m + a\beta$, so the perceived slope changes the true slope generated by the market.

If $a < 1$, a mistaken slope feeds back into the actual price equation with attenuation, and the least-squares estimate is pulled toward the REE slope.

The mapping is $T(\beta) = m + a\beta$ (scalar case), giving

$$\dot{\beta} = (a - 1)\beta + m, \quad \beta_f = \frac{m}{1 - a}, \tag{139.14}$$

with Jacobian $\mathcal{M} = a - 1 < 0$ iff $a < 1$.

The simulation below draws the exogenous shifter x_t and lets agents update the slope in the regression of p_t on x_t.

It uses $a = 0.7$.

The drift panel shows that mistaken slopes are pushed back toward the REE slope rather than amplified.

The next cell adapts the RLS simulator to the supply-shifter regression.

```
def simulate_bray_savin(m, a, σ_x, σ_u, β0, T_periods=500,

```

The interpretation is parallel to Bray's cobweb model.

The difference is that agents are now learning how prices co-move with an exogenous variable, not just learning an unconditional mean.

139.10 Example 4: Hyperinflation / asset prices

Consider the present-value asset pricing model

$$y_t = \lambda \mathbb{E}_t y_{t+1} + x_t, \quad x_t = \rho x_{t-1} + \varepsilon_t, \tag{139.15}$$

where $|\lambda| < 1$, $|\rho| < 1$, and agents perceive $y_t = \beta_t x_{t-1} + v_t$.

Under the perceived law, $\mathbb{E}_t y_{t+1} = \beta_t x_t$, so (139.15) becomes

$$y_t = (\lambda\beta_t + 1)x_t = (\lambda\beta_t + 1)\rho x_{t-1} + (\lambda\beta_t + 1)\varepsilon_t.$$

The coefficient on x_{t-1} in the actual law of motion is therefore $(\lambda\beta_t + 1)\rho$, which gives the operator T below.

If y_t is a price level, the equation resembles a Cagan-style hyperinflation model.

If y_t is an asset price and x_t is a dividend or fundamental, it is a present-value relation.

In both cases, beliefs about the future value of y enter the current value of y.

The product $\lambda\rho$ measures the strength of the forward-looking feedback: λ discounts the future and ρ measures how persistent the fundamental is.

When $|\lambda\rho| < 1$, a mistaken perceived coefficient does not amplify without bound.

The mapping is $T(\beta) = (\lambda\beta + 1)\rho$ and the REE is

$$\beta_f = \frac{\rho}{1 - \lambda\rho}. \tag{139.16}$$

The small ODE is

$$\dot{\beta} = (\lambda\rho - 1)\beta + \rho, \tag{139.17}$$

with Jacobian $\mathcal{M} = \lambda\rho - 1 < 0$ for $|\lambda\rho| < 1$, so the small ODE is stable.

The convergence theorem then applies under the exogenous-regressor conditions above.

The simulation uses $\lambda = 0.8$ and $\rho = 0.9$, so $\lambda\rho = 0.72$.

This means the feedback from expectations is strong enough to matter but still less than one.

The ODE panel below uses τ itself on the horizontal axis, where τ is the total step size accumulated by least squares.

The code simulates the autoregressive fundamental x_t and updates an OLS regression of y_t on x_{t-1}.

The next cell simulates the autoregressive fundamental and the matching RLS update.

It keeps the covariance estimate R_t bounded away from zero, mirroring the projection idea above and avoiding misleading early-sample explosions.

```
def simulate_present_value_rls(λ, ρ, σ_ε, β0, T_periods=500,

```
REE: β_f = ρ/(1 - lambda*ρ) = 3.2143
Jacobian M = lambda*ρ - 1 = -0.2800  (< 0: E-stable)
```

The REE coefficient is larger than ρ because current prices capitalize expected future fundamentals.

Learning converges because each revision in β_t changes expectations, but the discounted persistence term $\lambda\rho$ prevents revisions from feeding back explosively.

139.11 Example 5: Investment under uncertainty

Let's now consider a version of the Lucas-Prescott investment model where agents learn about the aggregate capital stock K_t by regressing on (K_{t-1}, w_{t-1}) where w_t is an exogenous cost shock.

Firms choose investment using a perceived law of motion for aggregate capital.

Those investment choices then determine the actual law of motion for aggregate capital through market clearing.

Learning is therefore about a state variable that agents themselves help create through their investment decisions.

The perceived law of motion is

$$K_t = \beta_1 K_{t-1} + \beta_2 w_{t-1} + \eta_t,$$

while the actual law (from firms' optimal investment decisions and market clearing) is

$$K_t = T_1(\beta) K_{t-1} + T_2(\beta) w_{t-1} + V(\beta) u_t, \tag{139.18}$$

where the nonlinear mappings T_1, T_2 come from solving the firms' linear quadratic control problems.

The two coefficients have different economic roles.

β_1 describes persistence in aggregate capital, while β_2 describes how the exogenous shock w_t affects next period's capital.

Because the optimal investment rule depends on the whole perceived law of motion, the map T is nonlinear.

This is why the larger ODE is harder to analyze here than in the scalar examples with exogenous regressors.

The small ODE decomposes as:

$$\dot{\beta}_1 = T_1(\beta_1) - \beta_1, \quad \dot{\beta}_2 = T_2(\beta_1, \beta_2) - \beta_2, \tag{139.19}$$

and E-stability can be verified analytically for $|\beta_1| < b^{-1/2}$ (where b is the discount factor).

The phase portrait below plots the vector field $T(\beta) - \beta$ over (β_1, β_2) space.

Each arrow shows how the perceived law of motion would be revised if the economy were currently operating under that belief.

The plotted trajectories are deterministic ODE paths, not noisy least-squares sample paths.

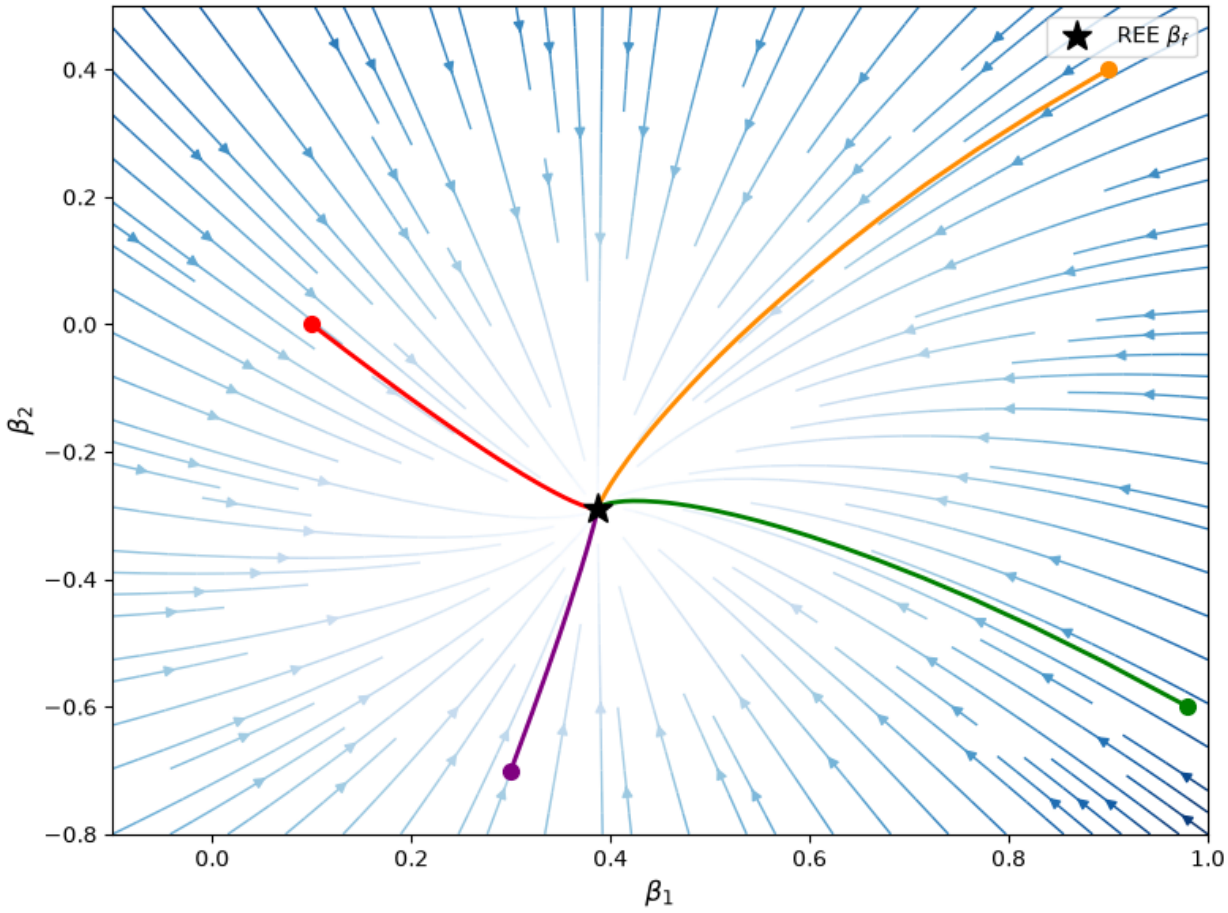

Fig. 139.5: Investment phase portrait

The star marks the REE.

The paths converge because the capital-persistence coefficient β_1 is stabilized first, and then the shock coefficient β_2 adjusts given the limiting value of β_1.

This recursive structure is why the small ODE is tractable even though the full least-squares system has endogenous regressors.

139.12 Connection to rational learning

The framework of Marcet and Sargent [1989] belongs to the program of learning *about* a rational expectations equilibrium, as distinct from learning *within* one — a distinction emphasized by Bray and Kreps [1987].

Learning *within* an REE (the subject of the companion lecture *Rational Learning and Rational Expectations*) refers to Bayesian inference inside a correctly specified model.

In that setting the data-generating process is stationary from the agent's perspective, and Bayes' rule is fully rationalized.

Learning *about* an REE involves an agent who does not know the equilibrium price function.

Because the agent's beliefs shift the equilibrium price, the data the agent uses to update beliefs are themselves generated by a non-stationary process.

As Marcet and Sargent [1989] put it,

> The models do not incorporate fully optimal behavior or rational expectations, because agents operate under the continually falsified assumption that the law of motion is time invariant and known for sure.

Yet it is a compelling rule.

Convergence holds despite the misspecification whenever E-stability combines with the required boundedness and domain-of-attraction conditions.

Unlike Bayesian learning, it does not require strong prior assumptions about the statistical structure of the economy.

139.13 Summary

This lecture studied least-squares learning in the self-referential models of Marcet and Sargent [1989].

The central object is the map T from a perceived law of motion to the actual law of motion generated when agents act on that perception.

A rational expectations equilibrium is a fixed point of this map.

Recursive least squares converges to that fixed point when the associated ODE $\dot{\beta} = T(\beta) - \beta$ is locally stable and the learning process remains in a region where the model is well defined.

It complements rational learning, studied in *Rational Learning and Rational Expectations*, where Bayesian agents learn *within* an equilibrium structure that is already specified.

The Phillips curve lectures apply this machinery to a government that learns: a scalar case in *The Credibility Problem*, the self-confirming equilibrium as a rest point in *Self-Confirming Equilibria*, constant-gain mean dynamics and escapes in *Adaptive Learning and Escape Dynamics* and *Escaping Nash Inflation*, and priors under which E-stability no longer guarantees convergence in *Priors, Escapes, and Learning Cycles*.

139.14 Exercises

Exercise 139.14.1

Consider the scalar model with $T(\beta) = a + b\beta$.

1. Derive a formula for the unique REE β_f in terms of a and b.
2. Show that the small ODE $\dot{\beta} = T(\beta) - \beta$ is globally stable if and only if $b < 1$.

3. Simulate $N = 200$ paths of length $T = 500$ for $a = 1$ and each of $b \in \{0.3, 0.7, 0.9, 0.99\}$ (all less than 1).

Plot the cross-path average of β_t for each b value on the same figure and comment on how the rate of convergence changes as $b \to 1$.

Solution

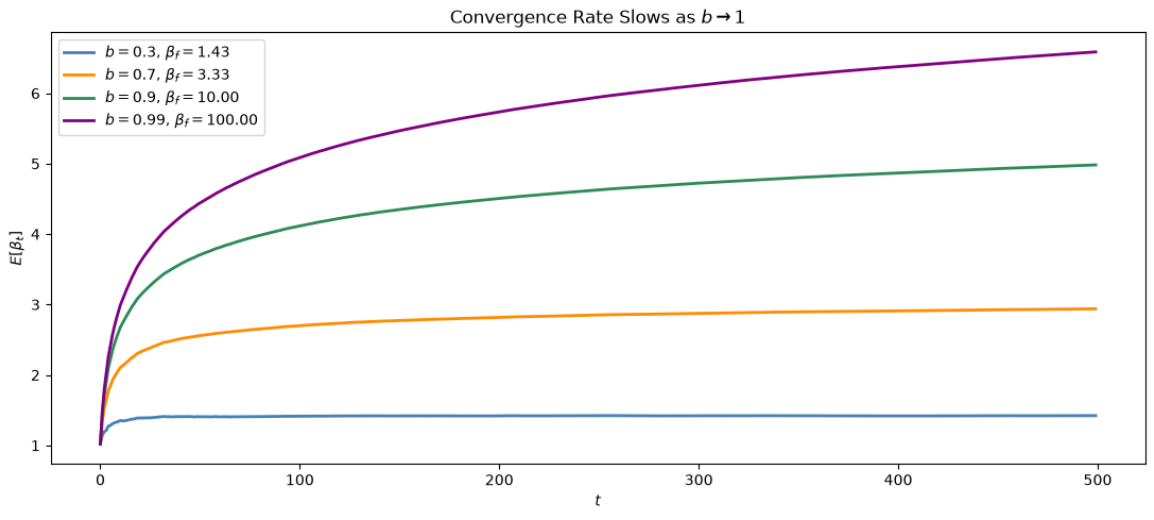
Here is one solution:

Part 1. The REE satisfies $\beta_f = T(\beta_f) = a + b\beta_f$, so

$$\beta_f(1-b) = a \implies \beta_f = \frac{a}{1-b}.$$

Part 2. The small ODE is $\dot{\beta} = a + b\beta - \beta = a - (1-b)\beta$.

This is linear with slope $-(1-b)$, so the unique fixed point $\beta_f = a/(1-b)$ is globally stable iff $1 - b > 0$, i.e., $b < 1$.



Part 3.

```
a_ex, T_ex, N_ex = 1.0, 500, 200
b_values = [0.3, 0.7, 0.9, 0.99]
colors_ex = ['steelblue', 'darkorange', 'seagreen', 'purple']

fig, ax = plt.subplots(figsize=(11, 5))
for b_val, col in zip(b_values, colors_ex):
    def T_fn(β, b_val=b_val):
        return a_ex + b_val * β

    paths = simulate_rls_scalar(T_fn, σ_u=1.0, β0=0.0,
                                T_periods=T_ex, N_paths=N_ex, seed=0)
    bf = a_ex / (1 - b_val)
    ax.plot(np.mean(paths, axis=0), color=col, lw=2,
            label=f'$b={b_val}$, $\\beta_f={bf:.2f}$')

ax.set_xlabel('$t$')
ax.set_ylabel('$E[\\beta_t]$')
ax.set_title('Convergence Rate Slows as $b \\to 1$')
ax.legend()
plt.tight_layout()
plt.show()
```

As $b \to 1$, the Jacobian $\mathcal{M} = b - 1$ approaches zero, so the ODE becomes slow to return to the fixed point.

Convergence still occurs, but it takes longer.

Exercise 139.14.2

Proposition 139.4.3 states that $\mathbb{P}(\beta_t \to \hat{\beta}) = 0$ for any $\hat{\beta} \neq \beta_f$ in the interior.

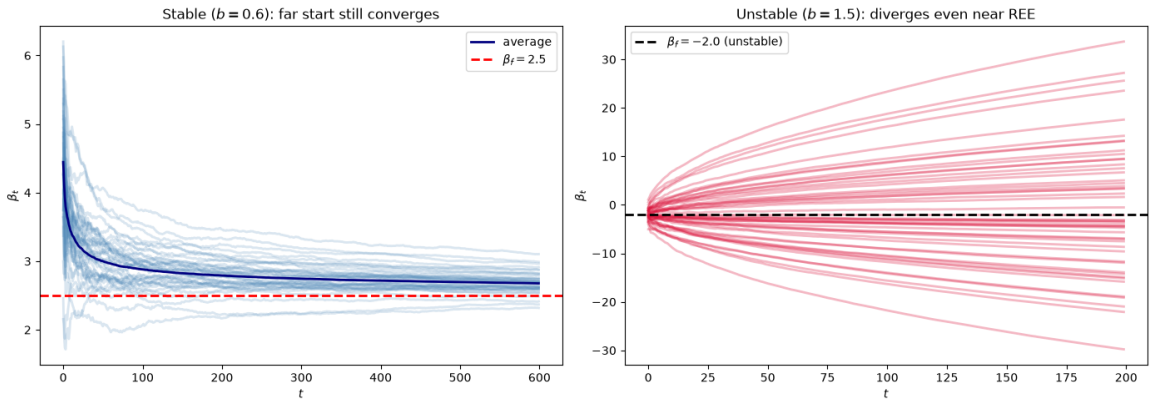
1. Using the Bray model with $a = 1$, $b = 0.6$, simulate 100 paths of length $T = 600$ starting from $\beta_0 = 6$ (far from $\beta_f = 2.5$) and show that paths still converge to β_f.
2. Now consider the *unstable* case $b = 1.5$, simulate 50 paths of length $T = 200$ starting from $\beta_0 = -1.9$ (close to the REE $\beta_f = -2$), and describe what happens.

Solution

Here is one solution:

Parts 1 and 2.

```
fig, axes = plt.subplots(1, 2, figsize=(14, 5))



def T_st(β):
    return 1.0 + 0.6 * β

paths_far = simulate_rls_scalar(T_st, 1.0, β0=6.0,
                                T_periods=600, N_paths=100, seed=1)
ax = axes[0]
for i in range(40):
    ax.plot(paths_far[i], color='steelblue', alpha=0.2, lw=2)
ax.plot(np.mean(paths_far, axis=0), color='navy', lw=2, label='average')
ax.axhline(2.5, color='red', ls='--', lw=2, label='$\\beta_f = 2.5$')
ax.set_title('Stable ($b=0.6$): far start still converges')
ax.set_xlabel('$t$')
ax.set_ylabel('$\\beta_t$')
ax.legend()
```

```
def T_un(β):
    return 1.0 + 1.5 * β

β_f_un = 1.0 / (1 - 1.5)
paths_un = simulate_rls_scalar(T_un, 1.0, β0=-1.9,
                               T_periods=200, N_paths=50, seed=2)
ax = axes[1]
for i in range(50):
    ax.plot(paths_un[i], color='crimson', alpha=0.3, lw=2)
ax.axhline(β_f_un, color='black', ls='--', lw=2,
           label=f'$\\beta_f = {β_f_un}$ (unstable)')
ax.set_title('Unstable ($b=1.5$): diverges even near REE')
ax.set_xlabel('$t$')
ax.set_ylabel('$\\beta_t$')
ax.legend()

plt.tight_layout()
plt.show()
```

Geometrically, the slope $dT/d\beta - 1 = b - 1 = 0.5$ is positive at the REE.

The ODE therefore pushes β away from β_f in both directions.

Exercise 139.14.3

The present-value model: effect of λ on E-stability

In the present-value model (139.15), $T(\beta) = (\lambda\beta + 1)\rho$ and the Jacobian is $\mathcal{M} = \lambda\rho - 1$.

1. For $\rho = 0.9$ and each of $\lambda \in \{0.5, 0.8, 0.95, 0.99\}$, compute β_f and $\mathcal{M}$ and determine whether the REE is E-stable.
2. For the E-stable cases, simulate 100 paths of length $T = 400$ and plot representative noisy paths in calendar time, then plot the limiting ODE paths in accumulated-gain time.
3. At $\lambda = 0.99$, $\mathcal{M} = 0.99\rho - 1 < 0$.

   Simulate paths for this near-boundary case and compare the convergence speed with the $\lambda = 0.5$ case, providing an intuitive explanation.

Solution

Here is one solution:

Part 1.

```
ρ_ex = 0.9
λ_values = [0.5, 0.8, 0.95, 0.99]

print(f"{'lambda':>8}  {'β_f':>10}  {'M = λ*ρ-1':>15}  {'E-stable':>10}")
print("-" * 50)
for lv in λ_values:
    bf = ρ_ex / (1 - lv * ρ_ex) if abs(lv * ρ_ex) < 1 else float('inf')
    M_jac = lv * ρ_ex - 1
    estab = "YES" if M_jac < 0 else "NO"
    print(f"{lv:>8.2f}  {bf:>10.4f}  {M_jac:>15.4f}  {estab:>10}")
```

```
  lambda          β_f        M = λ*ρ-1    E-stable
--------------------------------------------------
    0.50       1.6364          -0.5500         YES
    0.80       3.2143          -0.2800         YES
    0.95       6.2069          -0.1450         YES
    0.99       8.2569          -0.1090         YES
```

Parts 2 and 3.

```
fig, axes = plt.subplots(len(λ_values), 2, figsize=(13, 14))
colors_λ = ['steelblue', 'darkorange', 'seagreen', 'purple']

for row, (lv, col) in enumerate(zip(λ_values, colors_λ)):
    def ode_fn(β, λ_val=lv):
        return (λ_val * β + 1) * ρ_ex - β

    bf = ρ_ex / (1 - lv * ρ_ex)

    paths_λ = simulate_present_value_rls(
        lv, ρ_ex, 1.0, β0=0.0,
        T_periods=400, N_paths=100, seed=3
    )

    ax = axes[row, 0]
    for i in range(20):
        ax.plot(paths_λ[i], color=col, alpha=0.2, lw=2)
    ax.axhline(bf, color='red', ls=':', lw=2,
               label=f'$\\beta_f={bf:.2f}$')
    ax.set_title(f'RLS paths, $\\lambda={lv}$')
    ax.set_xlabel('$t$')
    ax.set_ylabel('$\\beta_t$')
    ax.legend(fontsize=8)

    τ_grid = np.linspace(0.0, 30.0, 300)
    sol_low = solve_ivp(
        lambda τ, y: [ode_fn(y[0])],
        (0.0, τ_grid[-1]),
        [0.0],
        t_eval=τ_grid,
        max_step=0.05
    ).y[0]
    sol_high = solve_ivp(
        lambda τ, y: [ode_fn(y[0])],
        (0.0, τ_grid[-1]),
        [1.5 * bf],
        t_eval=τ_grid,
        max_step=0.05
    ).y[0]

    ax = axes[row, 1]
```

In each row, the left panel shows finite-sample RLS paths in calendar time and the right panel shows deterministic ODE paths in accumulated-gain time.

When $\lambda = 0.99$, $\mathcal{M} = 0.99\rho - 1 \approx -0.109$ is small in absolute value.

The ODE is nearly flat near β_f, so the restoring force is weak and convergence is slow.

When $\lambda = 0.5$, $\mathcal{M} = -0.55$, which gives a stronger restoring force and faster convergence.

AFFINE MODELS OF ASSET PRICES

140.1 Overview

This lecture describes a class of **affine** or **exponential quadratic** models of the stochastic discount factor that have become widely used in empirical finance.

These models are presented in chapter 15 of Ljungqvist and Sargent [2018].

The models discussed here take a different approach from the time-separable CRRA stochastic discount factor of Hansen and Singleton [1983], studied in our *companion lecture*.

The CRRA stochastic discount factor is

$$m_{t+1} = \exp\left(-r_t - \frac{1}{2}\sigma_c^2\gamma^2 - \gamma\sigma_c\varepsilon_{t+1}\right)$$

where ρ is the rate of time preference, γ is the coefficient of relative risk aversion, log consumption growth is $g + \sigma_c\varepsilon_{t+1}$, and $r_t = \rho + \gamma g - \frac{1}{2}\sigma_c^2\gamma^2$.

This model asserts that exposure to the random part of aggregate consumption growth, $\sigma_c\varepsilon_{t+1}$, is the *only* priced risk, the sole source of discrepancies among expected returns across assets.

Empirical difficulties with this specification (the equity premium puzzle, the risk-free rate puzzle, and the Hansen-Jagannathan bounds discussed in Doubts or Variability?) motivate the alternative approach described in this lecture.

Put bluntly, the model to be studied in this lecture declares the Lucas asset pricing model's stochastic discount factor to be a failure.

The **affine model** maintains $\mathbb{E}(m_{t+1}R_{j,t+1}) = 1$ but *divorces* the stochastic discount factor from consumption risk, and consequently, from much of macroeconomics too.

Instead, it

- specifies an analytically tractable stochastic process for m_{t+1}, and
- uses overidentifying restrictions from $\mathbb{E}(m_{t+1}R_{j,t+1}) = 1$ applied to N assets to let the data reveal risks and their prices.

Note

Researchers including [Bansal and Yaron, 2004] and [Hansen *et al.*, 2008] have been less willing to give up on consumption-based models of the stochastic discount factor.

Key applications we study include:

1. *Pricing risky assets*: how risk prices and exposures determine excess returns.
2. *Affine term structure models*: bond yields as affine functions of a state vector (Ang and Piazzesi [2003]).
3. *Risk-neutral probabilities*: a change-of-measure representation of the pricing equation.

4. *Distorted beliefs*: reinterpreting risk price estimates when agents hold systematically biased forecasts (Piazzesi *et al.* [2015]); see also Risk Aversion or Mistaken Beliefs?.

The lecture uses lognormal pricing tools that also appear in *Asset Pricing: Finite State Models* and *Stochastic Consumption, Risk Aversion, and the Temporal Behavior of Asset Returns*.

The change-of-measure arguments rely on likelihood ratios of the kind studied in *Likelihood Ratio Processes* and *Statistical Divergence Measures*.

We start with the following imports:

```
import numpy as np
import matplotlib.pyplot as plt
from collections import namedtuple
from numpy.linalg import eigvals
from scipy.linalg import solve_discrete_lyapunov
from scipy.stats import norm
```

140.2 The model

140.2.1 State dynamics and short rate

The model has two components.

Component 1 is a vector autoregression that describes the state of the economy and the evolution of the short rate:

$$z_{t+1} = \mu + \phi z_t + C\varepsilon_{t+1} \tag{140.1}$$

$$r_t = \delta_0 + \delta_1^\top z_t \tag{140.2}$$

Here

- ϕ is a stable $m \times m$ matrix,
- C is an $m \times m$ matrix,
- $\varepsilon_{t+1} \sim \mathcal{N}(0, I)$ is an i.i.d. $m \times 1$ random vector,
- z_t is an $m \times 1$ state vector.

Equation (140.2) says that the **short rate** r_t, the net yield on a one-period risk-free claim, is an affine function of the state z_t.

Component 2 is a vector of **risk prices** λ_t and an associated stochastic discount factor m_{t+1}:

$$\lambda_t = \lambda_0 + \lambda_z z_t \tag{140.3}$$

$$\log(m_{t+1}) = -r_t - \frac{1}{2}\lambda_t^\top \lambda_t - \lambda_t^\top \varepsilon_{t+1} \tag{140.4}$$

Here λ_0 is $m \times 1$ and λ_z is $m \times m$.

The entries of λ_t that multiply corresponding entries of the risks ε_{t+1} are called **risk prices** because they determine how exposures to each risk component affect expected returns (as we show below).

Because λ_t is affine in z_t, the stochastic discount factor m_{t+1} is **exponential quadratic** in the state z_t.

We implement the model components as follows.

```
AffineModel = namedtuple('AffineModel',
    ('μ', 'Φ', 'C', 'δ_0', 'δ_1', 'λ_0', 'λ_z', 'm', 'Φ_rn', 'μ_rn'))

def create_affine_model(μ, Φ, C, δ_0, δ_1, λ_0, λ_z):
    """Create an affine term structure model."""
    μ = np.asarray(μ, float)
    Φ = np.asarray(Φ, float)
    C = np.asarray(C, float)
    δ_1 = np.asarray(δ_1, float)
    λ_0, λ_z = np.asarray(λ_0, float), np.asarray(λ_z, float)
    return AffineModel(μ=μ, Φ=Φ, C=C, δ_0=float(δ_0), δ_1=δ_1,
                       λ_0=λ_0, λ_z=λ_z, m=len(μ),
                       Φ_rn=Φ - C @ λ_z, μ_rn=μ - C @ λ_0)

def simulate(model, z0, T, rng=None):
    """Simulate z_{t+1} = μ + Φ z_t + C ε_{t+1} for T periods."""
    if rng is None:
        rng = np.random.default_rng(42)
    Z = np.zeros((T + 1, model.m))
    Z[0] = z0
    for t in range(T):
        ε = rng.standard_normal(model.m)
        Z[t + 1] = model.μ + model.Φ @ Z[t] + model.C @ ε
    return Z

def short_rate(model, z):
    """Compute r_t = δ_0 + δ_1^⊤ z_t."""
    return model.δ_0 + model.δ_1 @ z

def risk_prices(model, z):
    """Compute λ_t = λ_0 + λ_z z_t."""
    return model.λ_0 + model.λ_z @ z
```

140.2.2 Properties of the SDF

Since $\lambda_t^\top \varepsilon_{t+1}$ is conditionally normal, it follows that

$$\mathbb{E}_t(m_{t+1}) = \exp(-r_t)$$

and

$$\operatorname{std}_t(m_{t+1}) \approx \|\lambda_t\|.$$

Exercise 140.2.1

Show that the SDF defined in (140.4) satisfies

$$\mathbb{E}_t(m_{t+1}) = \exp(-r_t)$$

and

$$\operatorname{std}_t(m_{t+1}) \approx \|\lambda_t\|$$

where $\|\lambda_t\| = \sqrt{\lambda_t^\top \lambda_t}$ denotes the Euclidean norm of the risk price vector.

For the second result, use the lognormal variance formula and the approximations $\exp(x) \approx 1 + x$ and $\exp(-r_t) \approx 1$ for small x and r_t.

Solution

From (140.4), we have

$$m_{t+1} = \exp\left(-r_t - \frac{1}{2}\lambda_t^\top \lambda_t - \lambda_t^\top \varepsilon_{t+1}\right)$$

Since $-\lambda_t^\top \varepsilon_{t+1} \sim \mathcal{N}(0, \lambda_t^\top \lambda_t)$, we have $\mathbb{E}_t[\exp(-\lambda_t^\top \varepsilon_{t+1})] = \exp\left(\frac{1}{2}\lambda_t^\top \lambda_t\right)$.

Therefore,

$$\mathbb{E}_t(m_{t+1}) = \exp(-r_t - \frac{1}{2}\lambda_t^\top \lambda_t)\mathbb{E}_t[\exp(-\lambda_t^\top \varepsilon_{t+1})] = \exp(-r_t)$$

m_{t+1} is conditionally lognormal with $\log m_{t+1} \sim \mathcal{N}(-r_t - \frac{1}{2}\lambda_t^\top \lambda_t, \lambda_t^\top \lambda_t)$.

By the lognormal variance formula $\mathrm{Var}(\exp(X)) = (\exp(\sigma^2) - 1)\exp(2\mu + \sigma^2)$ for $X \sim \mathcal{N}(\mu, \sigma^2)$, we have

$$\begin{aligned}\mathrm{Var}_t(m_{t+1}) &= (\exp(\lambda_t^\top \lambda_t) - 1)\exp(-2r_t) \\ &\approx \lambda_t^\top \lambda_t \exp(-2r_t)\end{aligned}$$

by the approximation $\exp(x) \approx 1 + x$ for small x.

Hence,

$$\mathrm{std}_t(m_{t+1}) \approx \|\lambda_t\| \exp(-r_t)$$

With $\exp(-r_t) \approx 1$ for small r_t, we obtain

$$\mathrm{std}_t(m_{t+1}) \approx \|\lambda_t\|$$

The first equation confirms that r_t is the net yield on a risk-free one-period bond.

That is why r_t is called **the short rate** in the exponential quadratic literature.

The second equation says that the conditional standard deviation of the SDF is approximately the magnitude of the vector of risk prices, a measure of overall **market price of risk**.

The approximation comes from an exact formula: because m_{t+1} is conditionally lognormal,

$$\frac{\mathrm{std}_t(m_{t+1})}{\mathbb{E}_t(m_{t+1})} = \sqrt{\exp(\lambda_t^\top \lambda_t) - 1}$$

By the Hansen–Jagannathan bound [Hansen and Jagannathan, 1991], this ratio bounds the conditional Sharpe ratio of every excess return, so $\|\lambda_t\|$ tells us how large Sharpe ratios can be.

140.3 Pricing risky assets

140.3.1 Lognormal returns

Consider a risky asset j whose gross return has a lognormal conditional distribution:

$$R_{j,t+1} = \exp\left(\nu_t(j) - \frac{1}{2}\alpha_t(j)^\top \alpha_t(j) + \alpha_t(j)^\top \varepsilon_{t+1}\right) \tag{140.5}$$

where the **exposure vector**

$$\alpha_t(j) = \alpha_0(j) + \alpha_z(j)\, z_t \tag{140.6}$$

Here $\alpha_0(j)$ is $m \times 1$ and $\alpha_z(j)$ is $m \times m$.

The components of $\alpha_t(j)$ express the **exposures** of $\log R_{j,t+1}$ to corresponding components of the risk vector ε_{t+1}.

The specification (140.5) implies $\mathbb{E}_t R_{j,t+1} = \exp(\nu_t(j))$, so $\nu_t(j)$ is the log of the expected gross return.

140.3.2 Expected excess returns

Applying the pricing equation $\mathbb{E}_t(m_{t+1} R_{j,t+1}) = 1$ together with the formula for the mean of a lognormal random variable gives

$$\nu_t(j) = r_t + \alpha_t(j)^\top \lambda_t \tag{140.7}$$

Exercise 140.3.1

Using the SDF (140.4) and the return specification (140.5), derive the expected excess return formula (140.7):

$$\nu_t(j) = r_t + \alpha_t(j)^\top \lambda_t$$

Hint: Start by computing $\log(m_{t+1} R_{j,t+1})$, identify its conditional distribution, and apply the pricing condition $\mathbb{E}_t(m_{t+1} R_{j,t+1}) = 1$.

Solution

Combining (140.4) and (140.5), we get

$$\log(m_{t+1} R_{j,t+1}) = -r_t + \nu_t(j) - \frac{1}{2}\lambda_t^\top \lambda_t - \frac{1}{2}\alpha_t(j)^\top \alpha_t(j) + (\alpha_t(j) - \lambda_t)^\top \varepsilon_{t+1}$$

This is conditionally normal with mean $\mu = -r_t + \nu_t(j) - \frac{1}{2}\lambda_t^\top \lambda_t - \frac{1}{2}\alpha_t(j)^\top \alpha_t(j)$ and variance $\sigma^2 = (\alpha_t(j) - \lambda_t)^\top (\alpha_t(j) - \lambda_t)$.

Since $\mathbb{E}_t[\exp(X)] = \exp(\mu + \frac{1}{2}\sigma^2)$ for $X \sim \mathcal{N}(\mu, \sigma^2)$, the pricing condition $\mathbb{E}_t(m_{t+1} R_{j,t+1}) = 1$ requires $\mu + \frac{1}{2}\sigma^2 = 0$.

Expanding $\frac{1}{2}\sigma^2 = \frac{1}{2}\alpha_t(j)^\top \alpha_t(j) - \alpha_t(j)^\top \lambda_t + \frac{1}{2}\lambda_t^\top \lambda_t$ and adding to μ, the $\frac{1}{2}\lambda_t^\top \lambda_t$ and $\frac{1}{2}\alpha_t(j)^\top \alpha_t(j)$ terms cancel, leaving

$$-r_t + \nu_t(j) - \alpha_t(j)^\top \lambda_t = 0$$

which gives (140.7).

This is a central result.

It says:

> The log expected gross return on asset j equals the short rate plus the inner product of the asset's exposure vector $\alpha_t(j)$ with the risk price vector λ_t.

Each component of λ_t prices the corresponding component of ε_{t+1}.

An asset that loads heavily on a risk component with a large risk price earns a correspondingly high expected return.

Exercise 140.3.2

Suppose that a representative agent has CRRA utility with risk aversion γ and discount factor $\beta = e^{-\rho}$, and that log consumption growth is $\log(c_{t+1}/c_t) = g + \sigma_c^\top \varepsilon_{t+1}$, where σ_c is an $m \times 1$ vector.

1. Show that $m_{t+1} = \beta(c_{t+1}/c_t)^{-\gamma}$ has the form (140.4) with a constant risk price vector $\lambda_t = \gamma\sigma_c$, and find r_t.
2. Define the conditional Sharpe ratio of the log return on asset j as $(\nu_t(j) - r_t)/\|\alpha_t(j)\|$. Use (140.7) and the Cauchy–Schwarz inequality to show that the largest such Sharpe ratio is $\|\lambda_t\|$, and that it is attained by returns whose exposure vector is proportional to λ_t.
3. Suppose that $\|\sigma_c\| = 0.02$ per year and that some asset has an annual Sharpe ratio of 0.4. Using the exact bound $\sqrt{\exp(\lambda^\top\lambda) - 1} \geq 0.4$, compute the smallest γ consistent with the CRRA model, and compare it with the first-order answer $\gamma \geq 0.4/0.02$.

Solution

Part 1. Taking logs,

$$\log m_{t+1} = -\rho - \gamma g - \gamma\sigma_c^\top \varepsilon_{t+1}$$

Matching the shock term with (140.4) gives $\lambda_t = \gamma\sigma_c$.

Matching the constant gives $-r_t - \frac{1}{2}\gamma^2\sigma_c^\top\sigma_c = -\rho - \gamma g$, so

$$r_t = \rho + \gamma g - \frac{1}{2}\gamma^2\sigma_c^\top\sigma_c$$

This is the CRRA model from the overview, now written as a special case of the affine model with $\lambda_z = 0$.

Part 2. By (140.7), the Sharpe ratio is $\alpha_t(j)^\top\lambda_t/\|\alpha_t(j)\|$.

The Cauchy–Schwarz inequality gives $\alpha_t(j)^\top\lambda_t \leq \|\alpha_t(j)\|\,\|\lambda_t\|$, with equality exactly when $\alpha_t(j)$ is a positive multiple of λ_t.

The following check maximizes the Sharpe ratio over many random exposure vectors.

```
rng = np.random.default_rng(1234)
λ_example = np.array([0.3, 0.1])
α_draws = rng.standard_normal((20_000, 2))
sharpe = α_draws @ λ_example / np.linalg.norm(α_draws, axis=1)
print(f"largest Sharpe ratio over draws: {sharpe.max():.5f}")
print(f"||λ||:                           {np.linalg.norm(λ_example):.5f}")
```

```
largest Sharpe ratio over draws: 0.31623
||λ||:                           0.31623
```

Part 3.

```
σ_c_norm, target_sr = 0.02, 0.4
λ_norm_required = np.sqrt(np.log(1 + target_sr**2))
print(f"required ||λ|| (exact bound): {λ_norm_required:.4f}")
print(f"implied γ (exact bound):      {λ_norm_required / σ_c_norm:.1f}")
print(f"implied γ (first order):      {target_sr / σ_c_norm:.1f}")
```

```
required ||λ|| (exact bound): 0.3853
implied γ (exact bound):      19.3
implied γ (first order):      20.0
```

Either way, the CRRA model needs a coefficient of relative risk aversion near 20.

This is the equity premium puzzle expressed in the language of this lecture.

The affine model sidesteps the puzzle by treating λ_t as free parameters to be estimated from asset returns rather than tying them to consumption growth.

140.4 Affine term structure of yields

One of the most important applications is the **affine term structure model** studied by Ang and Piazzesi [2003].

140.4.1 Bond prices

Let $p_t(n)$ be the price at time t of a risk-free pure discount bond maturing at $t+n$ (paying one unit of consumption).

The one-period gross return on holding an $(n+1)$-period bond from t to $t+1$ is

$$R_{t+1} = \frac{p_{t+1}(n)}{p_t(n+1)}$$

The pricing equation $\mathbb{E}_t(m_{t+1} R_{t+1}) = 1$ implies

$$p_t(n+1) = \mathbb{E}_t(m_{t+1}\, p_{t+1}(n)) \tag{140.8}$$

with the initial condition

$$p_t(1) = \mathbb{E}_t(m_{t+1}) = \exp(-r_t) = \exp(-\delta_0 - \delta_1^\top z_t).$$

140.4.2 Exponential affine prices

The recursion (140.8) has an **exponential affine** solution:

$$p_t(n) = \exp(\bar{A}_n + \bar{B}_n^\top z_t) \tag{140.9}$$

where the scalar $\bar{A}_n$ and the $m \times 1$ vector $\bar{B}_n$ satisfy the **Riccati difference equations**

$$\bar{A}_{n+1} = \bar{A}_n + \bar{B}_n^\top(\mu - C\lambda_0) + \frac{1}{2}\bar{B}_n^\top CC^\top \bar{B}_n - \delta_0 \tag{140.10}$$

$$\bar{B}_{n+1}^\top = \bar{B}_n^\top(\phi - C\lambda_z) - \delta_1^\top \tag{140.11}$$

with initial conditions $\bar{A}_1 = -\delta_0$ and $\bar{B}_1 = -\delta_1$.

Exercise 140.4.1

Derive the Riccati difference equations (140.10) and (140.11) by substituting the conjectured bond price (140.9) into the pricing recursion (140.8) and matching coefficients.

Hint: Substitute $p_{t+1}(n) = \exp(\bar{A}_n + \bar{B}_n^\top z_{t+1})$ and $\log m_{t+1}$ from (140.4) into (140.8).

Use the state dynamics (140.1) to express z_{t+1} in terms of z_t and ε_{t+1}, then evaluate the conditional expectation using the lognormal moment generating function.

Solution

We want to show that if $p_t(n) = \exp(\bar{A}_n + \bar{B}_n^\top z_t)$, then the recursion $p_t(n+1) = \mathbb{E}_t(m_{t+1}\, p_{t+1}(n))$ yields $p_t(n+1) = \exp(\bar{A}_{n+1} + \bar{B}_{n+1}^\top z_t)$ with $\bar{A}_{n+1}$ and $\bar{B}_{n+1}$ given by (140.10) and (140.11).

From (140.4) and (140.9),

$$\log(m_{t+1}\, p_{t+1}(n)) = -r_t - \frac{1}{2}\lambda_t^\top \lambda_t - \lambda_t^\top \varepsilon_{t+1} + \bar{A}_n + \bar{B}_n^\top z_{t+1}$$

Substituting $z_{t+1} = \mu + \phi z_t + C\varepsilon_{t+1}$ from (140.1) and $r_t = \delta_0 + \delta_1^\top z_t$ from (140.2) gives

$$\log(m_{t+1}\, p_{t+1}(n)) = \bar{A}_n + \bar{B}_n^\top \mu - \delta_0 + (\bar{B}_n^\top \phi - \delta_1^\top) z_t - \frac{1}{2}\lambda_t^\top \lambda_t + (\bar{B}_n^\top C - \lambda_t^\top)\varepsilon_{t+1}$$

Since $\varepsilon_{t+1} \sim \mathcal{N}(0, I)$, and writing the exponent as $a + b^\top \varepsilon_{t+1}$ where $b = C^\top \bar{B}_n - \lambda_t$, we have

$$\mathbb{E}_t[\exp(a + b^\top \varepsilon_{t+1})] = \exp\left(a + \frac{1}{2} b^\top b\right)$$

Computing $\frac{1}{2} b^\top b$:

$$\frac{1}{2}(\bar{B}_n^\top C - \lambda_t^\top)(\bar{B}_n^\top C - \lambda_t^\top)^\top = \frac{1}{2}\bar{B}_n^\top C C^\top \bar{B}_n - \bar{B}_n^\top C \lambda_t + \frac{1}{2}\lambda_t^\top \lambda_t$$

The $\frac{1}{2}\lambda_t^\top \lambda_t$ cancels with the $-\frac{1}{2}\lambda_t^\top \lambda_t$ already in a, and $-\bar{B}_n^\top C \lambda_t = -\bar{B}_n^\top C(\lambda_0 + \lambda_z z_t)$.

$$\log p_t(n+1) = \underbrace{\bar{A}_n + \bar{B}_n^\top(\mu - C\lambda_0) + \frac{1}{2}\bar{B}_n^\top C C^\top \bar{B}_n - \delta_0}_{\bar{A}_{n+1}} + \underbrace{(\bar{B}_n^\top(\phi - C\lambda_z) - \delta_1^\top)}_{\bar{B}_{n+1}^\top} z_t$$

Matching the constant and the coefficient on z_t gives the Riccati equations (140.10) and (140.11).

Setting $n = 0$ with $p_t(1) = \exp(-r_t) = \exp(-\delta_0 - \delta_1^\top z_t)$ gives $\bar{A}_1 = -\delta_0$ and $\bar{B}_1 = -\delta_1$.

140.4.3 Yields

The **yield to maturity** on an n-period bond is the constant rate y at which one would discount the face value to obtain the observed price, i.e., $p_t(n) = e^{-n\,y}$.

Solving for y gives

$$y_t(n) = -\frac{\log p_t(n)}{n}$$

Substituting (140.9) gives

$$y_t(n) = A_n + B_n^\top z_t \tag{140.12}$$

where $A_n = -\bar{A}_n/n$ and $B_n = -\bar{B}_n/n$.

Yields are affine functions of the state vector z_t.

This is the defining property of affine term structure models.

We now implement the bond pricing formulas (140.10), (140.11), and (140.12).

```
def bond_coefficients(model, n_max):
    """Compute (A_bar_n, B_bar_n) for n = 1, ..., n_max."""
    A_bar = np.zeros(n_max + 1)
    B_bar = np.zeros((n_max + 1, model.m))
    A_bar[1], B_bar[1] = -model.δ_0, -model.δ_1
    CC = model.C @ model.C.T
    for n in range(1, n_max):
        Bn = B_bar[n]
        A_bar[n + 1] = (A_bar[n] + Bn @ model.μ_rn
                        + 0.5 * Bn @ CC @ Bn
                        - model.δ_0)
        B_bar[n + 1] = model.ψ_rn.T @ Bn - model.δ_1
    return A_bar, B_bar

def compute_yields(model, z, n_max):
    """Compute yield curve y_t(n) for n = 1, ..., n_max."""
    A_bar, B_bar = bond_coefficients(model, n_max)
    return np.array([(-A_bar[n] - B_bar[n] @ z) / n
                     for n in range(1, n_max + 1)])

def bond_prices(model, z, n_max):
    """Compute bond prices p_t(n) for n = 1, ..., n_max."""
    A_bar, B_bar = bond_coefficients(model, n_max)
    return np.array([np.exp(A_bar[n] + B_bar[n] @ z)
                     for n in range(1, n_max + 1)])
```

140.4.4 A one-factor Gaussian example

To build intuition, we start with a single-factor ($m = 1$) Gaussian model.

With $m = 1$, the state z_t follows an AR(1) process $z_{t+1} = \mu + \phi z_t + C\varepsilon_{t+1}$.

The unconditional standard deviation of z_t is $\sigma_z = C/\sqrt{1-\phi^2}$, which determines the range of short rates the model generates via $r_t = \delta_0 + \delta_1 z_t$.

```
# One-factor Gaussian model (quarterly)
μ      = np.array([0.0])
φ      = np.array([[0.95]])
C      = np.array([[1.0]])
δ_0    = 0.01                  # 1%/quarter ≈ 4% p.a.
δ_1    = np.array([0.001])
λ_0    = np.array([-0.05])
λ_z    = np.array([[-0.01]])

model_1f = create_affine_model(μ, φ, C, δ_0, δ_1, λ_0, λ_z)
```

140.4.5 Yield curve shapes

We compute yield curves $y_t(n)$ across a range of short-rate states z_t.

```
n_max_1f = 200
maturities_1f = np.arange(1, n_max_1f + 1)

z_low  = np.array([-5.0])
z_mid  = np.array([0.0])
z_high = np.array([5.0])

fig, ax = plt.subplots(figsize=(9, 5.5))

r_low = short_rate(model_1f, z_low) * 4 * 100
r_mid = short_rate(model_1f, z_mid) * 4 * 100
r_high = short_rate(model_1f, z_high) * 4 * 100

for z, label in [
    (z_low,  f"Low state  ($y_t(1) = ${r_low:.1f}%)"),
    (z_mid,  f"Median state ($y_t(1) = ${r_mid:.1f}%)"),
    (z_high, f"High state ($y_t(1) = ${r_high:.1f}%)"),
]:
    y = compute_yields(model_1f, z, n_max_1f) * 4 * 100
    line, = ax.plot(maturities_1f, y, lw=2.2, label=label)
    ax.plot(1, y[0], 'o', color=line.get_color(), ms=7, zorder=5)

r_bar = short_rate(model_1f, np.array([0.0])) * 4 * 100
ax.axhline(r_bar, color='grey', ls=':', lw=1.2, alpha=0.7,
           label=f"Mean short rate ({r_bar:.1f}%)")

# Long-run yield: B_bar_n converges, so y_inf = lim -A_bar_n / n
φ_Cλ = (model_1f.φ_rn)[0, 0]          # φ - Cλ_z (scalar)
B_inf = -model_1f.δ_1[0] / (1 - φ_Cλ) # fixed point of B recursion
A_increment = (B_inf * model_1f.μ_rn[0]
               + 0.5 * B_inf**2 * (model_1f.C @ model_1f.C.T)[0, 0]
               - model_1f.δ_0)
y_inf = -A_increment * 4 * 100         # annualised %
ax.axhline(y_inf, color='black', ls='--', lw=1.2, alpha=0.7,
           label=f"Long-run yield ({y_inf:.1f}%)")

ax.set_xlabel("Maturity (quarters)")
ax.set_ylabel("Yield (% per annum)")
ax.legend(fontsize=10, loc='best')
ax.set_xlim(1, n_max_1f)
```

(continues on next page)

(continued from previous page)

```
ax2 = ax.twiny()
ax2.set_xlim(ax.get_xlim())
year_ticks = [4, 40, 80, 120, 160, 200]
ax2.set_xticks(year_ticks)
ax2.set_xticklabels([f"{t/4:.0f}y" for t in year_ticks])
ax2.set_xlabel("Maturity (years)")

plt.tight_layout()
plt.show()
```

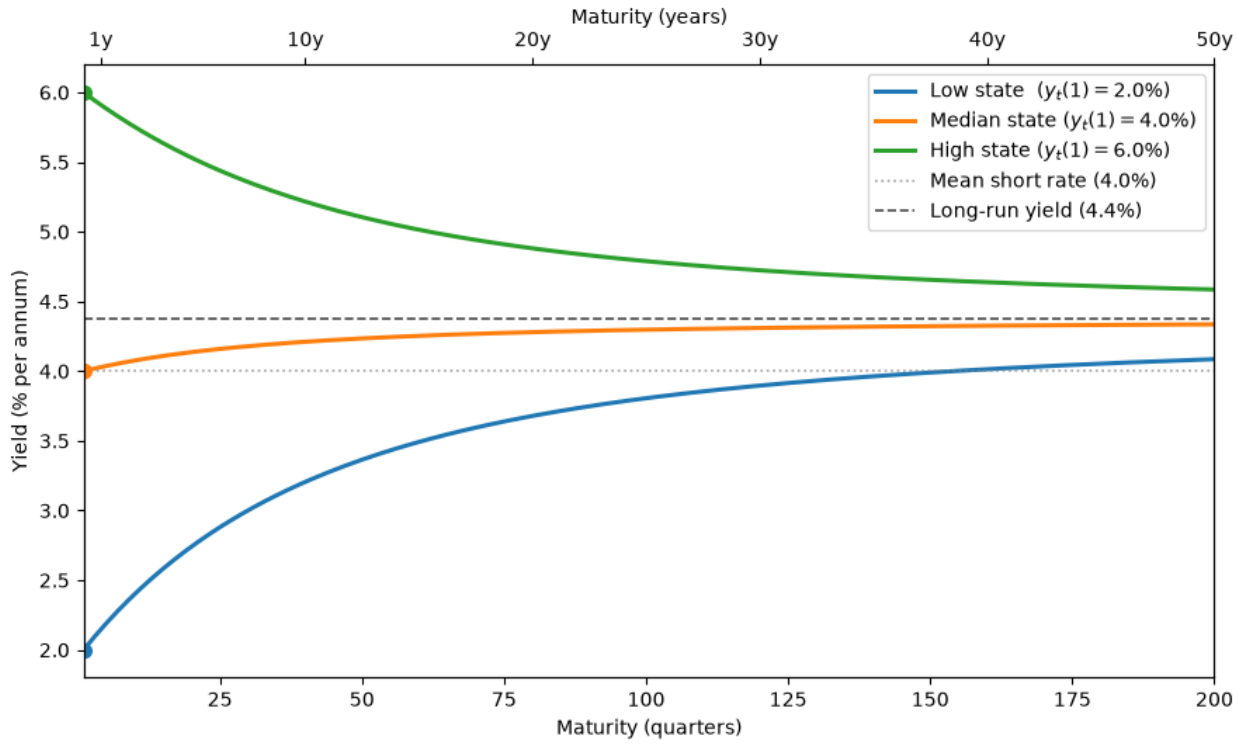


Fig. 140.1: Yield curves under the one-factor affine model

When the short rate is low, the yield curve is upward-sloping, while when the short rate is high, it is downward-sloping.

All three curves approach the same long-run yield y_∞, which lies above the mean short rate δ_0.

The approach is slow.

Because $\bar{B}_n$ converges to a finite limit, the state enters $y_t(n)$ through $\bar{B}_n^\top z_t / n$, so gaps between curves shrink only at rate $1/n$.

That is why we plot maturities out to 50 years: at 15 years the three curves are still spread between about 3.5% and 5.0%, while at 50 years they lie between about 4.1% and 4.6%.

Exercise 140.4.2

Show that the long-run yield satisfies

$$y_\infty = \delta_0 - \bar{B}_\infty^\top(\mu - C\lambda_0) - \tfrac{1}{2}\bar{B}_\infty^\top CC^\top \bar{B}_\infty \tag{140.13}$$

where $\bar{B}_\infty = -(I - (\phi - C\lambda_z)^\top)^{-1}\delta_1$ is the fixed point of the recursion (140.11).

Then explain why $y_\infty > \delta_0$ under this parameterization.

Hint: Use (140.12) and the Riccati equations (140.10)–(140.11).

For the inequality, consider each subtracted term separately.

Solution

The recursion (140.11) is a linear difference equation $\bar{B}_{n+1} = (\phi - C\lambda_z)^\top \bar{B}_n - \delta_1$.

When $\phi - C\lambda_z$ has eigenvalues inside the unit circle, $\bar{B}_n$ converges to $\bar{B}_\infty = -(I - (\phi - C\lambda_z)^\top)^{-1}\delta_1$.

Since $\bar{B}_\infty$ is finite, $\bar{B}_n^\top z_t/n \to 0$ in (140.12), so $y_t(n) \to \lim_{n\to\infty} -\bar{A}_n/n$ regardless of z_t.

To find this limit, write $\bar{A}_n = \bar{A}_1 + \sum_{k=1}^{n-1}(\bar{A}_{k+1} - \bar{A}_k)$.

By (140.10), each increment depends on $\bar{B}_k$, which converges to $\bar{B}_\infty$, so the increment converges to $L \equiv \bar{B}_\infty^\top(\mu - C\lambda_0) + \frac{1}{2}\bar{B}_\infty^\top CC^\top \bar{B}_\infty - \delta_0$.

Therefore $\bar{A}_n/n \to L$ and $y_\infty = -L$, giving (140.13).

To see why $y_\infty > \delta_0$, note that the two subtracted terms in (140.13) have opposite signs under this parameterization.

The quadratic term $\frac{1}{2}\bar{B}_\infty^\top CC^\top \bar{B}_\infty = \frac{1}{2}\|C^\top \bar{B}_\infty\|^2 \geq 0$ always.

This is a **convexity effect** from Jensen's inequality that pushes y_∞ below δ_0.

The linear term $\bar{B}_\infty^\top(\mu - C\lambda_0)$ is negative because $\bar{B}_\infty < 0$ (since $\delta_1 > 0$) while $\mu - C\lambda_0 > 0$ (since $\lambda_0 < 0$).

Subtracting this negative quantity raises y_∞ above δ_0.

This is a **risk-premium effect**: positive term premiums tilt the average yield curve upward.

Under this parameterization the risk-premium effect dominates the convexity effect, so $y_\infty > \delta_0$.

Let's also simulate the short rate path:

```
T = 200
Z = simulate(model_1f, np.array([0.0]), T)
short_rates = np.array([short_rate(model_1f, Z[t]) * 4 * 100
                        for t in range(T + 1)])
r_bar_pct = short_rate(model_1f, np.array([0.0])) * 4 * 100

fig, ax = plt.subplots(figsize=(10, 4))
quarters = np.arange(T + 1)
line, = ax.plot(quarters, short_rates, lw=1.3)
ax.axhline(r_bar_pct, ls="--", lw=1.3,
           label=f"Unconditional mean ({r_bar_pct:.1f}%)")
ax.fill_between(quarters, short_rates, r_bar_pct,
                alpha=0.08, color=line.get_color())
ax.set_xlabel("Quarter")
ax.set_ylabel("Short rate (% p.a.)")
ax.set_xlim(0, T)
```

(continues on next page)

(continued from previous page)

```
ax.legend(fontsize=11)
plt.tight_layout()
plt.show()
```

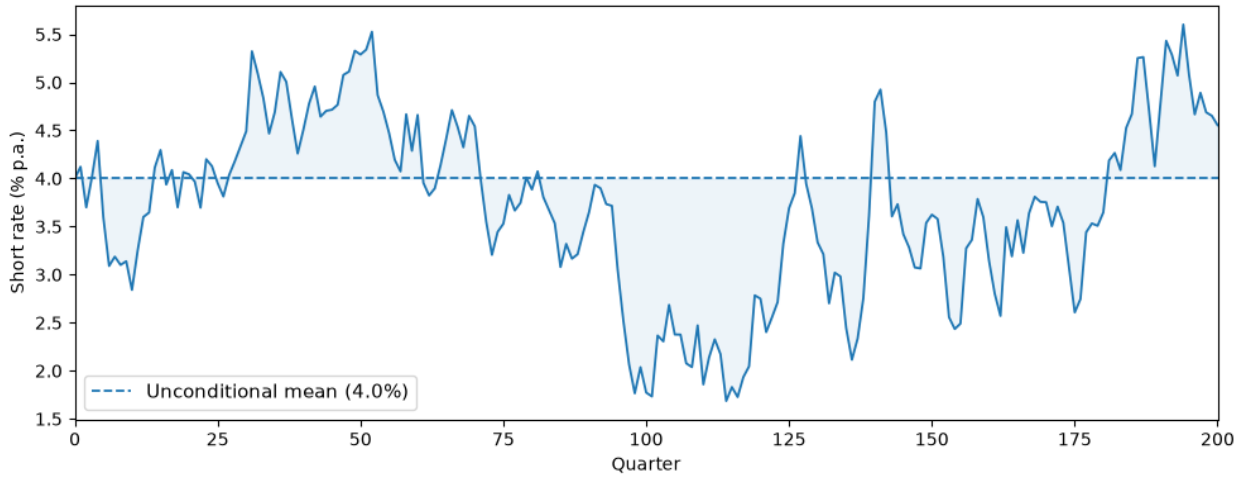

Fig. 140.2: Simulated short rate path

Because r_t is an affine function of a Gaussian state, a Gaussian affine model assigns positive probability to negative short rates.

Under the stationary distribution of the one-factor model, r_t is normal with mean δ_0 and standard deviation $\delta_1 \sigma_z$, which lets us compute that probability.

```
σ_z = model_1f.C[0, 0] / np.sqrt(1 - model_1f.ψ[0, 0]**2)
σ_r = model_1f.δ_1[0] * σ_z
print(f"Stationary std of r_t: {σ_r * 4 * 100:.2f}% p.a.")
print(f"P(r_t < 0):            {norm.cdf(-model_1f.δ_0 / σ_r):.2e}")
```

```
Stationary std of r_t: 1.28% p.a.
P(r_t < 0):            8.97e-04
```

The probability is small in this calibration, but it can be substantial in calibrations fit to periods of low interest rates.

Square-root models such as Cox *et al.* [1985] and shadow-rate models such as Black [1995] are two ways of keeping nominal rates non-negative, at the cost of some of the tractability that the Gaussian specification delivers.

140.4.6 A two-factor model

To match richer yield-curve dynamics, practitioners routinely use $m \geq 2$ factors.

We now introduce a two-factor specification with state $z_t = (z_{1t},\, z_{2t})^\top$, where

$$z_{t+1} = \mu + \phi\, z_t + C\, \varepsilon_{t+1}, \qquad \phi = \begin{pmatrix} 0.97 & -0.03 \\ 0 & 0.90 \end{pmatrix}, \qquad C = I_2$$

The first factor z_{1t} is highly persistent ($\phi_{11} = 0.97$) and drives most of the variation in the short rate through δ_1, so we interpret it as a **level** factor.

The second factor z_{2t} mean-reverts faster ($\phi_{22} = 0.90$) and affects the short rate with a smaller loading, capturing the **slope** of the yield curve.

The off-diagonal entry $\phi_{12} = -0.03$ allows the level factor to respond to the current slope state z_{2t}.

The short rate is $r_t = \delta_0 + \delta_1^\top z_t$ with $\delta_1 = (0.002,\ 0.001)^\top$, so both factors raise the short rate when positive, but the level factor has twice the impact.

Risk prices are $\lambda_t = \lambda_0 + \lambda_z z_t$ with $\lambda_0 = (-0.01,\ -0.005)^\top$ and $\lambda_z = \text{diag}(-0.005,\ -0.003)$.

The negative diagonal entries of λ_z make $\phi - C\lambda_z$ have larger eigenvalues than ϕ, so the state is more persistent under the risk-neutral measure and the yield curve is more sensitive to the current state at long horizons.

```
# Two-factor model: z = [level, slope]
μ_2  = np.array([0.0,  0.0])
φ_2  = np.array([[0.97, -0.03],
                 [0.00,  0.90]])
C_2  = np.eye(2)
δ_0_2 = 0.01
δ_1_2 = np.array([0.002, 0.001])
λ_0_2 = np.array([-0.01, -0.005])
λ_z_2 = np.array([[-0.005, 0.0],
                  [ 0.0, -0.003]])

model_2f = create_affine_model(μ_2, φ_2, C_2, δ_0_2, δ_1_2, λ_0_2, λ_z_2)

print(f"Eigenvalues of φ:       {eigvals(φ_2).real.round(4)}")
print(f"Eigenvalues of φ - Cλ_z: {eigvals(model_2f.φ_rn).real.round(4)}")
```

```
Eigenvalues of φ:       [0.97 0.9 ]
Eigenvalues of φ - Cλ_z: [0.975 0.903]
```

This confirms that the eigenvalues of $\phi - C\lambda_z$ are larger than those of ϕ, so the state is more persistent under the risk-neutral measure.

The following figure shows yield curves across different states of the world, as well as the factor loadings $B_{n,1}$ and $B_{n,2}$ that determine how yields load on the level and slope factors at each maturity

```
n_max_2f = 60
maturities_2f = np.arange(1, n_max_2f + 1)

states = {
    "Normal":              np.array([0.0,   0.0]),
    "Low short rate":      np.array([-4.0,  3.0]),
    "High short rate":     np.array([4.0,  -3.0]),
}

fig, (ax1, ax2) = plt.subplots(1, 2, figsize=(14, 5.5))

for label, z in states.items():
    r_now = short_rate(model_2f, z) * 4 * 100
    y = compute_yields(model_2f, z, n_max_2f) * 4 * 100
    line, = ax1.plot(maturities_2f, y, lw=2.2,
                     label=f"{label} (r₁ = {r_now:.1f}%)")
    ax1.plot(1, y[0], 'o', color=line.get_color(), ms=7, zorder=5)

ax1.set_xlabel("Maturity (quarters)")
ax1.set_ylabel("Yield (% p.a.)")
ax1.legend(fontsize=10)
```

(continues on next page)

(continued from previous page)

```
ax1.set_xlim(1, n_max_2f)

A_bar, B_bar = bond_coefficients(model_2f, n_max_2f)
ns = np.arange(1, n_max_2f + 1)
B_n = np.array([-B_bar[n] / n for n in ns])

ax2.plot(ns, B_n[:, 0], lw=2.2,
         label=r"Level loading $B_{n,1}$")
ax2.plot(ns, B_n[:, 1], lw=2.2,
         label=r"Slope loading $B_{n,2}$")
ax2.axhline(0, color='black', lw=0.6)
ax2.set_xlabel("Maturity (quarters)")
ax2.set_ylabel(r"Yield loading $B_{n,k}$")
ax2.legend(fontsize=11)
ax2.set_xlim(1, n_max_2f)

for ax in (ax1, ax2):
    ax_top = ax.twiny()
    ax_top.set_xlim(ax.get_xlim())
    year_ticks = [4, 12, 20, 40, 60]
    ax_top.set_xticks(year_ticks)
    ax_top.set_xticklabels([f"{t/4:.0f}y" for t in year_ticks])

plt.tight_layout()
plt.show()
```

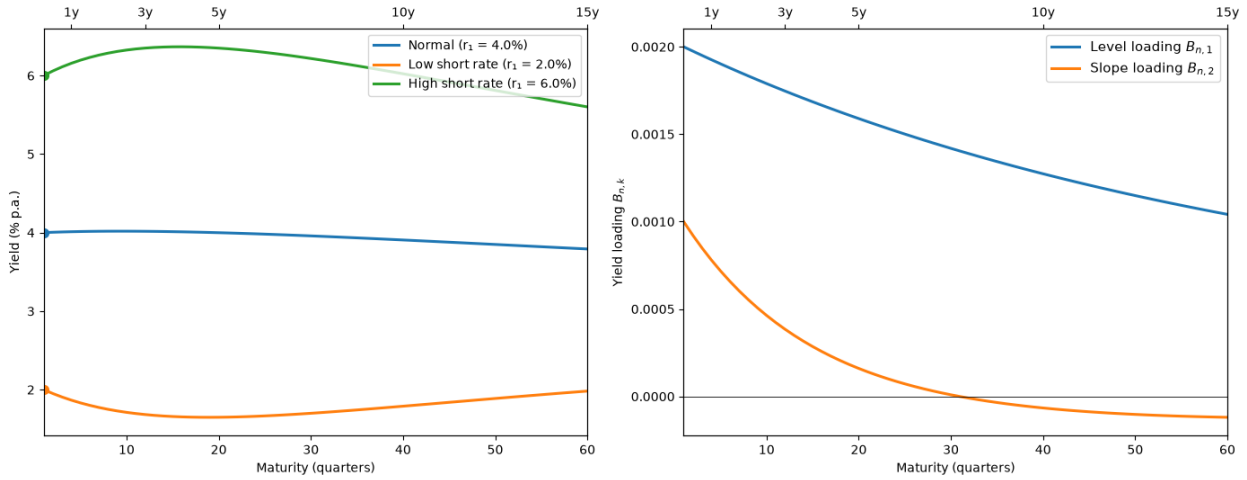

Fig. 140.3: Yield curves and factor loadings under the two-factor model

The right panel shows how yields at different maturities respond to the two factors.

The level loading $B_{n,1}$ declines gradually with maturity, from 0.002 at one quarter to about half that at 15 years, so the persistent factor moves yields at all maturities.

The slope loading $B_{n,2}$ starts at 0.001, decays quickly, and turns slightly negative beyond about 30 quarters.

The sign change reflects the off-diagonal entry $\phi_{12} = -0.03$: a high z_{2t} raises the short rate today but pushes the level factor, and hence future short rates, down.

As a result, the level factor dominates yields at long maturities, while the slope factor matters mainly at the short end.

As in the one-factor case, the curves in the left panel are still approaching their common long-run yield at 60 quarters.

140.5 Risk premiums

A key object in the affine term structure model is the **term premium**, the expected excess return on a long-term bond relative to rolling over short-term bonds.

For an $(n+1)$-period bond held for one period, the shock loading is $\alpha_n = C^\top \bar{B}_n$, so (140.7) gives

$$\log \mathbb{E}_t R_{t+1}^{(n+1)} - r_t \;=\; \bar{B}_n^\top C \lambda_t$$

The term premium equals the inner product of the bond's shock exposure $\bar{B}_n^\top C$ with the risk price vector λ_t.

This formula measures the premium as the log of an expected gross return.

The expected log excess return is smaller by a Jensen's inequality term:

$$\mathbb{E}_t \log R_{t+1}^{(n+1)} - r_t = \bar{B}_n^\top C \lambda_t - \tfrac{1}{2} \bar{B}_n^\top C C^\top \bar{B}_n$$

Only the first term depends on the state, so the two measures differ by a maturity-specific constant that does not affect how term premiums vary over time.

Because the term premium equals $\bar{B}_n^\top C \lambda_t$, its sign depends on the *current* risk-price vector λ_t, which is state-dependent whenever $\lambda_z \neq 0$.

To see this more concretely, consider a state where $C\lambda_t$ is negative componentwise (for example, $z_t = 0$ in our calibration below).

When $\delta_1 > 0$, a positive shock ε_{t+1} raises the short rate and lowers long-bond prices, so the bond shock loading $\alpha_n = C^\top \bar{B}_n$ is negative.

A negative $C\lambda_t$ then means the stochastic discount factor m_{t+1} loads positively on ε_{t+1}, i.e. the SDF is high in states where interest rates rise and bond prices fall.

This makes $\mathrm{Cov}_t(m_{t+1}, R_{t+1}^{(n+1)}) < 0$, so long bonds are risky and carry a positive term premium.

Algebraically, $\bar{B}_n < 0$ and $C\lambda_t < 0$ combine to give $\bar{B}_n^\top C \lambda_t > 0$.

In other states, however, components of λ_t can change sign.

With $\lambda_z < 0$, a low value of the level factor z_{1t} pushes the first component of λ_t above zero.

Since long bonds load mainly on the level shock, their term premiums then turn negative.

Exercise 140.5.1

Derive the term premium formula above by computing the one-period holding return on an $(n+1)$-period bond and identifying its shock loading.

Hint: Use $R_{t+1}^{(n+1)} = p_{t+1}(n)/p_t(n+1)$ with $\log p_t(n) = \bar{A}_n + \bar{B}_n^\top z_t$, substitute the state dynamics (140.1), and apply the Riccati equations (140.10)–(140.11) to simplify.

Solution

The one-period holding return on an $(n+1)$-period bond is $R_{t+1}^{(n+1)} = p_{t+1}(n)/p_t(n+1)$, so

$$\log R_{t+1}^{(n+1)} = \bar{A}_n + \bar{B}_n^\top z_{t+1} - \bar{A}_{n+1} - \bar{B}_{n+1}^\top z_t$$

Substituting $z_{t+1} = \mu + \phi z_t + C\varepsilon_{t+1}$ from (140.1):

$$= \underbrace{(\bar{A}_n + \bar{B}_n^\top \mu - \bar{A}_{n+1})}_{\text{constant}} + \underbrace{(\bar{B}_n^\top \phi - \bar{B}_{n+1}^\top)}_{\text{loading on } z_t} z_t + \underbrace{\bar{B}_n^\top C}_{\text{shock loading}} \varepsilon_{t+1}$$

We now use the Riccati equations to simplify each piece.

For the constant piece, (140.10) gives $\bar{A}_{n+1} = \bar{A}_n + \bar{B}_n^\top(\mu - C\lambda_0) + \frac{1}{2}\bar{B}_n^\top CC^\top \bar{B}_n - \delta_0$, so

$$\bar{A}_n + \bar{B}_n^\top \mu - \bar{A}_{n+1} = \bar{B}_n^\top C\lambda_0 - \tfrac{1}{2}\bar{B}_n^\top CC^\top \bar{B}_n + \delta_0$$

For the z_t coefficient, (140.11) gives $\bar{B}_{n+1}^\top = \bar{B}_n^\top(\phi - C\lambda_z) - \delta_1^\top$, so

$$\bar{B}_n^\top \phi - \bar{B}_{n+1}^\top = \bar{B}_n^\top C\lambda_z + \delta_1^\top$$

Combining the pieces:

$$\log R_{t+1}^{(n+1)} = \underbrace{(\delta_0 + \delta_1^\top z_t)}_{r_t} + \bar{B}_n^\top C \underbrace{(\lambda_0 + \lambda_z z_t)}_{\lambda_t} - \tfrac{1}{2}\bar{B}_n^\top CC^\top \bar{B}_n + \bar{B}_n^\top C\,\varepsilon_{t+1}$$

Writing $\alpha_n = C^\top \bar{B}_n$, this takes the generic return form (140.5):

$$\log R_{t+1}^{(n+1)} = \underbrace{(r_t + \alpha_n^\top \lambda_t)}_{\nu_t} - \tfrac{1}{2}\alpha_n^\top \alpha_n + \alpha_n^\top \varepsilon_{t+1}$$

Since $\mathbb{E}_t R_{t+1}^{(n+1)} = \exp(\nu_t)$, we obtain

$$\log \mathbb{E}_t R_{t+1}^{(n+1)} - r_t = \alpha_n^\top \lambda_t = \bar{B}_n^\top C\lambda_t$$

The following figure plots term premiums across maturities for different states of the world, as well as the level and slope factor contributions to the term premium in the normal state

```
def term_premiums(model, z, n_max):
    """
    Compute one-period term premiums on bonds of maturity 1, ..., n_max.

    An n-period bond held for one period becomes an (n-1)-period bond,

```

The left panel shows that the sign of the term premium depends on the state.

In the high-rate state, $\lambda_t \approx (-0.025, 0.001)$, and the term premium is positive and rises with maturity, reaching about 0.6% per year at 15 years.

In the low-rate state, the first component of λ_t has turned positive, $\lambda_t \approx (0.005, -0.011)$, and the term premium is negative at every maturity, falling to about -0.15% per year at 15 years.

Investors in the low-rate state accept a lower expected return on long bonds than on rolling over short bonds because long bonds pay off well in the states that they value most.

The right panel decomposes the term premium at $z_t = 0$, where both components of λ_t are negative.

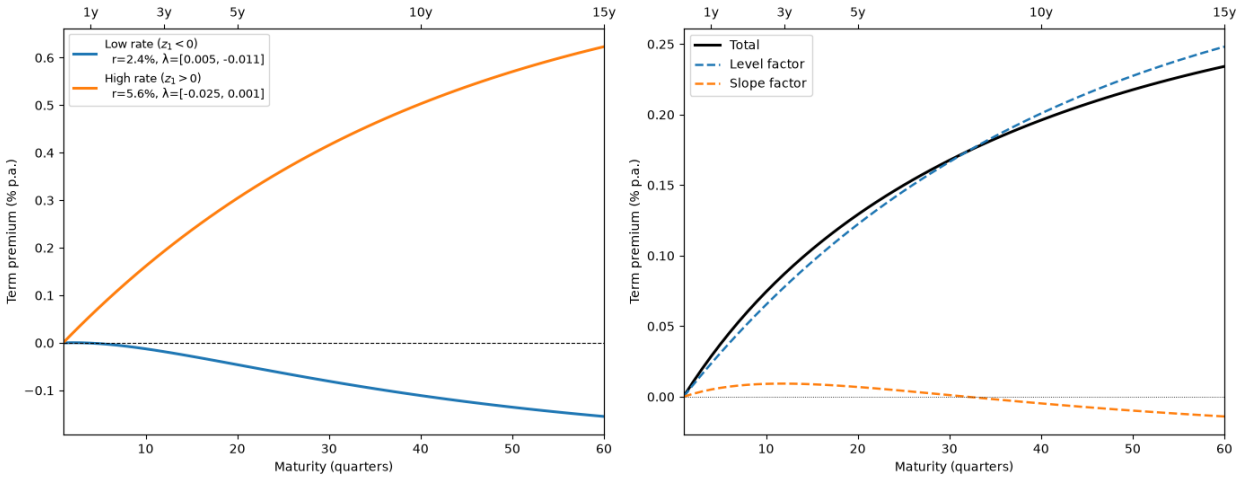

Fig. 140.4: Term premiums and factor decomposition under the two-factor model

The level factor accounts for almost all of the premium at long maturities.

The slope contribution is small and turns negative beyond about 30 quarters, mirroring the sign change in the slope loading shown earlier.

Exercise 140.5.2

The expectations hypothesis says that expected excess returns on long bonds are constant over time, so that they cannot be forecast by the yield spread.

1. Simulate the two-factor model `model_2f` for $T = 200{,}000$ quarters. Regress the one-quarter excess holding return on a 20-quarter bond, $\log p_{t+1}(19) - \log p_t(20) - r_t$, on a constant and the spread $y_t(20) - r_t$.
2. Compute the population regression slope implied by the model, using $\bar{B}_n$ and the stationary covariance matrix Σ_z of z_t, and compare it with your estimate.
3. Repeat both steps with $\lambda_z = 0$ and explain the result.
4. In U.S. data, Fama and Bliss [1987] and Campbell and Shiller [1991] find that high spreads forecast *high* excess returns on long bonds. Does `model_2f` reproduce this pattern? What happens if you flip the sign of λ_z?

Solution

From (140.7) and the term-premium formula, the log excess holding return on a 20-quarter bond is

$$x_{t+1} = \bar{B}_{19}^\top C \lambda_t - \tfrac{1}{2} \bar{B}_{19}^\top C C^\top \bar{B}_{19} + \bar{B}_{19}^\top C \varepsilon_{t+1}$$

Its conditional mean is a constant plus $a^\top z_t$ with $a = \lambda_z^\top C^\top \bar{B}_{19}$.

The spread is $s_t = y_t(20) - r_t = \text{constant} + b^\top z_t$ with $b = -\bar{B}_{20}/20 - \delta_1$.

Because ε_{t+1} is orthogonal to z_t, the population slope is

$$\beta = \frac{a^\top \Sigma_z b}{b^\top \Sigma_z b}$$

where Σ_z solves $\Sigma_z = \phi \Sigma_z \phi^\top + C C^\top$.

```
def eh_regression(model, n=20, T=200_000, seed=1):
    """OLS and population slopes of excess returns on the yield spread."""
    A_bar, B_bar = bond_coefficients(model, n)
    z_bar = np.linalg.solve(np.eye(model.m) - model.ψ, model.μ)
    Z = simulate(model, z_bar, T, rng=np.random.default_rng(seed))

    r = model.δ_0 + Z[:-1] @ model.δ_1
    log_p = lambda k, z: A_bar[k] + z @ B_bar[k]
    excess = log_p(n - 1, Z[1:]) - log_p(n, Z[:-1]) - r
    spread = -log_p(n, Z[:-1]) / n - r

    X = np.column_stack([np.ones(T), spread])
    coef = np.linalg.lstsq(X, excess, rcond=None)[0]
    resid = excess - X @ coef
    se = np.sqrt(resid.var() / (T * spread.var()))

    Σ_z = solve_discrete_lyapunov(model.ψ, model.C @ model.C.T)
    a = model.λ_z.T @ model.C.T @ B_bar[n - 1]
    b = -B_bar[n] / n - model.δ_1
    β_pop = (a @ Σ_z @ b) / (b @ Σ_z @ b)
    return coef[1], se, β_pop

cases = {
    "λ_z as calibrated": λ_z_2,
    "λ_z = 0":           np.zeros((2, 2)),
    "λ_z sign flipped":  -λ_z_2,
}
print(f"{'case':>20}  {'OLS slope':>10}  {'s.e.':>7}  {'population':>10}")
for label, lz in cases.items():
    mod = create_affine_model(μ_2, ψ_2, C_2, δ_0_2, δ_1_2, λ_0_2, lz)
    b_ols, se, b_pop = eh_regression(mod)
    print(f"{label:>20}  {b_ols:>10.4f}  {se:>7.4f}  {b_pop:>10.4f}")
```

```
                case   OLS slope      s.e.  population
   λ_z as calibrated     -0.1614    0.0280     -0.1723
             λ_z = 0      0.0112    0.0250      0.0000
    λ_z sign flipped      0.1728    0.0224      0.1618
```

With the calibrated λ_z, the OLS slope is close to the population slope of about -0.17 and is many standard errors from zero, so the expectations hypothesis fails in simulated data.

With $\lambda_z = 0$, the vector a is zero, so expected excess returns are constant and the population slope is exactly zero.

The OLS estimate is then within sampling error of zero.

The expectations hypothesis holds in an affine model exactly when risk prices do not vary with the state.

The calibrated model gets the *sign* of the Fama–Bliss and Campbell–Shiller finding wrong: a high spread forecasts a low excess return.

Flipping the sign of λ_z reverses the sign of the slope, which shows that the regression evidence is informative about λ_z and not just about the size of average term premiums.

140.6 Risk-neutral probabilities

We return to the VAR and short-rate equations (140.1)–(140.2), which for convenience we repeat here:

$$z_{t+1} = \mu + \phi z_t + C\varepsilon_{t+1}, \qquad r_t = \delta_0 + \delta_1^\top z_t$$

where $\varepsilon_{t+1} \sim \mathcal{N}(0, I)$.

We suppose that this structure describes the data-generating mechanism.

Finance economists call this the **physical measure** P, to distinguish it from the **risk-neutral measure** Q that we now describe.

Under the physical measure, the conditional distribution of z_{t+1} given z_t is $\mathcal{N}(\mu + \phi z_t,\ CC^\top)$.

140.6.1 Change of measure

With the risk-price vector $\lambda_t = \lambda_0 + \lambda_z z_t$ from (140.3), define the non-negative random variable

$$\frac{\xi_{t+1}^Q}{\xi_t^Q} = \exp\left(-\tfrac{1}{2}\lambda_t^\top \lambda_t - \lambda_t^\top \varepsilon_{t+1}\right) \tag{140.14}$$

This is a log-normal random variable with mean 1, so it is a valid likelihood ratio that can be used to twist the conditional distribution of z_{t+1}.

To see what the twist does to the shocks, multiply the standard normal density of ε_{t+1} by (140.14):

$$(2\pi)^{-m/2} \exp\left(-\tfrac{1}{2}\varepsilon^\top \varepsilon\right) \exp\left(-\tfrac{1}{2}\lambda_t^\top \lambda_t - \lambda_t^\top \varepsilon\right) = (2\pi)^{-m/2} \exp\left(-\tfrac{1}{2}(\varepsilon + \lambda_t)^\top (\varepsilon + \lambda_t)\right)$$

So under Q the shock is $\varepsilon_{t+1} \sim \mathcal{N}(-\lambda_t, I)$: the twist shifts its mean by $-\lambda_t$ and leaves its covariance matrix unchanged.

Substituting $\varepsilon_{t+1} = -\lambda_t + \varepsilon_{t+1}^Q$ into (140.1) shows that multiplying the physical conditional distribution by this likelihood ratio transforms it into the **risk-neutral conditional distribution**

$$z_{t+1} \mid z_t \overset{Q}{\sim} \mathcal{N}(\mu - C\lambda_0 + (\phi - C\lambda_z) z_t,\ CC^\top)$$

In other words, under Q the state follows

$$z_{t+1} = (\mu - C\lambda_0) + (\phi - C\lambda_z)\, z_t + C\varepsilon_{t+1}^Q$$

where $\varepsilon_{t+1}^Q \sim \mathcal{N}(0, I)$ under Q.

The risk-neutral distribution twists the conditional mean from $\mu + \phi z_t$ to $\mu - C\lambda_0 + (\phi - C\lambda_z) z_t$.

The adjustments $-C\lambda_0$ (constant) and $-C\lambda_z$ (state-dependent) encode how the pricing equation $\mathbb{E}_t^P m_{t+1} R_{j,t+1} = 1$ adjusts expected returns for exposure to the risks ε_{t+1}.

Exercise 140.6.1

How different are the risk-neutral and physical measures?

A natural measure is relative entropy (Kullback–Leibler divergence), discussed in *Statistical Divergence Measures*.

1. Show that the conditional relative entropy of Q with respect to P, $\mathbb{E}_t^Q\left[\log(\xi_{t+1}^Q / \xi_t^Q)\right]$, and the conditional relative entropy of P with respect to Q, $\mathbb{E}_t^P\left[-\log(\xi_{t+1}^Q / \xi_t^Q)\right]$, both equal $\frac{1}{2}\lambda_t^\top \lambda_t$.

2. Suppose that z_0 is drawn from the stationary distribution of z_t under P. Show that the relative entropy of P with respect to Q for a sample $z_1, \ldots, z_T$ equals T times $\$\frac{1}{2}\left(\bar{\lambda}^\top \bar{\lambda} + \text{tr}(\lambda_z \Sigma_z \lambda_z^\top)\right) where \bar z = (I - \phi)^{-1}\mu, \bar\lambda = \lambda_0 + \lambda_z \bar z, and \Sigma_z solves \Sigma_z = \phi\Sigma_z\phi^\top + CC^\top\$$.
3. Evaluate this formula for `model_2f`, verify it by simulation, and use Pinsker's inequality to bound how well any test based on 100 years of quarterly data on z_t could distinguish P from Q.

Solution

Part 1. We showed above that $\varepsilon_{t+1} \sim \mathcal{N}(-\lambda_t, I)$ under Q, while $\varepsilon_{t+1} \sim \mathcal{N}(0, I)$ under P.

Hence

$$\mathbb{E}_t^Q \left[-\tfrac{1}{2}\lambda_t^\top \lambda_t - \lambda_t^\top \varepsilon_{t+1}\right] = -\tfrac{1}{2}\lambda_t^\top \lambda_t + \lambda_t^\top \lambda_t = \tfrac{1}{2}\lambda_t^\top \lambda_t$$

and

$$\mathbb{E}_t^P \left[\tfrac{1}{2}\lambda_t^\top \lambda_t + \lambda_t^\top \varepsilon_{t+1}\right] = \tfrac{1}{2}\lambda_t^\top \lambda_t$$

The two divergences coincide because the two conditional distributions are normal with the same covariance matrix.

Part 2. When C is invertible, the path $z_1, \ldots, z_T$ and the shocks $\varepsilon_1, \ldots, \varepsilon_T$ determine each other given z_0.

The log likelihood ratio of the path is therefore the sum of the one-period log likelihood ratios, and by the law of iterated expectations its expectation under P is $\sum_{t=0}^{T-1} \mathbb{E}^P \left[\frac{1}{2}\lambda_t^\top \lambda_t\right]$.

Under the stationary distribution, $\lambda_t = \bar\lambda + \lambda_z(z_t - \bar z)$ with $\mathbb{E}(z_t - \bar z) = 0$ and $\text{Var}(z_t) = \Sigma_z$.

Therefore $\mathbb{E}(\lambda_t^\top \lambda_t) = \bar\lambda^\top \bar\lambda + \text{tr}(\lambda_z \Sigma_z \lambda_z^\top)$ for every t, which gives the formula.

Part 3. Pinsker's inequality says that the total variation distance between two distributions is at most $\sqrt{D/2}$, where D is their relative entropy.

With equal prior probabilities on P and Q, the smallest achievable probability of choosing the wrong model is $(1 - \text{TV})/2$, so it is at least $(1 - \sqrt{D/2})/2$.

```
z_bar_2 = np.linalg.solve(np.eye(2) - model_2f.φ, model_2f.μ)
Σ_z_2 = solve_discrete_lyapunov(model_2f.φ, model_2f.C @ model_2f.C.T)
λ_bar_2 = risk_prices(model_2f, z_bar_2)
entropy = 0.5 * (λ_bar_2 @ λ_bar_2
                 + np.trace(model_2f.λ_z @ Σ_z_2 @ model_2f.λ_z.T))

Z_sim = simulate(model_2f, z_bar_2, 200_000, rng=np.random.default_rng(7))
Λ_sim = model_2f.λ_0 + Z_sim @ model_2f.λ_z.T
entropy_sim = 0.5 * np.mean(np.sum(Λ_sim**2, axis=1))

T_years = 100
D = 4 * T_years * entropy
print(f"relative entropy per quarter (formula):    {entropy:.6f}")
print(f"relative entropy per quarter (simulation): {entropy_sim:.6f}")
print(f"relative entropy over {T_years} years:           {D:.4f}")
print(f"lower bound on error probability:          {(1 - np.sqrt(D / 2)) / 2:.3f}")
```

```
relative entropy per quarter (formula):    0.000312
relative entropy per quarter (simulation): 0.000310
relative entropy over 100 years:           0.1250
lower bound on error probability:          0.375
```

Even with a century of quarterly data, no test can push the average probability of choosing the wrong model below about 37%.

Yet the gap between these two hard-to-distinguish measures is exactly what generates the term premiums plotted above.

Time-series data on the state alone therefore say little about risk prices, which is why estimates of λ_0 and λ_z rely heavily on the cross-section of bond yields.

This echoes the detection-error calculations of Doubts or Variability?, where plausible amounts of model uncertainty are calibrated in the same way.

140.6.2 Asset pricing in a nutshell

Let $\mathbb{E}^P$ denote an expectation under the physical measure that nature uses to generate the data.

Our key asset pricing equation is $\mathbb{E}_t^P m_{t+1} R_{j,t+1} = 1$ for all returns $R_{j,t+1}$.

Using (140.14), we can express the SDF (140.4) as

$$m_{t+1} = \frac{\xi_{t+1}^Q}{\xi_t^Q} \exp(-r_t)$$

Then the condition $\mathbb{E}_t^P(\exp(-r_t) \frac{\xi_{t+1}^Q}{\xi_t^Q} R_{j,t+1}) = 1$ is equivalent to

$$\mathbb{E}_t^Q R_{j,t+1} = \exp(r_t) \tag{140.15}$$

Under the risk-neutral measure, expected returns on all assets equal the risk-free return.

140.6.3 Verification via risk-neutral pricing

Bond prices can be computed by discounting at r_t under Q:

$$p_t(n) = \mathbb{E}_t^Q \left[\exp\left(-\sum_{s=0}^{n-1} r_{t+s} \right) \right]$$

We can verify that this agrees with (140.9) by iterating the affine recursion under the risk-neutral VAR.

Below we confirm this numerically

```
def bond_price_mc_Q(model, z0, n, n_sims=50_000, rng=None):
    """Estimate p_t(n) by Monte Carlo under Q; return estimate and std. error."""
    if rng is None:
        rng = np.random.default_rng(0)
    m = len(z0)
    Z = np.tile(z0, (n_sims, 1))
    disc = np.zeros(n_sims)
    for _ in range(n):
        disc += model.δ_0 + Z @ model.δ_1
        ε = rng.standard_normal((n_sims, m))
        Z = model.μ_rn + Z @ model.ψ_rn.T + ε @ model.C.T
    payoffs = np.exp(-disc)
    return payoffs.mean(), payoffs.std() / np.sqrt(n_sims)
```

(continues on next page)

    se_bp = se / analytic * 10_000
    print(f"{n:>10}  {analytic:>10.6f}  {mc:>11.6f}"
          f"  {error_bp:>11.2f}  {se_bp:>10.2f}  {error_bp / se_bp:>8.2f}")
```

```
  Maturity    Analytic  Monte Carlo  Error (bps)  s.e. (bps)   z-score
------------------------------------------------------------------------
         4    0.960592     0.960571        -0.23        0.25     -0.89
        12    0.886276     0.886200        -0.86        1.35     -0.64
        24    0.787066     0.787580         6.53        3.47      1.88
        40    0.676314     0.676398         1.24        6.61      0.19
```

The table reports each Monte Carlo error alongside its standard error, both in basis points of the analytical price.

All the z-scores are within ± 2, so the differences between analytical and simulated prices are consistent with pure simulation noise.

This validates the Riccati recursion (140.10)–(140.11).

140.7 Distorted beliefs

Piazzesi *et al.* [2015] assemble survey evidence suggesting that economic experts' forecasts are systematically biased relative to the physical measure.

140.7.1 The subjective measure

Let $\{z_t\}_{t=1}^T$ be a record of observations on the state and let $\{\check{z}_{t+1}\}_{t=1}^T$ be a record of one-period-ahead expert forecasts.

Let $\check{\mu}, \check{\phi}$ be the regression coefficients in

$$\check{z}_{t+1} = \check{\mu} + \check{\phi}\, z_t + e_{t+1}$$

where the residual e_{t+1} has mean zero, is orthogonal to z_t, and satisfies $\mathbb{E}\, e_{t+1} e_{t+1}^\top = CC^\top$.

By comparing estimates of μ, ϕ from (140.1) with estimates of $\check{\mu}, \check{\phi}$ from the experts' forecasts, Piazzesi *et al.* [2015] deduce that the experts' beliefs are systematically distorted.

To organize this evidence, let $\kappa_t = \kappa_0 + \kappa_z z_t$ and define the likelihood ratio

$$\frac{\xi_{t+1}^S}{\xi_t^S} = \exp\left(-\tfrac{1}{2}\kappa_t^\top \kappa_t - \kappa_t^\top \varepsilon_{t+1}\right) \tag{140.16}$$

This is log-normal with mean 1, so it is a valid likelihood ratio.

Multiplying the physical conditional distribution of z_{t+1} by this likelihood ratio transforms it to the experts' **subjective conditional distribution**

$$z_{t+1} \mid z_t \overset{S}{\sim} \mathcal{N}(\mu - C\kappa_0 + (\phi - C\kappa_z)\, z_t,\; CC^\top)$$

In the experts' forecast regression, $\breve{\mu}$ estimates $\mu - C\kappa_0$ and $\breve{\phi}$ estimates $\phi - C\kappa_z$.

Piazzesi *et al.* [2015] find that the experts behave as if the level and slope of the yield curve are more persistent than under the physical measure: $\breve{\phi}$ has larger eigenvalues than ϕ.

140.7.2 Pricing under distorted beliefs

Piazzesi *et al.* [2015] explore the hypothesis that a representative agent with these distorted beliefs prices assets and makes returns satisfy

$$\mathbb{E}_t^S(m_{t+1}^\star\, R_{j,t+1}) = 1$$

where $\mathbb{E}_t^S$ is the conditional expectation under the subjective S measure and $m_{t+1}^\star$ is the SDF of an agent with these beliefs.

To express the agent's SDF, define the **subjective shocks**

$$\varepsilon_{t+1}^S = \varepsilon_{t+1} + \kappa_t$$

By the same argument we used for the risk-neutral measure, $\varepsilon_{t+1}^S \sim \mathcal{N}(0, I)$ under S, and the state evolves as

$$z_{t+1} = (\mu - C\kappa_0) + (\phi - C\kappa_z)z_t + C\varepsilon_{t+1}^S$$

The agent's SDF is exponential quadratic in these subjective shocks:

$$m_{t+1}^\star = \exp\!\big(-r_t - \tfrac{1}{2}\lambda_t^{\star\top}\lambda_t^\star - \lambda_t^{\star\top}\varepsilon_{t+1}^S\big)$$

where $\lambda_t^\star = \lambda_0^\star + \lambda_z^\star z_t$ is the agent's vector of risk prices.

Because $\mathbb{E}_t^S m_{t+1}^\star = \exp(-r_t)$, the short rate in this SDF is the market short rate r_t that we observe.

Using (140.16) to convert to the physical measure, the subjective pricing equation becomes

$$\mathbb{E}_t^P\big[\exp\!\big(-r_t - \tfrac{1}{2}\lambda_t^{\star\top}\lambda_t^\star - \lambda_t^{\star\top}(\varepsilon_{t+1} + \kappa_t)\big)\exp\!\big(-\tfrac{1}{2}\kappa_t^\top\kappa_t - \kappa_t^\top\varepsilon_{t+1}\big)\, R_{j,t+1}\big] = 1$$

The constant terms in the combined exponent are $-r_t - \frac{1}{2}\lambda_t^{\star\top}\lambda_t^\star - \lambda_t^{\star\top}\kappa_t - \frac{1}{2}\kappa_t^\top\kappa_t = -r_t - \frac{1}{2}(\lambda_t^\star + \kappa_t)^\top(\lambda_t^\star + \kappa_t)$, so the two exponentials combine exactly into

$$\mathbb{E}_t^P\big[\exp\!\big(-r_t - \tfrac{1}{2}(\lambda_t^\star + \kappa_t)^\top(\lambda_t^\star + \kappa_t) - (\lambda_t^\star + \kappa_t)^\top\varepsilon_{t+1}\big)\, R_{j,t+1}\big] = 1$$

Comparing this with the rational-expectations econometrician's pricing equation

$$\mathbb{E}_t^P\big[\exp\!\big(-r_t - \tfrac{1}{2}\lambda_t^\top\lambda_t - \lambda_t^\top\varepsilon_{t+1}\big)\, R_{j,t+1}\big] = 1$$

we see that what the econometrician interprets as λ_t is actually

$$\widehat{\lambda}_t = \lambda_t^\star + \kappa_t$$

140.7.3 What bond prices can and cannot reveal

The decomposition has a simple interpretation in terms of the risk-neutral measure.

Starting from the physical measure, the econometrician reaches Q by twisting with $\hat{\lambda}_t$:

$$\mu - C\hat{\lambda}_0 = (\mu - C\kappa_0) - C\lambda_0^\star, \qquad \phi - C\hat{\lambda}_z = (\phi - C\kappa_z) - C\lambda_z^\star$$

The right sides show that the agent reaches the *same* Q by twisting the subjective measure with $\lambda_t^\star$.

Since bond prices depend only on Q, the econometrician and the agent agree about every bond price.

They disagree about expected returns.

The term premium measured by the econometrician is $\bar{B}_n^\top C\hat{\lambda}_t$, while the premium that the agent expects is $\bar{B}_n^\top C\lambda_t^\star$.

The difference, $\bar{B}_n^\top C\kappa_t$, is the part of measured excess returns that the agent does not expect and that therefore shows up as predictable forecast errors.

Bond prices and data on z_t identify $\hat{\lambda}_t$, but they cannot split it into $\lambda_t^\star$ and κ_t.

Splitting it requires direct evidence on beliefs, such as the survey forecasts used by Piazzesi *et al.* [2015].

The same identification problem is central to *The Recovery Theorem* and *Misspecified Recovery*, which ask when risk-neutral prices alone can reveal subjective beliefs.

140.7.4 A numerical illustration

We keep the same physical state dynamics and short-rate specification as above, choose the agent's risk prices $\lambda_t^\star$, and deduce the econometrician's risk prices $\hat{\lambda}_t = \lambda_t^\star + \kappa_t$.

We set the subjective parameters $\check{\mu}, \check{\phi}$ to match the evidence in Piazzesi *et al.* [2015] that experts behave as if the level and slope of the yield curve are more persistent than under the physical measure.

In particular, we use

$$\check{\phi} = \begin{pmatrix} 0.985 & -0.025 \\ 0.00 & 0.94 \end{pmatrix}$$

```
ψ_P = ψ_2.copy()
μ_P = μ_2.copy()

# Subjective parameters: experts believe factors are MORE persistent
ψ_S = np.array([[0.985, -0.025], [0.00, 0.94]])
μ_S = np.array([0.005, 0.0])

# κ_t = κ_0 + κ_z z_t twists P into S
κ_z = np.linalg.solve(C_2, ψ_P - ψ_S)
κ_0 = np.linalg.solve(C_2, μ_P - μ_S)

# Agent's risk prices, which price subjective shocks ε^S
λ_star_0 = np.array([-0.03, -0.015])
λ_star_z = np.array([[-0.006, 0.0], [0.0, -0.004]])

# Econometrician's risk prices, which price physical shocks ε
λ_hat_0 = λ_star_0 + κ_0
λ_hat_z = λ_star_z + κ_z
```

The agent's model pairs the subjective dynamics with $\lambda_t^\star$, and the econometrician's model pairs the physical dynamics with $\widehat{\lambda}_t$.

We first confirm that the two models imply the same risk-neutral dynamics and hence the same bond prices.

```
# Agent: subjective dynamics, risk prices λ*
model_subj = create_affine_model(
    μ_S, ψ_S, C_2, δ_0_2, δ_1_2, λ_star_0, λ_star_z)
# Econometrician: physical dynamics, risk prices λ̂ = λ* + κ
model_econ = create_affine_model(
    μ_P, ψ_P, C_2, δ_0_2, δ_1_2, λ_hat_0, λ_hat_z)

print("Same risk-neutral dynamics:",
      np.allclose(model_subj.ψ_rn, model_econ.ψ_rn)
      and np.allclose(model_subj.μ_rn, model_econ.μ_rn))
print("Same yields at z = (1, -1):",
      np.allclose(compute_yields(model_subj, np.array([1.0, -1.0]), 60),
                  compute_yields(model_econ, np.array([1.0, -1.0]), 60)))
```

```
Same risk-neutral dynamics: True
Same yields at z = (1, -1): True
```

Now we compare the term premium the agent expects with the term premium the econometrician measures.

```
z_ref = np.array([0.0, 0.0])
n_max_db = 60
maturities_db = np.arange(1, n_max_db + 1)

tp_subj = term_premiums(model_subj, z_ref, n_max_db) * 4 * 100
tp_econ = term_premiums(model_econ, z_ref, n_max_db) * 4 * 100

fig, (ax1, ax2) = plt.subplots(1, 2, figsize=(14, 5.5))

ax1.plot(maturities_db, tp_subj, lw=2.2,

ax1.set_xlim(1, n_max_db)

mask = np.abs(tp_subj) > 1e-8
ratio = np.full_like(tp_subj, np.nan)
ratio[mask] = tp_econ[mask] / tp_subj[mask]

ax2.plot(maturities_db[mask], ratio[mask], lw=2.2)
ax2.axhline(1, color="black", lw=0.8, ls="--",
            label="No distortion (ratio = 1)")
ax2.set_xlabel("Maturity (quarters)")
ax2.set_ylabel(r"$\hat{tp}\, /\, tp^\star$")
ax2.legend(fontsize=11)
ax2.set_xlim(1, n_max_db)
```

(continues on next page)

(continued from previous page)

```
for ax in (ax1, ax2):
    ax_top = ax.twiny()
    ax_top.set_xlim(ax.get_xlim())
    year_ticks = [4, 12, 20, 40, 60]
    ax_top.set_xticks(year_ticks)
    ax_top.set_xticklabels([f"{t/4:.0f}y" for t in year_ticks])

plt.tight_layout()
plt.show()

for n in [4, 20, 40, 60]:
    print(f"n = {n:>2}: agent {tp_subj[n-1]:.3f}%, "
          f"econometrician {tp_econ[n-1]:.3f}%, "
          f"ratio {tp_econ[n-1] / tp_subj[n-1]:.2f}")
```

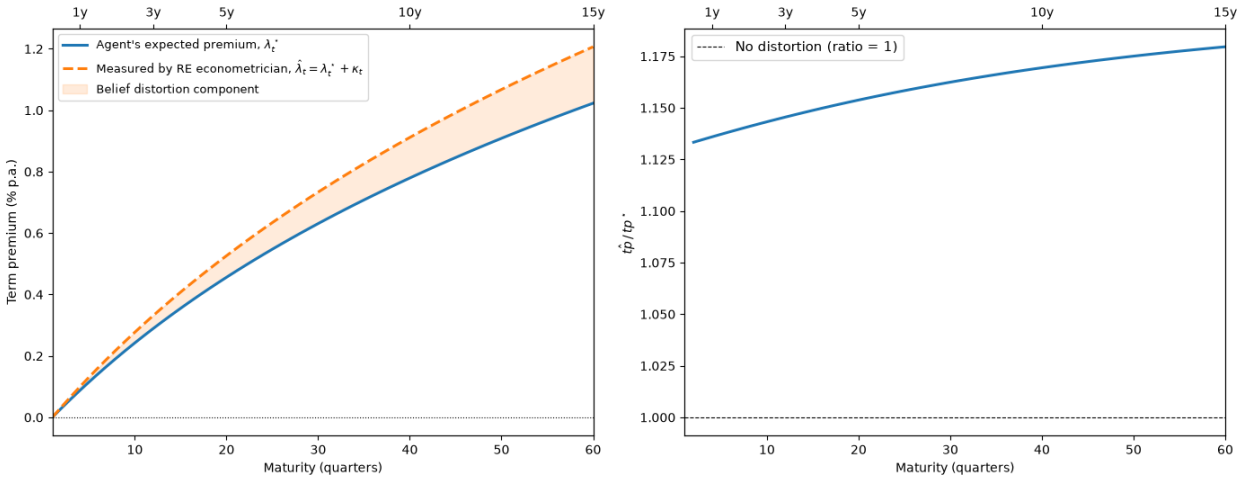

Fig. 140.5: Subjective vs. measured term premiums and overstatement ratio

```
n =  4: agent 0.087%, econometrician 0.099%, ratio 1.14
n = 20: agent 0.456%, econometrician 0.526%, ratio 1.15
n = 40: agent 0.779%, econometrician 0.911%, ratio 1.17
n = 60: agent 1.023%, econometrician 1.207%, ratio 1.18
```

At $z_t = 0$, the distortion is $\kappa_t = \kappa_0 = (-0.005, 0)$, which comes from the experts' upward bias $\check{\mu}_1 = 0.005$ in forecasting the level factor.

Experts who expect higher future interest rates expect lower returns on long bonds than the returns that actually materialize on average.

The econometrician therefore overstates the term premium that the agent requires, by 14 to 18 percent in this calibration.

The persistence distortion κ_z makes the size and even the sign of the gap depend on the state.

```
for label, z in [("High rate", np.array([3.0, -2.0])),
                 ("Low rate",  np.array([-3.0, 2.0]))]:
    gap = (term_premiums(model_econ, z, n_max_db)
           - term_premiums(model_subj, z, n_max_db)) * 4 * 100
    print(f"{label}: belief-distortion gap at 5 and 15 years = "
          f"{gap[19]:.2f}%, {gap[59]:.2f}%")
```

```
High rate: belief-distortion gap at 5 and 15 years = 0.37%, 1.89%
Low rate: belief-distortion gap at 5 and 15 years = -0.23%, -1.53%
```

When rates are high, experts extrapolate them too far into the future, so the econometrician's measured premium exceeds the agent's premium by almost 2 percentage points at 15 years.

When rates are low, the gap reverses sign.

A rational-expectations econometrician therefore attributes to time-varying risk prices movements in measured excess returns that actually come from the agent's systematic forecast errors.

Our Risk Aversion or Mistaken Beliefs? lecture explores this confounding in greater depth.

140.8 Concluding remarks

The affine model of the stochastic discount factor provides a flexible and tractable framework for studying asset prices.

Key features are:

1. **Analytical tractability:** Bond prices are exponential affine in z_t; expected returns decompose cleanly into a short rate plus a risk-price×exposure inner product.
2. **Empirical flexibility:** The free parameters $(\mu, \phi, C, \delta_0, \delta_1, \lambda_0, \lambda_z)$ can be estimated by maximum likelihood (the *Kalman filter* chapter describes the relevant methods) without imposing restrictions from a full general equilibrium model.
3. **Multiple risks:** The vector structure accommodates many sources of risk (monetary policy, real activity, volatility, etc.).
4. **Belief distortions:** The framework naturally accommodates non-rational beliefs via likelihood-ratio twists of the physical measure, as in Piazzesi *et al.* [2015].
5. **Limits to identification:** Bond prices reveal only the risk-neutral measure, so separating risk prices from belief distortions requires additional evidence, such as survey forecasts; see also *The Recovery Theorem* and *Misspecified Recovery*.

The model also connects directly to the Hansen–Jagannathan bounds studied in Doubts or Variability? and to robust control interpretations of the stochastic discount factor described in other chapters of Ljungqvist and Sargent [2018].

For finite-state approaches to asset pricing that complement the continuous-state framework here, see *Asset Pricing: Finite State Models*.

141.1 Overview

Asset prices are forward-looking: they encode investors' expectations about future economic states and their valuations of different risks.

A long-standing question in finance is whether one can *recover* the probability distribution used by investors – their subjective beliefs – from observed asset prices alone.

Option prices reveal **state prices**; once these are normalized by the riskless discount factor, the resulting probabilities are the **risk-neutral probabilities** implied by asset prices after risk adjustments have been folded in.

These are not the **natural probabilities** that investors actually assign to future states of the world.

The two differ because risk-neutral probabilities blend together two distinct objects: the market's true beliefs about the future, and investors' aversion to risk.

The link between them is the **pricing kernel**, which reweights natural probabilities to deliver state prices.

Separating beliefs from risk aversion has traditionally required parametric assumptions about the preferences of a representative investor.

Ross [2015] showed otherwise.

Ross's theorem says that, in a finite-state Markov economy, state prices can be enough.

Suppose the Arrow–Debreu state-price transition matrix is arbitrage-free and irreducible.

If the pricing kernel also satisfies a structural restriction called **transition independence**, then state prices uniquely determine both the natural probability transition matrix and the transition pricing kernel.

No historical return data or assumed utility function is needed if some assumptions about the structure of the pricing kernel hold.

This is the **Recovery Theorem**.

It has several important implications:

- It shows how state-price transition data can identify the market's forward-looking natural distribution when the assumption holds.
- It provides tests of the efficient market hypothesis.
- It sheds light on the "dark matter" of finance: the probability of rare catastrophic events embedded in market prices.

This lecture covers

- the Arrow–Debreu framework linking state prices, risk-neutral probabilities, the pricing kernel, and natural probabilities,
- Ross's Recovery Theorem and its proof via the Perron–Frobenius theorem,
- an implementation that recovers the natural distribution from a simulated state-price matrix,
- how option prices and forward equations can be used to estimate transition state prices, and
- comparisons between risk-neutral and recovered natural densities.

Let's import the packages we'll need.

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.linalg import eig
from scipy.stats import norm
import matplotlib.cm as cm
```

141.2 Model setup

141.2.1 Arrow–Debreu state prices

Consider a discrete-time, discrete-state economy.

At each date the economy occupies one of m states $\theta_1, \ldots, \theta_m$.

An **Arrow–Debreu security** pays \$1 if the economy is in state θ_j next period and nothing otherwise.

Denote by $p(\theta_i, \theta_j)$ the price today, when the current state is θ_i, of the Arrow–Debreu security paying in state θ_j next period.

Collect these into an $m \times m$ **state price transition matrix**

$$P = [p(\theta_i, \theta_j)]_{i,j=1}^{m}.$$

As in *Competitive Equilibria with Arrow Securities*, the row sums give the state-dependent riskless discount factor: $\sum_j p(\theta_i, \theta_j) = e^{-r(\theta_i)}$.

Here $r(\theta_i)$ is the one-period continuously compounded riskless rate in current state θ_i.

More generally, if an asset pays $g(\theta_j)$ next period, then its price in state θ_i is

$$p_g(\theta_i) = \sum_j p(\theta_i, \theta_j) g(\theta_j).$$

Let

$$b(\theta_i) \equiv \sum_j p(\theta_i, \theta_j) = e^{-r(\theta_i)}$$

be the price of a one-period riskless bond in state θ_i.

Normalizing Arrow prices by this bond price gives the **risk-neutral transition probabilities**

$$q^*(\theta_i, \theta_j) = \frac{p(\theta_i, \theta_j)}{b(\theta_i)} = e^{r(\theta_i)} p(\theta_i, \theta_j).$$

Thus the same asset price can be written as

$$p_g(\theta_i) = b(\theta_i) \sum_j q^*(\theta_i, \theta_j) g(\theta_j) = e^{-r(\theta_i)} E_i^*[g(\theta_{t+1})].$$

Here E_i^* denotes conditional expectation under $q^*(\theta_i, \cdot)$.

The asterisk marks the risk-neutral, or martingale, probability measure.

It is useful to separate this one-period normalization from the dynamic transition structure.

If $Q(\theta_i, \theta_j, T)$ denotes the risk-neutral probability of moving from θ_i to θ_j over T periods, and $0 < t < T$ is an intermediate horizon, then the Markov forward equation is

$$Q(\theta_i, \theta_j, T) = \sum_k Q(\theta_i, \theta_k, t) Q(\theta_k, \theta_j, T - t).$$

In matrix notation, multiperiod risk-neutral transition matrices compose by matrix multiplication.

141.2.2 The pricing kernel

Using the stochastic-discount-factor notation studied in *Asset Pricing: Finite State Models* and the Arrow-security notation used in *Competitive Equilibria with Arrow Securities*, the pricing kernel $\phi(\theta_i, \theta_j)$ relates state prices to natural probabilities via

$$p(\theta_i, \theta_j) = \phi(\theta_i, \theta_j)\, f(\theta_i, \theta_j),$$

where $f(\theta_i, \theta_j)$ is the natural (conditional) probability of transitioning from state θ_i to θ_j.

As in the representative-agent equilibrium calculation in *Competitive Equilibria with Arrow Securities*, the canonical additively separable model with discount factor β gives

$$\phi(\theta_i, \theta_j) = \frac{p(\theta_i, \theta_j)}{f(\theta_i, \theta_j)} = \frac{\beta U'(c(\theta_j))}{U'(c(\theta_i))}. \tag{141.1}$$

This formula has a special structure: the kernel can be written as a ratio of two state-specific terms.

Ross calls this property **transition independence**.

We will say more about it soon.

141.2.3 The identification challenge

Before stating the restriction, it helps to see why one is needed at all.

Given P, any pair (ϕ, f) satisfying $p_{ij} = \phi_{ij} f_{ij}$ for every (i, j) is consistent with observed state prices.

The state-price matrix P supplies m^2 equations.

A natural transition matrix F contributes $m(m-1)$ free entries (rows sum to one), and an arbitrary kernel ϕ contributes another m^2 – a total of $2m^2 - m$ unknowns against only m^2 equations.

The system is under-identified by $m^2 - m$ parameters, so some structural restriction on the kernel is needed to pin down ϕ and f separately.

The transition independence restriction does the job, as we will see in the next section.

141.2.4 Transition independence

Definition (Transition Independence)

A pricing kernel is **transition independent** if there exists a positive function h on the state space and a positive scalar β such that for every transition from state θ_i to θ_j,

$$\phi(\theta_i, \theta_j) = \beta \frac{h(\theta_j)}{h(\theta_i)}.$$

Transition independence says the kernel depends on the *ending* state and normalizes by the *beginning* state.

In the representative-agent complete-markets environment above, it holds under intertemporally additive separable utility (where $h = U'$).

In particular, this holds for (141.1).

Transition independence helps because it ties all m^2 entries of ϕ together: once the m state-specific values are known, the whole kernel is pinned down.

It therefore cuts ϕ from m^2 free entries down to m, so the system becomes exactly identified.

Under transition independence, the state-price equation becomes

$$p(\theta_i, \theta_j) = \beta \frac{h(\theta_j)}{h(\theta_i)} f(\theta_i, \theta_j).$$

In matrix notation, defining the diagonal matrix D with $D_{ii} = h(\theta_i)/\beta$,

$$DP = \beta F D,$$

or equivalently,

$$F = \frac{1}{\beta} D P D^{-1}.$$

141.3 The recovery theorem

141.3.1 Reduction to an eigenvalue problem

Since F is a stochastic matrix, its rows sum to one: $Fe = e$ where e is the vector of ones.

Substituting the expression for F:

$$\frac{1}{\beta} DPD^{-1}e = e \quad \Longrightarrow \quad Pz = \beta z, \quad z \equiv D^{-1}e.$$

This is an **eigenvalue problem** where we seek a positive vector z and scalar β satisfying $Pz = \beta z$.

In principle every eigenvalue-eigenvector pair of P is a formal solution, but only the one with a strictly positive eigenvector is economically valid: $D_{ii} = 1/z_i$ must be positive (so $z_i > 0$), and F must have nonnegative entries.

The Perron–Frobenius theorem guarantees that exactly one such pair exists.

Theorem (Perron–Frobenius)

If A is a nonnegative irreducible matrix, then

1. A has a positive real eigenvalue r equal to its spectral radius (the Perron root).
2. There exists a strictly positive eigenvector $z \gg 0$ with $Az = rz$, unique up to scaling.
3. No other eigenvector is strictly positive.

Other eigenvalues can have the same modulus when the matrix is imprimitive, but the strictly positive eigenvector is unique up to scale.

See Section 1.2.3 of Sargent and Stachurski [2024] for details.

See also the full statement in The Perron-Frobenius Theorem.

Applied to the recovery problem: the Perron root is β (the subjective discount factor) and the Perron vector z determines D via $D_{ii} = 1/z_i$.

141.3.2 Ross's recovery theorem

The three assumptions in the theorem each carry a specific role.

Assuming the Arrow–Debreu state prices are identified, no-arbitrage guarantees that P has nonnegative entries and that the state prices encode a well-defined pricing measure.

Irreducibility ensures the economy is not divided into disconnected sub-economies – without it, the Perron–Frobenius theorem gives multiple candidate eigenvectors and recovery breaks down.

Transition independence is the key economic restriction.

It says the pricing kernel factors as $\beta h(\theta_j)/h(\theta_i)$, so the entire kernel is pinned down by a single vector h (or equivalently z).

With these in mind, the Recovery Theorem follows from the Perron–Frobenius theorem.

Theorem (Recovery Theorem)

Suppose prices provide no arbitrage opportunities, that the state price transition matrix P is irreducible, and that the pricing kernel is transition independent.

Then there exists a positive solution (β, z, F) to the recovery problem in which z is unique up to normalization, and the implied natural probability transition matrix F and transition pricing kernel are unique.

Proof. Because P is nonnegative and irreducible, the Perron–Frobenius theorem gives a unique positive eigenvector $z \gg 0$ with positive eigenvalue $\lambda > 0$ satisfying $Pz = \lambda z$.

Setting

$$\beta = \lambda, \qquad D_{ii} = \frac{1}{z_i},$$

the natural probability transition matrix is uniquely recovered as

$$f_{ij} = \frac{1}{\beta} \frac{z_j}{z_i} p_{ij}.$$

To confirm F is stochastic, note that all entries are nonnegative (since $p_{ij} \geq 0$ and $z_i, z_j > 0$) and

$$\sum_j f_{ij} = \frac{1}{\beta z_i} \sum_j z_j \, p_{ij} = \frac{[Pz]_i}{\beta z_i} = \frac{\beta z_i}{\beta z_i} = 1.$$

Uniqueness follows from the uniqueness of the Perron–Frobenius eigenvector.

141.3.3 Pricing kernel from the eigenvector

The recovered transition-kernel values are

$$\phi(\theta_i, \theta_j) = \beta \frac{z_i}{z_j}, \qquad h(\theta_i) = \frac{\beta}{z_i},$$

where $h(\theta_i) = \beta / z_i$ follows from $D_{ii} = h(\theta_i)/\beta = 1/z_i$.

It is useful to distinguish the **full transition kernel** $\phi_{ij} = \beta z_i / z_j$, which depends on both origin and destination states, from the **relative kernel component** $1/z_j$, which depends only on the destination state.

Ross's Table I reports the destination-state shape $1/z_j$, normalized so that the middle state equals one.

Destination states with high z_j have *low* kernel values: for a fixed origin i, the kernel $\beta z_i / z_j$ is decreasing in z_j.

When h represents marginal utility and states are ordered by consumption or payoff, larger z_j corresponds to lower marginal utility – "good times" that require less insurance and so receive less pricing weight per unit of natural probability.

The same eigenvector argument also yields a useful limiting case.

If the one-period bond price is identical in every current state, then the vector of ones is already the Perron vector, so recovery has no state-dependent change of measure left to perform.

Corollary

If the riskless rate is the same in all states ($Pe = be$ for some scalar b), then the unique natural distribution consistent with recovery is the risk-neutral (martingale) distribution itself: $F = (1/b)P$.

Proof. When $Pe = be$, the vector of ones e is the Perron eigenvector with eigenvalue b.

By the uniqueness part of the Perron–Frobenius theorem, $z = e$ (up to scaling) and $\beta = b$.

Setting $z = e$ gives $D = I$, so

$$F = \frac{1}{\beta} DPD^{-1} = \frac{1}{b} P. \qquad \square$$

141.3.4 Single crossing and the risk premium

Ross also uses the representative-agent formula to compare the natural and risk-neutral densities directly.

For a fixed current state θ_i,

$$\frac{q^*(\theta_i, \theta_j)}{f(\theta_i, \theta_j)} = e^{r(\theta_i)} \phi(\theta_i, \theta_j) = e^{r(\theta_i)} \beta \frac{U'(c(\theta_j))}{U'(c(\theta_i))}. \tag{141.2}$$

If U' is decreasing in consumption, then the ratio in (141.2) is decreasing in next-period consumption $c(\theta_j)$.

Since both $q^*(\theta_i, \cdot)$ and $f(\theta_i, \cdot)$ integrate to one, there is a crossing point v defined by

$$e^{r(\theta_i)} \beta U'(v) = U'(c(\theta_i)).$$

Below v, risk-neutral probability exceeds natural probability; above v, the natural probability exceeds the risk-neutral probability.

Hence the natural consumption distribution first-order stochastically dominates the risk-neutral one.

In a one-period model where terminal consumption is the market payoff, this also gives a positive market risk premium.

Let R denote the market return under the natural law, let R^* denote the same return under the risk-neutral law, and let R_f denote the riskless return in the same one-period units.

The stochastic-dominance result can be represented as

$$R^* \sim R - Z + \epsilon,$$

where $Z \geq 0$ captures the downward shift induced by risk adjustment and ϵ is a residual satisfying $E[\epsilon \mid R - Z] = 0$.

Because R^* is the market return under the risk-neutral measure, its expectation is the riskless return: $E[R^*] = R_f$.

Taking expectations of the representation above therefore gives

$$E[R] = E[R^*] + E[Z] = R_f + E[Z],$$

which strictly exceeds R_f whenever Z is positive with positive probability – that is, whenever the two densities genuinely differ.

141.4 Numerical example

We now demonstrate the Recovery Theorem numerically.

141.4.1 Building a finite-state example

We build the economy directly on a finite grid of log payoff states $s_1, \dots, s_m$.

On this grid we choose three primitives:

1. a row-stochastic irreducible natural transition matrix F,
2. a subjective discount factor $\beta = e^{-\rho T}$, and
3. a CRRA transition pricing kernel $\phi_{ij} = \beta e^{-\gamma(s_j - s_i)}$.

The state-price matrix is then constructed from

$$p_{ij} = \phi_{ij} f_{ij}.$$

This means the Recovery Theorem assumptions hold by construction: P is nonnegative, F is a Markov transition matrix, and the kernel is transition independent with $z_i \propto e^{\gamma s_i}$.

To keep the example close to Ross's Section IV, we choose F to have lognormal-shaped rows.

The continuous benchmark is a lognormal payoff with CRRA utility:

$$U(S_T) = \frac{S_T^{1-\gamma}}{1-\gamma}, \qquad S_T = S_0 \exp\Big((\mu - \tfrac{1}{2}\sigma^2)T + \sigma\sqrt{T}\xi\Big),$$

where $\xi \sim N(0,1)$, μ is the expected growth-rate parameter, σ is volatility, T is the horizon, γ is the CRRA coefficient, and ρ is the continuously compounded subjective discount rate.

The T-period pricing kernel is

$$\phi_T = e^{-\rho T} \left(\frac{S_T}{S_0}\right)^{-\gamma}.$$

Equivalently, if $s = \log S_0$ and $s_T = \log S_T$, then the state-price density with respect to the future log state s_T is

$$p_T(s, s_T) = e^{-\rho T} e^{-\gamma(s_T - s)} \frac{1}{\sigma\sqrt{T}} n\left(\frac{s_T - s - (\mu - \frac{1}{2}\sigma^2)T}{\sigma\sqrt{T}}\right),$$

where n is the standard normal density.

Thus the natural log return satisfies

$$\log(S_T/S_0) \sim \mathcal{N}\big((\mu - \tfrac{1}{2}\sigma^2)T, \sigma^2 T\big).$$

Following Ross's Table I, we represent the distribution on a finite grid of states.

This example is Ross-inspired rather than an exact reproduction of Ross's Table I.

Ross's Table I uses a fixed future payoff distribution, so its rows of F are identical.

Here the same CRRA/lognormal pricing logic is embedded in a finite Markov transition matrix whose rows shift with the current state.

Ross uses states from -5 to $+5$ standard deviations; we use the same range below.

The truncation is an essential part of the finite-state model: it is what brings the example into the Perron–Frobenius setting.

In the unbounded continuous lognormal growth model, Ross shows that recovery is not unique.

On the finite grid, the natural transition probabilities and state prices are

$$f_{ij} \propto n\left(\frac{s_j - s_i - (\mu - \frac{1}{2}\sigma^2)T}{\sigma\sqrt{T}}\right)\Delta s, \qquad p_{ij} = e^{-\rho T}e^{-\gamma(s_j - s_i)}f_{ij},$$

where $s_i = \ln(S_i/S_0)$ and $s_j = \ln(S_j/S_0)$ are log states measured relative to today's index level, $n(\cdot)$ is the standard normal density, and the discretized probabilities f_{ij} are normalized row by row.

The next cell constructs this finite grid and builds P.

```
def build_state_price_matrix(μ, σ, γ, ρ, T=1.0, n_states=11, n_σ=5):
    """Build a discretized lognormal/CRRA state-price matrix."""
    states = np.linspace(-n_σ * σ * np.sqrt(T),
                         n_σ * σ * np.sqrt(T),
                         n_states)
    ds = states[1] - states[0]

    m = n_states
    P = np.zeros((m, m))
    F = np.zeros((m, m))

    drift = (μ - 0.5 * σ**2) * T

    # First build a row-stochastic natural transition matrix on the bounded grid
    for i in range(m):
        s_i = states[i]
        for j in range(m):
            s_j = states[j]
            log_return = s_j - s_i
            F[i, j] = norm.pdf(log_return, loc=drift,
                               scale=σ * np.sqrt(T)) * ds

        F[i] = F[i] / F[i].sum()

        # Price each Arrow claim as natural probability times the CRRA kernel
        for j in range(m):
            log_return = states[j] - s_i
            kernel = np.exp(-ρ * T) * np.exp(-γ * log_return)
            P[i, j] = kernel * F[i, j]

    return P, states
```

Now choose a calibration and build the state-price matrix.

```
μ = 0.08    # 8% annual expected return
σ = 0.20    # 20% annual volatility
γ = 3.0     # CRRA coefficient
ρ = 0.02    # 2% annual continuous discount rate
T = 1.0     # one-year horizon

P, states = build_state_price_matrix(μ, σ, γ, ρ, T,
                                     n_states=11, n_σ=5)

print("State-price row sums:")
```

(continues on next page)

(continued from previous page)

```
print(np.round(P.sum(axis=1), 4))
print(f"Middle-state risk-free rate: {-np.log(P[5].sum()):.4f}")
```

```
State-price row sums:
[0.7154 0.9046 0.9713 0.9798 0.9802 0.9802 0.9802 0.9806 0.9892 1.0621
 1.3429]
Middle-state risk-free rate: 0.0200
```

The row sums are the model-implied one-period bond prices in each current state.

They vary near the boundaries because the finite grid truncates and renormalizes the conditional transition probabilities.

The middle-state rate printed above happens to equal ρ only because this calibration satisfies $\mu = \frac{1}{2}\sigma^2(1+\gamma)$, which holds at $\mu = 0.08$, $\sigma = 0.2$ and $\gamma = 3$.

It is a coincidence of the numbers chosen here, not a check on the code or a general property.

141.4.2 Applying the recovery theorem

The Recovery Theorem requires computing the **Perron eigenvector** of P.

```
def recover_natural_distribution(P, tol=1e-10):
    """
    Recover natural probabilities and the relative pricing kernel
    from state prices.
    """

    m = P.shape[0]

    eigenvalues, eigenvectors = eig(P)
    eigenvalues = np.real_if_close(eigenvalues, tol=1000)
    eigenvectors = np.real_if_close(eigenvectors, tol=1000)

    # Ross recovery uses the Perron root and its strictly positive eigenvector
    real_mask = np.isreal(eigenvalues)
    real_eigenvalues = np.asarray(
        eigenvalues[real_mask].real, dtype=float)
    real_eigenvectors = np.asarray(
        eigenvectors[:, real_mask].real, dtype=float)

    order = np.argsort(real_eigenvalues)[::-1]

    for idx in order:
        β_candidate = real_eigenvalues[idx]
        z_candidate = real_eigenvectors[:, idx]

        if np.mean(z_candidate) < 0:
            z_candidate = -z_candidate

        # eig returns eigenvectors of unit Euclidean norm, so the smallest entry
        # of a legitimately positive z can be far below any absolute threshold
        # (it is of order e^{-2γ n_σ σ√T} here). We therefore rescale and test
        # the sign, which makes the test invariant to the eigenvector's scale.
        z_candidate = z_candidate / np.max(np.abs(z_candidate))

        if β_candidate > 0 and np.all(z_candidate > 0):
```

(continues on next page)

(continued from previous page)

```
            β_recovered = β_candidate
            z = z_candidate
            break
    else:
        raise ValueError("No strictly positive real eigenvector found")

    z = z / z[m // 2]

    D = np.diag(1.0 / z)
    D_inv = np.diag(z)

    # Converts state prices into probabilities
    F = (1.0 / β_recovered) * D @ P @ D_inv

    min_entry = F.min()
    row_sum_error = np.max(np.abs(F.sum(axis=1) - 1.0))

    if min_entry < -tol:
        raise ValueError(f"Recovered F has negative entries: min={min_entry}")

    if row_sum_error > 1e-8:
        raise ValueError(
            f"Recovered F row sums are not one: max error={row_sum_error}"
        )

    # The kernel relative to the middle state normalization
    ψ_relative = 1.0 / z

    return F, z, β_recovered, ψ_relative
```

The Perron vector also recovers the shape of the pricing kernel.

Ross's Table I reports this shape with the middle state normalized to one, which is $1/z_j$ under our normalization $z_{\text{mid}} = 1$.

```
F, z, β_rec, ψ_relative = recover_natural_distribution(P)

print("Ross-normalized kernel 1/z (middle state = 1):")
print(np.round(ψ_relative, 4))
```

```
Ross-normalized kernel 1/z (middle state = 1):
[20.0855 11.0232  6.0496  3.3201  1.8221  1.      0.5488  0.3012  0.1653
  0.0907  0.0498]
```

Because we know the data-generating natural transition matrix used to construct P, we can verify that recovery works in this simulation.

```
def true_lognormal_transition_matrix(states, μ, σ, T):
    """
    Construct the bounded-grid natural transition matrix used in the simulation.
    """
    m = len(states)
    ds = states[1] - states[0]
    drift = (μ - 0.5 * σ**2) * T
    F_true = np.zeros((m, m))

    for i in range(m):
        log_returns = states - states[i]
```

(continues on next page)

(continued from previous page)

```
        F_true[i] = norm.pdf(log_returns, loc=drift,
                             scale=σ * np.sqrt(T)) * ds
        F_true[i] = F_true[i] / F_true[i].sum()

    return F_true

F_true = true_lognormal_transition_matrix(states, μ, σ, T)
P_reconstructed = β_rec * (z[:, None] / z[None, :]) * F

print("Recovery numerical checks")
print(f"max |F - true F| = {np.max(np.abs(F - F_true)):.2e}")
print(f"max |P - recovered kernel times F| = "
      f"{np.max(np.abs(P - P_reconstructed)):.2e}")
```

```
Recovery numerical checks
max |F - true F| = 3.46e-14
max |P - recovered kernel times F| = 1.11e-16
```

Indeed, the discrepancies are at the level of numerical roundoff.

141.5 Natural vs. risk-neutral distributions

A key insight of Ross [2015] is that the natural distribution can differ systematically from the risk-neutral one.

In this CRRA example, where states are ordered from low to high payoff, the single-crossing argument in *Single crossing and the risk premium* implies that the natural marginal density **first-order stochastically dominates** the risk-neutral density: the CDF of the natural distribution lies *below* that of the risk-neutral distribution.

Because the pricing kernel is declining (investors fear bad outcomes), risk-neutral probabilities overweight bad states and underweight good states relative to the natural measure.

We first plot the natural distribution against the risk-neutral one and the recovered relative pricing kernel.

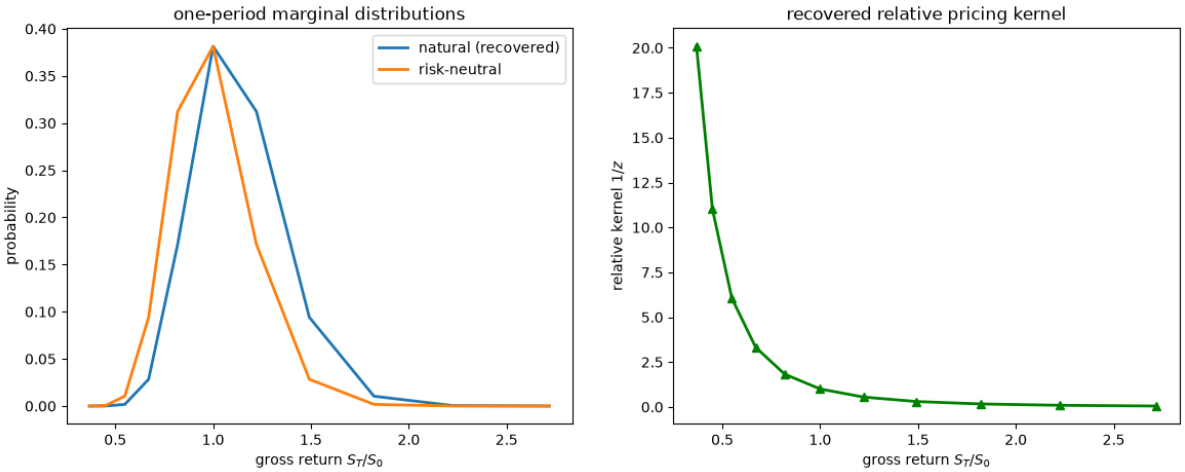
```
mid = len(states) // 2

row_sums = P.sum(axis=1, keepdims=True)

# Normalize Arrow prices by the one-period riskless bond price in each state
Q_rn = P / row_sums

f_nat = F[mid, :]
f_rn = Q_rn[mid, :]

gross_returns = np.exp(states)



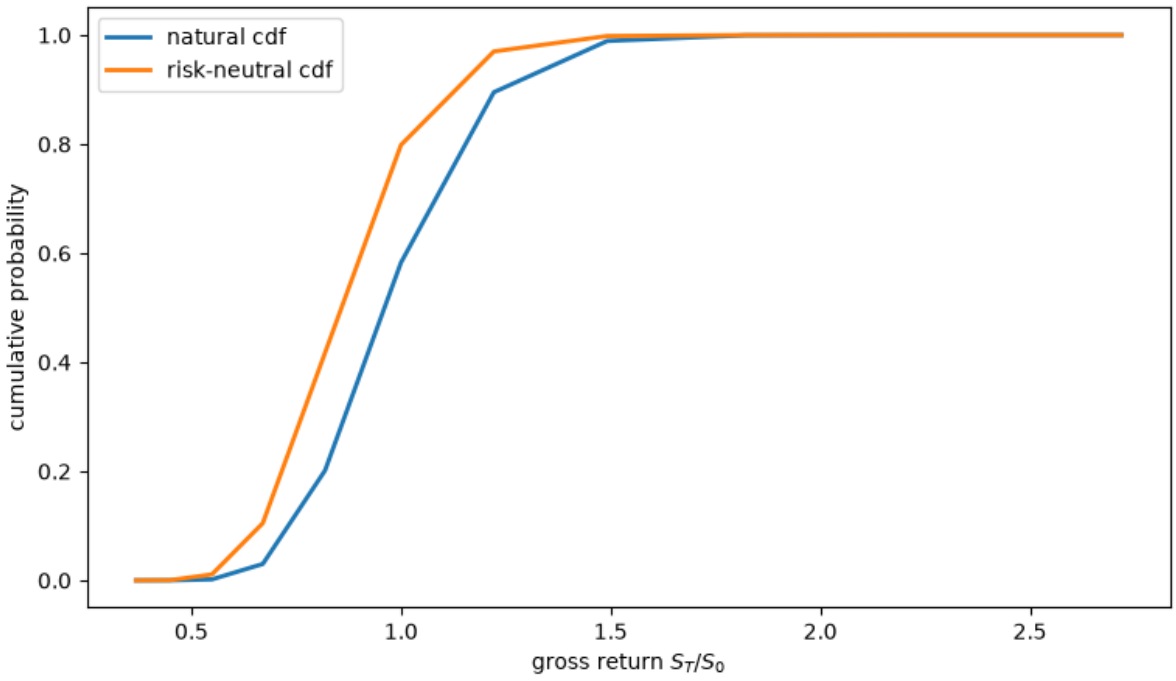
fig, axes = plt.subplots(1, 2, figsize=(14, 5))

axes[0].plot(gross_returns, f_nat, label='natural (recovered)', lw=2)
axes[0].plot(gross_returns, f_rn, label='risk-neutral', lw=2)
axes[0].set_xlabel('gross return $S_T / S_0$')
axes[0].set_ylabel('probability')
axes[0].set_title('one-period marginal distributions')
axes[0].legend()
```

(continues on next page)

(continued from previous page)

```
axes[1].plot(gross_returns, ψ_relative, 'g-^', lw=2)
axes[1].set_xlabel('gross return $S_T / S_0$')
axes[1].set_ylabel('relative kernel $1/z$')
axes[1].set_title('recovered relative pricing kernel')
plt.show()
```



The CDF clearly shows the first-order stochastic dominance.

```
cdf_nat = np.cumsum(f_nat)
cdf_rn = np.cumsum(f_rn)

fig, ax = plt.subplots(figsize=(9, 5))
ax.plot(gross_returns, cdf_nat, lw=2, label='natural cdf')
ax.plot(gross_returns, cdf_rn, lw=2, label='risk-neutral cdf')
ax.set_xlabel('gross return $S_T / S_0$')
ax.set_ylabel('cumulative probability')
ax.legend()
plt.show()

print(f"Natural CDF <= Risk-neutral CDF at all states: "
      f"{np.all(cdf_nat <= cdf_rn + 1e-10)}")
```

```
Natural CDF <= Risk-neutral CDF at all states: True
```

The gap between the two CDFs is generated by the slope of the pricing kernel.

In the CRRA benchmark, this slope is controlled by the risk-aversion coefficient γ.

We next vary γ to see how the recovered kernel and the natural/risk-neutral wedge change.

141.6 Effect of risk aversion

The shape of the pricing kernel, and hence the gap between natural and risk-neutral probabilities, depends on the coefficient of risk aversion γ.

We illustrate this by plotting the relative pricing kernel $1/z$ and the gap between the natural and risk-neutral densities for a range of values of γ.

The left panel uses a logarithmic vertical axis because $1/z$ spans about seven orders of magnitude across these values of γ, so on a linear axis the curves for small γ would be flat against the horizontal axis and invisible.

On the log axis the economic content is immediate: since $1/z_j = e^{-\gamma s_j}$ exactly, $\log(1/z_j)$ is linear in the log state s_j with slope $-\gamma$, so the recovered kernel is log-linear and γ is simply its slope.

```
γs = [1.0, 2.0, 3.0, 5.0, 8.0]
colors = cm.viridis(np.linspace(0.1, 0.9, len(γs)))

fig, axes = plt.subplots(1, 2, figsize=(14, 5))

for γ_val, color in zip(γs, colors):
    P_g, states_g = build_state_price_matrix(μ, σ, γ_val, ρ, T)
    F_g, z_g, β_g, ψ_relative_g = recover_natural_distribution(P_g)
    mid_g = len(states_g) // 2
```

(continues on next page)

(continued from previous page)

```
    f_nat_g = F_g[mid_g, :]
    row_sum = P_g[mid_g].sum()
    f_rn_g = P_g[mid_g] / row_sum

    gross = np.exp(states_g)

    axes[0].plot(gross, ψ_relative_g, color=color, lw=2,
                 label=f'$\\gamma={γ_val:.0f}$')
    axes[1].plot(gross, f_nat_g - f_rn_g, color=color, lw=2,
                 label=f'$\\gamma={γ_val:.0f}$')

axes[0].set_yscale('log')
axes[0].set_xlabel('gross return')
axes[0].set_ylabel('relative kernel $1/z$')
axes[0].set_title('relative pricing kernel vs risk aversion')
axes[0].legend(fontsize=9)

axes[1].axhline(0, color='k', lw=0.8, ls='--')
axes[1].set_xlabel('gross return')
axes[1].set_ylabel('natural minus risk-neutral probability')
axes[1].set_title('natural minus risk-neutral density')
axes[1].legend(fontsize=9)

plt.show()
```

Because the states are ordered from low to high payoff, the plots show the single-crossing property discussed in *Single crossing and the risk premium*: for returns below some threshold v, risk-neutral probability exceeds natural probability; above v the natural probability dominates.

A higher γ amplifies this wedge.

A caution about the large-γ cases: the one-period bond price in the middle state rises to 1.1972 at $\gamma = 5$ and 2.1815 at $\gamma = 8$, implied riskless rates of -18% and -78%, and the largest row sum of P reaches 3.63.

This is the usual CRRA precautionary-savings blow-up rather than a defect of the recovery calculation, whose Perron root remains $e^{-\rho T}$ for every γ.

We include these values to make the shape of the kernel visible across a wide range, not as plausible calibrations of an actual economy.

141.7 Recovering the discount rate

A useful by-product of the Recovery Theorem is the *recovered subjective discount factor* β, which equals the Perron–Frobenius eigenvalue of P.

If the horizon is T, the corresponding continuously compounded subjective discount rate is

$$\rho = -\frac{\log \beta}{T}.$$

In the numerical examples below, $T = 1$, so this reduces to $\rho = -\log \beta$.

Corollary 1 of Ross [2015] states that β is bounded above by the largest state-dependent one-period discount factor — equivalently, the maximum row sum of P:

$$\beta \leq \max_i \sum_j p(\theta_i, \theta_j).$$

Sweeping the true ρ over a grid and reporting the recovered values alongside the recovery error confirms that the eigenvalue calculation pins down β accurately:

```
true_ρs = np.linspace(0.00, 0.06, 13)
recovered_ρs = np.empty_like(true_ρs)

for k, rho in enumerate(true_ρs):
    P_d, _ = build_state_price_matrix(μ, σ, γ=3.0, ρ=rho, T=1.0)
    _, _, β_d, _ = recover_natural_distribution(P_d)
    recovered_ρs[k] = -np.log(β_d)

print(
    f"max |true ρ - recovered ρ| = {np.max(np.abs(true_ρs - recovered_ρs)):.2e}")
np.column_stack([true_ρs, recovered_ρs])
```

```
max |true ρ - recovered ρ| = 2.11e-15
```

```
array([[ 0.0000000e+00, -4.4408921e-16],
       [ 5.0000000e-03,  5.0000000e-03],
       [ 1.0000000e-02,  1.0000000e-02],
       [ 1.5000000e-02,  1.5000000e-02],
       [ 2.0000000e-02,  2.0000000e-02],
       [ 2.5000000e-02,  2.5000000e-02],
       [ 3.0000000e-02,  3.0000000e-02],
       [ 3.5000000e-02,  3.5000000e-02],
       [ 4.0000000e-02,  4.0000000e-02],
       [ 4.5000000e-02,  4.5000000e-02],
       [ 5.0000000e-02,  5.0000000e-02],
       [ 5.5000000e-02,  5.5000000e-02],
       [ 6.0000000e-02,  6.0000000e-02]])
```

141.8 Tail risk: natural vs. risk-neutral probabilities of catastrophe

One of the most striking applications of the Recovery Theorem is its ability to separate the market's recovered natural probability of catastrophes from the risk premium attached to them.

Mehra and Prescott [1985] posed the equity premium puzzle, and Barro [2006] argues that a small probability of rare macroeconomic disasters can help account for it.

The risk-neutral probability of a large decline is elevated both because (a) the market assigns a high natural probability to such events and (b) the pricing kernel upweights bad outcomes.

Ross's recovery machinery lets us decompose these two forces.

The next cell plots left-tail probabilities under the recovered natural and the risk-neutral measures from the middle state, so the gap between the curves isolates the pricing-kernel contribution to crash probabilities.

```
thresholds = np.linspace(-0.40, 0.10, 200)

def tail_prob(f_dist, states, threshold):
    """Left-tail probability for log returns."""
    return float(np.sum(f_dist[states <= threshold]))

P_base, states_base = build_state_price_matrix(
    μ, σ, γ=3.0, ρ=0.02, T=1.0,
    n_states=41, n_σ=5)
F_base, z_base, β_base, ψ_relative_base = recover_natural_distribution(P_base)

mid_b = len(states_base) // 2
f_nat_base = F_base[mid_b]
f_rn_base = P_base[mid_b] / P_base[mid_b].sum()

prob_nat = [tail_prob(f_nat_base, states_base, t) for t in thresholds]
prob_rn = [tail_prob(f_rn_base, states_base, t) for t in thresholds]

fig, ax = plt.subplots(figsize=(10, 5))
ax.plot(np.exp(thresholds), prob_nat, lw=2, label='natural (recovered)')
ax.plot(np.exp(thresholds), prob_rn, lw=2, label='risk-neutral')
ax.set_xlabel('gross return threshold')

```

This is a simulation illustrating Ross's decomposition.

The risk-neutral density assigns higher probability to large drops than the recovered natural density.

In this CRRA simulation, increasing risk aversion makes the risk-neutral crash probability rise faster than the recovered natural crash probability.

We will say more in Exercise 141.12.3.

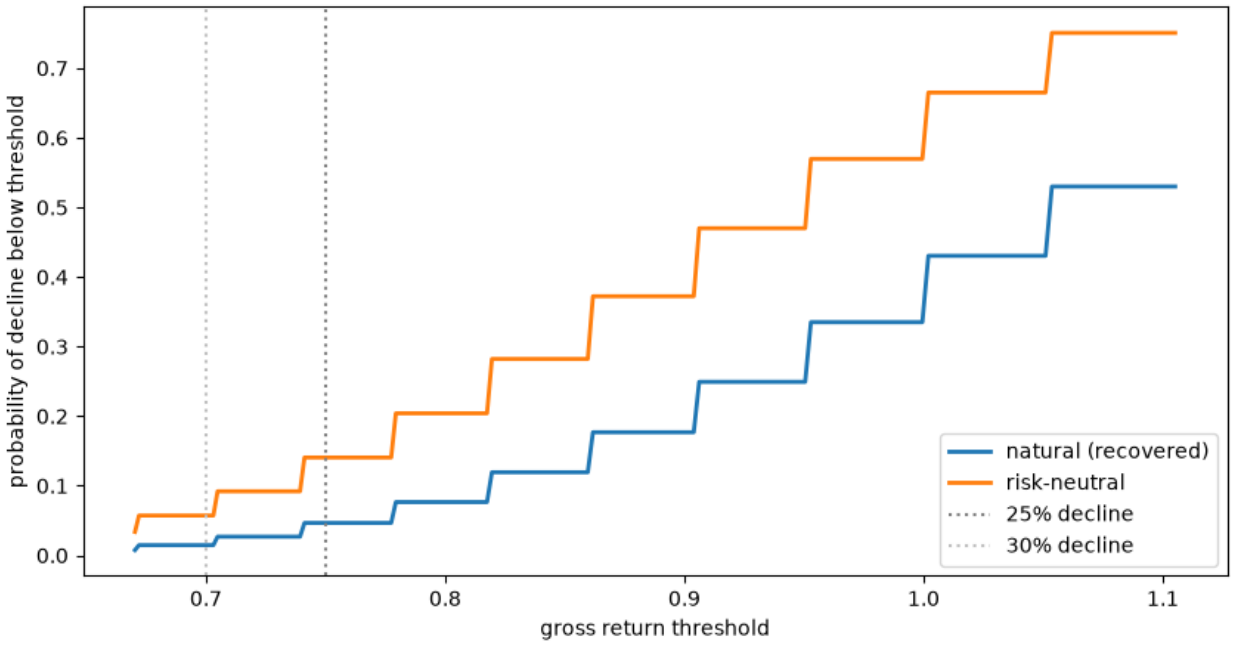

Fig. 141.1: Tail probabilities under the recovered natural and risk-neutral measures

141.9 From option prices to transition prices

The numerical example above starts from a known state-price transition matrix P.

Empirically, Ross starts one step earlier: option prices reveal state-price densities at different maturities from the current state, and the transition matrix must be inferred from those maturity-by-maturity state prices.

Let $C(K,T)$ be the price of a call option with strike K and maturity T.

If $p(S,T)$ is the state-price density for terminal index level S, then

$$C(K,T) = \int_K^\infty (S-K)p(S,T)\,dS.$$

Differentiating twice with respect to the strike gives the Breeden and Litzenberger [1978] formula

$$p(K,T) = \frac{\partial^2 C(K,T)}{\partial K^2}.$$

After discretizing strikes and maturities, let

$$p_t(c) = (p_t(c,1), \ldots, p_t(c,m))$$

be the vector of state prices at horizon t observed from today's state c.

Here c indexes the current state and t counts discrete maturity steps.

The first one-period vector $p_1(c)$ identifies the row of P corresponding to the current state c, supplying m equations.

If the one-period state-price transition matrix P is time homogeneous, these vectors satisfy the forward recursion

$$p_{t+1}(c) = p_t(c)P, \qquad t = 1, \ldots, m-1.$$

Componentwise,

$$p_{t+1}(c, j) = \sum_k p_t(c, k) p(k, j).$$

The remaining $m - 1$ forward equations $p_{t+1}(c) = p_t(c)P$, each with m components, supply the remaining $m(m - 1)$ equations.

Together these give m^2 equations for the m^2 transition prices $p(k, j)$.

In practice this step is numerically delicate because the second derivative in the option-price formula amplifies measurement error, and because additional shape restrictions such as positivity or unimodality may be needed to obtain a reasonable transition matrix.

141.10 Testing efficient markets

The recovered pricing kernel can also be used to test market efficiency, under the assumptions of the Recovery Theorem.

If a trading strategy has a very high Sharpe ratio, then some pricing kernel must be volatile enough to price that payoff.

The Hansen–Jagannathan bound [Hansen and Jagannathan, 1991] says that, for any excess return with mean μ_{excess} and standard deviation σ_{excess},

$$\frac{|\mu_{\text{excess}}|}{\sigma_{\text{excess}}} \leq e^{rT}\, \sigma(\phi),$$

where ϕ is the one-period pricing kernel of (141.1) and r is the continuously compounded riskless rate over horizon T.

Ross's point is that recovery gives an estimate of the relevant volatility $\sigma(\phi)$.

Hence it gives an upper bound on the Sharpe ratio of any strategy based on the same stock-market information used in recovery.

If such a strategy has a Sharpe ratio above the bound, then it is too profitable to be consistent with efficiency, under the assumptions of the Recovery Theorem.

The same logic gives a bound on return predictability.

Suppose excess returns are decomposed as

$$x_{t+1} = \mu(I_t) + \epsilon_{t+1},$$

where I_t is the stock-market information set and ϵ_{t+1} is unpredictable from I_t.

Then the R^2 of a forecasting regression based on I_t is bounded above by the variance of the recovered kernel:

$$R^2 \leq e^{2rT}\, \sigma^2(\phi).$$

Only the component of the kernel projected on this information set is relevant.

Adding unrelated noise to a candidate pricing kernel would raise its variance, but it would not justify stronger return predictability from stock-market information.

141.11 Limitations and extensions

The Recovery Theorem is a remarkable theoretical result, but several caveats apply in practice.

Finite state space:

Ross's theorem is proved for a finite-state irreducible Markov chain.

Recovery on a continuous state space requires a boundedness or compactness restriction: Carr and Yu [2012], discussed below, establish recovery for a bounded diffusion.

In continuous, unbounded state spaces (e.g., a lognormal diffusion), uniqueness fails because any exponential $e^{\alpha x}$ satisfies the characteristic equation.

To see the issue, consider the continuous lognormal growth state-price density above.

The natural continuous-space analogue of the Perron–Frobenius problem is

$$\int p_T(s, y) v(y)\, dy = \lambda v(s).$$

Here y is a possible future log state, v is a candidate positive eigenfunction, and λ is its eigenvalue.

For every real α, the exponential function $v_\alpha(s) = e^{\alpha s}$ solves this equation with eigenvalue

$$\lambda(\alpha) = \exp\!\left(-\rho T + (\alpha - \gamma)(\mu - \tfrac{1}{2}\sigma^2)T + \tfrac{1}{2}\sigma^2 T(\alpha - \gamma)^2\right).$$

The positive eigenfunction is therefore not unique.

This is why truncation or boundedness assumptions matter: they turn the continuous operator problem back into a Perron–Frobenius problem with a unique positive eigenvector.

Carr and Yu [2012] establish recovery with a bounded diffusion.

Transition independence:

If the kernel is not transition independent, recovery is not guaranteed.

Borovička *et al.* [2016] show that Ross recovery can confound the long-run risk component of the kernel with the natural probability distribution, yielding an incorrect decomposition.

We discuss this in the sequel lecture *Misspecified Recovery*.

See also

Long-term Risk: An Operator Approach develops the general operator treatment of this problem, in which the principal eigenfunction of the pricing operator and the resulting multiplicative martingale factorization of the stochastic discount factor are precisely what transition independence assumes away.

Be warned that the symbol ϕ denotes the pricing kernel in the present lecture but the principal eigenfunction there; it is this lecture's eigenvector z that plays the role of that lecture's ϕ.

Empirical estimation:

Extracting reliable state prices from observed option prices requires careful interpolation and extrapolation.

The mapping from implied volatilities to state prices via the Breeden and Litzenberger [1978] formula involves second derivatives, which amplify measurement error.

141.12 Exercises

Exercise 141.12.1

The Perron–Frobenius vector and the pricing kernel.

Consider the 3×3 state price matrix

$$P = \begin{pmatrix} 0.5950 & 0.1700 & 0.0272 \\ 0.159375 & 0.5525 & 0.1360 \\ 0.06640625 & 0.31875 & 0.5525 \end{pmatrix}.$$

1. Compute the Perron eigenvalue β and the corresponding eigenvector z of P.
2. Use z to recover the natural probability transition matrix F via
$$f_{ij} = \frac{1}{\beta} \frac{z_j}{z_i} p_{ij}.$$
3. Verify that each row of F sums to one and all entries are positive.
4. For destination state j, the relative kernel component is $1/z_j$; for a transition from state i to state j, the full pricing kernel is $\beta z_i / z_j$. Compute $1/z_j$ for each state.

Does the kernel decrease as we move from state 1 to state 3 (i.e., from bad to good states)?

Solution

Here is one solution:

```
P_ex = np.array([
    [0.5950, 0.1700, 0.0272],
    [0.159375, 0.5525, 0.1360],
    [0.06640625, 0.31875, 0.5525]
])

eigenvalues, eigenvectors = eig(P_ex)
real_mask = np.isreal(eigenvalues)
real_ev = eigenvalues[real_mask].real
real_evec = eigenvectors[:, real_mask].real

idx = np.argmax(real_ev)
β_ex = real_ev[idx]
z_ex = real_evec[:, idx]
if z_ex.min() < 0:
    z_ex = -z_ex
z_ex = z_ex / z_ex[1]

print(f"β = {β_ex:.6f}")
print(f"z = {z_ex}")

D_ex = np.diag(1.0 / z_ex)
D_inv_ex = np.diag(z_ex)
F_ex = (1.0 / β_ex) * D_ex @ P_ex @ D_inv_ex

print("\nRecovered F:")
print(np.round(F_ex, 4))
```

```
print(f"\nRow sums: {np.round(F_ex.sum(axis=1), 8)}")
print(f"Nonnegative: {(F_ex >= -1e-10).all()}")

ψ_relative_ex = 1.0 / z_ex
print(f"\nrelative kernel 1/z = {np.round(ψ_relative_ex, 4)}")
print(f"Decreasing: {ψ_relative_ex[0] > ψ_relative_ex[1] > ψ_relative_ex[2]}")
```

```
β = 0.850000
z = [0.8  1.   1.25]

Recovered F:
[[0.7  0.25 0.05]
 [0.15 0.65 0.2 ]
 [0.05 0.3  0.65]]

Row sums: [1. 1. 1.]
Nonnegative: True

relative kernel 1/z = [1.25 1.   0.8 ]
Decreasing: True
```

Exercise 141.12.2

Stochastic dominance.

Using the recovered F and the normalized risk-neutral matrix $Q = P/\text{row sums}$ from the exercise above:

1. Compute the one-step marginal distributions $f_j = F_{2,j}$ and $q_j = Q_{2,j}$ starting from state 2 (index 1 in Python).
2. Compute the CDFs $\hat{F}_k = \sum_{j \le k} f_j$ and $\hat{Q}_k = \sum_{j \le k} q_j$ for each state.
3. Verify numerically that $\hat{F}_k \le \hat{Q}_k$ for every k, confirming stochastic dominance in this ordered three-state example.

Solution

Here is one solution:

```
eigenvalues, eigenvectors = eig(P_ex)
real_mask = np.isreal(eigenvalues)
real_ev = eigenvalues[real_mask].real
real_evec = eigenvectors[:, real_mask].real
idx = np.argmax(real_ev)
β_ex = real_ev[idx]
z_ex = real_evec[:, idx]
if z_ex.min() < 0:
    z_ex = -z_ex
z_ex = z_ex / z_ex[1]

D_ex = np.diag(1.0 / z_ex)
D_inv_ex = np.diag(z_ex)
F_ex = (1.0 / β_ex) * D_ex @ P_ex @ D_inv_ex

start = 1
```

```
f_marg = F_ex[start]
q_marg = P_ex[start] / P_ex[start].sum()

print("One-step marginals from state 2:")
print(f"natural      = {np.round(f_marg, 4)}")
print(f"risk-neutral = {np.round(q_marg, 4)}")

cdf_nat = np.cumsum(f_marg)
cdf_rn = np.cumsum(q_marg)

print("\nCDFs:")
for k in range(3):
    print(f"state {k+1}: natural = {cdf_nat[k]:.4f}, risk-neutral = {cdf_rn[k]:.4f}
 ↪")

dominates = np.all(cdf_nat <= cdf_rn + 1e-10)
print(f"\nNatural CDF <= risk-neutral CDF: {dominates}")
```

```
One-step marginals from state 2:
natural      = [0.15 0.65 0.2 ]
risk-neutral = [0.188  0.6516 0.1604]

CDFs:
state 1: natural = 0.1500, risk-neutral = 0.1880
state 2: natural = 0.8000, risk-neutral = 0.8396
state 3: natural = 1.0000, risk-neutral = 1.0000

Natural CDF <= risk-neutral CDF: True
```

Exercise 141.12.3

Risk aversion and tail risk.

Write a function `tail_risk_ratio(γ, threshold, μ, σ, ρ, T)` that:

1. Constructs the state price matrix P using `build_state_price_matrix` with the given parameters and `n_states=41`.
2. Applies `recover_natural_distribution` to obtain F.
3. Computes $P(\text{log-return} \leq \text{threshold})$ under both the natural and risk-neutral distributions starting from the middle state.
4. Returns the ratio $p_{\text{risk-neutral}}/p_{\text{natural}}$.

Using this function, plot the ratio as a function of $\gamma \in [1, 10]$ for a 30 percent simple decline, i.e. `threshold = np.log(0.70)`.

Explain the economic interpretation: why does a higher γ raise the ratio?

Solution

Here is one solution:

```
def tail_risk_ratio(γ, threshold, μ=0.08, σ=0.20, ρ=0.02, T=1.0):
    """Risk-neutral / natural left-tail probability."""
    P_g, states_g = build_state_price_matrix(
```

```
        μ, σ, γ, ρ, T, n_states=41, n_σ=5)

    F_g, _, _, _ = recover_natural_distribution(P_g)

    mid_g = len(states_g) // 2

    f_nat_g = F_g[mid_g]
    f_rn_g = P_g[mid_g] / P_g[mid_g].sum()

    p_nat = float(np.sum(f_nat_g[states_g <= threshold]))
    p_rn = float(np.sum(f_rn_g[states_g <= threshold]))

    if p_nat < 1e-12:
        return np.nan
    return p_rn / p_nat

γs = np.linspace(1.0, 10.0, 20)
threshold_30 = np.log(0.70)
ratios = [tail_risk_ratio(g, threshold_30) for g in γs]

plt.figure(figsize=(9, 5))
plt.plot(γs, ratios, '-o', ms=5, lw=2)
plt.xlabel('risk aversion coefficient $\\gamma$')
plt.ylabel('risk-neutral / natural tail probability')
plt.title('tail risk ratio for a 30% decline vs risk aversion')
plt.show()
```

A higher coefficient of risk aversion γ makes the pricing kernel steeper: the market assigns a larger premium per unit of probability to bad-state payoffs.

Risk-neutral probabilities incorporate this premium, so in this CRRA simulation the risk-neutral crash probability rises faster with γ than the recovered natural crash probability.

Recovery separates the market's estimated natural crash probability from the pricing-kernel premium attached to crash states.

142.1 Overview

Standard short-horizon asset pricing tells us how equilibrium prices compensate investors for tiny, instantaneous exposures to shocks.

That is, they tell us about the *short end* of the term structure of risk prices.

But many of the most interesting asset pricing questions (e.g., the equity premium puzzle, the slope of the yield curve, the prices of long-dated options) concern the *long end* of the term structure of risk prices.

This lecture studies the long end using the operator approach of Hansen and Scheinkman [2009].

At center stage will be a stochastic discount factor process and a return process that are multiplicative across time in the sense that conditional expectations define a *semigroup* of valuation operators indexed by horizon t.

Long-horizon behavior of the semigroup is controlled by a single eigenvalue problem on the state space.

By solving that eigenvalue problem and selecting an appropriate eigenfunction, we can factor the multiplicative functional M_t into three economically meaningful pieces: a deterministic exponential trend, a non-negative martingale that changes

probability measure, and a transient state-dependent component.

In particular, the factorization takes the form

$$M_t = \exp(\rho t)\, \widehat{M}_t \, \frac{\phi(X_0)}{\phi(X_t)}, \tag{142.1}$$

where

- ρ is a scalar (the **principal eigenvalue**) giving the asymptotic growth or decay rate,
- ϕ is a strictly positive **principal eigenfunction** on the state space, capturing the long-run dependence on the current state,
- $\widehat{M}$ is a positive martingale used to change probability measure (the **martingale component**), and
- $\phi(X_0)/\phi(X_t)$ is a transient component that washes out as the twisted process settles into its stationary distribution.

In finite-state problems this is exactly the Perron-Frobenius decomposition of a positive matrix; in general state spaces it is a continuous-state counterpart.

We will refer to (142.1) as the **multiplicative factorization** associated with $(\rho, \phi, \widehat{M})$.

Alvarez and Jermann [2005] applied a related permanent-transitory decomposition to stochastic discount factors.

The operator approach links that decomposition to an explicit eigenvalue problem.

See also

This lecture is closely related to the lecture Additive and Multiplicative Functionals, which studies the same kind of permanent-transitory decomposition for additive and multiplicative functionals in a discrete-time linear-Gaussian setting.

Reading these two lectures together is a good way to learn about representations of long-run risks in both continuous and discrete time.

We will build up to (142.1) and use it to compute long-run risk prices in concrete models.

The plan of this lecture is to:

1. Set up positive multiplicative functionals M (discount factors, returns, stochastic growth) and the valuation semigroups they generate.
2. Introduce the **generator** of a semigroup, a local operator whose eigenvalue problem controls long-run behavior.
3. Find the principal eigenfunction ϕ and derive the factorization.
4. Work two examples in detail: a finite-state Markov chain (where everything reduces to Perron-Frobenius theory) and an affine diffusion model (where the eigenfunction is exponential-affine and we get closed-form formulas).
5. Use the factorization to compute long-run risk prices and compare them to the local risk prices appropriate for short-horizon asset pricing.

A recurring theme is that shocks to persistent state variables drive a wedge between local and long-run risk prices.

Generating that wedge is the mechanism through which long-run risk models like Bansal and Yaron [2004] generate large equity premia.

We start with the following imports

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.linalg import eig, expm
```

142.2 Multiplicative functionals

142.2.1 Setting

Let $\{X_t : t \geq 0\}$ be a continuous-time Markov process with state space $\mathcal{D}_0$, and let $\mathcal{F}_t$ denote the filtration generated by its history.

We will work with a strong Markov process whose sample paths are càdlàg (defined below).

To arrive at the explicit formulas presented later we will specialize to a semimartingale that decomposes into a continuous component X^c and a pure-jump component X^j:

$$X_t = X_t^c + X_t^j.$$

We write the continuous-component dynamics as

$$dX_t^c = \xi(X_{t-})\,dt + \Gamma(X_{t-})\,dB_t,$$

and the pure-jump component as

$$dX_t^j = \int (y - X_{t-})\,\zeta(dy, dt),$$

where ζ is the random counting measure of jumps indexed by the *post-jump state* y, so that $\zeta(B, [0, t])$ counts the number of jumps in $[0, t]$ landing in the Borel set B.

Its compensator is $\eta(dy \mid X_{t-})\,dt$, the rate at which X jumps from X_{t-} into a region dy.

We will use this "y = post-jump state" convention throughout, matching the form $\phi(y) - \phi(x)$ that appears in the generator below.

We also impose two simplifying assumptions:

- **Finite jumps** on finite time intervals: only finitely many jumps occur on any bounded interval; this keeps integrals against the jump measure well-defined and finite.
- **Sufficient rank in** Γ so that the Brownian shocks relevant for pricing can be recovered from the state history; this makes the Markov state X "rich enough" to describe valuation.

These assumptions let us write the generator in closed form and use martingale-based changes of measure freely.

142.2.2 Functionals and càdlàg paths

We need a name for "a process that records something about the history of X".

This includes, for example, a stochastic discount factor or a cumulated return.

Definition 142.2.1 (Functional)

A **functional** is a real-valued adapted process $\{M_t : t \geq 0\}$ constructed from the history of X, so that M_t is $\mathcal{F}_t$-measurable for each t.

We will always work with the **càdlàg** version of a functional, the French acronym for "right-continuous with left limits".

Concretely, for almost every sample path ω,

$$\lim_{s \downarrow t} M_s(\omega) = M_t(\omega) \qquad \text{for all } t \geq 0,$$

and the left limit $M_{t-}(\omega) := \lim_{s \uparrow t} M_s(\omega)$ exists and is finite for all $t > 0$.

Thus, paths can jump, but each jump $\Delta M_t := M_t - M_{t-}$ occurs instantaneously.

At the jump time t, the value is the post-jump value, not the pre-jump value.

Note

Why is the càdlàg property worth insisting on?

Because we will later want to (i) integrate functionals against time, (ii) apply optional stopping arguments, and (iii) take limits like $\lim_{t\to\infty} t^{-1} \log M_t$.

All three operations need the joint measurability in (ω, t) that càdlàg paths give us automatically.

142.2.3 Multiplicativity

The central restriction we impose on the functional M is that it is *multiplicative across time*.

Definition 142.2.2 (Multiplicative Functional)

A functional $\{M_t : t \geq 0\}$ is **multiplicative** if $M_0 = 1$ and

$$M_{t+u} = M_u(\theta_t)\, M_t, \qquad t, u \geq 0, \tag{142.2}$$

where θ_t shifts the underlying Markov path forward by t units.

Why is this a useful condition to require?

Think of $M_t = S_t$, a stochastic discount factor.

The date-0 value of a date-t payoff Π_t is $\mathbb{E}[S_t \Pi_t \mid \mathcal{F}_0]$.

If we instead buy this payoff at intermediate date τ, its date-τ price must be

$$\mathbb{E}\left[\frac{S_t}{S_\tau}\Pi_t \,\middle|\, \mathcal{F}_\tau\right].$$

For the price to depend only on the current Markov state X_τ (and not on the entire history up to τ), the ratio S_t/S_τ must be a function only of the Markov path *after* τ.

Thus, $S_{\tau+u}/S_\tau = S_u(\theta_\tau)$, which is exactly (142.2).

So multiplicativity is the Markov form of the law of one price.

The same structural property is then carried over to stochastic growth and cumulated returns.

142.2.4 Additive functionals

It is often easier to work with the *log* of a strictly positive multiplicative functional.

If $M_t > 0$, we can write $M_t = \exp(A_t)$, and the multiplicative property (142.2) becomes the corresponding additive property of A.

Definition 142.2.3 (Additive Functional)

A functional $\{A_t : t \geq 0\}$ is **additive** if $A_0 = 0$ and

$$A_{t+u} = A_u(\theta_t) + A_t.$$

So exponentials of additive functionals are exactly the strictly positive multiplicative functionals.

In our jump-diffusion setting, a useful parameterization is

$$A_t = \int_0^t \beta(X_s)\, ds + \int_0^t \gamma(X_{s-})^\top dB_s + \sum_{0 \leq s \leq t} \kappa(X_s, X_{s-}), \tag{142.3}$$

where the three functions (β, γ, κ) play the following roles:

- $\beta(x)$ is a **state-dependent drift** rate (e.g., a pure discount factor with short rate $r(x)$ has $\beta(x) = -r(x)$).
- $\gamma(x)$ is a **Brownian loading**, controlling how Brownian shocks feed into A at state x.
- $\kappa(y, x)$ is a **jump amplitude** that fires whenever X jumps from x to y.

For everything to be well defined, we impose the natural integrability conditions

$$\int_0^t |\beta(X_s)|\, ds < \infty, \qquad \int_0^t \|\gamma(X_s)\|^2\, ds < \infty,$$

together with $\kappa(x, x) = 0$ (no jump if the state doesn't change) and

$$\int \exp[\kappa(y, x)]\, \eta(dy \mid x) < \infty.$$

This parameterization is rich enough for everything we do in this lecture, though additive functionals can also include things like occupation times.

142.3 Semigroups

A multiplicative functional M together with the Markov process X defines a **valuation operator** for each horizon t:

$$\mathbb{M}_t \psi(x) = \mathbb{E}\left[M_t \psi(X_t) \mid X_0 = x\right].$$

You should read $\mathbb{M}_t \psi(x)$ as "the date-0 value, starting from state x, of a date-t payoff $\psi(X_t)$", weighted by M_t.

The family of operators $\{\mathbb{M}_t\}_{t \geq 0}$ has a key compositional structure, the *semigroup property*.

Definition 142.3.1 (One-Parameter Semigroup)

A family of linear operators $\{T_t : t \geq 0\}$ is a **one-parameter semigroup** if $T_0 = I$ and $T_{t+s} = T_t T_s$ for all $s, t \geq 0$.

It is **positive** if $T_t \psi \geq 0$ whenever $\psi \geq 0$.

Definition 142.3.2 (Multiplicative Semigroup)

Given a multiplicative functional M, the associated **multiplicative semigroup** is the family of operators

$$\mathbb{M}_t\psi(x) = \mathbb{E}\left[M_t\psi(X_t) \mid X_0 = x\right]. \tag{142.4}$$

The semigroup identity $\mathbb{M}_{t+u} = \mathbb{M}_t\mathbb{M}_u$ follows from iterated expectations and the multiplicative property of M.

Economically, this is the *Markov law of iterated values*: to value a date-$(t+u)$ payoff today, we can either

- discount it directly from $t+u$ back to 0 in one step (apply $\mathbb{M}_{t+u}$), or
- first discount it from $t+u$ back to t (apply $\mathbb{M}_u$), then discount the resulting date-t price back to 0 (apply $\mathbb{M}_t$).

The semigroup identity says these two procedures give the same answer.

This is the operator-level version of the intertemporal consistency that rules out arbitrage across horizons.

Four positive multiplicative functionals will appear often below.

Symbol	Object	Semigroup
S	stochastic discount factor	$\{\mathbb{S}_t\}$
V	cumulated return on an asset	$\{\mathbb{V}_t\}$
G	stochastic growth in cash flows	$\{\mathbb{G}_t\}$
$Q = GS$	valuation of growing cash flows	$\{\mathbb{Q}_t\}$

The first three are primitives.

The fourth combines discounting and growth to value cash flows that grow stochastically over time.

Definition 142.3.3 (Stochastic Discount Factor)

A **stochastic discount factor** S is a positive multiplicative functional for which $\mathbb{E}[S_tZ_t \mid X_0 = x]$ is the date-0 value of an $\mathcal{F}_t$-measurable payoff Z_t.

Definition 142.3.4 (Valuation Functional)

Given a stochastic discount factor S, a **valuation functional** V is a positive multiplicative functional such that $\{V_tS_t : t \geq 0\}$ is a martingale.

Definition 142.3.5 (Stochastic Growth Functional)

A **stochastic growth functional** G is a positive multiplicative functional, interpreted as a multiplicative growth factor applied to a date-0 cash flow.

Consider a cash flow $D_t = D_0\, G_t\, \psi(X_t)$, where $D_0 > 0$ is the date-0 level and ψ is a Borel state-payoff function.

Discounting with S and growing with G, its date-0 value is

$$D_0\, \mathbb{Q}_t\psi(X_0), \qquad \mathbb{Q}_t\psi(x) = \mathbb{E}\left[G_tS_t\psi(X_t) \mid X_0 = x\right].$$

Definition 142.3.6 (Cash-Flow Valuation Semigroup)

The **cash-flow valuation semigroup** is the multiplicative semigroup generated by $Q = GS$.

The long-horizon behavior of $\mathbb{Q}_t$ is the central object of the lecture: it tells us how current prices value cash-flow growth risk that materializes far in the future.

Note

The factorization $D_t = D_0 G_t \psi(X_t)$ is not unique.

For any positive function φ,

$$D_t = D_0 \left[G_t \frac{\varphi(X_t)}{\varphi(X_0)} \right] \left[\frac{\psi(X_t)\varphi(X_0)}{\varphi(X_t)} \right],$$

so a transient state-dependent factor can be shuffled between G and ψ without changing D_t.

We resolve this indeterminacy by normalizing the growth component so that its permanent part is a martingale: $G_t = \exp(\delta t)\widehat{G}_t$, with $\widehat{G}$ a martingale and δ a constant trend.

The eigenfunction construction below will tell us exactly which martingale to pick.

142.3.1 Local pricing restriction

Before tackling long horizons, it is good to understand valuation at the *short* end.

That is the standard instantaneous risk-return relation.

This will give us a benchmark against which to compare long-run risk prices.

For a textbook discrete-time treatment of the same SDF-based asset-pricing ideas, see Elementary Asset Pricing Theory.

For an estimation perspective on Euler-equation-based asset pricing, see *Estimating Euler Equations by Generalized Method of Moments*.

The key starting point is that a valuation functional V must satisfy the no-arbitrage requirement that VS is a martingale (*Definition 142.3.4*).

We parameterize the stochastic discount factor S and valuation functional V as additive functionals with coefficients $(\beta^s, \gamma^s, \kappa^s)$ and $(\beta^v, \gamma^v, \kappa^v)$ respectively, in the notation of (142.3).

For a generic positive multiplicative functional $M = \exp(A)$ with parameters (β, γ, κ), applying Itô's formula to $\exp(A_t)$ and requiring the drift of dM_t/M_{t-} to vanish gives the **local martingale restriction**:

$$\beta(x) + \frac{\gamma(x)^\top \gamma(x)}{2} + \int \left(\exp[\kappa(y, x)] - 1 \right) \eta(dy \mid x) = 0. \tag{142.5}$$

The three terms correspond to:

- the drift of A itself,
- the Itô correction from the Brownian part (because $M = e^A$ picks up a quadratic-variation contribution), and
- the compensated jumps of M at the multiplier $\exp[\kappa(y, x)]$.

We ask you to verify this in Exercise 142.11.4.

Applying this to VS, whose parameters add: $(\beta^v + \beta^s, \gamma^v + \gamma^s, \kappa^v + \kappa^s)$, gives the **local pricing restriction**

$$\beta^v + \beta^s = -\frac{\|\gamma^v + \gamma^s\|^2}{2} - \int (\exp[\kappa^v(y,\cdot) + \kappa^s(y,\cdot)] - 1)\, \eta(dy \mid \cdot). \tag{142.6}$$

This determines the drift β^v of any candidate valuation functional in terms of its Brownian and jump exposures.

To turn this into an *expected return*, note that the expected net rate of return on V is

$$\epsilon^v = \beta^v + \frac{\|\gamma^v\|^2}{2} + \int (\exp[\kappa^v(y,\cdot)] - 1)\, \eta(dy \mid \cdot).$$

Combining with (142.6) gives

$$\begin{aligned} \epsilon^v = &-\beta^s - \gamma^v \cdot \gamma^s - \frac{\|\gamma^s\|^2}{2} \\ &- \int (\exp[\kappa^v(y,\cdot) + \kappa^s(y,\cdot)] - \exp[\kappa^v(y,\cdot)])\, \eta(dy \mid \cdot). \end{aligned} \tag{142.7}$$

Thus, the Brownian local risk-price vector is $-\gamma^s(x)$, expressed in the same exposure units as $\gamma^v(x)$.

Jump risk is priced through the function κ^s.

This local relation is one end of the term structure of risk prices.

The eigenvalue calculations below describe the other end.

142.4 The generator

So far we have a family of operators $\{\mathbb{M}_t\}_{t\geq 0}$, one for each horizon t.

That is more information than we can use directly.

What we care about is the long-run behavior: how $\mathbb{M}_t\psi$ grows as $t \to \infty$.

The **generator** $\mathbb{A}$ compresses the entire semigroup into one time-independent operator on the state space.

It records the *instantaneous* rate of change of $M_t\psi(X_t)$, and its eigenvalues drive the long-run growth rate of $\mathbb{M}_t$.

This lets us turn an asymptotic question about a family of operators into a single eigenvalue problem.

142.4.1 Discrete-time intuition

The role of the generator is easiest to see when time is discrete, so we build the picture there once and then carry it over.

Let X_n be Markov and M_n a multiplicative functional, and define the one-period valuation operator

$$K\psi(x) = \mathbb{E}\left[M_1\psi(X_1) \mid X_0 = x\right].$$

Iterating gives the n-period operator K^n.

This parallels the logic of a transition matrix: just as P^n gives n-step probabilities, K^n weights n-period payoffs, with M_1 folded in at each step.

So one local object, K, controls the entire horizon-indexed family.

It also controls long-run growth: if $K\phi = \lambda\phi$, then

$$K^n\phi = \lambda^n\phi,$$

so λ is the long-run geometric growth (or decay) rate and ϕ is the long-run dependence on the current state.

The same operator gives the predictable rate of change of the weighted payoff.

By multiplicativity,

$$\mathbb{E}\left[M_{n+1}\psi(X_{n+1}) - M_n\psi(X_n) \mid \mathcal{F}_n\right] = M_n(K\psi - \psi)(X_n),$$

so subtracting the cumulative predictable change from the total change leaves a martingale:

$$M_n\psi(X_n) - \psi(X_0) - \sum_{j=0}^{n-1} M_j(K\psi - \psi)(X_j).$$

Here $K - I$ is the *local* rate of change of $M_n\psi(X_n)$, and through K^n it also controls long-run growth.

142.4.2 From discrete to continuous time

Continuous time keeps the same logic.

The natural counterpart $K - I$ is the **infinitesimal generator** of the semigroup $\{\mathbb{M}_t\}$, the time derivative at zero:

$$\mathbb{A}\psi(x) := \lim_{h \downarrow 0} \frac{\mathbb{M}_h\psi(x) - \psi(x)}{h},$$

so that for small $h > 0$,

$$\mathbb{M}_h\psi(x) \approx \psi(x) + h\,\mathbb{A}\psi(x).$$

Note

When $M \equiv 1$, the multiplicative semigroup reduces to the standard Markov transition semigroup $\mathbb{M}_t\psi(x) = \mathbb{E}[\psi(X_t) \mid X_0 = x]$, and $\mathbb{A}$ becomes the familiar infinitesimal generator $\mathcal{L}$ of X from textbook stochastic calculus.

For general M, $\mathbb{A}$ is the same kind of object but it carries extra terms that encode the instantaneous "yield" of M: discount rates, Brownian risk prices, jump multipliers.

That is exactly what we will see when we write down its closed form in (142.8) below.

Why is this the right object?

If $\mathbb{A}\phi = \rho\phi$, then the candidate

$$\hat{M}_t := \exp(-\rho t)\, M_t\, \frac{\phi(X_t)}{\phi(X_0)}$$

is automatically a *local* martingale.

When $\hat{M}$ is in fact a martingale (the content of Assumption 6.1 in Hansen and Scheinkman [2009]), taking expectations gives the continuous-time analogue of $K^n\phi = \lambda^n\phi$:

$$\mathbb{M}_t\phi = \exp(\rho t)\,\phi.$$

Without that upgrade we get only the supermartingale inequality $\mathbb{M}_t\phi \le \exp(\rho t)\,\phi$, which we will revisit below.

So the long-run behavior of $\mathbb{M}_t$ is encoded in an eigenvalue problem for the local operator $\mathbb{A}$, together with the martingale property of $\hat{M}$.

142.4.3 Extended generator

The limit definition above needs a qualification.

To make the limit $h \downarrow 0$ rigorous, the textbook definition requires $(\mathbb{M}_h\psi - \psi)/h$ to converge to $\mathbb{A}\psi$ in a chosen norm, typically uniform convergence over bounded continuous functions, where the semigroup is a contraction.

But the functions we care about most are the principal eigenfunctions ϕ solving $\mathbb{A}\phi = \rho\phi$, and these typically *grow* with the state X (in the affine-Gaussian benchmark, ϕ is exponential-affine in x).

So they do not lie in this space, and the limit need not converge for them.

Hansen and Scheinkman [2009] sidestep this by characterizing $\mathbb{A}$ through a *Doob-Meyer style* semimartingale decomposition of $M_t\psi(X_t)$, a pathwise condition that does not require any norm.

This is the continuous-time counterpart to writing $K - I$ as the predictable rate of change of $M_n\psi(X_n)$ in discrete time.

The resulting **extended generator** admits unbounded ψ, has a strictly larger domain than the textbook generator, and agrees with it where both are defined.

Concretely:

Definition 142.4.1 (Extended Generator)

Fix a Borel function ψ, and look for a second Borel function χ that will play the role of "the instantaneous rate of change of $M_t\psi(X_t)$ at the current state".

We ask whether there exists χ such that

$$N_t = M_t\psi(X_t) - \psi(X_0) - \int_0^t M_s\chi(X_s)\,ds$$

is a local martingale.

We then say ψ lies in the domain of the **extended generator** $\mathbb{A}$ of M, and we *define* the operator by

$$\mathbb{A}\psi := \chi.$$

The three terms play the same roles as in discrete time:

- $M_t\psi(X_t) - \psi(X_0)$ is the total change in the weighted payoff over $[0, t]$,
- $\int_0^t M_s\chi(X_s)\,ds$ accumulates the expected rate of change along the path,
- N_t is the residual.

Requiring N_t to be a local martingale pins down $\chi = \mathbb{A}\psi$ as the instantaneous expected rate of change of $M_t\psi(X_t)$ at the current state.

- When $M \equiv 1$, the definition reduces to Dynkin's formula for the standard Markov generator $\mathcal{L}\psi(x) = \lim_{t\downarrow 0} t^{-1}[\mathbb{E}\psi(X_t) - \psi(x)]$.
- When X is a jump diffusion, Itô's formula applied to $M_t\psi(X_t)$ produces the closed-form expression for $\mathbb{A}\psi$ in (142.8) below.

142.4.4 A closed form for jump diffusions

For the jump-diffusion setting introduced above, we can compute $\mathbb{A}$ explicitly by applying Itô's formula to $M_t\phi(X_t)$.

Suppose the continuous part of X satisfies

$$dX_t^c = \xi(X_t)dt + \Gamma(X_t)dB_t$$

with diffusion matrix $\Sigma = \Gamma\Gamma^\top$, and let $\eta(dy \mid x)$ denote the jump compensator.

If $M = \exp(A)$ is parameterized by (β, γ, κ) as in (142.3), then for smooth ϕ,

$$\begin{aligned}\mathbb{A}\phi(x) = &\left[\xi(x) + \Gamma(x)\gamma(x)\right]^\top \frac{\partial\phi(x)}{\partial x} \\ &+ \frac{1}{2}\,\text{trace}\left[\Sigma(x)\frac{\partial^2\phi(x)}{\partial x\partial x^\top}\right] \\ &+ \int [\phi(y) - \phi(x)]\exp[\kappa(y,x)]\eta(dy \mid x) \\ &+ \left[\beta(x) + \frac{\gamma(x)^\top\gamma(x)}{2} + \int \left(\exp[\kappa(y,x)] - 1\right)\eta(dy \mid x)\right]\phi(x).\end{aligned} \tag{142.8}$$

The four terms have transparent interpretations:

1. The first term is the standard Markov drift, modified by $\Gamma\gamma$, a *covariance correction* between the Brownian shocks driving X and those driving M.
2. The second is the standard diffusion (Itô) term.
3. The third integrates ϕ against the jump-compensated transition rates, reweighted by the jump multiplier $\exp[\kappa(y,x)]$.
4. The fourth is a multiplicative *yield-like* term that multiplies $\phi(x)$ itself and combines the drift of M, the Brownian Itô correction, and the compensated jumps.

Note

When $M = S$ is a stochastic discount factor, the local risk prices are spread across the four pieces of the generator rather than concentrated in the level term.

- Brownian factor prices enter through the drift modification $\xi \to \xi + \Gamma\gamma$ in the first line.
- Jump-risk prices enter through the tilted jump measure $\eta \to \exp[\kappa]\,\eta$ in the third line.
- The level term in the fourth line contains the instantaneous risk-free rate component (the *short end* of the term structure) plus the jump-compensator contribution $\int(\exp[\kappa] - 1)\,\eta$.

We ask readers to verify the derivation of (142.8) in Exercise 142.11.5.

We will apply this formula directly in the affine-diffusion example below.

142.5 Principal eigenfunctions

We now arrive at the central technical question of the lecture:

> Which positive payoffs grow at a constant proportional rate under the valuation semigroup?

The answer, when it exists, is a positive eigenfunction of the generator.

Definition 142.5.1 (Eigenfunction of the Extended Generator)

A Borel function ϕ is an **eigenfunction** of $\mathbb{A}$ with eigenvalue ρ if

$$\mathbb{A}\phi = \rho\phi. \tag{142.9}$$

A **principal eigenfunction** is an eigenfunction ϕ that is strictly positive on the state space: $\phi(x) > 0$ for all $x \in \mathcal{D}_0$.

The strict-positivity requirement matters because ϕ will appear in denominators throughout: it has to be safe to divide by it.

142.5.1 From eigenfunction to factorization

Why does an eigenfunction of $\mathbb{A}$ give us the multiplicative factorization (142.1)?

The discrete-time analogy points the way.

If $K\phi = \lambda\phi$, then

$$\lambda^{-n} M_n \frac{\phi(X_n)}{\phi(X_0)}$$

is a martingale: the eigenvalue equation absorbs the one-step drift of $M_n\phi(X_n)$ exactly.

In continuous time, λ^n becomes $\exp(\rho t)$, and the candidate martingale is

$$\hat{M}_t = \exp(-\rho t)\, M_t \frac{\phi(X_t)}{\phi(X_0)}. \tag{142.10}$$

Let's check that $\hat{M}$ is indeed a local martingale.

By the definition of $\mathbb{A}$, the semimartingale $Z_t := M_t\phi(X_t)$ admits the decomposition

$$dZ_t = M_t\, \mathbb{A}\phi(X_t)\, dt + dN_t,$$

where N is a local martingale.

The eigenvalue equation $\mathbb{A}\phi = \rho\phi$ replaces the drift by $\rho Z_t\, dt$, and integration by parts gives

$$d(\exp(-\rho t)Z_t) = \exp(-\rho t)\left[dZ_t - \rho Z_t\, dt\right] = \exp(-\rho t)\, dN_t.$$

So $\exp(-\rho t)Z_t$ is a local martingale, and dividing by $\phi(X_0)$ shows the same for $\hat{M}$.

Rearranging (142.10) for M_t recovers the factorization (142.1), with $\hat{M}$ in the role of the martingale component.

Definition 142.5.2 (Martingale Component and Twisted Measure)

When $\hat{M}$ is a martingale (not merely a local martingale), it is the **martingale component** associated with (ρ, ϕ) and defines the **twisted probability measure** by weighting date-t events with $\hat{M}_t$:

$$\widehat{\Pr}(F \mid X_0 = x) = \mathbb{E}[\hat{M}_t \mathbf{1}_F \mid X_0 = x], \qquad F \in \mathcal{F}_t.$$

The verification establishes only that $\hat{M}$ is a *local* martingale, but the definition above (and the change-of-measure interpretation of $\hat{M}$) require it to be a martingale.

We close this gap by adopting Assumption 6.1 of Hansen and Scheinkman [2009]:

> The local martingale $\hat{M}$ defined in (142.10) is a martingale, i.e. $\mathbb{E}[\hat{M}_t \mid X_0 = x] = 1$ for every $t \geq 0$ and x.

We carry this assumption from here on.

Even without closing the gap we still get one-sided control.

Since $\hat{M}$ is nonnegative with $\hat{M}_0 = 1$, it is a supermartingale, so $\mathbb{E}[\hat{M}_t \mid X_0 = x] \leq 1$.

Taking expectations in (142.10),

$$\mathbb{M}_t \phi(x) \leq \exp(\rho t)\, \phi(x),$$

so ρ is at least an upper bound on the long-run growth rate of $\mathbb{M}_t \phi$.

When $\hat{M}$ is in fact a martingale, $\mathbb{E}[\hat{M}_t] = 1$, the inequality becomes an equality, and the local condition $\mathbb{A}\phi = \rho\phi$ lifts to the semigroup eigenvalue equation

$$\mathbb{M}_t \phi = \exp(\rho t)\, \phi, \qquad t \geq 0. \tag{142.11}$$

142.5.2 Stability of the twisted process

We now have a factorization (142.1) for *any* principal eigenfunction.

But for (ρ, ϕ) to describe **long-run** behavior of $\mathbb{M}_t$ the twisted process must settle into a stationary regime as $t \to \infty$.

If it doesn't, the transient factor $\phi(X_0)/\phi(X_t)$ will not vanish, and we cannot read off the asymptotics from ρ alone.

We need three conditions, each ruling out a specific way in which the twisted process can fail to settle down.

Let $\hat{E}$ and $\widehat{\Pr}$ denote expectation and probability under the twisted measure, and let $\hat{\mathbb{A}}$ be the generator of X under that measure.

Condition 1: a stationary distribution exists.

Definition 142.5.3 (Stationary Distribution of the Twisted Process)

A probability measure $\hat{\varsigma}$ on $\mathcal{D}_0$ is a **stationary distribution** for the twisted process if

$$\int \hat{\mathbb{A}}\psi \, d\hat{\varsigma} = 0$$

for every ψ in the L^∞ domain of $\hat{\mathbb{A}}$.

$\hat{\varsigma}$ is the candidate long-run distribution.

Without it, the twisted process has no steady state, and the long-run limit cannot be expressed as a state-space integral.

Condition 2: every important region is reachable.

Definition 142.5.4 (Irreducible Skeleton)

The discretely sampled skeleton $\{X_{\Delta j} : j = 0, 1, ...\}$ is **irreducible** relative to $\hat{\varsigma}$ if there exists $\Delta > 0$ such that, for every Borel set $\Lambda \subseteq \mathcal{D}_0$ with $\hat{\varsigma}(\Lambda) > 0$,

$$\hat{E}\left[\sum_{j=0}^{\infty} \mathbf{1}_{\{X_{\Delta j} \in \Lambda\}} \,\middle|\, X_0 = x\right] > 0 \qquad \text{for all } x \in \mathcal{D}_0.$$

Without it, the long-run distribution could depend on the starting state; different basins of attraction would give different limits.

Condition 3: every important region is visited infinitely often.

Definition 142.5.5 (Harris Recurrence)

The process X is **Harris recurrent** under the twisted measure if, for every Borel set $\Lambda \subseteq \mathcal{D}_0$ with $\hat{\varsigma}(\Lambda) > 0$,

$$\widehat{\Pr}\left\{\int_0^{\infty} \mathbf{1}_{\{X_t \in \Lambda\}}\, dt = \infty \,\middle|\, X_0 = x\right\} = 1 \qquad \text{for all } x \in \mathcal{D}_0.$$

Reachability (Condition 2) is not enough.

A set may be reachable but visited with vanishingly small probability, so time averages fail to converge to $\hat{\varsigma}$-averages.

Harris recurrence is the continuous-state counterpart to a "recurrent state" in a finite chain.

Collecting the three conditions:

Definition 142.5.6 (Stochastically Stable Twisted Process)

The $\hat{M}$-twisted Markov process is **stochastically stable** if it has a stationary distribution $\hat{\varsigma}$, the skeleton $\{X_{\Delta j}\}$ is irreducible relative to $\hat{\varsigma}$, and X is Harris recurrent under the twisted measure.

142.5.3 The long-run approximation

Under the martingale condition for $\hat{M}$, strict positivity of M, and stochastic stability, the long-run limit takes a clean form:

$$\lim_{t \to \infty} \exp(-\rho t)\, \mathbb{M}_t \psi = \phi \int \frac{\psi}{\phi}\, d\hat{\varsigma}. \tag{142.12}$$

Read this as follows:

- The factor $\exp(\rho t)$ captures the exponential growth or decay of the semigroup; once we divide it out, what remains has a finite limit.
- The state dependence in that limit is *entirely* captured by $\phi(x)$.

- The scalar $\int (\psi/\phi)\, d\hat{\varsigma}$ is the **long-run intensity** of the payoff ψ, weighted by $1/\phi$ and averaged against the twisted stationary distribution.

The two precise cases of Proposition 7.1 of Hansen and Scheinkman [2009] are:

- **Sampled grid, $\hat{\varsigma}$-almost every starting state.** Fix any $\Delta > 0$ and assume $\int |\psi|/\phi \, d\hat{\varsigma} < \infty$; then the limit holds along $t = \Delta j$ for $\hat{\varsigma}$-almost every $x \in \mathcal{D}_0$.
- **Continuous t, every starting state.** If ψ/ϕ is bounded then the limit holds for every $x \in \mathcal{D}_0$ and every $t \to \infty$, with no continuity assumption on ψ.

Note

There can be more than one positive eigenfunction of $\mathbb{A}$ for which the associated $\hat{M}$ is a martingale, possibly with different eigenvalues.

Stochastic stability selects a particular one.

By Proposition 7.2 of Hansen and Scheinkman [2009], the stable eigenfunction's eigenvalue ρ is the **smallest** among all eigenvalues of $\mathbb{A}$ that admit a strictly positive eigenfunction satisfying the maintained conditions.

Any other positive eigenfunction sharing this ρ is proportional to ϕ $\hat{\varsigma}$-almost surely.

The finite-state section below states the same selection in the more familiar Perron-Frobenius language, calling ρ the eigenvalue with the *largest* real part among all eigenvalues of A.

These two descriptions identify the same eigenvalue because in the irreducible finite-state case only one eigenvalue of A admits a strictly positive eigenvector.

In the affine example below the two sets pull apart, since the quadratic (142.18) has two roots c_f that both give strictly positive exponential-affine eigenfunctions with distinct eigenvalues.

Stochastic stability picks the smaller ρ by rejecting the root that produces an explosive twisted process.

142.6 A finite-state Markov chain

We now apply the framework to a concrete example.

We start with the simplest case: a finite-state Markov chain.

For background on finite Markov chains in discrete time, see *Finite Markov Chains*.

For the asset-pricing applications of finite-state chains that motivate the construction here, see *Asset Pricing: Finite State Models*.

Here, every abstract object collapses to a familiar one:

Abstract object	Finite-state version
Markov process X	continuous-time chain with intensity matrix U
Generator $\mathbb{A}$	a matrix A
Semigroup $\mathbb{M}_t$	matrix exponential $\exp(tA)$
Principal eigenfunction ϕ	Perron right eigenvector
Principal eigenvalue ρ	dominant real eigenvalue of A
Stationary distribution $\hat{\varsigma}$	left eigenvector of twisted generator

So the long-run analysis reduces to Perron-Frobenius theory.

(For an introduction to the Perron-Frobenius theorem, see The Perron-Frobenius Theorem.)

142.6.1 Setup

Let X take values in $\{x_1, \dots, x_N\}$ and let U be its intensity matrix.

Definition 142.6.1 (Intensity Matrix)

An **intensity matrix** U for a finite-state continuous-time Markov chain satisfies $u_{ij} \geq 0$ for $i \neq j$ and $\sum_j u_{ij} = 0$ for each state i.

Off-diagonal entries u_{ij} are the jump rates from state i to state j; the diagonal entry $u_{ii} = -\sum_{j \neq i} u_{ij}$ is minus the exit rate from state i.

Let the multiplicative functional have

- a **discount or decay rate** r_i in state i (the analogue of the drift $\beta(X_s)$ in the additive parameterization), and
- a **jump multiplier** $\exp[\kappa(x_j, x_i)]$ that fires whenever the state jumps from i to j.

In code below, `κ[j, i]` means $\kappa(x_j, x_i)$.

Then the generator matrix A for the multiplicative semigroup is

$$a_{ij} = \begin{cases} u_{ii} - r_i, & i = j, \\ u_{ij} \exp[\kappa(x_j, x_i)], & i \neq j. \end{cases} \tag{142.13}$$

The off-diagonal entries are the chain's jump rates *weighted* by the jump multipliers; the diagonal entries combine the exit rate with the in-state decay rate.

The semigroup is then just $\mathbb{M}_t = \exp(tA)$.

For an irreducible chain with strictly positive jump multipliers, the principal eigenvalue ρ is the unique real eigenvalue of A with largest real part, and the associated right eigenvector is strictly positive.

The twisted generator under the principal eigenpair (ρ, ϕ) is

$$\hat{A} = D_\phi^{-1} A D_\phi - \rho I,$$

where $D_\phi = \operatorname{diag}(\phi)$.

The row sums of $\hat{A}$ vanish, so $\hat{A}$ is itself a valid intensity matrix.

The stationary distribution $\hat{\varsigma}$ solves $\hat{\varsigma}^\top \hat{A} = 0$.

The helper functions below implement these three calculations.

    """Stationary distribution of a finite-state generator."""
    vals, vecs = eig(Q.T)
    idx = np.argmin(np.abs(vals))
    π = vecs[:, idx].real

    if π.sum() < 0:
        π = -π

    π = np.maximum(π, 0)
    return π / π.sum()
```

142.6.2 Two states

Consider a boom-recession economy.

State 1 is a *boom* (higher short rate $r_1 = 0.05$, switching to recession at rate $\lambda_1 = 0.30$).

State 2 is a *recession* (lower short rate $r_2 = 0.02$, switching to boom at rate $\lambda_2 = 0.50$).

For now we set the log jump multipliers κ to zero — equivalently, the jump multipliers $\exp[\kappa]$ to one — so the SDF only changes continuously through the in-state decay rates.

```
λ_1 = 0.30
λ_2 = 0.50

U = np.array([[-λ_1,  λ_1],
              [ λ_2, -λ_2]])

r = np.array([0.05, 0.02])
κ = np.zeros((2, 2))

A = build_generator(U, r, κ)
ρ, ψ = principal_eigenpair(A)

print("A =")
print(np.round(A, 4))
print(f"\nρ = {ρ:.6f}")
print(f"ψ = {ψ}")
print(f"long-run zero-coupon yield = {-ρ:.4f}")
```

```
A =
[[-0.35  0.3 ]
 [ 0.5  -0.52]]

ρ = -0.038484
ψ = [0.98116799 1.01883201]
long-run zero-coupon yield = 0.0385
```

Note that $-\rho$ is the asymptotic yield on a zero-coupon bond: from (142.1), the date-0 price of a long zero-coupon bond decays like $\exp(\rho t)$, so its yield is $-\rho$.

Let's verify the semigroup eigenvalue equation $\mathbb{M}_t \phi = \exp(\rho t)\phi$ numerically.

```
for t in [1.0, 5.0, 25.0]:
    lhs = expm(t * A) @ ψ
    rhs = np.exp(ρ * t) * ψ
    err = np.max(np.abs(lhs - rhs))
    print(f"t = {t:4.1f}, error = {err:.2e}")
```

```
t =  1.0, error = 1.11e-16
t =  5.0, error = 1.11e-16
t = 25.0, error = 3.33e-16
```

The error is at machine precision for every t, so the equation holds exactly up to floating-point noise from the eigendecomposition.

Next we compute the twisted generator $\hat{A}$ and the stationary distribution $\hat{\varsigma}$ of the chain under the twisted measure.

This is the candidate long-run distribution that appears in the long-run limit (142.12).

```
A_hat = twisted_generator(A, ρ, ψ)
ς_hat = stationary_distribution(A_hat)

print("twisted generator row sums:")
print(np.round(A_hat.sum(axis=1), 12))

print("\ntwisted stationary distribution:")
print(f"  boom      {ς_hat[0]:.4f}")
print(f"  recession {ς_hat[1]:.4f}")
```

```
twisted generator row sums:
[-0.  0.]

twisted stationary distribution:
  boom      0.6072
  recession 0.3928
```

This twisted stationary distribution (not the original chain's stationary distribution) is what determines long-horizon valuations.

It differs from the stationary distribution of the original chain because the eigenfunction ϕ reweights states by how persistently they affect the multiplicative functional.

For any payoff function ψ, the long-run limit (142.12) is the vector

$$\phi \sum_i \frac{\psi_i}{\phi_i} \hat{\varsigma}_i.$$

Let's check that the rescaled semigroup converges to this limit as t grows.

```
ψ = np.array([1.0, 2.0])
limit = ψ * np.sum((ψ / ψ) * ς_hat)

for t in [1, 5, 20, 80]:
    approx = np.exp(-ρ * t) * expm(t * A) @ ψ
    print(f"t = {t:2d}, normalized value = {approx}")

print("\nlimit =", limit)
```

```
t =  1, normalized value = [1.19917652 1.68031101]
t =  5, normalized value = [1.35687434 1.42719756]
t = 20, normalized value = [1.36377325 1.41612444]
t = 80, normalized value = [1.3637733  1.41612436]

limit = [1.3637733  1.41612436]
```

The numerical values converge to the limit; the next plot shows the same convergence pictorially.

```
t_grid = np.linspace(0.01, 80, 400)
rescaled = np.array([np.exp(-ρ * t) * expm(t * A) @ ψ for t in t_grid])

fig, ax = plt.subplots()
ax.plot(t_grid, rescaled[:, 0], lw=2, label="starting from boom")
ax.plot(t_grid, rescaled[:, 1], lw=2, label="starting from recession")
ax.axhline(limit[0], color="C0", ls="--", lw=1, alpha=0.7)
ax.axhline(limit[1], color="C1", ls="--", lw=1, alpha=0.7)
ax.set_xlabel("$t$")
ax.set_ylabel(r"$e^{-\rho t}\,(\mathbb{M}_t \psi)(x)$")
ax.legend()
plt.show()
```

The two solid curves trace the rescaled values starting from each state, and the dashed horizontal lines mark the limits predicted by (142.12).

Both curves settle onto their predicted limits, confirming that the long-run behavior depends on the starting state only through ϕ.

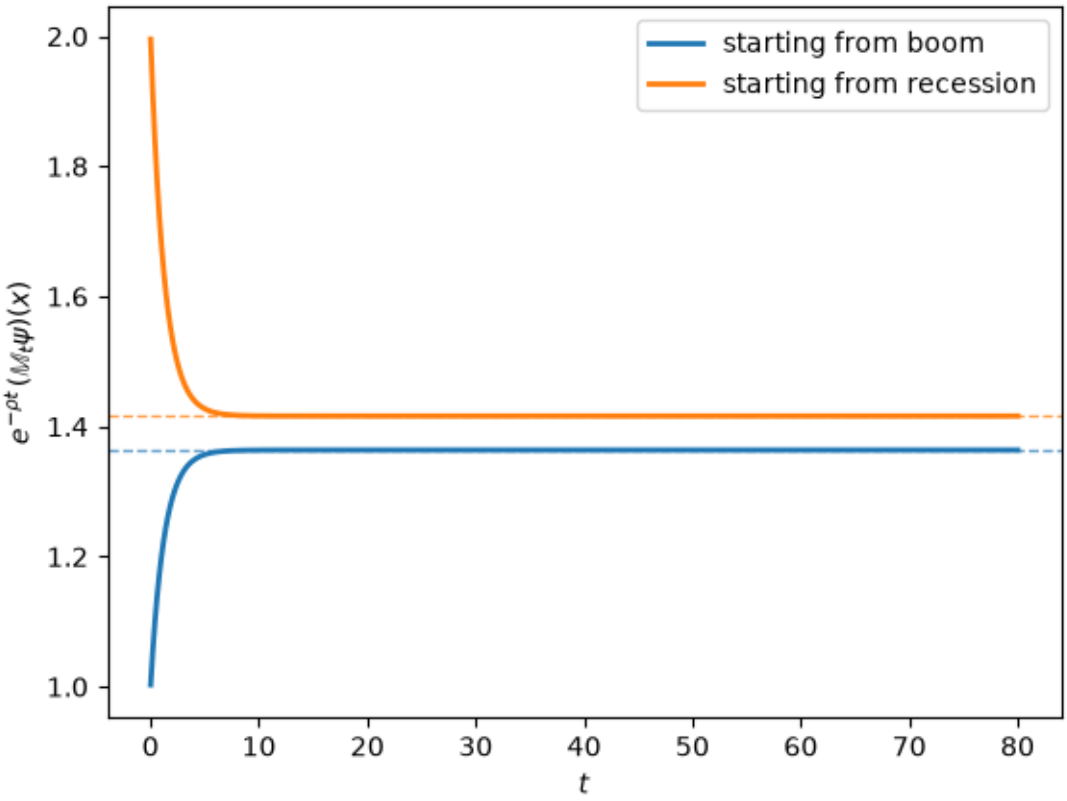

Fig. 142.1: Convergence of the rescaled semigroup to its long-run limit

Note

The asymptotic exponential rate of convergence is governed by the gap between the *real part* of the leading eigenvalue ρ and the largest real part among the remaining eigenvalues of A.

For an irreducible Metzler matrix the leading eigenvalue is real and its real part is strictly larger than the others, so this gap is well defined.

Exercise 142.11.3 works through a three-state example where the gap can be checked directly.

142.6.3 Adding jumps

State transitions in this chain are discontinuous, so it is natural to allow the multiplicative functional to jump at the transition times.

These jumps are the analogue of the κ function in the jump-diffusion parameterization.

A natural example arises with a stochastic discount factor that jumps *down* when the economy moves from recession into boom and *up* on the reverse transition.

The matrix `κ_jump` below encodes this.

We use the convention `κ[j, i]` = log jump multiplier of M for the transition $i \to j$, with state index 0 = boom and state index 1 = recession.

```
# recession (1) -> boom (0): SDF jumps down on good news (exp(-0.20))
# boom (0) -> recession (1): SDF jumps up on bad news (exp(+0.30))
κ_jump = np.array([[ 0.0, -0.20],
                   [ 0.30,  0.0]])

A_jump = build_generator(U, r, κ_jump)
ρ_jump, ψ_jump = principal_eigenpair(A_jump)

print(f"ρ without jumps = {ρ:.6f}")
print(f"ρ with jumps    = {ρ_jump:.6f}")
print("\nψ with jumps:")
print(ψ_jump)
```

```
ρ without jumps = -0.038484
ρ with jumps    = -0.019067

ψ with jumps:
[1.10059123 0.89940877]
```

To see how the long-run rate ρ responds to jump risk, we hold the boom-to-recession log multiplier fixed at its calibrated value and trace out ρ as the recession-to-boom log multiplier varies.

The right benchmark to compare against is therefore the eigenvalue at $\kappa(\text{rec} \to \text{boom}) = 0$ with the boom-to-recession jump still switched on, which the black dot marks.

```
κ_boom_to_rec = κ_jump[1, 0]

κ_grid = np.linspace(-0.5, 0.5, 100)
ρ_grid = np.empty_like(κ_grid)

for n, k in enumerate(κ_grid):
    κ_temp = np.array([[0.0, k],
```

(continues on next page)

(continued from previous page)

```
                        [κ_boom_to_rec, 0.0]])
    A_temp = build_generator(U, r, κ_temp)
    ρ_grid[n], _ = principal_eigenpair(A_temp)

ρ_no_up_jump, _ = principal_eigenpair(
    build_generator(U, r, np.array([[0.0, 0.0],
                                    [κ_boom_to_rec, 0.0]]))
)

fig, ax = plt.subplots()
ax.plot(κ_grid, ρ_grid, lw=2)
ax.plot([0.0], [ρ_no_up_jump], "o", color="black",
        label="no recession-to-boom jump")
ax.axvline(0, color="black", ls=":", lw=1)
ax.set_xlabel("jump log multiplier for recession to boom")
ax.set_ylabel("principal eigenvalue")
ax.legend()
plt.show()

print(f"ρ at κ(rec -> boom) = 0 = {ρ_no_up_jump:.6f}")
```

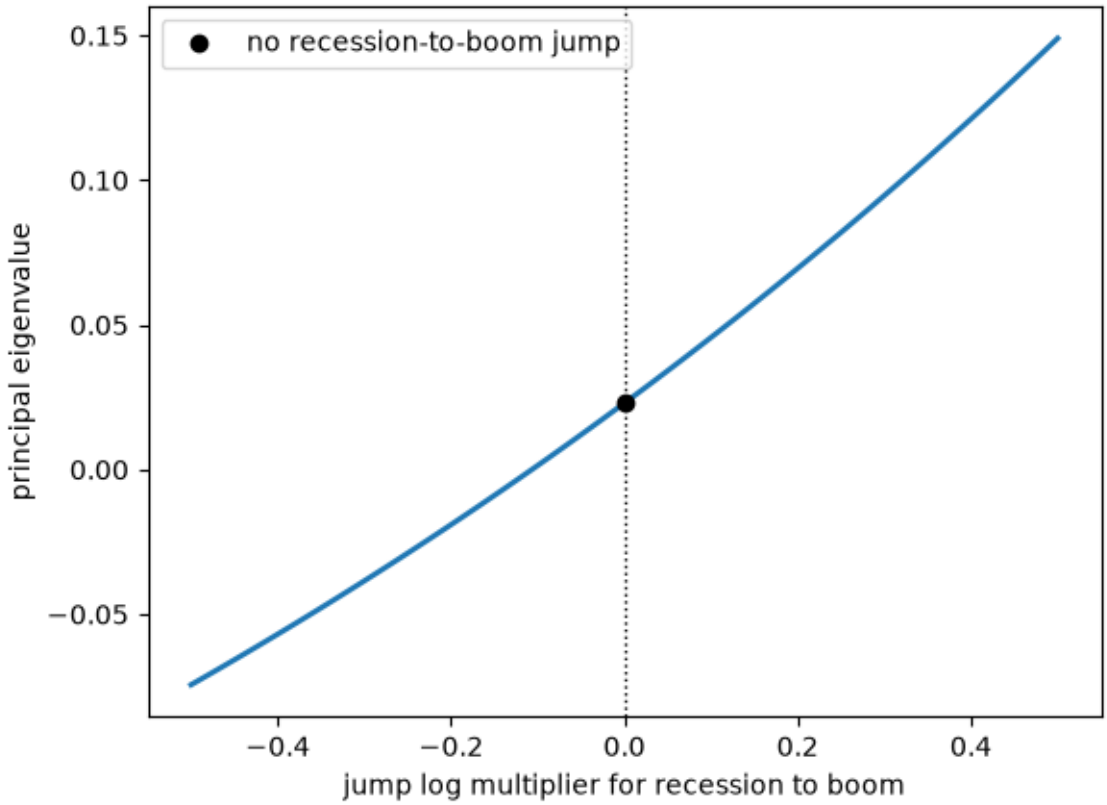

Fig. 142.2: Jumps and the long-run growth rate, holding the boom-to-recession log multiplier fixed

```
ρ at κ(rec -> boom) = 0 = 0.022934
```

The principal eigenvalue is monotonically increasing in the recession-to-boom log multiplier: as that multiplier rises, M jumps less downward (or more upward) on good news, which mechanically pushes ρ up.

The black dot sits at $\rho = 0.022934$.

Switching the recession-to-boom jump on at the calibrated $\kappa = -0.20$ moves ρ down to -0.019067, the value printed above.

The economically sensible region for a stochastic discount factor is to the left of zero, where the log multiplier is negative and M jumps down on good news.

142.7 The affine diffusion example

We now move to a continuous-state model.

We will use a two-factor affine specification that captures the two main empirical features of asset returns:

- **stochastic volatility**, where the dispersion of shocks is itself a state variable, and
- **predictable growth**, where a small, persistent state variable shifts expected growth rates.

This is the kind of state process used in long-run risk models like Bansal and Yaron [2004].

We work with two independent state components: a Feller square-root process X^f (stochastic volatility) and an Ornstein-Uhlenbeck process X^o (predictable growth):

$$\begin{aligned} dX_t^f &= \xi_f(\bar{x}_f - X_t^f)dt + \sqrt{X_t^f}\sigma_f dB_t^f, \\ dX_t^o &= \xi_o(\bar{x}_o - X_t^o)dt + \sigma_o dB_t^o. \end{aligned} \tag{142.14}$$

The parameters $\xi_f, \xi_o > 0$ are mean-reversion speeds, $\bar{x}_f, \bar{x}_o$ are the unconditional means, and σ_f, σ_o are diffusion coefficients.

The OU process X^o is the continuous-time analogue of the AR(1) process studied in AR(1) Processes, and continuous-time linear asset-pricing models in the same family are developed in *Affine Models of Asset Prices*.

We follow a sign convention with $\sigma_o > 0$ and $\sigma_f < 0$: a positive B^f shock then *reduces* volatility, in line with the empirical "leverage effect."

Now consider a multiplicative functional $M = \exp(A)$ with affine parameters:

$$\begin{aligned} A_t = \bar{\beta} t + \int_0^t \beta_f X_s^f \, ds + \int_0^t \beta_o X_s^o \, ds \\ + \int_0^t \sqrt{X_s^f}\, \gamma_f \, dB_s^f + \int_0^t \gamma_o \, dB_s^o. \end{aligned} \tag{142.15}$$

So the drift of A is affine in the state ($\bar{\beta} + \beta_f X^f + \beta_o X^o$), the Brownian loadings are constant in the B^o direction and proportional to $\sqrt{X^f}$ in the B^f direction.

142.7.1 Why exponential-affine eigenfunctions work

When the state is affine and the drift of A is affine, applying the generator to an exponential-affine function $\phi(x^f, x^o) = \exp(c_f x^f + c_o x^o)$ returns another exponential-affine function.

This closure property turns the eigenvalue equation $\mathbb{A}\phi = \rho\phi$ into a small system of algebraic equations in (c_f, c_o, ρ).

Definition 142.7.1 (Exponential-Affine Eigenfunction)

An eigenfunction ϕ of $\mathbb{A}$ on a state space $\mathcal{D}_0 \subseteq \mathbb{R}^n$ is **exponential-affine** if

$$\phi(x) = \exp(c_0 + c^\top x) \qquad \text{for all } x \in \mathcal{D}_0,$$

for some constant $c_0 \in \mathbb{R}$ and vector $c \in \mathbb{R}^n$.

Substituting $\phi(x^f, x^o) = \exp(c_f x^f + c_o x^o)$ into the generator formula (142.8) and matching coefficients of x^f, x^o, and the constant term gives

$$0 = \beta_f + \frac{\gamma_f^2}{2} + c_f(\gamma_f \sigma_f - \xi_f) + c_f^2 \frac{\sigma_f^2}{2}, \tag{142.16}$$

and

$$c_o = \frac{\beta_o}{\xi_o}. \tag{142.17}$$

The two candidate values for c_f are

$$c_f = \frac{\xi_f - \gamma_f \sigma_f \pm \sqrt{(\xi_f - \gamma_f \sigma_f)^2 - \sigma_f^2(2\beta_f + \gamma_f^2)}}{\sigma_f^2}. \tag{142.18}$$

The eigenvalue is then determined by matching the constant term:

$$\rho = \bar{\beta} + \frac{\gamma_o^2}{2} + c_f \xi_f \bar{x}_f + c_o(\xi_o \bar{x}_o + \gamma_o \sigma_o) + c_o^2 \frac{\sigma_o^2}{2}. \tag{142.19}$$

Equation (142.18) gives two candidate values of c_f, and we need to know which one is the principal eigenfunction.

This is where stochastic stability (*Definition 142.5.6*) does real work.

Under the twisted measure, the drift of X^f is

$$\xi_f(\bar{x}_f - x^f) + x^f \sigma_f(\gamma_f + c_f \sigma_f),$$

so the mean-reversion coefficient becomes

$$\xi_f - \sigma_f(\gamma_f + c_f \sigma_f).$$

If this is positive, the twisted square-root process stays stationary; if it is negative, the twisted process is explosive and the eigenfunction is not the long-run-relevant one.

So we **pick the root that keeps the twisted process mean-reverting**, exactly the way stochastic stability selects the principal eigenfunction in the abstract theory.

```
def solve_affine_eigenfunction(params):
    """Solve the exponential-affine eigenvalue problem."""
    ξ_f = params["ξ_f"]
    xbar_f = params["xbar_f"]
    σ_f = params["σ_f"]

    xbar_o = params["xbar_o"]
    σ_o = params["σ_o"]
    β_bar = params["β_bar"]
```

(continues on next page)

(continued from previous page)

```
    β_f = params["β_f"]
    β_o = params["β_o"]
    γ_f = params["γ_f"]
    γ_o = params["γ_o"]

    co = β_o / ξ_o

    disc = ((ξ_f - γ_f * σ_f) ** 2
            - σ_f ** 2 * (2 * β_f + γ_f ** 2))

    if disc < 0:
        raise ValueError("No real affine eigenfunction for these parameters.")

    root = np.sqrt(disc)
    cf_roots = (
        ((ξ_f - γ_f * σ_f) - root) / σ_f ** 2,
        ((ξ_f - γ_f * σ_f) + root) / σ_f ** 2
    )

    def mean_reversion(cf):
        return ξ_f - σ_f * (γ_f + cf * σ_f)

    for cf in cf_roots:
        mr = mean_reversion(cf)
        if mr > 0:
            break
    else:
        raise ValueError("Neither root gives a stationary twisted process.")

    ρ = (β_bar
         + γ_o ** 2 / 2
         + cf * ξ_f * xbar_f
         + co * (ξ_o * xbar_o + γ_o * σ_o)
         + co ** 2 * σ_o ** 2 / 2)

    return cf, co, ρ, mr
```

142.7.2 A Breeden SDF

To make things concrete, we now plug in a specific stochastic discount factor: the Breeden CRRA consumption-based SDF.

Breeden [1979] derived the continuous-time SDF for an investor with time-separable CRRA preferences over a consumption stream.

We specify log consumption with the same affine state X^o driving expected growth and $\sqrt{X^f}$ driving volatility:

$$dc_t = X_t^o\,dt + \sqrt{X_t^f}\,\vartheta_f\,dB_t^f + \vartheta_o\,dB_t^o.$$

With time-separable CRRA utility (risk aversion a) and subjective discount rate b, the stochastic discount factor is

$$S_t = \exp(-bt - a(c_t - c_0)),$$

i.e. an exponential of $-b$ times time minus a times log consumption growth.

Reading off the additive functional coefficients gives

$$\bar{\beta}^s = -b, \quad \beta_f^s = 0, \quad \beta_o^s = -a, \quad \gamma_f^s = -a\vartheta_f, \quad \gamma_o^s = -a\vartheta_o. \tag{142.20}$$

We will use these parameters in the numerical example below.

142.7.3 Recursive preferences (optional)

A famous limitation of CRRA preferences is that they conflate risk aversion with the elasticity of intertemporal substitution.

Recursive preferences Epstein and Zin [1989], Kreps and Porteus [1978] separate the two, and add a forward-looking continuation-value term to the discount-factor expression.

This is what powers the equity-premium results in Bansal and Yaron [2004].

A QuantEcon lecture that studies long-run dynamics under recursive preferences in a different setting is *Survival and Long-Run Dynamics under Recursive Preferences*.

This section derives the SDF coefficients for the unit-elasticity recursive specification.

You can skip on a first read and come back later — the numerical example uses the simpler Breeden parameters above.

For the unit-elasticity recursive specification, conjecture a continuation value of the form

$$W_t = \frac{1}{1-a}\exp\left[(1-a)(w_f X_t^f + w_o X_t^o + c_t + \bar{w})\right], \qquad a > 1. \tag{142.21}$$

Matching the local mean of this continuation value gives

$$\begin{aligned} 0 &= -\xi_f w_f + \frac{(1-a)\sigma_f^2}{2} w_f^2 + (1-a)\vartheta_f \sigma_f w_f + \frac{(1-a)\vartheta_f^2}{2} - b w_f, \\ 0 &= -\xi_o w_o + 1 - b w_o, \\ b\bar{w} &= \xi_f \bar{x}_f w_f + \xi_o \bar{x}_o w_o + \frac{(1-a)\sigma_o^2}{2} w_o^2 + (1-a)\vartheta_o \sigma_o w_o + \frac{(1-a)\vartheta_o^2}{2}. \end{aligned} \tag{142.22}$$

The relevant solution has $w_o = 1/(\xi_o + b)$, selects the stable root of the quadratic for w_f, and then determines $\bar{w}$ from the constant equation.

The stochastic discount factor is the product $S_t = \exp(A_t^B)\exp(A_t^W)$, where the Breeden-like logarithmic component is

$$A_t^B = -bt - \int_0^t X_s^o ds - \int_0^t \sqrt{X_s^f}\vartheta_f dB_s^f - \int_0^t \vartheta_o dB_s^o$$

The continuation-value martingale component is

$$\begin{aligned} A_t^W = (1-a)\int_0^t \sqrt{X_s^f}(\vartheta_f + w_f\sigma_f) dB_s^f + (1-a)\int_0^t (\vartheta_o + w_o\sigma_o) dB_s^o \\ - \frac{(1-a)^2}{2}\int_0^t X_s^f (\vartheta_f + w_f\sigma_f)^2 ds - \frac{(1-a)^2}{2}(\vartheta_o + w_o\sigma_o)^2 t. \end{aligned} \tag{142.23}$$

Thus the recursive-utility SDF has affine parameters

$$\begin{aligned} \bar{\beta}^s &= -b - \frac{(1-a)^2}{2}(\vartheta_o + w_o\sigma_o)^2, \\ \beta_f^s &= -\frac{(1-a)^2}{2}(\vartheta_f + w_f\sigma_f)^2, \\ \beta_o^s &= -1, \\ \gamma_f^s &= -a\vartheta_f - (a-1)w_f\sigma_f, \\ \gamma_o^s &= -a\vartheta_o - (a-1)w_o\sigma_o. \end{aligned} \tag{142.24}$$

The local Brownian risk prices are therefore $\sqrt{x^f}[a\vartheta_f + (a-1)w_f\sigma_f]$ for B^f exposure and $a\vartheta_o + (a-1)w_o\sigma_o$ for B^o exposure.

The numerical example below uses the simpler Breeden specification, but the same operator calculation applies once the SDF parameters are replaced by (142.24).

142.7.4 Numerical example

Let's set up parameters and solve for the principal eigenpair.

We use illustrative parameters loosely in the long-run-risk family: a mean-reverting volatility factor X^f with mean 0.04, a more persistent predictable-growth factor X^o with mean 0.02, risk aversion $a = 4$, and a time discount rate $b = 0.03$.

These are chosen to make the operator calculations transparent, not to match asset-price moments.

With time-separable CRRA preferences and $a = 4$ they imply an instantaneous riskless rate of about 10.6% at the state means and a long zero-coupon yield of 9.6% (printed below), which is the familiar risk-free rate puzzle rather than a resolution of it.

```
params_state = {
    "ξ_f": 0.70,
    "xbar_f": 0.04,
    "σ_f": -0.20,
    "ξ_o": 0.50,
    "xbar_o": 0.02,
    "σ_o": 0.01,
}

a = 4.0
b = 0.03
ϑ_f = 0.06
ϑ_o = 0.02

params_sdf = {
    **params_state,
    "β_bar": -b,
    "β_f": 0.0,
    "β_o": -a,
    "γ_f": -a * ϑ_f,
    "γ_o": -a * ϑ_o,
}

cf_s, co_s, ρ_s, mr_s = solve_affine_eigenfunction(params_sdf)

print("principal eigenfunction ψ(xf, xo) = exp(cf xf + co xo)")
print(f"cf = {cf_s:.6f}")
print(f"co = {co_s:.6f}")
print(f"ρ = {ρ_s:.6f}")
print(f"twisted mean-reversion coefficient for Xf = {mr_s:.6f}")
print(f"long-run zero-coupon yield = {-ρ_s:.4f}")
```

```
principal eigenfunction ψ(xf, xo) = exp(cf xf + co xo)
cf = 0.044232
co = -8.000000
ρ = -0.095962
twisted mean-reversion coefficient for Xf = 0.650231
long-run zero-coupon yield = 0.0960
```

The long-run zero-coupon yield $-\rho_s$ represents the asymptotic decay rate in the SDF expectation $\mathbb{E}[S_t]$.

We can also check that the rejected root for c_f would have produced a non-stationary twisted process, a clear example of stochastic stability selecting one of two algebraically valid eigenfunctions.

```
ξ_f = params_sdf["ξ_f"]
σ_f = params_sdf["σ_f"]
γ_f = params_sdf["γ_f"]
β_f = params_sdf["β_f"]

disc = ((ξ_f - γ_f * σ_f) ** 2
        - σ_f ** 2 * (2 * β_f + γ_f ** 2))
root = np.sqrt(disc)

cf_candidates = np.array([
    ((ξ_f - γ_f * σ_f) - root) / σ_f ** 2,
    ((ξ_f - γ_f * σ_f) + root) / σ_f ** 2
])

for cf in cf_candidates:
    mr = ξ_f - σ_f * (γ_f + cf * σ_f)
    print(f"cf = {cf:8.4f}, twisted mean reversion = {mr:8.4f}")
```

```
cf =   0.0442, twisted mean reversion =   0.6502
cf =  32.5558, twisted mean reversion =  -0.6502
```

142.7.5 The martingale component

Now that we have the eigenpair (ρ, ϕ), we can write down all three pieces of the factorization (142.1) explicitly.

The martingale component $\hat{M}_t = \exp(\hat{A}_t)$ defined in (142.10) has log

$$\begin{aligned}\hat{A}_t = &\int_0^t \sqrt{X_s^f}(\gamma_f + c_f\sigma_f)\, dB_s^f + \int_0^t (\gamma_o + c_o\sigma_o)\, dB_s^o \\ &- \frac{1}{2}\int_0^t X_s^f(\gamma_f + c_f\sigma_f)^2\, ds - \frac{1}{2}\int_0^t (\gamma_o + c_o\sigma_o)^2\, ds.\end{aligned}$$

The first line is the Brownian integral (the "exponential martingale" piece); the second is the Itô correction needed to make it a martingale.

Under the twisted measure induced by $\hat{M}$, the drifts of the state variables shift to

$$\begin{aligned}dX_t^f &: \quad \xi_f(\bar{x}_f - X_t^f) + X_t^f\sigma_f(\gamma_f + c_f\sigma_f), \\ dX_t^o &: \quad \xi_o(\bar{x}_o - X_t^o) + \sigma_o(\gamma_o + c_o\sigma_o).\end{aligned}$$

The drift distortions are exactly the Girsanov shifts induced by the Brownian loadings of $\hat{M}$.

Let's now simulate the state and check the factorization numerically.

The first check is the *algebraic identity*: once we define $\hat{M}$ through (142.10), the equation $M_t = \exp(\rho t)\hat{M}_t\phi(X_0)/\phi(X_t)$ is automatic for any choice of (ρ, ϕ), and the error below is just floating-point round-off.

The second, substantive, check is whether the eigenpair (ρ, ϕ) we solved for really makes $\hat{M}$ a martingale, which we approximate by computing $\mathbb{E}[\hat{M}_t]$ across many simulated paths.

```
def brownian_increments(n, dt, seed=1234):
    """Independent Brownian increments for the simulation."""
    rng = np.random.default_rng(seed)
    draws = rng.normal(scale=np.sqrt(dt), size=(n, 2))
    return draws[:, 0], draws[:, 1]

def simulate_states(params, T=40.0, dt=0.01, seed=1234):
    """Euler simulation of the affine state process."""
    n = int(T / dt)
    t = np.linspace(0, T, n + 1)

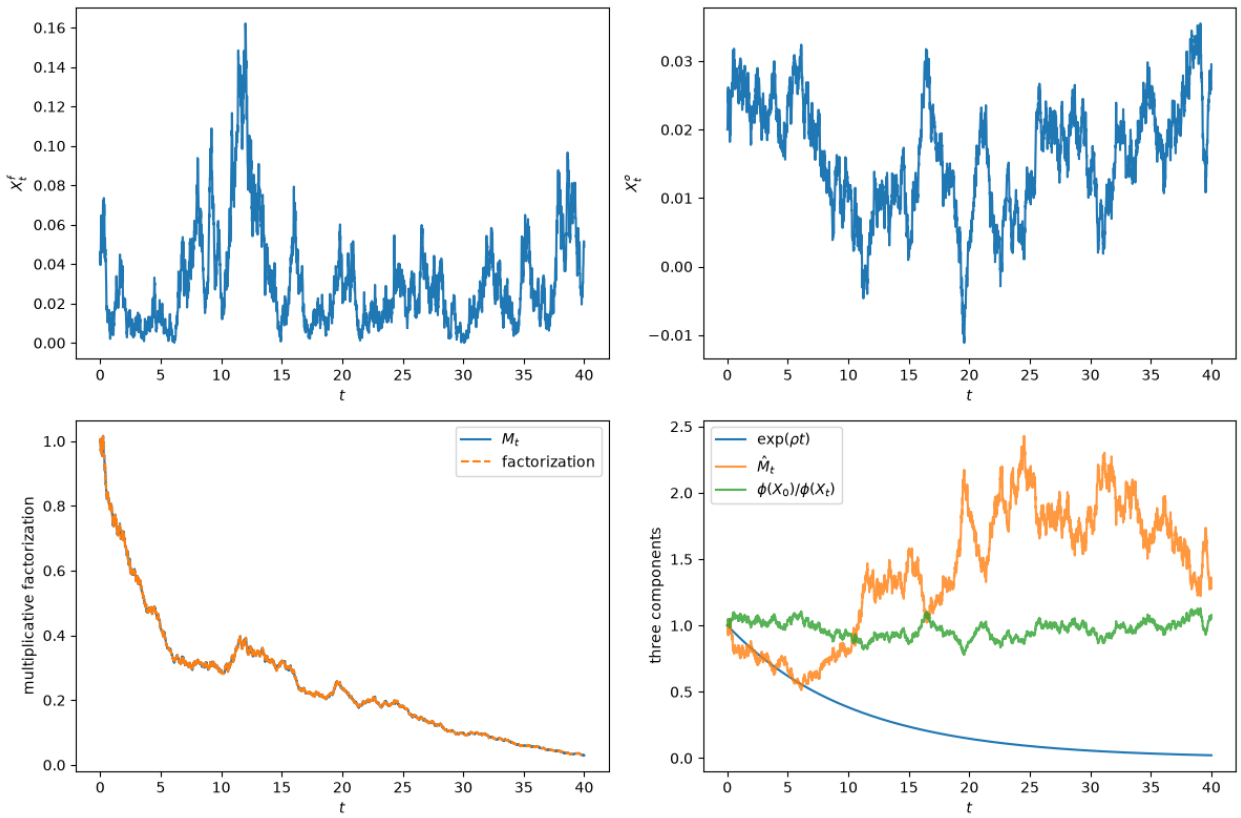

Fig. 142.3: Affine state paths and multiplicative factorization

The figure shows how the three components evolve over time.

142.8 Long-run risk prices

We can now use the factorization to compute long-run analogues of the instantaneous risk prices that arise in standard continuous-time asset pricing.

We can ask:

> If an investor takes on a small exposure to a shock today, how much extra expected return do they need when that return is measured as a long-horizon rate rather than an instantaneous one?

The two answers, local and long-run, need not agree.

A shock that moves a persistent state variable has a small *immediate* effect on the cash flow but a large *cumulative* effect on future expected growth and discounting, which is why the two answers come apart.

So the long-run risk price is the local price *plus a persistence correction.*

The size of the correction depends on the speed of mean reversion.

142.8.1 Defining the prices

Definition 142.8.1 (Local Brownian Risk Price)

The **local Brownian risk price** is the state-dependent vector $-\gamma^s(x)$.

A small Brownian exposure γ_i^v earns a required expected return of $-\gamma_i^v \gamma_i^s$ per unit time, so a unit of exposure γ_i^v is priced at $-\gamma_i^s$.

For the local price we just read off the SDF coefficients.

Definition 142.8.2 (Long-Run Risk Price)

The **long-run risk price** is the marginal change in the long-run required return on a cash flow with respect to a small change in its risk exposure.

When we work with growing cash flows, the long-run required return is $R_\infty = -\rho + \delta$, where ρ is the principal eigenvalue of the GS semigroup and δ is the trend growth rate, held fixed.

Computing the long-run price requires solving the principal eigenvalue problem, which captures how a shock propagates through the persistent state component.

142.8.2 Two frontiers

We will see *two* related ways to vary risk exposure, each leading to a slightly different long-run risk price:

1. **Valuation-functional frontier:**
   - Hold the SDF S fixed and vary the asset's Brownian exposures (γ_f^v, γ_o^v).
   - Use the local pricing restriction to determine the drift β^v, then compute ρ^v for the V-semigroup.
2. **Cash-flow frontier:**
   - Hold the SDF S fixed and vary the cash-flow's growth exposures (γ_f^g, γ_o^g).
   - Set $M = GS$ and compute the principal eigenvalue ρ of the cash-flow valuation semigroup.

In simple log-normal examples, these two frontiers coincide.

But they can differ with stochastic volatility, nonlinear dynamics, or jump risk.

We will work out both types of examples in the affine model below: in the B^o direction the two frontiers agree exactly, while in the B^f direction stochastic volatility pulls them apart.

142.8.3 Stochastic discount factor decomposition

Before getting into risk prices, a natural benchmark is the case $M = S$: applying the factorization (142.1) directly to the SDF itself.

The factorization becomes

$$S_t = \exp(\rho t)\widehat{M}_t \frac{\phi(X_0)}{\phi(X_t)}.$$

This is the **permanent-transitory decomposition** of Alvarez and Jermann [2005], linked now to a concrete eigenfunction construction.

The factor $\exp(\rho t)$ is the deterministic trend in the SDF and the martingale $\widehat{M}$ is its random *permanent* component; the state-dependent ratio is *transient* and washes out.

See also

The same spectral decomposition of the pricing operator is the central tool in *The Recovery Theorem*, which uses it to "recover" subjective beliefs from observed prices, and in *Misspecified Recovery*, which examines what goes wrong when the permanent martingale component is mistakenly assumed away.

For a long zero-coupon bond,

$$\exp(-\rho t)\,\mathbb{E}[S_t \mid X_0 = x] \to \phi(x) \int \frac{1}{\phi}\, d\hat{\varsigma},$$

so long-maturity discount bond prices depend on the current state primarily through the eigenfunction ϕ.

142.8.4 Comparison in the affine model

For the affine specification, we can write closed-form expressions for both local and long-run prices of a B^o shock.

The local price is just

$$\text{local price of } B^o = -\gamma_o^s.$$

The long-run price (which we will derive below using the valuation-functional frontier) is

$$\text{long-run price of } B^o = -\gamma_o^s - \frac{\beta_o^s}{\xi_o}\sigma_o. \tag{142.25}$$

The extra term $-(\beta_o^s/\xi_o)\sigma_o$ is the **persistence correction**.

It arises because:

- a B^o shock moves the persistent growth predictor X^o, and
- X^o mean reverts at rate ξ_o, so the cumulative effect of the shock on future SDF growth scales like $1/\xi_o$.

As ξ_o shrinks, persistence grows and the long-run price diverges from the local one, which is the central economic content of long-run risk models.

The local price of B^f exposure is state dependent (it scales with $\sqrt{X_t^f}$), and the long-run price of B^f exposure is nonlinear, since c_f is the root of a quadratic.

```
γ_s_o = params_sdf["γ_o"]
β_s_o = params_sdf["β_o"]
ξ_o = params_sdf["ξ_o"]
σ_o = params_sdf["σ_o"]

local_price_o = -γ_s_o
long_run_price_o = -γ_s_o - (β_s_o / ξ_o) * σ_o

print(f"local price of B^o exposure    = {local_price_o:.4f}")
print(f"long-run price of B^o exposure = {long_run_price_o:.4f}")
```

```
local price of B^o exposure    = 0.0800
long-run price of B^o exposure = 0.1600
```

The next cell illustrates how persistence changes the wedge between local and long-run prices.

```
ξ_o_grid = np.array([0.10, 0.20, 0.50, 1.00, 2.00, 5.00])
local_grid = np.full_like(ξ_o_grid, local_price_o)
long_grid = -γ_s_o - (β_s_o / ξ_o_grid) * σ_o

fig, ax = plt.subplots()
ax.plot(ξ_o_grid, local_grid, "--", lw=2, label="local")
ax.plot(ξ_o_grid, long_grid, "o-", lw=2, label="long-run")
ax.set_xscale("log")
ax.set_xlabel("mean-reversion speed $\\xi_o$")
ax.set_ylabel("risk price")
ax.legend()
plt.show()
```

As we can see, the long-run price of B^o exposure is sensitive to the mean-reversion speed ξ_o, but the local price is a constant.

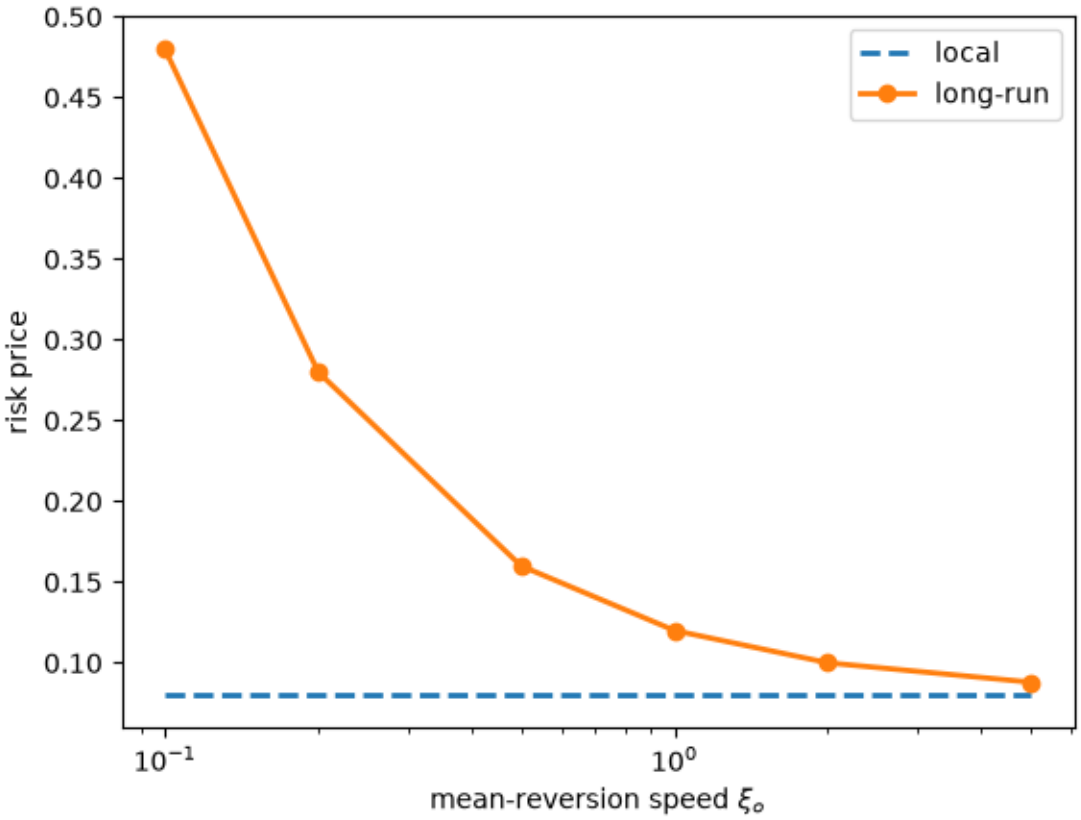

Fig. 142.4: Persistence and long-run risk prices

142.8.5 Changing valuation functionals

Now we work out the long-run risk price formula by varying the asset's exposure, the **valuation-functional frontier** introduced above.

We hold the SDF S fixed and pick Brownian exposures (γ_f^v, γ_o^v) for the asset return, parameterizing the valuation functional as

$$
\begin{aligned}
A_t^v = \bar{\beta}^v t + \int_0^t \beta_f^v X_s^f ds + \int_0^t \beta_o^v X_s^o ds \\
+ \int_0^t \sqrt{X_s^f} \gamma_f^v dB_s^f + \int_0^t \gamma_o^v dB_s^o.
\end{aligned}
$$

The martingale restriction on VS determines the drift coefficients from the chosen Brownian exposures (γ_f^v, γ_o^v):

$$
\begin{aligned}
\bar{\beta}^v &= -\bar{\beta}^s - \frac{1}{2}(\gamma_o^s + \gamma_o^v)^2, \\
\beta_f^v &= -\beta_f^s - \frac{1}{2}(\gamma_f^s + \gamma_f^v)^2, \\
\beta_o^v &= -\beta_o^s.
\end{aligned}
\tag{142.26}
$$

Applying the affine eigenvalue formula to $M = V$ gives

$$
\begin{aligned}
\rho^v &= \bar{\beta}^v + \frac{(\gamma_o^v)^2}{2} + c_f^v \xi_f \bar{x}_f + c_o^v(\xi_o \bar{x}_o + \gamma_o^v \sigma_o) + (c_o^v)^2 \frac{\sigma_o^2}{2} \\
&= -\bar{\beta}^s - \frac{(\gamma_o^s)^2}{2} - \gamma_o^s \gamma_o^v + c_f^v \xi_f \bar{x}_f + c_o^v(\xi_o \bar{x}_o + \gamma_o^v \sigma_o) + (c_o^v)^2 \frac{\sigma_o^2}{2},
\end{aligned}
\tag{142.27}
$$

where $c_o^v = \beta_o^v/\xi_o = -\beta_o^s/\xi_o$ and c_f^v solves the same quadratic equation as in (142.16) with (β_f, γ_f) replaced by (β_f^v, γ_f^v).

Holding γ_f^v fixed, differentiating (142.27) with respect to γ_o^v gives the long-run valuation-functional price of B^o exposure:

$$
\frac{\partial \rho^v}{\partial \gamma_o^v} = -\gamma_o^s + c_o^v \sigma_o = -\gamma_o^s - \frac{\beta_o^s}{\xi_o} \sigma_o. \tag{142.28}
$$

This matches the formula (142.25) we previewed above, namely the local price plus the persistence correction $-(\beta_o^s/\xi_o)\sigma_o$.

Let's verify the formula numerically by finite-differencing the eigenvalue computation.

```
def valuation_params_from_exposure(γ_v_o, γ_v_f=0.0):

formula                 = 0.160000
```

142.8.6 Changing cash-flow risk

The second long-run frontier varies the cash-flow's exposure to risk rather than the return.

We pick a growth functional $G_t = \exp(A_t^g)$ with the affine parameterization

$$\begin{aligned} A_t^g = \delta t + \int_0^t \sqrt{X_s^f}\gamma_f^g dB_s^f + \int_0^t \gamma_o^g dB_s^o \\ - \frac{1}{2}\int_0^t \left[X_s^f(\gamma_f^g)^2 + (\gamma_o^g)^2\right] ds. \end{aligned} \tag{142.29}$$

The last line is the Itô compensator that makes $\exp(A_t^g - \delta t) = \hat{G}_t$ a *local* martingale, with δ the constant trend growth rate.

In this affine setting the three abstract conditions of *Definition 142.5.6* — a stationary distribution, an irreducible skeleton, and Harris recurrence — all follow once the twisted X^f is mean reverting and does not hit zero.

Alongside them sits the separate requirement that $\hat{G}$ itself be a martingale, the Assumption-6.1 analogue for the growth twist.

Take nonattainment first.

Under the twist the drift of X^f becomes

$$\xi_f \bar{x}_f - [\xi_f - \sigma_f(\gamma_f + c_f\sigma_f)]x^f, \qquad \gamma_f = \gamma_f^s + \gamma_f^g,$$

while Girsanov leaves the diffusion coefficient $\sqrt{x^f}\sigma_f$ unchanged.

Writing this drift in the canonical square-root form $\hat{\kappa}(\hat{\theta} - x^f)$, the twist rescales the mean-reversion speed $\hat{\kappa}$ and the long-run mean $\hat{\theta}$, but it leaves their *product* $\hat{\kappa}\hat{\theta} = \xi_f\bar{x}_f$ fixed.

Since the **Feller-type nonattainment** inequality sees only that product, it is the same one that governs the original process,

$$2\xi_f\bar{x}_f \geq \sigma_f^2,$$

with no exposure parameter in it at all.

Mean reversion of the twisted X^f, i.e. $\hat{\kappa} > 0$, is a genuinely separate requirement, and it is picked by the same root-selection argument we used for the SDF in (142.18).

Neither condition is sufficient on its own.

Note

Nonattainment is free here, but stability overall is not: changing growth risk can still violate it and invalidate the long-run approximation, so the choice of (γ_f^g, γ_o^g) isn't free.

At this calibration, for instance, a large negative γ_f^g drives the discriminant in (142.18) below zero, so no real exponential-affine eigenfunction exists at all.

To price the cash flow $D_t = D_0 G_t \psi(X_t)$, use the semigroup generated by $M = GS$.

The combined affine parameters are

$$\begin{aligned}
\bar{\beta} &= \bar{\beta}^s + \delta - \frac{(\gamma_o^g)^2}{2}, \\
\beta_f &= \beta_f^s - \frac{(\gamma_f^g)^2}{2}, \\
\beta_o &= \beta_o^s, \\
\gamma_f &= \gamma_f^s + \gamma_f^g, \\
\gamma_o &= \gamma_o^s + \gamma_o^g.
\end{aligned}$$

Let ρ be the principal eigenvalue of this GS semigroup.

Then $-\rho$ is the long-run decay rate in value, and

$$R_\infty = -\rho + \delta$$

is the asymptotic required return net of the cash-flow growth rate.

```
def required_return_for_growth_exposure(γ_g_o, γ_g_f=0.0, δ=0.02):
    """Long-run required return for a cash-flow growth exposure."""
    p = dict(params_sdf)
    p.update({
        "β_bar": params_sdf["β_bar"] + δ - 0.5 * γ_g_o ** 2,
        "β_f": params_sdf["β_f"] - 0.5 * γ_g_f ** 2,
        "β_o": params_sdf["β_o"],
        "γ_f": params_sdf["γ_f"] + γ_g_f,
        "γ_o": params_sdf["γ_o"] + γ_g_o,
    })

    _, _, ρ, _ = solve_affine_eigenfunction(p)
    return -ρ + δ
```

```
γ_g_o_grid = np.linspace(-0.5, 0.5, 101)
required_returns = np.array([
    required_return_for_growth_exposure(g) for g in γ_g_o_grid
])

local_line = (required_return_for_growth_exposure(0.0)
              + local_price_o * γ_g_o_grid)

fig, ax = plt.subplots()
ax.plot(γ_g_o_grid, required_returns, lw=2,
        label="long-run required return")
ax.plot(γ_g_o_grid, local_line, "--", lw=2,
        label="local slope")
ax.set_xlabel("cash-flow exposure $\\gamma_o^g$")
ax.set_ylabel("rate of return")
ax.legend()
plt.show()
```

The slope of the long-run line is the risk price in (142.25), and the dashed line shares the same value at $\gamma_o^g = 0$ but with slope equal to the local Brownian risk price $-\gamma_o^s$.

The gap between the two slopes is the *persistence correction*; the dashed line is a slope comparator, not the actual Breeden local expected-return frontier (which is state dependent in X^f and X^o).

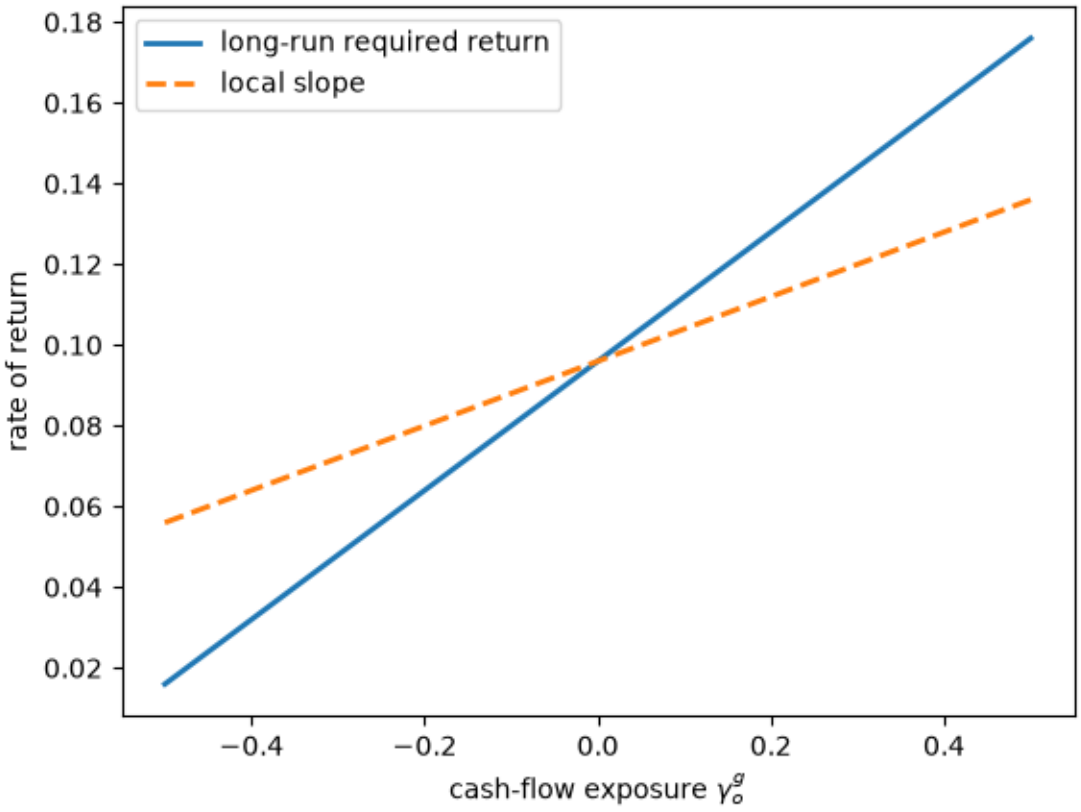

Fig. 142.6: Local and long-run pricing of persistent growth risk

```
finite_difference = (
    required_return_for_growth_exposure(0.001)
    - required_return_for_growth_exposure(-0.001)
) / 0.002

print(f"finite-difference slope = {finite_difference:.6f}")
print(f"formula                 = {long_run_price_o:.6f}")
```

```
finite-difference slope = 0.160000
formula                 = 0.160000
```

142.8.7 Where the two frontiers come apart

We promised above that the valuation-functional and cash-flow frontiers can differ.

In the B^o direction they do not: the two finite differences just computed agree to six decimals, because γ_o enters the eigenvalue (142.19) linearly.

The B^f direction is the interesting one, because there the exposure feeds through c_f, which solves the quadratic (142.16).

```
def central_difference(f, h=1e-5):
    return (f(h) - f(-h)) / (2 * h)

valuation_price_f = central_difference(
    lambda g: valuation_eigenvalue_for_exposure(0.0, g)
)
cashflow_price_f = central_difference(
    lambda g: required_return_for_growth_exposure(0.0, g)
)
local_price_f = -params_sdf["γ_f"] * params_sdf["xbar_f"]

print(f"B^f local price (at x^f = xbar_f) = {local_price_f:.6f}")
print(f"B^f valuation-functional frontier = {valuation_price_f:.6f}")
print(f"B^f cash-flow frontier            = {cashflow_price_f:.6f}")
```

```
B^f local price (at x^f = xbar_f) = 0.009600
B^f valuation-functional frontier = 0.009905
B^f cash-flow frontier            = 0.010716
```

The three numbers differ in the third decimal place.

The local price evaluated at $x^f = \bar{x}_f$ is the smallest, the valuation-functional frontier is slightly larger, and the cash-flow frontier is larger still.

The reason is that a B^f exposure shifts c_f nonlinearly, and the two frontiers load that nonlinearity differently: the valuation frontier also adjusts β_f^v through the local pricing restriction (142.26), whereas the cash-flow frontier adjusts β_f through the Itô compensator in (142.29).

This is the discrepancy anticipated in the discussion of the two frontiers above, and it is absent in the B^o direction precisely because X^o has constant volatility.

142.9 Assumptions behind the scenes

The examples above make the eigenfunction calculation look routine.

For finite-state chains and the affine model, it really is; Perron-Frobenius theory and closed-form algebra handle every requirement.

But in a general state space, three things can go wrong, each corresponding to one of the assumptions we have been carrying.

The rest of this section examines each in turn.

142.9.1 Issue 1: $\widehat{M}$ might fail to be a martingale

A positive eigenfunction ϕ gives us a candidate martingale $\widehat{M}$ from (142.10), but $\widehat{M}$ is only a nonnegative local martingale, hence a supermartingale.

A supermartingale is not enough to define a probability measure: we need $\mathbb{E}[\widehat{M}_t] = 1$, i.e. a genuine martingale, the content of Assumption 6.1 in Hansen and Scheinkman [2009].

A standard way to verify this is a two-sided **Girsanov construction**: write the drift and jump distortion induced by $\widehat{M}$, check that the distorted Markov process is well-behaved, and verify that the reverse density (the inverse of $\widehat{M}$) is locally integrable.

142.9.2 Issue 2: the twisted process might fail to be stable

Even with $\widehat{M}$ a martingale, the long-run limit (142.12) requires that the twisted process actually settles into a steady state.

This is where stochastic stability (our trio of stationary distribution, irreducibility of the skeleton, and Harris recurrence) does real work.

The affine example illustrates this concretely, since we *rejected* one of the two algebraically valid eigenfunctions because it implied an explosive twisted square-root process.

142.9.3 Issue 3: a principal eigenfunction might not exist

In a general state space, even *existence* of a strictly positive eigenfunction is not automatic.

A standard sufficient condition starts with a **Lyapunov-type drift bound**: there is a function $V \geq 1$ on the state space and a constant a_0 such that

$$\frac{\mathbb{A}V}{V} \leq a_0.$$

Roughly: V doesn't grow too fast under the semigroup.

With this in hand, for any $\alpha > a_0$ define the **resolvent operator**

$$F_\alpha \psi(x) = \int_0^\infty \exp(-\alpha t)\, \mathbb{E}\left[M_t \, \frac{V(X_t)}{V(x)} \, \psi(X_t) \,\middle|\, X_0 = x \right] dt. \tag{142.30}$$

F_α is the Laplace transform of the semigroup generated by the *rescaled* multiplicative functional $M_t V(X_t)/V(X_0)$.

The existence proof then proceeds in three steps:

1. **Irreducibility for the resolvent.** There exists a reference measure ν such that $F_\alpha \mathbf{1}_\Lambda(x) > 0$ for every x whenever $\nu(\Lambda) > 0$, so the resolvent doesn't "miss" any region of state space.

2. **Nummelin minorization.** Irreducibility yields a *bounded nonnegative function* s on the state space, with $\int s\, d\nu > 0$, such that for every nonnegative ψ,

$$F_\alpha \psi(x) \geq s(x) \int \psi\, d\nu.$$

   The function s (often called the *minorization function*) measures how strongly the resolvent dominates a fixed reference measure ν.

3. **Eigenfunction extraction.** The minorization, combined with additional boundedness or strengthened drift assumptions, identifies a critical spectral value for F_α and an associated positive eigenfunction.

   - Inverting the resolvent transform produces a positive eigenfunction for the original semigroup.

These steps are all nontrivial and are out of scope for this lecture.

The details are in Section 9 of Hansen and Scheinkman [2009].

We can summarize the chain of conditions as:

Want	Need
A factorization (142.1)	A positive eigenfunction ϕ
$\widehat{M}$ to define a probability measure	$\widehat{M}$ is a martingale (Assumption 6.1)
The long-run limit (142.12)	Stochastic stability of the twisted process
A unique principal eigenfunction	Stability selects among positive eigenfunctions

In the finite-state case, all four follow from one Perron-Frobenius calculation; in the affine model, they reduce to picking the right root of a quadratic.

In general, each must be checked separately.

The full theory in Hansen and Scheinkman [2009] also delivers stronger L^p approximation results and Lyapunov criteria for stochastic stability, which we don't reproduce here.

142.10 Summary

The Hansen-Scheinkman approach studies long-run risk by studying positive eigenfunctions of valuation semigroups.

The main steps are:

1. Model discounting, growth, or cumulated returns by a positive multiplicative functional M.
2. Build the semigroup $\mathbb{M}_t \psi(x) = \mathbb{E}[M_t \psi(X_t) \mid X_0 = x]$.
3. When V is a valuation functional, use the local pricing restriction that VS is a martingale to determine the drift of V from its Brownian and jump exposures, and then apply the eigenvalue problem to $M = V$; for cash-flow valuation take $M = Q = GS$, the functional generating the semigroup $\{\mathbb{Q}_t\}$, where the pricing restriction falls on S alone and G enters only as a growth twist.
4. Solve the principal eigenvalue problem $\mathbb{A}\phi = \rho\phi$.
5. Use the factorization $M_t = \exp(\rho t)\widehat{M}_t \phi(X_0)/\phi(X_t)$.
6. Under the twisted probability measure induced by $\widehat{M}$, use stability to obtain long-run approximations of the form (142.12).

In finite-state problems, this is Perron-Frobenius theory.

In affine diffusion problems, exponential-affine eigenfunctions often produce closed-form formulas.

The long-run risk prices that emerge can differ sharply from local risk prices when shocks move persistent state variables.

This persistence effect is the economic channel emphasized in long-run risk asset-pricing models and in the empirical work of Hansen *et al.* [2008].

142.11 Exercises

Exercise 142.11.1

Consider a two-state Markov chain with intensity matrix

$$U = \begin{bmatrix} -\lambda & \lambda \\ \mu & -\mu \end{bmatrix}.$$

Let the multiplicative functional have decay rate $r_1 > 0$ in state 1, decay rate $r_2 = 0$ in state 2, and no jumps.

1. Write down the generator matrix A.
2. Find the principal eigenvalue ρ in terms of λ, μ, and r_1.
3. Verify numerically with $\lambda = 0.4$, $\mu = 0.6$, and $r_1 = 0.05$.
4. Show that $-r_1 < \rho < 0$.

Solution

Here is one solution:

1. The generator is

$$A = \begin{bmatrix} -\lambda - r_1 & \lambda \\ \mu & -\mu \end{bmatrix}.$$

2. The characteristic equation is

$$\rho^2 + (\lambda + \mu + r_1)\rho + \mu r_1 = 0.$$

Hence the principal eigenvalue is the larger root

$$\rho = \frac{-(\lambda + \mu + r_1) + \sqrt{(\lambda + \mu + r_1)^2 - 4\mu r_1}}{2}.$$

3. Numerical verification:

```
λ, μ, r1 = 0.4, 0.6, 0.05

disc = (λ + μ + r1) ** 2 - 4 * μ * r1
ρ_formula = (-(λ + μ + r1) + np.sqrt(disc)) / 2

U_ex = np.array([[-λ, λ],
                 [μ, -μ]])
r_ex = np.array([r1, 0.0])
κ_ex = np.zeros((2, 2))

A_ex = build_generator(U_ex, r_ex, κ_ex)
ρ_numeric, ψ_numeric = principal_eigenpair(A_ex)

print(f"formula   ρ = {ρ_formula:.8f}")
print(f"numeric   ρ = {ρ_numeric:.8f}")
print(f"difference  = {abs(ρ_formula-ρ_numeric):.2e}")
```

```
formula  ρ = -0.02939431
numeric  ρ = -0.02939431
difference   = 0.00e+00
```

4. Let

$$q(x) = x^2 + (\lambda + \mu + r_1)x + \mu r_1.$$

Then $q(0) = \mu r_1 > 0$ and

$$q(-r_1) = -\lambda r_1 < 0.$$

Since the parabola opens upward, one root lies in $(-r_1, 0)$.

The principal eigenvalue is the larger root, so $-r_1 < \rho < 0$.

Exercise 142.11.2

Fig. 142.4 shows the long-run price of B^o exposure falling towards the local price as the mean-reversion speed ξ_o rises.

This exercise asks you to pin down the *rate* at which it falls.

Define the **persistence wedge**

$$w(\xi_o) = \text{long-run price of } B^o - \text{local price of } B^o.$$

1. Using (142.25) together with the Breeden coefficients (142.20), show analytically that

$$w(\xi_o) = \frac{a\sigma_o}{\xi_o},$$

so the wedge is exactly proportional to $1/\xi_o$ and, in particular, does not depend on the consumption loading ϑ_o.

2. Verify this numerically on the grid $\xi_o \in \{0.1, 0.2, 0.5, 1, 2, 5\}$ by checking that the product $\xi_o\, w(\xi_o)$ is constant across the grid and equal to $a\sigma_o$.
3. Plot w against ξ_o on log-log axes and confirm that the fitted slope is -1, the signature of exactly hyperbolic decay.

Solution

Here is one solution:

1. The local price is $-\gamma_o^s$ and, by (142.25), the long-run price is $-\gamma_o^s - (\beta_o^s/\xi_o)\sigma_o$.

Subtracting, the common term $-\gamma_o^s$ cancels and only the persistence correction survives:

$$w(\xi_o) = -\frac{\beta_o^s}{\xi_o}\sigma_o.$$

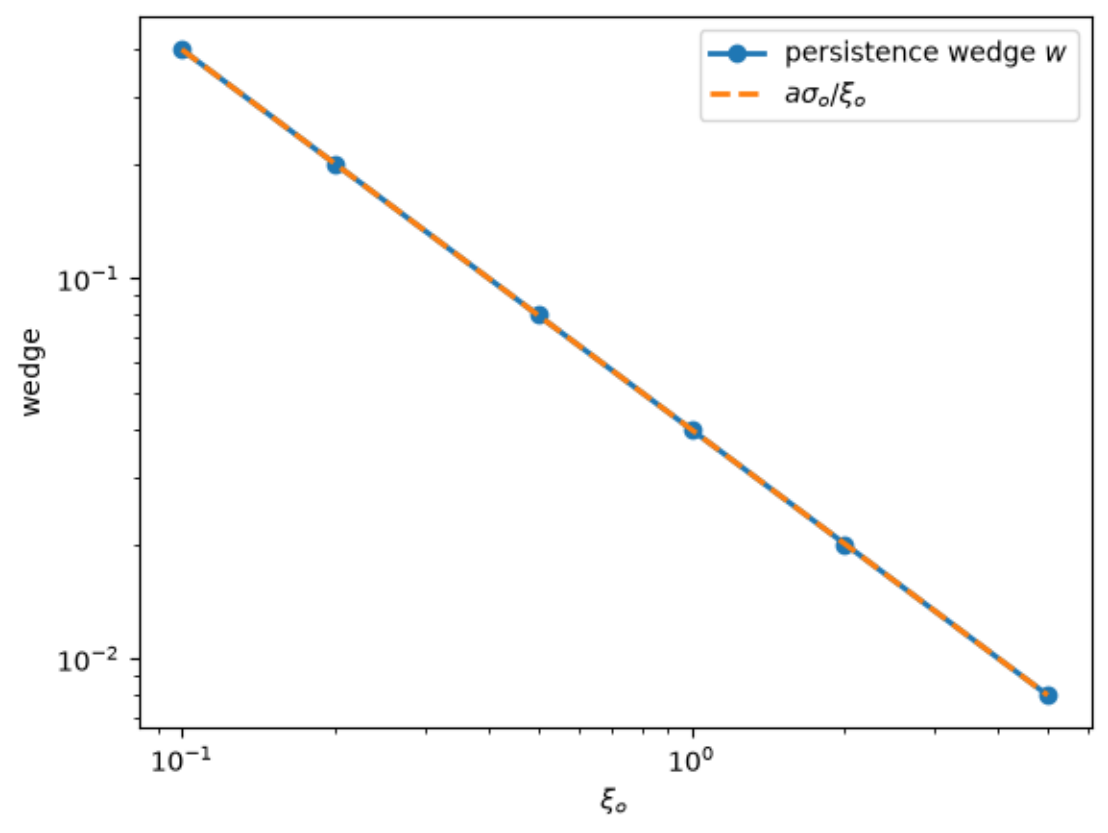
The Breeden coefficients (142.20) set $\beta_o^s = -a$, which gives $w(\xi_o) = a\sigma_o/\xi_o$.

Because ϑ_o enters only through $\gamma_o^s = -a\vartheta_o$, which appears identically in both prices, it cancels and cannot affect the wedge.

2. and *3.* Numerically:

```
ξ_vals = np.array([0.1, 0.2, 0.5, 1.0, 2.0, 5.0])
wedge = -(params_sdf["β_o"] / ξ_vals) * params_sdf["σ_o"]

print(f"a * σ_o = {a * params_sdf['σ_o']:.6f}\n")
for ξ, w in zip(ξ_vals, wedge):
    print(f"ξ_o = {ξ:3.1f}: wedge = {w:.6f}, ξ_o * wedge = {ξ * w:.6f}")



slope, _ = np.polyfit(np.log(ξ_vals), np.log(wedge), 1)
print(f"\nlog-log slope = {slope:.6f}")

fig, ax = plt.subplots()
ax.loglog(ξ_vals, wedge, "o-", lw=2, label="persistence wedge $w$")
ax.loglog(ξ_vals, a * params_sdf["σ_o"] / ξ_vals, "--", lw=2,
          label="$a\\sigma_o/\\xi_o$")
ax.set_xlabel("$\\xi_o$")
ax.set_ylabel("wedge")
ax.legend()
plt.show()
```

```
a * σ_o = 0.040000

ξ_o = 0.1: wedge = 0.400000, ξ_o * wedge = 0.040000
ξ_o = 0.2: wedge = 0.200000, ξ_o * wedge = 0.040000
ξ_o = 0.5: wedge = 0.080000, ξ_o * wedge = 0.040000
ξ_o = 1.0: wedge = 0.040000, ξ_o * wedge = 0.040000
ξ_o = 2.0: wedge = 0.020000, ξ_o * wedge = 0.040000
ξ_o = 5.0: wedge = 0.008000, ξ_o * wedge = 0.040000

log-log slope = -1.000000
```

The product $\xi_o \, w(\xi_o)$ prints as 0.040000 at every grid point, matching $a\sigma_o = 4 \times 0.01$, and the fitted log-log slope is -1.000000.

So the two prices do not merely converge: the wedge decays at the exact hyperbolic rate $a\sigma_o/\xi_o$.

The economics behind the rate is that a B^o shock displaces X^o by σ_o on impact, and that displacement decays at rate ξ_o, so its cumulative effect on expected growth is σ_o/ξ_o.

Each unit of that cumulative effect is priced by the SDF's loading a on X^o.

Exercise 142.11.3

Consider a three-state chain with states {expansion, normal, contraction}, intensity matrix

$$U = \begin{bmatrix} -0.40 & 0.30 & 0.10 \\ 0.20 & -0.50 & 0.30 \\ 0.10 & 0.20 & -0.30 \end{bmatrix},$$

decay-rate vector $r = (0.06, 0.04, 0.01)$, and no jumps in the multiplicative functional.

Let $\psi = (3, 1, 2)$.

1. Compute the principal eigenpair (ρ, ϕ) and twisted stationary distribution $\hat{\varsigma}$, and report the theoretical limit

$$\phi \sum_i \frac{\psi_i}{\phi_i} \hat{\varsigma}_i.$$

2. Plot

$$\max_i \left| \exp(-\rho t)(\mathbb{M}_t \psi)_i - \phi_i \sum_j \frac{\psi_j}{\phi_j} \hat{\varsigma}_j \right|$$

on a logarithmic scale.

3. Compare the convergence rate to the spectral gap between the largest and second-largest real parts of the eigenvalues of A.

Solution

Here is one solution:

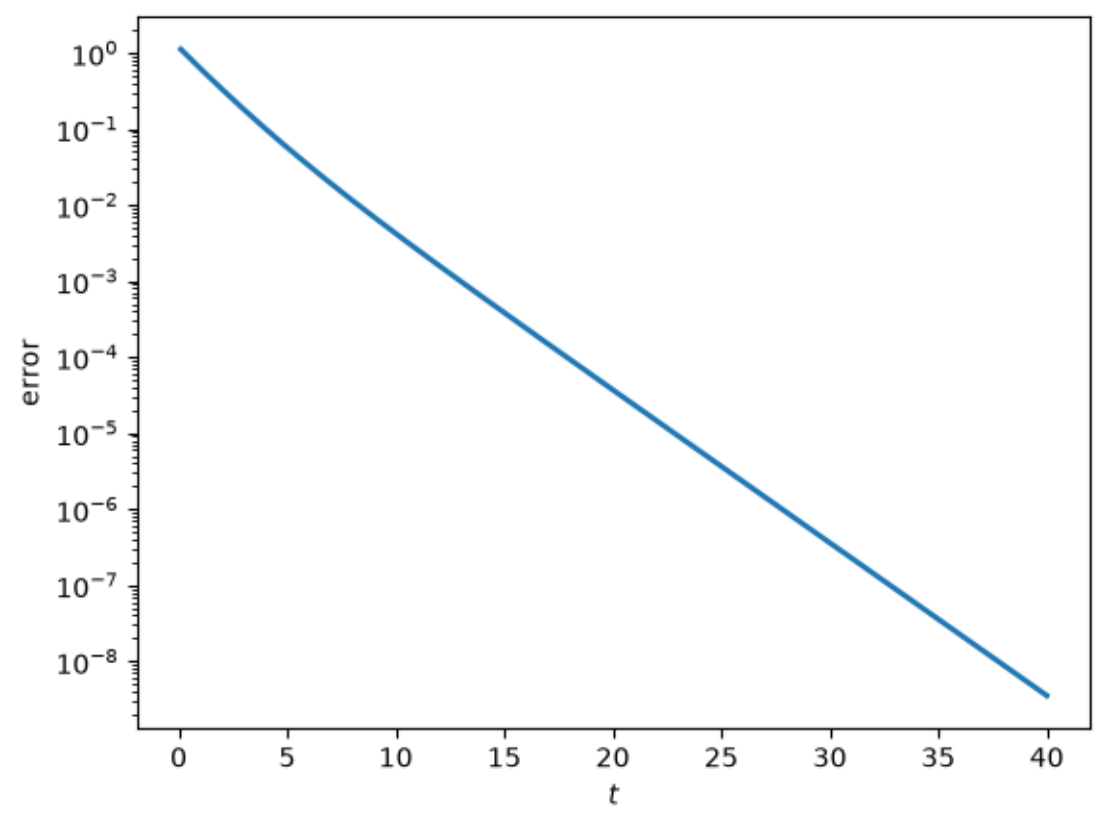
```
state_names = ["expansion", "normal", "contraction"]

U3 = np.array([[-0.40,  0.30,  0.10],
               [ 0.20, -0.50,  0.30],
               [ 0.10,  0.20, -0.30]])

r3 = np.array([0.06, 0.04, 0.01])
κ3 = np.zeros((3, 3))

A3 = build_generator(U3, r3, κ3)
ρ3, ψ3 = principal_eigenpair(A3)
A3_hat = twisted_generator(A3, ρ3, ψ3)
ς3 = stationary_distribution(A3_hat)

ψ = np.array([3.0, 1.0, 2.0])
limit = ψ3 * np.sum((ψ / ψ3) * ς3)



print("limit:")
for name, value in zip(state_names, limit):
    print(f"  {name:11s} {value:.6f}")

t_vals = np.linspace(0.1, 40, 300)
errors = np.array([
    np.max(np.abs(np.exp(-ρ3 * t_val) * expm(t_val * A3) @ ψ - limit))
    for t_val in t_vals
])

eigenvalues = eig(A3, right=False)
real_parts = np.sort(eigenvalues.real)[::-1]
gap = real_parts[0] - real_parts[1]

fig, ax = plt.subplots()
ax.semilogy(t_vals, errors, lw=2)
ax.set_xlabel("$t$")
ax.set_ylabel("error")
plt.show()
```

```
limit:
  expansion   1.808490
  normal      1.906080
  contraction 2.021897
```

For part 3 we estimate the empirical decay rate by fitting a straight line to $\log(\text{error})$ over a window in which the leading correction term dominates, and compare the fitted slope to the gap.

```
mask = (t_vals > 20) & (t_vals < 40)
fitted_slope, _ = np.polyfit(t_vals[mask], np.log(errors[mask]), 1)

print(f"empirical decay rate = {-fitted_slope:.6f}")
print(f"spectral gap         = {gap:.6f}")
```

```
empirical decay rate = 0.462900
spectral gap         = 0.462679
```

The normalized semigroup converges at an exponential rate governed by the separation between the dominant eigenvalue and the remaining eigenvalues.

In this finite-state example, that separation is the spectral gap, and the two numbers printed above agree to three decimal places.

The small remaining discrepancy is the contribution of the third eigenvalue, which has not yet died out completely; fitting over a later window shrinks it further.

Exercise 142.11.4

Derive the local martingale restriction (142.5) from Itô's formula.

Let $M = \exp(A)$ for the additive functional A in (142.3), with parameters (β, γ, κ).

1. Decompose $A_t = A_t^c + A_t^j$ into its continuous and pure-jump parts and write down dA_t^c and the jump mag-

nitudes ΔA_t.

2. Apply Itô's formula for semimartingales to $f(a) = e^a$ to show that

$$dM_t = M_{t-}\, dA_t^c + \tfrac{1}{2}\, M_{t-}\, d\langle A^c, A^c\rangle_t + M_{t-}\big(\exp[\Delta A_t] - 1\big) \quad \text{at jumps.}$$

3. Use $d\langle A^c, A^c\rangle_t = \gamma^\top \gamma\, dt$ and rewrite the jump term as an integral against the random counting measure ζ.
4. Split ζ into its compensator $\eta(dy \mid X_{t-})\, dt$ and the compensated martingale measure $\tilde{\zeta} = \zeta - \eta(dy \mid X_{t-})\, dt$.
5. Collect drift (predictable) and martingale terms and conclude that M is a local martingale iff the drift vanishes at every state, which gives (142.5).

Solution

Here is one solution.

1. From the parameterization (142.3),

$$dA_t^c = \beta(X_t)\, dt + \gamma(X_{t-})^\top\, dB_t, \qquad \Delta A_t = \kappa(X_t, X_{t-}) \text{ at a jump time.}$$

2. For $f(a) = e^a$ we have $f'(a) = f''(a) = e^a$, so $f'(A_{t-}) = f''(A_{t-}) = M_{t-}$.

The (generalized) Itô's formula for a semimartingale gives

$$dM_t = f'(A_{t-})\, dA_t^c + \tfrac{1}{2}\, f''(A_{t-})\, d\langle A^c, A^c\rangle_t + \big[f(A_t) - f(A_{t-})\big].$$

Since $A_t = A_{t-} + \Delta A_t$ at a jump, $f(A_t) - f(A_{t-}) = M_{t-}\big(\exp[\Delta A_t] - 1\big)$, which is the stated expression.

3. Substituting $d\langle A^c, A^c\rangle_t = \gamma(X_{t-})^\top \gamma(X_{t-})\, dt$ and rewriting the jump contribution as an integral against the random counting measure ζ of (X, A) gives

$$\begin{aligned}\frac{dM_t}{M_{t-}} &= \beta(X_t)\, dt + \gamma(X_{t-})^\top dB_t + \tfrac{1}{2}\, \gamma(X_{t-})^\top \gamma(X_{t-})\, dt \\ &\quad + \int \big(\exp[\kappa(y, X_{t-})] - 1\big)\, \zeta(dy, dt).\end{aligned}$$

4. Writing $\zeta = \tilde{\zeta} + \eta(dy \mid X_{t-})\, dt$ separates the jump integral into a martingale and a predictable drift contribution:

$$\int \big(\exp[\kappa(y, X_{t-})] - 1\big)\zeta(dy, dt) = \int \big(\exp[\kappa(y, X_{t-})] - 1\big)\tilde{\zeta}(dy, dt) + \int \big(\exp[\kappa(y, X_{t-})] - 1\big)\eta(dy \mid X_{t-})\, dt.$$

5. Collecting drift and martingale terms,

$$\begin{aligned}\frac{dM_t}{M_{t-}} &= \left[\beta(X_t) + \tfrac{1}{2}\gamma^\top\gamma + \int \big(\exp[\kappa(y, X_{t-})] - 1\big)\, \eta(dy \mid X_{t-})\right] dt \\ &\quad + \gamma^\top dB_t + \int \big(\exp[\kappa(y, X_{t-})] - 1\big)\, \tilde{\zeta}(dy, dt).\end{aligned}$$

The Brownian and compensated-jump terms are local martingales, so M is a local martingale iff the bracketed drift vanishes for every state x, giving (142.5).

Exercise 142.11.5

Derive the closed-form expression for the extended generator in (142.8).

Take the jump-diffusion setting in which the Markov state satisfies

$$dX_t^c = \xi(X_t)dt + \Gamma(X_t)dB_t$$

between jumps, with $\Sigma = \Gamma\Gamma^\top$ and jump compensator $\eta(dy \mid x)$.

Let $M = \exp(A)$ for the additive functional A in (142.3) and let ϕ be a smooth, strictly positive function.

Recall from *Definition 142.4.1* that $\mathbb{A}\phi = \chi$ if

$$N_t = M_t\phi(X_t) - \phi(X_0) - \int_0^t M_s\chi(X_s)\,ds$$

is a local martingale.

The task therefore has two pieces: identify the predictable drift of $M_t\phi(X_t)$ to read off a candidate χ, and verify that the residual N_t really is a local martingale.

(1) Apply Itô's formula to $Y_t = \exp(A_t)\phi(X_t)$ between jumps and show that the continuous part of dY_t has drift

$$M_t\left[(\xi + \Gamma\gamma)^\top\frac{\partial\phi}{\partial x} + \frac{1}{2}\operatorname{trace}\left(\Sigma\frac{\partial^2\phi}{\partial x\partial x^\top}\right) + \left(\beta + \frac{\gamma^\top\gamma}{2}\right)\phi\right]dt.$$

(2) Show that at a jump time t with $X_{t-} = x$ and $X_t = y$,

$$\Delta Y_t = M_{t-}\big[\exp[\kappa(y,x)]\phi(y) - \phi(x)\big],$$

and conclude that the predictable jump compensator contributes drift

$$M_{t-}\int\big\{\exp[\kappa(y,x)]\phi(y) - \phi(x)\big\}\eta(dy \mid x)\,dt.$$

(3) Decompose

$$\exp[\kappa(y,x)]\phi(y) - \phi(x) = \exp[\kappa(y,x)]\big[\phi(y) - \phi(x)\big] + \big[\exp[\kappa(y,x)] - 1\big]\phi(x),$$

combine with part (1) to obtain the full predictable drift coefficient $\chi(x)$, and check that it matches the closed form (142.8).

(4) Identify the continuous Itô integrand from part (1) as a local martingale N_t^c and the compensated jump sum from part (2) as a local martingale N_t^j.

Show that the semimartingale decomposition of $Y_t = M_t\phi(X_t)$ implies

$$M_t\phi(X_t) - \phi(X_0) - \int_0^t M_s\,\chi(X_s)\,ds = N_t^c + N_t^j,$$

which is a local martingale.

Conclude via *Definition 142.4.1* that $\mathbb{A}\phi = \chi$.

Solution

Here is one solution:

(1) Set $g(a,x) = e^a \phi(x)$, so that $Y_t = g(A_t, X_t)$.

Between jumps, the continuous parts of A and X are

$$dA_t^c = \beta(X_t)\,dt + \gamma(X_t)^\top dB_t, \qquad dX_t^c = \xi(X_t)\,dt + \Gamma(X_t)\,dB_t,$$

with quadratic covariations

$$d\langle A^c, A^c\rangle_t = \gamma^\top\gamma\,dt, \qquad d\langle X^c, X^c\rangle_t = \Sigma\,dt, \qquad d\langle A^c, X^c\rangle_t = \Gamma\gamma\,dt.$$

The partial derivatives of g satisfy

$$\partial_a g = g, \quad \partial_{aa} g = g, \quad \partial_x g = e^a \frac{\partial\phi}{\partial x}, \quad \partial_{ax} g = e^a \frac{\partial\phi}{\partial x}, \quad \partial_{xx} g = e^a \frac{\partial^2\phi}{\partial x \partial x^\top}.$$

Itô's formula yields a continuous local martingale N_t^c (the dB_t part) plus the drift

$$M_t\Big[\beta\phi + \tfrac{1}{2}\gamma^\top\gamma\,\phi + \xi^\top\tfrac{\partial\phi}{\partial x} + \tfrac{1}{2}\,\mathrm{trace}\big(\Sigma\,\tfrac{\partial^2\phi}{\partial x\partial x^\top}\big) + (\Gamma\gamma)^\top\tfrac{\partial\phi}{\partial x}\Big]\,dt.$$

Grouping the gradient terms gives the expression in the question.

(2) At a jump time t, $\Delta A_t = \kappa(X_t, X_{t-}) = \kappa(y,x)$, so $M_t = M_{t-}\exp[\kappa(y,x)]$ and

$$\Delta Y_t = M_t\phi(X_t) - M_{t-}\phi(X_{t-}) = M_{t-}\big[\exp[\kappa(y,x)]\phi(y) - \phi(x)\big].$$

The sum of jumps minus its predictable compensator is a local martingale N_t^j, and the compensator itself contributes the predictable drift quoted in the question.

(3) Adding the jump drift from (2) to the continuous drift from (1), the predictable drift of $Y_t = M_t\phi(X_t)$ at state x is $M_t\,\chi(x)\,dt$ with

$$\begin{aligned}\chi(x) = (\xi + \Gamma\gamma)^\top\frac{\partial\phi}{\partial x} + \frac{1}{2}\,\mathrm{trace}\left(\Sigma\frac{\partial^2\phi}{\partial x\partial x^\top}\right) + \left(\beta + \frac{\gamma^\top\gamma}{2}\right)\phi(x) \\ + \int \exp[\kappa(y,x)]\big[\phi(y) - \phi(x)\big]\,\eta(dy \mid x) + \phi(x)\int\big[\exp[\kappa(y,x)] - 1\big]\,\eta(dy \mid x).\end{aligned}$$

Collecting the terms multiplying $\phi(x)$ recovers (142.8).

(4) Putting the two martingale pieces together and integrating the drift, steps (1) and (2) give the semimartingale decomposition

$$M_t\phi(X_t) = \phi(X_0) + \int_0^t M_s\,\chi(X_s)\,ds + N_t^c + N_t^j.$$

Rearranging,

$$N_t := M_t\phi(X_t) - \phi(X_0) - \int_0^t M_s\,\chi(X_s)\,ds = N_t^c + N_t^j,$$

which is a local martingale because it is a sum of local martingales.

This is exactly the property required by *Definition 142.4.1*, so $\chi = \mathbb{A}\phi$.

143.1 Overview

The lecture *The Recovery Theorem* studies the case in which recovery is valid.

There, **transition independence** lets us use Arrow prices to separate investors' beliefs from the pricing kernel.

This lecture asks what the same Perron–Frobenius approach delivers when that restriction is not imposed.

The eigenfunction, martingale-factorization, and twisted-measure machinery that we use here is developed at length in *Long-term Risk: An Operator Approach*.

We will keep three probability measures separate.

The first is the correctly specified probability measure, which governs the Markov state in the model.

The second is the one-period risk-neutral probability measure, which comes from normalizing one-period Arrow prices by bond prices.

The third is the probability measure recovered by Perron–Frobenius Theory, also called the long-term risk-neutral measure.

The central question is whether the recovered probability measure equals the correctly specified probability measure.

Borovička *et al.* [2016] show that, in general, the answer is no.

The paper studies the ratio of the recovered probability measure to the correctly specified probability measure.

The reason is that the stochastic discount factor can contain a martingale component that changes the probability measure.

If that martingale component is identically one, Ross recovery returns the correctly specified transition probabilities.

If it is not identically one, the recovered probability measure absorbs long-term risk adjustments, because martingale increments compound along histories.

In the examples below, the recovered probability measure assigns more probability to adverse long-run-risk states than the correctly specified probability measure.

We will:

- use results from *The Recovery Theorem* without re-proving them,
- study misspecification through the martingale component,
- show why recursive utility and permanent shocks make the recovered probability measure differ from the correctly specified probability measure,
- measure the difference in a long-run risk model.

We will use the following imports.

```
import numpy as np
import matplotlib.pyplot as plt
from scipy import linalg
from scipy.integrate import solve_ivp

```

The next cell contains code inherited from the previous lecture.

It row-normalizes Arrow prices, finds the Perron–Frobenius eigenvalue and positive right eigenvector, and computes stationary distributions.

143.2 Three transition matrices

Let $\mathbf{P} = [p_{ij}]$ denote the correctly specified transition matrix and $\mathbf{Q} = [q_{ij}]$ the Arrow price matrix.

Here "correctly specified" means that $\mathbf{P}$ is the transition matrix that governs the Markov state in the model.

The one-period stochastic discount factor (SDF) satisfies

$$q_{ij} = s_{ij} p_{ij}. \tag{143.1}$$

We will compare $\mathbf{P}$ with two probability matrices constructed from $\mathbf{Q}$.

The first one is the **one-period risk-neutral matrix**.

It divides each row of $\mathbf{Q}$ by the price of a one-period discount bond in the current state:

$$\bar{p}_{ij} = \frac{q_{ij}}{\sum_k q_{ik}}.$$

This matrix absorbs one-period risk adjustments into transition probabilities.

The second one is the transition matrix associated with the **long-term risk-neutral probability**.

It starts from the Perron–Frobenius eigenvalue and positive right eigenvector of $\mathbf{Q}$.

Let $(\exp(\widehat{\eta}), \widehat{e})$ solve

$$\mathbf{Q}\widehat{e} = \exp(\widehat{\eta})\widehat{e}. \tag{143.2}$$

Then define

$$\widehat{p}_{ij} = \exp(-\widehat{\eta})q_{ij}\frac{\widehat{e}_j}{\widehat{e}_i}. \tag{143.3}$$

The factor $\widehat{e}_j/\widehat{e}_i$ is chosen to cancel any SDF component of the form $\exp(\widehat{\eta})\widehat{e}_i/\widehat{e}_j$.

The result is a stochastic matrix $\widehat{\mathbf{P}}$.

This construction assumes that $\mathbf{Q}$ has a unique positive right eigenvector up to scale.

For a finite irreducible nonnegative matrix, the Perron root has a strictly positive right eigenvector unique up to scale.

For long-horizon dominance and convergence, one typically imposes a stronger condition such as primitivity or aperiodicity; the paper uses a positivity condition on $\sum_{t=0}^{\infty}\lambda^t\mathbf{Q}^t$.

In general state spaces this guarantee does not carry over: multiple positive eigenfunctions may exist, and an additional selection condition is needed to pin down the long-term risk-neutral measure.

The general framework in the next section makes that selection condition explicit.

Following Borovička *et al.* [2016], $\widehat{\mathbf{P}}$ is called a **long-term risk-neutral** transition matrix.

The name means that the Perron–Frobenius eigenvalue and eigenvector isolate the part of pricing that dominates long-maturity Arrow claims.

It is not the same transition matrix as the one-period risk-neutral matrix $\bar{\mathbf{P}}$.

In *The Recovery Theorem*, transition independence restricts the SDF to

$$s_{ij} = \exp(-\delta)\frac{m_j}{m_i}$$

for a positive vector m and scalar δ, which pins down the split between s_{ij} and p_{ij}.

Here we drop that restriction.

The question is whether the transition matrix associated with the long-term risk-neutral probability, $\widehat{\mathbf{P}}$, still equals the correctly specified matrix $\mathbf{P}$.

143.2.1 Degenerate martingale component

We start with a three-state economy: recession, normal, and expansion.

The correctly specified transition matrix is deliberately simple.

For trend-stationary consumption and power utility, the SDF is

$$s_{ij} = A\left(\frac{c_j}{c_i}\right)^{-\gamma}, \qquad A = \exp(-\delta - \gamma g_c),$$

where δ is the subjective discount rate, γ is risk aversion, and g_c is trend consumption growth.

This is a case where Ross recovery should return the correctly specified transition matrix.

```
P_true = np.array([
    [0.70, 0.25, 0.05],
    [0.15, 0.65, 0.20],
    [0.05, 0.30, 0.65],
])

c_levels = np.array([0.997, 1.000, 1.003])
state_names = ['recession', 'normal', 'expansion']

δ = -np.log(0.99)    # monthly subjective discount rate
γ_power = 5.0        # risk aversion
g_c = 0.002          # monthly trend growth

# Price Arrow claims as actual probabilities times the power-utility SDF
S_power = (
    np.exp(-δ - γ_power * g_c)
    * (c_levels[None, :] / c_levels[:, None])**(-γ_power)
)
Q_power = S_power * P_true
```

We now compute the one-period risk-neutral matrix and the transition matrix associated with the long-term risk-neutral probability from the same Arrow price matrix.

```
P_bar, q_bonds = risk_neutral_probs(Q_power)
η_hat, exp_η, e_hat, P_hat = perron_frobenius(Q_power)
π_true = stationary_dist(P_true)
π_bar = stationary_dist(P_bar)
π_hat = stationary_dist(P_hat)
```

These two matrices should not be expected to agree.

The row-normalized matrix $\bar{\mathbf{P}}$ is a short-horizon risk-neutral change of measure: it folds the one-period SDF into transition probabilities, so it generally differs from the correctly specified matrix $\mathbf{P}$.

The reason $\hat{\mathbf{P}}$ can equal $\mathbf{P}$ comes from the Perron–Frobenius construction in *The Recovery Theorem*.

In the transition-independent case, the pricing kernel has the form $s_{ij} = \exp(\hat{\eta})\hat{e}_i/\hat{e}_j$.

Substituting this into the Perron–Frobenius transition formula gives

$$\hat{p}_{ij} = \exp(-\hat{\eta})q_{ij}\frac{\hat{e}_j}{\hat{e}_i} = \exp(-\hat{\eta})\left(\exp(\hat{\eta})\frac{\hat{e}_i}{\hat{e}_j}p_{ij}\right)\frac{\hat{e}_j}{\hat{e}_i} = p_{ij}.$$

Thus the transition matrix $\hat{\mathbf{P}}$ associated with the long-term risk-neutral probability cancels the transition-independent part of the SDF.

In this power-utility benchmark, the whole SDF has exactly that form, so the remaining martingale increment should be one and $\hat{\mathbf{P}}$ should coincide with $\mathbf{P}$.

The next calculation checks this by comparing the Perron–Frobenius eigenfunction with c_i^γ and then computing the ratio $\hat{\mathbf{P}}/\mathbf{P}$.

Define the one-period martingale increment

$$\hat{h}_{ij} = \frac{\hat{p}_{ij}}{p_{ij}} = \exp(-\hat{\eta})s_{ij}\frac{\hat{e}_j}{\hat{e}_i}.$$

When $\hat{h}_{ij} = 1$ for every transition, $\hat{\mathbf{P}}$ and $\mathbf{P}$ are the same.

The section *Martingale component* defines this ratio formally in (143.4) and explains why it is a one-period martingale increment.

We ask you to verify in Exercise 143.9.2 that $\hat{e}_i = c_i^\gamma$ and $\exp(\hat{\eta}) = A$ in this example, so that $\hat{h}_{ij} \equiv 1$.

```
H_power = np.divide(P_hat, P_true, out=np.ones_like(P_true), where=P_true > 0)
e_theory = c_levels**y_power

print("Perron-Frobenius eigenfunction: numerical vs c^gamma")
for name, e_num, e_th in zip(state_names, e_hat / e_hat[1],
                             e_theory / e_theory[1]):
    print(f"{name:9s}: {e_num:.6f}  {e_th:.6f}")

print("\nmartingale increment h_hat = P_hat / P")
print(np.round(H_power, 6))

print("\nconditional means under P")
print(np.round((P_true * H_power).sum(axis=1), 6))

print(f"\nmax |h_hat - 1| = "
      f"{np.max(np.abs(H_power[P_true > 0] - 1)):.2e}")
```

```
Perron-Frobenius eigenfunction: numerical vs c^gamma
recession: 0.985090  0.985090
normal   : 1.000000  1.000000
expansion: 1.015090  1.015090

martingale increment h_hat = P_hat / P
[[1. 1. 1.]
 [1. 1. 1.]
 [1. 1. 1.]]

conditional means under P
[1. 1. 1.]

max |h_hat - 1| = 1.33e-15
```

The output separates a short-horizon risk adjustment from the Perron–Frobenius approach.

The one-period risk-neutral matrix $\bar{\mathbf{P}}$ is close to, but not the same as, the correctly specified matrix $\mathbf{P}$.

It changes the transition probabilities because one-period Arrow prices include one-period risk adjustments.

By contrast, the long-term risk-neutral matrix $\hat{\mathbf{P}}$ is exactly the same as $\mathbf{P}$ in this example.

The calculation confirms why: the martingale increment $\hat{h}_{ij}$ is one for every transition.

This is the condition under which Ross recovery returns the correctly specified transition matrix.

In this example, that cancellation exhausts the SDF, so the martingale component is degenerate.

143.3 Martingale component

Let $(\hat{\eta}, \hat{e})$ be the Perron–Frobenius eigenvalue exponent and positive right eigenvector of $\mathbf{Q}$:

$$\mathbf{Q}\hat{e} = \exp(\hat{\eta})\hat{e}.$$

The associated long-term risk-neutral transition matrix is

$$\hat{p}_{ij} = \exp(-\hat{\eta}) q_{ij} \frac{\hat{e}_j}{\hat{e}_i}.$$

To see whether recovery has changed the probability measure, compare each recovered transition probability with the corresponding correctly specified transition probability.

For feasible transitions with $p_{ij} > 0$, define the one-period martingale increment

$$\hat{h}_{ij} = \frac{\hat{p}_{ij}}{p_{ij}}. \tag{143.4}$$

If $\hat{h}_{ij} > 1$, the recovered probability measure assigns more probability to transition (i, j) than the correctly specified probability measure.

If $\hat{h}_{ij} < 1$, it assigns less probability to that transition.

For a fixed current state i, the numbers $\hat{h}_{ij}$ average to one under the correctly specified transition probabilities:

$$\sum_j \hat{h}_{ij} p_{ij} = 1.$$

Thus $\hat{h}_{ij}$ is a one-period martingale increment.

Multiplying these increments along a history of states gives the ratio of the recovered probability measure to the correctly specified probability measure for the whole history.

That ratio process is a martingale, which is why the last term in (143.5) is called a martingale component.

Using (143.1), (143.3), and (143.4), the one-period SDF can be written as

$$s_{ij} = \exp(\hat{\eta}) \frac{\hat{e}_i}{\hat{e}_j} \hat{h}_{ij}. \tag{143.5}$$

The Perron–Frobenius approach therefore separates the SDF into:

Part	Role
$\exp(\hat{\eta})$	deterministic long-run discounting
$\hat{e}_i / \hat{e}_j$	state-dependent long-run term
$\hat{h}_{ij}$	martingale increment that changes probabilities

If $\hat{h}_{ij} = 1$ for every feasible transition, then the transition matrix associated with the recovered probability measure and the correctly specified transition matrix are the same.

This is the condition under which Ross recovery returns the correctly specified transition matrix.

Proposition 143.3.1 (Finite-state martingale component)

Under the finite-state assumptions used in this lecture, for a Markov model with correctly specified transition matrix **P** and Arrow matrix **Q**, the probability measure recovered by Perron–Frobenius Theory returns the correctly specified transition matrix if and only if $\hat{h}_{ij} = 1$ for every transition with $p_{ij} > 0$.

Equivalently, recovery returns the correctly specified transition matrix if and only if the SDF in (143.5) has no non-constant martingale component:

$$s_{ij} = \exp(\hat{\eta}) \frac{\hat{e}_i}{\hat{e}_j}.$$

Proof. Using $q_{ij} = s_{ij} p_{ij}$,

$$\hat{h}_{ij} = \frac{\hat{p}_{ij}}{p_{ij}} = \exp(-\hat{\eta}) s_{ij} \frac{\hat{e}_j}{\hat{e}_i}.$$

Thus $\hat{\mathbf{P}} = \mathbf{P}$ if and only if $\hat{h}_{ij} = 1$ on every feasible transition.

This condition is the same as saying that the SDF takes the form displayed in *Proposition 143.3.1*.

This finite-state implication is a special case of the paper's general identification result.

If a pair (S, P) explains asset prices and H is a positive multiplicative martingale, then the same asset prices are also explained by the changed probability measure P^H together with the adjusted stochastic discount factor

$$S_t^H = S_t \frac{H_0}{H_t}.$$

More generally, any strictly positive martingale can change probability measures, but multiplicativity preserves the Markov structure used here.

Thus Arrow prices alone cannot usually distinguish a change in beliefs from a change in the SDF.

Ross recovery becomes an identification result only after imposing a restriction such as

$$S_t = \exp(-\delta t) \frac{m(X_t)}{m(X_0)},$$

which rules out a nontrivial martingale component.

The power-utility example above illustrates the proposition.

In that benchmark, the martingale increment $\hat{h}_{ij}$ is identically one.

143.4 From matrices to the general framework

The finite-state calculation has three objects:

1. the correctly specified transition probabilities p_{ij},
2. the SDF increments s_{ij},
3. the Arrow prices $q_{ij} = s_{ij} p_{ij}$.

It also has one diagnostic object:

$$\hat{h}_{ij} = \frac{\hat{p}_{ij}}{p_{ij}} = \exp(-\hat{\eta}) s_{ij} \frac{\hat{e}_j}{\hat{e}_i}.$$

The numbers $\hat{h}_{ij}$ are one-period martingale increments.

They change the probability of a one-period transition from p_{ij} to $\hat{p}_{ij} = \hat{h}_{ij} p_{ij}$.

The general framework in Borovička *et al.* [2016] does the same thing without assuming that states are finite.

The transition matrix becomes a Markov probability measure, the Arrow price matrix becomes a family of pricing operators, and the one-period ratios $\hat{h}_{ij}$ become increments of a positive multiplicative martingale.

The point of this section is to build that dictionary.

143.4.1 Probability space and state

Start with a probability space $(\Omega, \mathcal{F}, P)$.

Here P is the correctly specified probability measure.

In the rational-expectations interpretation of the paper, this is the actual, or original, probability measure governing the state.

In the finite-state section, P was represented by the transition matrix $\mathbf{P} = [p_{ij}]$.

The index set is either discrete time, $\mathbb{T} = \{0, 1, 2, ...\}$, or continuous time, $\mathbb{T} = \mathbb{R}_+$.

The main state process is $X = \{X_t : t \in \mathbb{T}\}$, which is stationary and Markov under P.

A second process $W = \{W_t : t \in \mathbb{T}\}$ records shocks that drive X and other economic quantities.

In discrete time, the shock increment between dates t and $t+1$ is

$$\Delta W_{t+1} = W_{t+1} - W_t.$$

The known function ϕ_x maps today's state and the next shock increment into tomorrow's state.

The discrete-time state evolution is

$$X_{t+1} = \phi_x(X_t, \Delta W_{t+1}).$$

The conditional law generated by this equation is the general-state replacement for the finite-matrix row indexed by the current state x.

Assumption 143.4.1 (Markov state and shock increments)

The process X is ergodic under P.

The conditional distribution of ΔW_{t+1} given X_t is time invariant and independent of past shock histories conditioned on X_t.

The filtration $\{\mathcal{F}_t\}$ is generated by the initial condition X_0 and by the history of shocks through date t.

143.4.2 Information and Y

The Markov state and the information that reveals shocks need not coincide.

The state X_t is observed at date t.

The next shock ΔW_{t+1} need not be directly observed from the pair (X_t, X_{t+1}).

If (X_t, X_{t+1}) does reveal ΔW_{t+1}, then X alone carries the relevant shock information.

If it does not, introduce an auxiliary process $Y = \{Y_t\}$ with stationary increments.

The known function ϕ_y maps today's state and the next shock increment into the increment of Y.

The discrete-time evolution for the auxiliary increment is

$$Y_{t+1} - Y_t = \phi_y(X_t, \Delta W_{t+1}).$$

The pair $(X_{t+1}, Y_{t+1} - Y_t)$ is then rich enough, together with X_t, to recover the shock increment ΔW_{t+1}.

This device lets the model handle shocks or growth components that affect payoffs and SDFs but are not fully summarized by the next Markov state alone.

Write the enlarged process as $Z = (X, Y)$.

The process Z is Markov with a triangular structure: the conditional distribution of $(X_{t+1}, Y_{t+1} - Y_t)$ depends on the past only through X_t.

Histories of Z, together with X_0, generate the same information as the shock history.

This is why the next Perron–Frobenius problem can first be posed with eigenfunctions of X alone.

The section *Additional state vector* later returns to what changes when the eigenfunction is allowed to depend on Y as well.

143.4.3 Multiplicative functionals

The general framework needs a way to describe objects that compound over time.

This is the role of a positive multiplicative functional $M = \{M_t\}$.

Its log increment is a function of today's state and the next shock increment:

$$\log \frac{M_{t+1}}{M_t} = \kappa(X_t, \Delta W_{t+1}).$$

Equivalently,

$$\frac{M_{t+1}}{M_t} = \exp\{\kappa(X_t, \Delta W_{t+1})\}.$$

Thus M_t / M_0 is a product of positive one-period increments.

This is the Condition-1 version of a multiplicative functional used in the paper.

The formal definition is slightly broader, but this form covers the models studied below.

Under *Assumption 143.4.1*, the logarithm of M has stationary increments.

Products and reciprocals of positive multiplicative functionals are again positive multiplicative functionals.

Exponential functions of linear combinations of the components of Y are examples.

Stochastic discount factors, stochastic growth factors, and positive multiplicative martingales are all modeled this way.

In the finite-state model, the SDF increment s_{ij} is one example of a multiplicative-functional increment.

The ratio h_{ij} that changes probabilities is another.

143.4.4 Stochastic discount factors and pricing operators

A stochastic discount factor $S = \{S_t\}$ is a positive multiplicative functional with $S_0 = 1$ and finite first moments conditional on X_0.

Let Φ_t be a bounded payoff measurable with respect to the date-t information.

The date-τ price of Φ_t is

$$\Pi_{\tau,t}(\Phi_t) = E\left[\frac{S_t}{S_\tau}\Phi_t \mid \mathcal{F}_\tau\right].$$

The ratio S_t/S_τ is the stochastic discount factor from date t back to date τ.

If the payoff is a bounded function $f(X_t)$ of the future Markov state, this pricing formula defines a horizon-t operator Q_t by

$$[Q_t f](x) = E[S_t f(X_t) \mid X_0 = x].$$

This operator is the general-state analogue of multiplying a payoff vector by the Arrow-price matrix $\mathbf{Q}$.

To see the connection, suppose again that the state space is finite and $t = 1$.

Then

$$[Q_1 f]_i = \sum_j s_{ij} p_{ij} f_j = \sum_j q_{ij} f_j.$$

Thus Q_1 is exactly the matrix $\mathbf{Q}$.

In discrete time, the multiplicative property of S implies that Q_t is obtained by applying the one-period operator Q_1 repeatedly.

In continuous time, the family $\{Q_t : t \geq 0\}$ is a semigroup of pricing operators.

143.4.5 Martingales and equivalent probability measures

Different stochastic discount factor / probability pairs can produce the same pricing operators, and that flexibility is the source of the identification problem.

For the Markov setting used here, the probability changes of interest are generated by positive multiplicative martingales.

At the level of probability changes, let $H = \{H_t\}$ be a strictly positive martingale with $E[H_0] = 1$ under P.

For an event A observable by date τ, the changed probability measure P^H is defined by

$$P^H(A) = E[1_A H_\tau].$$

The law of iterated expectations makes this definition consistent across dates.

When H is also a multiplicative functional, making it a multiplicative martingale, the change of probability preserves the Markov structure of Z.

The SDF that represents the same prices under P^H is

$$S_t^H = S_t \frac{H_0}{H_t}.$$

Thus the same pricing operators can be represented by the pair (S, P) or by the pair (S^H, P^H).

In the finite-state model, this is just

$$p_{ij}^H = h_{ij} p_{ij}, \qquad s_{ij}^H = \frac{s_{ij}}{h_{ij}},$$

so that

$$s_{ij}^H p_{ij}^H = s_{ij} p_{ij} = q_{ij}.$$

The same Arrow prices can therefore be explained by changing the probability measure and offsetting that change in the SDF.

This is also the precise sense in which Arrow prices alone do not identify beliefs.

143.4.6 What Perron–Frobenius recovers

Now return to the Perron–Frobenius step.

The finite-state equation was (143.2).

The general-state replacement is an eigenfunction problem for the pricing operators of the kind studied in *Long-term Risk: An Operator Approach*: find a scalar $\hat{\eta}$ and a positive function $\hat{e}$ such that, for every horizon t,

$$[Q_t \hat{e}](x) = \exp(\hat{\eta} t) \hat{e}(x). \tag{143.6}$$

The positive function $\hat{e}$ is the general-state counterpart of the Perron–Frobenius eigenvector.

The scalar $\hat{\eta}$ is the log eigenvalue.

In finite states, $\hat{e}$ is just a positive vector with one entry for each state.

In general state spaces, $\hat{e}(x)$ is a positive function of the current state.

Its job is to record the state-dependent part of long-horizon valuation.

Equation (143.6) says that a future payoff equal to $\hat{e}(X_t)$ has date-0 price $\exp(\hat{\eta} t)\hat{e}(X_0)$.

Thus $\hat{\eta}$ gives the common growth or discount rate, while $\hat{e}$ gives the state-dependent scaling.

Since eigenfunctions are defined only up to scale, uniqueness always means uniqueness up to multiplication by a positive constant.

In general state spaces, existence of a positive eigenfunction is also a substantive condition.

The eigenfunction equation implies the conditional moment restriction

$$E[S_t \hat{e}(X_t) \mid \mathcal{F}_\tau] = \exp((t-\tau)\hat{\eta}) S_\tau \hat{e}(X_\tau), \qquad t \geq \tau.$$

Use this restriction to define

$$\frac{\hat{H}_t}{\hat{H}_0} = \exp(-\hat{\eta} t) S_t \frac{\hat{e}(X_t)}{\hat{e}(X_0)}. \tag{143.7}$$

This process is a martingale because, for $t \geq \tau$,

$$
\begin{aligned}
E\left[\frac{\hat{H}_t}{\hat{H}_0} \mid \mathcal{F}_\tau\right] &= \frac{\exp(-\hat{\eta}t)}{\hat{e}(X_0)} E[S_t \hat{e}(X_t) \mid \mathcal{F}_\tau] \\
&= \frac{\exp(-\hat{\eta}t)}{\hat{e}(X_0)} \exp((t-\tau)\hat{\eta}) S_\tau \hat{e}(X_\tau) \\
&= \exp(-\hat{\eta}\tau) S_\tau \frac{\hat{e}(X_\tau)}{\hat{e}(X_0)} = \frac{\hat{H}_\tau}{\hat{H}_0}.
\end{aligned}
$$

The process is positive because S and $\hat{e}$ are positive.

Its one-period increment is

$$
\frac{\hat{H}_{t+1}}{\hat{H}_t} = \exp(-\hat{\eta}) \frac{S_{t+1}}{S_t} \frac{\hat{e}(X_{t+1})}{\hat{e}(X_t)}. \tag{143.8}
$$

In the finite-state model, when $X_t = i$ and $X_{t+1} = j$, (143.8) becomes

$$
\frac{\hat{H}_{t+1}}{\hat{H}_t} = \exp(-\hat{\eta}) s_{ij} \frac{\hat{e}_j}{\hat{e}_i} = \hat{h}_{ij} = \frac{\hat{p}_{ij}}{p_{ij}}.
$$

This is the same three-component decomposition as (143.5).

In finite states, (143.5) is equivalent to

$$
\frac{S_{t+1}}{S_t} = \exp(\hat{\eta}) \frac{\hat{e}(X_t)}{\hat{e}(X_{t+1})} \frac{\hat{H}_{t+1}}{\hat{H}_t}.
$$

The only change is notation: $\hat{h}_{ij}$ is the one-period density ratio in a finite Markov chain, while $\hat{H}_{t+1}/\hat{H}_t$ is the corresponding one-period density ratio in the general Markov setting.

Conditional on X_0, the likelihood ratio for histories through date t is $\hat{H}_t/\hat{H}_0$.

For the unconditional measure on $\mathcal{F}_t$, the Radon–Nikodym density is $\hat{H}_t$, where $\hat{H}_0$ adjusts the initial distribution.

If $\hat{H}_{t+1}/\hat{H}_t$ is not identically one, the recovered probability measure differs from the correctly specified probability measure.

We show the restriction that rules out this difference in the next section.

Note

The objects $(\hat{e}, \hat{\eta}, \hat{H})$ are the ones that *Long-term Risk: An Operator Approach* writes as $(\phi, \rho, \hat{M})$, working there with a generic multiplicative functional M in place of the stochastic discount factor S used here; what that lecture calls the **twisted measure** is what this lecture calls the long-term risk-neutral measure $\hat{\mathbf{P}} = P^{\hat{H}}$.

One symbol does not travel.

Here Q_t is the semigroup built from the stochastic discount factor alone, which that lecture writes $\mathbb{S}_t$; there, $\mathbb{Q}_t$ is instead the cash-flow valuation semigroup built from $Q = GS$, which also carries a stochastic growth factor.

143.4.7 Selection and recovery

In finite irreducible matrix problems, Perron–Frobenius theory gives a unique positive eigenvector up to scale, so the recovered transition matrix is pinned down by **Q**.

In general state spaces, a positive eigenfunction need not exist, and multiple positive eigenfunctions may solve the same pricing operator problem when one does.

The paper therefore imposes a selection condition on the probability measure induced by the candidate eigenfunction.

This is the same difficulty that *Long-term Risk: An Operator Approach* treats under "Stability of the twisted process"; see *Definition 142.5.6* there.

Assumption 143.4.2 (Ergodicity of the recovered measure)

The process X is stationary and ergodic under $P^{\hat{H}}$, the probability measure induced by the multiplicative martingale $\hat{H}$ defined in the previous section.

Proposition 143.4.1 (Uniqueness of the Perron–Frobenius solution)

There is at most one solution $(\hat{e}, \hat{\eta})$ to the Perron–Frobenius problem such that X is stationary and ergodic under the induced probability measure $P^{\hat{H}}$.

This selected solution, when it exists, identifies the long-term risk-neutral measure.

It does not by itself identify subjective beliefs.

To make recovery identify beliefs, an additional restriction is needed on the SDF.

The restriction used by Ross recovery is the paper's Condition 4:

Assumption 143.4.3

Let

$$S_t = \exp(-\delta t)\frac{m(X_t)}{m(X_0)}$$

for some positive function m and real number δ.

This is the transition-independence restriction from *The Recovery Theorem*, imposed on the SDF representation whose probability measure one wants to recover.

Under this restriction, setting $\hat{e} = 1/m$ and $\hat{\eta} = -\delta$ gives

$$\frac{\hat{H}_t}{\hat{H}_0} = \exp(\delta t)\left[\exp(-\delta t)\frac{m(X_t)}{m(X_0)}\right]\frac{1/m(X_t)}{1/m(X_0)} = 1.$$

Thus the martingale component is identically one after normalization.

This is the general-state version of the finite-state condition $\hat{h}_{ij} = 1$ for every feasible transition.

If this martingale is not identically one, the recovered probability measure absorbs it and generally differs from the correctly specified probability measure.

We will see a few important examples of this in the next section.

The section *Additional state vector* returns to what happens when the eigenfunction is allowed to depend on the auxiliary process Y.

143.4.8 Continuous-time version

Let's briefly restate the framework in continuous time before discussing examples where recovery fails.

We introduce the diffusion notation because the long-run risk example below is written in continuous time.

The objects are the same as before:

- X is the Markov state,
- Y records additional growing or shock-revealing components,
- M is a positive multiplicative functional, such as an SDF, a cash-flow growth process, or a martingale used to change probabilities.

In the continuous-time version, W is a Brownian motion.

The state, auxiliary process, and multiplicative functional satisfy

$$\begin{aligned} dX_t &= \mu_x(X_t)dt + \sigma_x(X_t)dW_t, \\ dY_t &= \mu_y(X_t)dt + \sigma_y(X_t)dW_t, \\ d\log M_t &= \beta(X_t)dt + \alpha(X_t)\cdot dW_t. \end{aligned}$$

Here μ_x and μ_y are drift functions, while σ_x and σ_y are shock-exposure matrices.

The function β is the drift of $\log M$, and α is the Brownian shock exposure of $\log M$.

The invertibility assumption on the stacked shock-exposure matrix is the continuous-time counterpart of the discrete-time condition that $(X_{t+1}, Y_{t+1} - Y_t)$ reveals the shock increment.

It lets the history of $Z = (X, Y)$ reveal the Brownian information.

For M to be a local martingale, its drift must satisfy

$$\beta(x) = -\frac{1}{2}\alpha(x)\cdot\alpha(x).$$

This follows from Ito's formula:

$$\frac{dM_t}{M_t} = \left(\beta(X_t) + \frac{1}{2}\alpha(X_t)\cdot\alpha(X_t)\right)dt + \alpha(X_t)\cdot dW_t.$$

A local martingale has zero drift in dM_t/M_t, which gives the displayed restriction.

Additional integrability conditions then ensure that this local martingale is a true martingale.

Under the probability measure induced by a martingale H with this exposure α, $\widetilde{W}_t = W_t - \int_0^t \alpha(X_s)ds$ is Brownian.

With this sign convention, the drift of X changes from μ_x to $\mu_x + \sigma_x\alpha$, and the drift of Y changes from μ_y to $\mu_y + \sigma_y\alpha$.

This is the continuous-time analogue of replacing p_{ij} by $h_{ij}p_{ij}$ in the finite-state model.

The Markov and triangular structure of Z is preserved, which is why the same Perron–Frobenius decomposition can be applied.

143.5 When recovery fails

Now let's discuss a few examples where the recovered probability measure differs from the correctly specified probability measure.

143.5.1 Recursive utility

We now use the martingale component to see when the recovered probability measure differs from the correctly specified probability measure.

In the previous example, all risk adjustment in the SDF could be written as a ratio of a function of today's state to a function of tomorrow's state.

The Perron–Frobenius transition formula cancels exactly that kind of term.

Recursive utility adds a continuation-value term.

The key point is that this term behaves like the martingale increment defined above.

For the unit-EIS Epstein–Zin case in Borovička *et al.* [2016], with $C_t = \exp(g_c t)c(X_t)$, write the translated continuation value as $V_t = g_c t + v(X_t)$, and define

$$v_i^* = \exp((1-\gamma)v_i).$$

The SDF is

$$s_{ij} = \exp(-\delta - g_c)\frac{c_i}{c_j}\frac{v_j^*}{\sum_k p_{ik} v_k^*}.$$

In this unit-EIS example, the Perron–Frobenius eigenfunction is $\widehat{e}_j = c_j$ and $\widehat{\eta} = -(\delta + g_c)$.

Applying the Perron–Frobenius transition formula therefore leaves

$$\widehat{p}_{ij} = p_{ij}\frac{v_j^*}{\sum_k p_{ik} v_k^*}.$$

The denominator is the conditional expectation of v_j^* given current state i.

Therefore the last fraction has conditional mean one under **P**.

It is therefore a martingale increment.

When v^* is not constant, that ratio varies across next-period states.

That variation is why the probability measure recovered by Perron–Frobenius Theory no longer gives the correctly specified transition matrix.

The next cell solves the finite-state continuation-value equation and builds the SDF.

```
def solve_ez_unit_eis(P, c, δ, γ, g_c, tol=1e-12, max_iter=10_000):
    """Finite-state unit-EIS Epstein-Zin continuation values and SDF."""
    β = np.exp(-δ)
    log_c = np.log(c)
    n = len(c)
    flow = (1 - β) * log_c + β * g_c

    if abs(γ - 1) < 1e-10:
        v = linalg.solve(np.eye(n) - β * P, flow)
        v_star = np.ones(n)
```

(continues on next page)

(continued from previous page)

```
        Pv_star = np.ones(n)
    else:
        v = log_c.copy()
        for _ in range(max_iter):
            v_star = np.exp((1 - γ) * v)
            Pv_star = P @ v_star
            v_new = flow + β / (1 - γ) * np.log(Pv_star)
            if np.max(np.abs(v_new - v)) < tol:
                v = v_new
                break
            v = v_new
        else:
            raise ValueError("Epstein-Zin fixed point did not converge.")

        v_star = np.exp((1 - γ) * v)
        Pv_star = P @ v_star

    S = (
        np.exp(-δ - g_c)
        * (c[:, None] / c[None, :])
        * (v_star[None, :] / Pv_star[:, None])
    )

    return v, v_star, S
```

At log utility, v^* is constant and the martingale increment is one.

As risk aversion rises, continuation values matter more.

The recovered probability measure then differs more from the correctly specified probability measure.

To make the mechanism visible in a small three-state example, the figure below uses the more dispersed consumption vector

$$c = (0.85, 1.00, 1.15).$$

The heatmap reports percentage deviations of the martingale increment from one: $100(\hat{h}_{ij} - 1)$.

Positive entries are transitions that receive more probability under the recovered probability measure than under the correctly specified probability measure.

The right panel reports the increase in the recovered recession probability, measured in percentage points.

```
c_recursive = np.array([0.85, 1.00, 1.15])

plt.show()
```

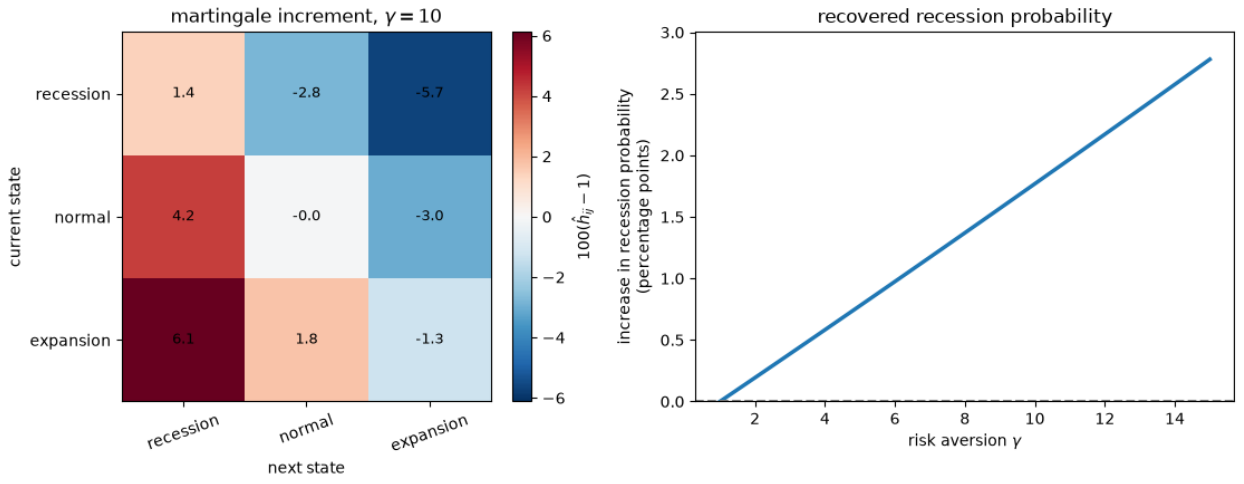

Fig. 143.1: Recursive utility generates a nonconstant martingale increment.

Recursive utility makes the recovered probability measure assign more probability to recession transitions.

At $\gamma = 10$, transitions into recession receive more probability under the recovered probability measure, while transitions into expansion receive less.

As risk aversion rises, the stationary recession probability under the recovered probability measure moves further above its correctly specified value.

Thus, as the continuation-value term creates a nonconstant $\hat{h}_{ij}$, the transition matrix associated with the long-term risk-neutral probability no longer equals the correctly specified transition matrix.

143.5.2 Permanent shocks

Recursive utility gives one nonconstant martingale component.

Permanent shocks provide another, but this example has to be read carefully, because what it delivers depends on the information set on which recovery is run.

Suppose consumption has a permanent shock,

$$\log C_{t+1} - \log C_t = g + x(X_{t+1}) - x(X_t) + \sigma\varepsilon_{t+1},$$

where ε_{t+1} is independent over time and independent of the Markov state X.

With power utility, the SDF contains

$$\exp(-\delta - \gamma g)\exp\{-\gamma[x(X_{t+1}) - x(X_t)]\}\exp(-\gamma\sigma\varepsilon_{t+1}).$$

The middle term depends only on the current and next Markov states.

It is a ratio of state functions, so the Perron–Frobenius transition formula can cancel it.

The last term depends on the new shock ε_{t+1}, which is not summarized by the Markov state.

After dividing by its conditional mean, that term becomes a martingale increment:

$$\frac{\exp(-\gamma\sigma\varepsilon_{t+1})}{E[\exp(-\gamma\sigma\varepsilon_{t+1})]}.$$

Whether that martingale increment breaks recovery depends on the information set on which the eigenfunction problem is posed, so we take the two cases in turn.

Consider first an analyst who prices claims written on the Markov state X alone.

Taking expectations over ε_{t+1}, the Arrow prices over the states of X are

$$q_{ij} = \exp(-\delta - \gamma g)\, E[\exp(-\gamma\sigma\varepsilon_{t+1})]\, \frac{\exp(-\gamma x_j)}{\exp(-\gamma x_i)}\, p_{ij}.$$

Because ε_{t+1} is independent of X, the permanent shock contributes the same constant to every entry of $\mathbf{Q}$ and factors out.

What is left is exactly transition independent in X, with $\hat{e}_i = \exp(\gamma x_i)$.

So Perron–Frobenius recovery of the transition matrix of X is exact here: the martingale increment over the states of X is identically one.

The next cell confirms this in a three-state example.

```
x_perm = np.array([-0.02, 0.0, 0.02])    # state effect on log consumption
σ_perm = 0.01                            # scale of the permanent shock
E_perm = np.exp(0.5 * (γ_power * σ_perm)**2)    # E[exp(-γ σ ε)] for ε ~ N(0, 1)

# Arrow prices over X: the permanent shock enters only through the constant E_perm
S_perm = (np.exp(-δ - γ_power * g_c) * E_perm
```

(continues on next page)

(continued from previous page)

```
          * np.exp(-y_power * x_perm)[None, :]
          / np.exp(-y_power * x_perm)[:, None])
Q_perm = S_perm * P_true

H_perm, _, e_perm, P_hat_perm = martingale_increment(Q_perm, P_true)

print("eigenfunction: numerical vs exp(gamma x)")
print(np.round(e_perm / e_perm[1], 6))
print(np.round(np.exp(y_power * x_perm) / np.exp(y_power * x_perm[1]), 6))
print(f"\nmax |P_hat - P| = {np.max(np.abs(P_hat_perm - P_true)):.1e}")
print(f"max |h_hat - 1| = {np.max(np.abs(H_perm[P_true > 0] - 1)):.1e}")
```

```
eigenfunction: numerical vs exp(gamma x)
[0.904837 1.       1.105171]
[0.904837 1.       1.105171]

max |P_hat - P| = 3.9e-16
max |h_hat - 1| = 1.3e-15
```

The recovered eigenfunction is $\exp(\gamma x_i)$ and both discrepancies are at machine precision.

Now enlarge the filtration so that it reveals consumption, and therefore reveals ε_{t+1} as well.

Relative to investors' information about (X, ε), the martingale increment displayed above is not identically one: it tilts the distribution of the permanent shock toward low realizations.

So the recovered law of consumption differs from investors' beliefs even under ordinary power utility, although the recovered law of the Markov state does not.

The conclusion can now be stated precisely.

Permanent consumption shocks make the recovered probability measure differ from investors' beliefs on the filtration that reveals those shocks, even under ordinary power utility.

Recovery over X alone also breaks down as soon as the permanent shock stops being independent of X, since the shock then no longer factors out of $\mathbf{Q}$ into a constant.

Enlarging the state or information structure to account for the shock does not repair recovery; it leads to the identification problem discussed in *Additional state vector*.

143.5.3 Long-run risk

We now move from small finite-state examples to a standard continuous-time macro-finance model.

The model is the Bansal–Yaron long-run risk model, using the calibration reported by Borovička *et al.* [2016].

The point is to compare the recovered probability measure with the correctly specified probability measure in a standard macro-finance model.

The construction has the same structure as before.

We first write the correctly specified state dynamics, then compute the probability measure implied by the Perron–Frobenius approach.

The state vector $X_t = (X_{1t}, X_{2t})'$ follows

$$
\begin{aligned}
dX_{1t} &= [\mu_{11}(X_{1t} - \iota_1) + \mu_{12}(X_{2t} - \iota_2)]dt + \sqrt{X_{2t}}\sigma_1 dW_t, \\
dX_{2t} &= \mu_{22}(X_{2t} - \iota_2)dt + \sqrt{X_{2t}}\sigma_2 dW_t.
\end{aligned}
$$

Log consumption has an affine drift and the same volatility scaling:

$$d\log C_t = [\beta_{c0} + \beta_{c1}(X_{1t} - \iota_1) + \beta_{c2}(X_{2t} - \iota_2)]dt + \sqrt{X_{2t}}\,\alpha_c \cdot dW_t.$$

Here X_1 is predictable consumption growth and X_2 is a stochastic volatility state.

Two conventions are used throughout this section and both matter for reading the code.

First, every drift is written relative to the long-run means (ι_1, ι_2), so a coefficient triple $(\beta_0, \beta_1, \beta_2)$ always means $\beta_0 + \beta_1(x_1 - \iota_1) + \beta_2(x_2 - \iota_2)$.

Second, each diffusion loading is scaled by $\sqrt{X_{2t}}$, so an Ito correction $\frac{1}{2}|\alpha|^2$ enters the coefficient on x_2 rather than the constant.

The two conventions work together, and it is worth seeing how, because the code below carries a term $-\frac{1}{2}|\alpha_{H^*}|^2$ in the x_2 coefficient of the drift of $\log S$ and a term $-\frac{1}{2}\iota_2|\alpha_{H^*}|^2$ in its constant, where α_{H^*} is the shock exposure of the continuation-value martingale defined below.

That is one correction, not two.

The continuation-value martingale contributes the drift $-\frac{1}{2}x_2|\alpha_{H^*}|^2$ to $\log S$, and writing this single term in centered form splits it into $-\frac{1}{2}|\alpha_{H^*}|^2$ multiplying $(x_2 - \iota_2)$ and $-\frac{1}{2}\iota_2|\alpha_{H^*}|^2$ left over in the constant.

The calibration below sets $\beta_{c1} = 1$, so X_1 *is* predictable consumption growth.

The representative agent has Epstein–Zin utility with unit elasticity of intertemporal substitution.

The continuation value introduces the continuous-time analogue of the martingale component above.

We denote that process by H^*, and the SDF satisfies

$$d\log S_t = -\delta dt - d\log C_t + d\log H_t^*.$$

Here H^* is the continuation-value martingale entering the Epstein–Zin SDF.

The multiplicative martingale $\hat{H}$ associated with the Perron–Frobenius problem is obtained only after also incorporating the Perron–Frobenius eigenfunction.

In models with martingale components in consumption growth, H^* and $\hat{H}$ need not coincide.

The next cell sets the calibration.

```
lrr_params = dict(
    δ=0.002,
    γ=10.0,
    μ11=-0.021,
    μ12=0.0,
    μ22=-0.013,
    ι1=0.0,
    ι2=1.0,
    σ1=np.array([0.0, 0.00034, 0.0]),
    σ2=np.array([0.0, 0.0, -0.038]),
    β_c0=0.0015,
    β_c1=1.0,
    β_c2=0.0,
    α_c=np.array([0.0078, 0.0, 0.0]),
)
```

The next code block computes how the different probability measures change the drift of the state vector.

The first quantity is the continuation value.

In this affine model, the translated continuation value is linear in the state:

$$v(x) = v_0 + v_1 x_1 + v_2 x_2.$$

This is why we call v_1 and v_2 slopes.

They are the derivatives of the continuation value with respect to predictable growth and volatility.

These slopes enter the continuation-value martingale H^*.

In the code, this martingale has shock exposure

$$\alpha_{H^*} = (1-\gamma)(\alpha_c + \sigma_1 v_1 + \sigma_2 v_2).$$

Since the SDF is $d\log S_t = -\delta dt - d\log C_t + d\log H_t^*$, its shock exposure is

$$\alpha_S = -\alpha_c + \alpha_{H^*}.$$

This vector α_S drives the one-period risk-neutral change of measure.

The second quantity is the Perron–Frobenius eigenfunction.

It is exponential-affine:

$$\hat{e}(x) = \exp(e_0 + e_1 x_1 + e_2 x_2).$$

Thus e_1 and e_2 are slopes of the log eigenfunction.

Because X_1 and X_2 have shock loadings σ_1 and σ_2, the Perron–Frobenius eigenfunction contributes the additional shock exposure

$$\sigma_1 e_1 + \sigma_2 e_2.$$

Therefore the one-period risk-neutral dynamics use only α_S, while the dynamics under the long-term risk-neutral measure use

$$\alpha_S + \sigma_1 e_1 + \sigma_2 e_2.$$

The functions below follow this order: compute (v_1, v_2), compute α_S and (e_1, e_2), and then translate these shock exposures into drifts for X.

```

```
        ι2=ι_bar_2,
        σ1=σ1,
        σ2=σ2,
    )
```

The quadratic for e_2 has two roots, and `solve_pf_lrr` selects between them using the criterion stated in *Assumption 143.4.2*, which *Proposition 143.4.1* shows leaves at most one solution.

Here the discarded root gives $\hat{\mu}_{22} = +0.0115$ and $\hat{\iota}_2 = -1.13$, an explosive volatility process reverting to a negative long-run mean, so X is certainly not stationary and ergodic under the measure it induces.

For the calibration used here, the recovered probability measure changes the long-run state distribution.

It lowers the mean of expected growth and raises the mean of volatility.

```
v1, v2 = solve_value_function(lrr_params)
e1, e2, η_lrr, α_s = solve_pf_lrr(lrr_params, v1, v2)
dyn_hat = recovered_lrr_dynamics(lrr_params, e1, e2, α_s)
dyn_bar = risk_neutral_lrr_dynamics(lrr_params, α_s)

long-term   -0.00273    1.12901   -0.00005   -0.01151
```

These numbers show the mechanism clearly.

The positive value slope v_1 says that the continuation value is very sensitive to predictable consumption growth.

The volatility slope v_2 is negative in this calibration, so higher volatility lowers continuation value.

The eigenfunction coefficient e_1 has the opposite sign: the eigenfunction declines in predictable growth.

The change of measure itself loads through $\alpha_S + \sigma_1 e_1 + \sigma_2 e_2$, and the eigenfunction term $\sigma_1 e_1$ reinforces the negative tilt already present in α_S.

Thus the recovered probability measure assigns more probability to histories with lower expected growth.

The positive e_2 works in the other direction for volatility, assigning more probability to higher-volatility states.

The table translates those coefficients into state dynamics.

Relative to the correctly specified probability measure, both risk-neutral measures lower the long-run mean of predictable growth and raise the long-run mean of volatility.

The long-term risk-neutral measure moves further in that direction than the one-period risk-neutral measure: ι_1 falls from 0 to about -0.0027, while ι_2 rises from 1 to about 1.13.

The small negative log eigenvalue means that $\exp(\eta)$ is slightly below one; with the usual yield sign convention, $-\eta$ is the corresponding long-run discount rate.

Stationary densities

The coefficient table gives one summary of the difference between probability measures.

A stationary-density plot gives another.

It shows not only that the means of X_1 and X_2 move, but also which combinations of growth and volatility become more likely.

This matters because treating the recovered probability measure as beliefs changes the whole forecast distribution, not just a pair of long-run averages.

Under the recovered probability measure, probability mass shifts toward adverse long-run-risk states.

These are states with lower predictable growth X_1 and higher volatility X_2.

The dashed contour adds the one-period risk-neutral probability measure.

In this calibration, the one-period risk-neutral and long-term risk-neutral stationary distributions are close to each other, and both are far from the correctly specified distribution.

The whole gap between $\mathbf{P}$ and $\hat{\mathbf{P}}$ is the martingale component $\hat{H}$, whose shock exposure is $\alpha_S + \sigma_1 e_1 + \sigma_2 e_2$.

What the closeness of the two risk-neutral densities shows is how that exposure is split: most of it comes from the one-period risk price α_S, while the Perron–Frobenius eigenfunction supplies the rest, about a tenth of the loading on the growth shock and about a quarter of the loading on the volatility shock.

The paper's Figure 1 reports model-implied stationary densities; the simulation below is a numerical approximation to those densities.

The plot below simulates the state process under each probability measure and estimates the stationary joint density of (X_2, X_1).

The horizontal line marks $X_1 = 0$ and the vertical line marks the correctly specified mean of volatility, $X_2 = \iota_2$.

The movement below the horizontal line means lower expected growth, while movement to the right of the vertical line means higher volatility.

Yield implications

The difference between probability measures matters for asset-pricing interpretation because yields mix two quantities: a payoff forecast and an asset price.

The recovered probability measure is called long-term risk-neutral because it absorbs the martingale component that prices long-horizon risk.

For stochastically growing cash flows, the paper's long-horizon result is that risk premia relative to maturity-matched bonds vanish under the recovered probability measure, subject to the stability and moment conditions used for the limit.

Under the correctly specified probability measure, those same long-term risk premia need not vanish.

For a cash flow G_t, write expectations under the correctly specified probability measure as E_P and expectations under the recovered probability measure as $E_{\hat{P}}$.

The yield computed under the correctly specified probability measure is

$$y_t^P[G](x) = \frac{1}{t}\log E_P[G_t \mid X_0 = x] - \frac{1}{t}\log E_P[S_t G_t \mid X_0 = x].$$

The first term is the payoff forecast.

The second term is the asset price, written using the original SDF representation.

Arrow prices determine the second term.

The question here is what happens to the first term if an analyst treats the recovered probability measure $\hat{\mathbf{P}}$ as investors' beliefs.

In that comparison, prices are held fixed and only the forecast term is recomputed:

$$y_t^{\hat{P}}[G](x) = \frac{1}{t}\log E_{\hat{P}}[G_t \mid X_0 = x] - \frac{1}{t}\log E_P[S_t G_t \mid X_0 = x].$$

For an aggregate-consumption payoff, the answer is substantial.

The recovered probability measure assigns more probability to low-growth, high-volatility states, so it forecasts lower future consumption.

Holding prices fixed, that lower forecast translates into lower consumption yields.

The zero-coupon bond is the comparison case.

Its payoff is one, so the forecast term is always $\log E[1] = 0$.

Changing beliefs therefore does not move the bond-yield panel.

The same solution to the Perron–Frobenius problem also appears in long-bond and forward-measure limits.

The limiting one-period return on a very long bond is

$$R^{\infty}_{t,t+1} = \exp(-\hat{\eta})\frac{\hat{e}(X_{t+1})}{\hat{e}(X_t)}.$$

The martingale increment satisfies

$$\frac{\hat{H}_{t+1}}{\hat{H}_t} = \frac{S_{t+1}}{S_t} R^{\infty}_{t,t+1}.$$

Thus the limiting one-period transition from forward measures coincides with the transition associated with the long-term risk-neutral probability.

The calculation below uses the affine formulas implied by the long-run risk model.

If a multiplicative functional M has log drift affine in X and diffusion proportional to $\sqrt{X_2}$, then

$$E[M_t \mid X_0 = x] = \exp\{\theta_0(t) + \theta_1(t)x_1 + \theta_2(t)x_2\},$$

where the coefficients solve Riccati equations.

The code below computes these affine expectations under the correctly specified measure, recomputes only the consumption forecast under the recovered probability measure, and keeps asset prices fixed.

It then plots median and interquartile yield bands across the same simulated initial states.

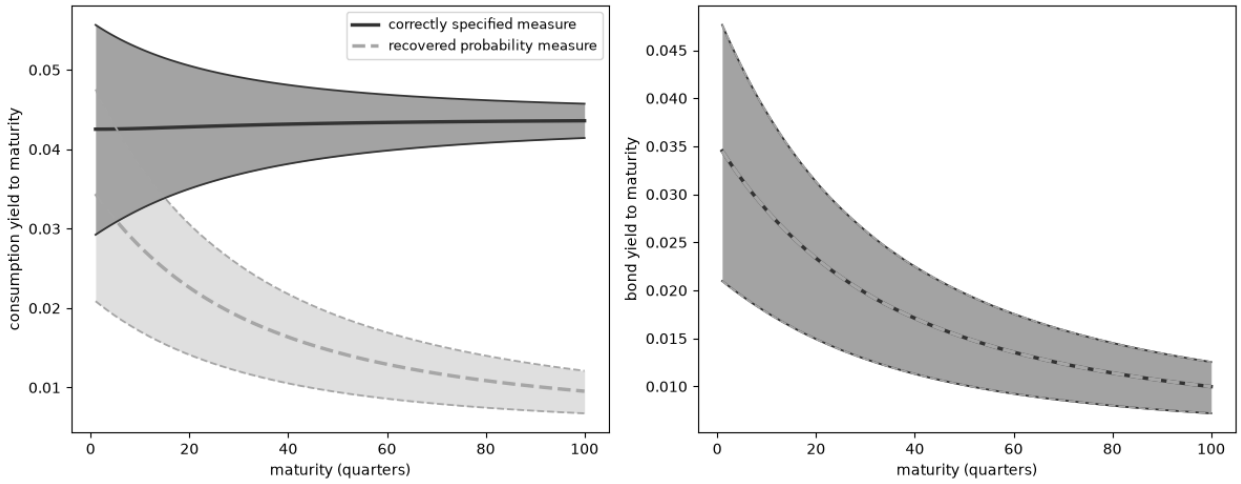

Fig. 143.2: Yield implications of using the recovered probability measure as beliefs. Dashed consumption-yield bands use payoff forecasts under the recovered probability measure with prices fixed; bond yields are unchanged because the zero-coupon payoff has no forecast term.

The left panel is the key one: treating the recovered probability measure as beliefs assigns more probability to low-growth, high-volatility states, so the implied forecast for consumption is lower and consumption yields fall when prices are held fixed.

The bond panel verifies the zero-coupon comparison.

Since $\log E[1] = 0$ under any measure, the solid and dashed bond-yield bands coincide.

Differencing the two panels gives the paper's headline long-horizon result, which the cell above has already computed.

```
prem_P = 1e4 * (qC_P[1] - qB_P[1])
prem_H = 1e4 * (qC_H[1] - qB_P[1])

print("median consumption premium over a maturity-matched bond, basis points")

```

(continues on next page)

(continued from previous page)

```
for q in [1, 8, 20, 40, 100]:
    print(f"{q:6d}q {prem_P[q - 1]:18.1f} {prem_H[q - 1]:13.1f}")

print(f"\nlargest absolute premium: {np.max(np.abs(prem_P)):.0f} bp under P, "
      f"{np.max(np.abs(prem_H)):.0f} bp under P-hat")
```

```
median consumption premium over a maturity-matched bond, basis points
maturity   correctly specified   recovered
     1q               80.2          -1.0
     8q              130.2          -5.3
    20q              194.7          -7.7
    40q              260.6          -7.4
   100q              336.1          -4.5

largest absolute premium: 336 bp under P, 8 bp under P-hat
```

Under the correctly specified probability measure the consumption claim earns 80 to 336 basis points over a maturity-matched bond.

Under the recovered probability measure that premium never exceeds 8 basis points in absolute value, which is the sense in which long-horizon risk premia relative to maturity-matched bonds vanish under the long-term risk-neutral measure.

143.6 Additional state vector

Borovička *et al.* [2016] then ask whether enlarging the state vector changes the recovery problem.

So far, the Perron–Frobenius eigenfunction has depended only on the Markov state X_t.

But many models also contain a growing component Y_t, such as log consumption, with increments driven by the same shock increments.

Here ΔW_{t+1} denotes the shock increment between dates t and $t+1$.

The map ϕ_x sends today's state and the next shock increment into tomorrow's state.

The map ϕ_y sends today's state and the next shock increment into the increment of Y.

$$X_{t+1} = \phi_x(X_t, \Delta W_{t+1}), \qquad Y_{t+1} - Y_t = \phi_y(X_t, \Delta W_{t+1}).$$

Let $\tilde{e}$ denote an eigenfunction candidate that is allowed to depend on both the stationary state X_t and the growing component Y_t.

Let ζ be a vector of loadings on Y, and let $\tilde{e}_\zeta$ be a positive function of X.

Then a natural candidate is

$$\tilde{e}(x, y) = \exp(\zeta \cdot y)\tilde{e}_\zeta(x).$$

This form is natural because Y enters through increments.

Along a path,

$$\exp(\zeta \cdot Y_{t+1}) = \exp(\zeta \cdot Y_t)\exp\{\zeta \cdot (Y_{t+1} - Y_t)\}.$$

Since $Y_{t+1} - Y_t$ is a function of $(X_t, \Delta W_{t+1})$, the ratio $\exp(\zeta \cdot Y_{t+1})/\exp(\zeta \cdot Y_t)$ is a one-period positive multiplicative functional increment.

For a fixed ζ, this factor tilts the one-period pricing operator by $\exp\{\zeta \cdot (Y_{t+1} - Y_t)\}$.

The x-dependent term is therefore not simply the earlier eigenfunction reused.

For each choice of ζ, the remaining x-dependent part solves a different Perron–Frobenius problem:

$$E\left[\frac{S_{t+1}}{S_t}\exp\{\zeta\cdot(Y_{t+1}-Y_t)\}\tilde{e}_\zeta(X_{t+1})\mid X_t=x\right]=\exp(\eta_\zeta)\tilde{e}_\zeta(x).$$

Changing ζ changes how much long-run growth risk is loaded into the eigenfunction.

Thus adding Y_t can make the subjective probability measure one possible solution, but it also creates a family of possible solutions.

The extra state variable therefore does not remove the identification problem; it makes the selection problem more explicit.

The paper also points out a related practical issue.

Highly persistent stationary processes can be hard to distinguish from processes with stationary increments.

A stationary approximation may have a unique solution to the Perron–Frobenius problem for each finite persistence level, but as persistence becomes extreme, the limiting problem can have many approximate solutions.

Numerically, this means the solution to the Perron–Frobenius problem can be sensitive exactly in the cases where a stationary model is being used to approximate stochastic growth.

There is, however, a structured way forward.

If the analyst supplies a reference multiplicative functional Y^r that is known to have the same martingale component as the SDF, then one can restrict the enlarged eigenfunction to the form

$$(Y^r)^{-1}e(x).$$

This restriction chooses which long-run martingale component is allowed into the eigenfunction.

With this extra structure, Arrow prices can again reveal subjective probabilities.

But the key input is external: the long-run martingale component has been supplied by the analyst, not recovered from Arrow prices alone.

143.7 Measuring the martingale component

The paper also asks how large the martingale component is in asset-market data.

Under rational expectations, this measures how important long-term risk adjustments are for valuation.

Under a subjective-beliefs interpretation, it measures the discrepancy between subjective beliefs and the correctly specified probability measure only after imposing that the subjective SDF itself has no martingale component.

With that extra restriction in place, a small martingale component would make the recovered probability measure close to beliefs, while a large one would make long-term risk adjustments more important for the recovered probability measure.

One family of measures applies a convex function to the martingale increment $\hat{H}_{t+1}/\hat{H}_t$.

For example, conditional relative entropy uses

$$E\left[\frac{\hat{H}_{t+1}}{\hat{H}_t}\log\frac{\hat{H}_{t+1}}{\hat{H}_t}\mid X_t=x\right].$$

This expression is zero only when the martingale increment is identically one.

With incomplete asset-market data, the full martingale increment is not observed.

The paper therefore uses pricing restrictions and long-bond return approximations to derive lower bounds on such discrepancy measures.

These bounds are a way to test whether the martingale component is economically small without requiring a full set of Arrow prices.

143.8 Lessons

The Perron–Frobenius approach remains useful under misspecification, but it no longer solves the belief-recovery problem by itself.

It delivers a probability measure that may include long-horizon risk premia.

That measure equals investors' beliefs only when the martingale component is identically one.

Recursive utility, permanent shocks, and long-run risk models give this martingale an economically important role, so transition independence is a substantive economic restriction, not a technical convenience.

143.9 Exercises

Exercise 143.9.1

A two-state martingale component.

Let

$$\mathbf{P} = \begin{pmatrix} 0.8 & 0.2 \\ 0.4 & 0.6 \end{pmatrix}, \qquad \mathbf{Q} = \begin{pmatrix} 0.72 & 0.15 \\ 0.36 & 0.42 \end{pmatrix}.$$

1. Compute the one-period risk-neutral transition matrix $\bar{\mathbf{P}}$.
2. Compute the transition matrix $\hat{\mathbf{P}}$ associated with the recovered probability measure.
3. Compute $\hat{h}_{ij} = \hat{p}_{ij}/p_{ij}$ and decide whether recovery returns the correctly specified transition matrix.

Solution

Here is one solution:

```
P2 = np.array([[0.8, 0.2],
               [0.4, 0.6]])
Q2 = np.array([[0.72, 0.15],
               [0.36, 0.42]])

Pbar2, qb2 = risk_neutral_probs(Q2)
H2, eta2, e2, Phat2 = martingale_increment(Q2, P2)

print("One-period risk-neutral transition matrix P_bar")
print(np.round(Pbar2, 4))
print("\nTransition matrix P_hat associated with the recovered probability measure
 ↪")
print(np.round(Phat2, 4))
print("\nMartingale increment h_hat")
```

```
print(np.round(H2, 4))
print("\nRecovery returns P:", np.allclose(H2[P2 > 0], 1))
```

```
One-period risk-neutral transition matrix P_bar
[[0.8276 0.1724]
 [0.4615 0.5385]]

Transition matrix P_hat associated with the recovered probability measure
[[0.8505 0.1495]
 [0.5039 0.4961]]

Martingale increment h_hat
[[1.0631 0.7476]
 [1.2597 0.8269]]

Recovery returns P: False
```

Exercise 143.9.2

Power utility benchmark.

For trend-stationary consumption and power utility,

$$s_{ij} = A \left(\frac{c_j}{c_i} \right)^{-\gamma}.$$

Show that $\hat{e}_i = c_i^\gamma$ is the Perron–Frobenius eigenvector and that $\hat{\mathbf{P}} = \mathbf{P}$.

Then verify the result numerically using the three-state baseline in the lecture.

Solution

The analytical check is:

$$[\mathbf{Q}\hat{e}]_i = \sum_j A \left(\frac{c_j}{c_i} \right)^{-\gamma} p_{ij} c_j^\gamma = A c_i^\gamma = A \hat{e}_i.$$

Thus $\exp(\hat{\eta}) = A$ and

$$\hat{p}_{ij} = \frac{1}{A} q_{ij} \frac{\hat{e}_j}{\hat{e}_i} = p_{ij}.$$

Below is the numerical check.

```
H_power, _, e_power, P_hat_power = martingale_increment(Q_power, P_true)
e_theory = c_levels**γ_power
e_theory = e_theory / e_theory.sum()

print("Perron-Frobenius eigenvector")
print(np.round(e_power, 6))
print("\nNormalized c^gamma")
print(np.round(e_theory, 6))
print("\nmax |P_hat - P|:",
      np.max(np.abs(P_hat_power - P_true)))
print("max |h_hat - 1|:",
      np.max(np.abs(H_power[P_true > 0] - 1)))
```

```
Perron-Frobenius eigenvector
[0.328344 0.333313 0.338343]

Normalized c^gamma
[0.328344 0.333313 0.338343]

max |P_hat - P|: 3.3306690738754696e-16
max |h_hat - 1|: 1.3322676295501878e-15
```

Exercise 143.9.3

Recursive utility and risk aversion.

Using the finite-state Epstein–Zin example with $c = (0.85, 1.00, 1.15)$, compute the stationary distribution of $\hat{\mathbf{P}}$ for $\gamma \in \{1, 5, 10, 15\}$.

Which state receives the largest increase in stationary probability as γ rises?

Solution

Here is one solution:

```
for γ in [1, 5, 10, 15]:
    _, _, S_g = solve_ez_unit_eis(P_true, c_recursive, δ, γ, g_c)
    Q_g = S_g * P_true
    _, _, _, P_hat_g = martingale_increment(Q_g, P_true)
    π_g = stationary_dist(P_hat_g)
    print(f"gamma={γ:2.0f}: {np.round(π_g, 4)}")

print("\nCorrectly specified:", np.round(π_true, 4))
```

```
gamma= 1: [0.2688 0.4409 0.2903]
gamma= 5: [0.2766 0.4399 0.2835]
gamma=10: [0.2865 0.4385 0.275 ]
gamma=15: [0.2966 0.4368 0.2666]

Correctly specified: [0.2688 0.4409 0.2903]
```

The recession state receives the largest increase.

Part XVII

Data and Empirics

CHAPTER

FOUR

PANDAS FOR PANEL DATA

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install --upgrade seaborn
```

We use the following imports.

```
import matplotlib.pyplot as plt
import seaborn as sns
sns.set_theme()
```

144.1 Overview

In an earlier lecture on pandas, we looked at working with simple data sets.

Econometricians often need to work with more complex data sets, such as panels.

Common tasks include

- Importing data, cleaning it and reshaping it across several axes.
- Selecting a time series or cross-section from a panel.
- Grouping and summarizing data.

`pandas` (derived from 'panel' and 'data') contains powerful and easy-to-use tools for solving exactly these kinds of problems.

In what follows, we will use a panel data set of real minimum wages from the OECD to create:

- summary statistics over multiple dimensions of our data
- a time series of the average minimum wage of countries in the dataset
- kernel density estimates of wages by continent

We will begin by reading in our long format panel data from a CSV file and reshaping the resulting `DataFrame` with `pivot_table` to build a `MultiIndex`.

Additional detail will be added to our `DataFrame` using pandas' `merge` function, and data will be summarized with the `groupby` function.

144.2 Slicing and Reshaping Data

We will read in a dataset from the OECD of real minimum wages in 32 countries and assign it to `realwage`.

The dataset can be accessed with the following link:

```
url1 = 'https://raw.githubusercontent.com/QuantEcon/data-lectures/main/lectures/
↪realwage.csv'
```

```
import pandas as pd

# Display 6 columns for viewing purposes
pd.set_option('display.max_columns', 6)

# Reduce decimal points to 2
pd.options.display.float_format = '{:,.2f}'.format

realwage = pd.read_csv(url1)
```

Let's have a look at what we've got to work with

```
realwage.head()  # Show first 5 rows
```

```
   Unnamed: 0        Time  Country                                  Series  \
0           0  2006-01-01  Ireland  In 2015 constant prices at 2015 USD PPPs
1           1  2007-01-01  Ireland  In 2015 constant prices at 2015 USD PPPs
2           2  2008-01-01  Ireland  In 2015 constant prices at 2015 USD PPPs
3           3  2009-01-01  Ireland  In 2015 constant prices at 2015 USD PPPs
4           4  2010-01-01  Ireland  In 2015 constant prices at 2015 USD PPPs

  Pay period     value
0     Annual 17,132.44
1     Annual 18,100.92
2     Annual 17,747.41
3     Annual 18,580.14
4     Annual 18,755.83
```

The data is currently in long format, which is difficult to analyze when there are several dimensions to the data.

We will use `pivot_table` to create a wide format panel, with a `MultiIndex` to handle higher dimensional data.

`pivot_table` arguments should specify the data (values), the index, and the columns we want in our resulting dataframe.

By passing a list in columns, we can create a `MultiIndex` in our column axis

```
realwage = realwage.pivot_table(values='value',
                                index='Time',
                                columns=['Country', 'Series', 'Pay period'])
realwage.head()
```

```
Country                                    Australia         \
Series     In 2015 constant prices at 2015 USD PPPs

Time
2006-01-01                                                12,594.40   6.05
2007-01-01                                                12,974.40   6.24
2008-01-01                                                14,097.56   6.78
2009-01-01                                                15,756.42   7.58
2010-01-01                                                16,391.31   7.88

[5 rows x 128 columns]
```

To more easily filter our time series data, later on, we will convert the index into a `DateTimeIndex`

```
realwage.index = pd.to_datetime(realwage.index)
type(realwage.index)
```

```
pandas.DatetimeIndex
```

The columns contain multiple levels of indexing, known as a `MultiIndex`, with levels being ordered hierarchically (Country > Series > Pay period).

A `MultiIndex` is the simplest and most flexible way to manage panel data in pandas

```
type(realwage.columns)
```

```
pandas.MultiIndex
```

```
realwage.columns.names
```

```
FrozenList(['Country', 'Series', 'Pay period'])
```

Like before, we can select the country (the top level of our `MultiIndex`)

```
realwage['United States'].head()
```

```
Series     In 2015 constant prices at 2015 USD PPPs         \

```

For the rest of lecture, we will work with a dataframe of the hourly real minimum wages across countries and time, measured in 2015 US dollars.

To create our filtered dataframe (`realwage_f`), we can use the `xs` method to select values at lower levels in the multiindex, while keeping the higher levels (countries in this case)

```
realwage_f = realwage.xs(('Hourly', 'In 2015 constant prices at 2015 USD exchange␣
↪rates'),
                         level=('Pay period', 'Series'), axis=1)
realwage_f.head()
```

```
Country     Australia  Belgium  Brazil  ...  Turkey  United Kingdom  \

144.3 Merging Dataframes and Filling NaNs

Similar to relational databases like SQL, pandas has built in methods to merge datasets together.

Using country information from WorldData.info, we'll add the continent of each country to `realwage_f` with the `merge` function.

The dataset can be accessed with the following link:

```
url2 = 'https://raw.githubusercontent.com/QuantEcon/data-lectures/main/lectures/
↪countries.csv'
```

```
worlddata = pd.read_csv(url2, sep=';')
worlddata.head()
```

```
    Country (en) Country (de)        Country (local)  ... Deathrate  \
0    Afghanistan  Afghanistan  Afganistan/Afqanestan  ...     13.70
1          Egypt      Ägypten                  Misr  ...      4.70
2  Åland Islands  Ålandinseln                 Åland  ...      0.00
3        Albania     Albanien              Shqipëria  ...      6.70
4        Algeria     Algerien     Al-Jaza'ir/Algérie  ...      4.30

  Life expectancy                                                Url
0           51.30  https://www.laenderdaten.info/Asien/Afghanista...
1           72.70  https://www.laenderdaten.info/Afrika/Aegypten/...
2            0.00  https://www.laenderdaten.info/Europa/Aland/ind...
3           78.30  https://www.laenderdaten.info/Europa/Albanien/...
4           76.80  https://www.laenderdaten.info/Afrika/Algerien/...

[5 rows x 17 columns]
```

First, we'll select just the country and continent variables from `worlddata` and rename the column to 'Country'

```
worlddata = worlddata[['Country (en)', 'Continent']]
worlddata = worlddata.rename(columns={'Country (en)': 'Country'})
worlddata.head()
```

```
         Country Continent
0    Afghanistan      Asia
1          Egypt    Africa
2  Åland Islands    Europe
3        Albania    Europe
4        Algeria    Africa
```

We want to merge our new dataframe, `worlddata`, with `realwage_f`.

The pandas `merge` function allows dataframes to be joined together by rows.

Our dataframes will be merged using country names, requiring us to use the transpose of `realwage_f` so that rows correspond to country names in both dataframes

```
realwage_f.transpose().head()
```

```
Time       2006-01-01  2007-01-01  2008-01-01  ...  2014-01-01  2015-01-01  \
Country                                        ...
Australia       12.06       12.46       12.24  ...       12.67       12.83
Belgium          9.70        9.82        9.87  ...       10.01        9.95
```

(continues on next page)

(continued from previous page)

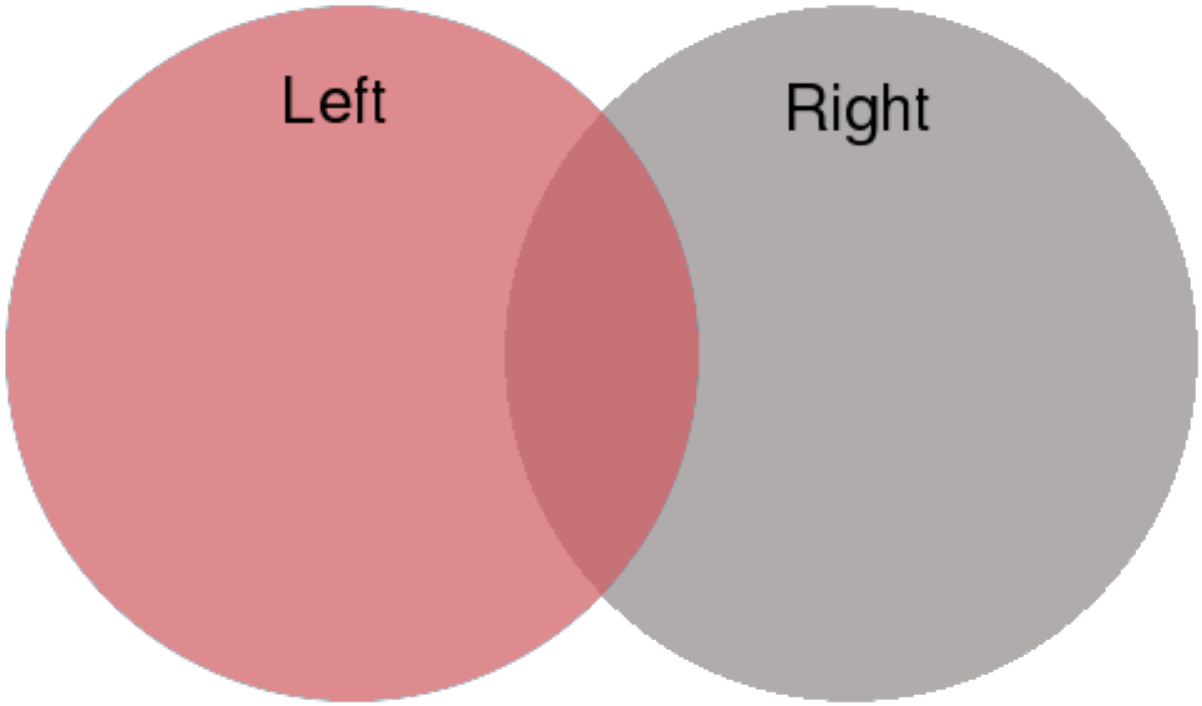
Chile            1.91

[5 rows x 11 columns]
```



We can use either left, right, inner, or outer join to merge our datasets:

- left join includes only countries from the left dataset
- right join includes only countries from the right dataset
- outer join includes countries that are in either the left and right datasets
- inner join includes only countries common to both the left and right datasets

By default, `merge` will use an inner join.

Here we will pass `how='left'` to keep all countries in `realwage_f`, but discard countries in `worlddata` that do not have a corresponding data entry `realwage_f`.

This is illustrated by the red shading in the following diagram

We will also need to specify where the country name is located in each dataframe, which will be the `key` that is used to merge the dataframes 'on'.

Our 'left' dataframe (`realwage_f.transpose()`) contains countries in the index, so we set `left_index=True`.

Our 'right' dataframe (`worlddata`) contains countries in the 'Country' column, so we set `right_on='Country'`

```
merged = pd.merge(realwage_f.transpose(), worlddata,
                  how='left', left_index=True, right_on='Country')
merged.head()
```

```
        2006-01-01 00:00:00  2007-01-01 00:00:00  2008-01-01 00:00:00  ...  \

100.00                 8.48     Canada  North America
38.00                  1.91      Chile  South America

[5 rows x 13 columns]
```

Countries that appeared in `realwage_f` but not in `worlddata` will have `NaN` in the Continent column.

To check whether this has occurred, we can use `.isnull()` on the continent column and filter the merged dataframe

```
merged[merged['Continent'].isnull()]
```

```
     2006-01-01 00:00:00  2007-01-01 00:00:00  2008-01-01 00:00:00  ...  \
NaN                 3.42                 3.74                 3.87  ...
NaN                 0.23                 0.45                 0.39  ...
NaN                 1.50                 1.64                 1.71  ...

     2016-01-01 00:00:00             Country  Continent
NaN                 5.28               Korea        NaN
NaN                 0.55  Russian Federation        NaN
NaN                 2.08     Slovak Republic        NaN

[3 rows x 13 columns]
```

We have three missing values!

One option to deal with NaN values is to create a dictionary containing these countries and their respective continents.

`.map()` will match countries in `merged['Country']` with their continent from the dictionary.

Notice how countries not in our dictionary are mapped with `NaN`

```
missing_continents = {'Korea': 'Asia',
                      'Russian Federation': 'Europe',
                      'Slovak Republic': 'Europe'}

merged['Country'].map(missing_continents)
```

```
17.00         NaN
23.00         NaN
32.00         NaN
100.00        NaN
38.00         NaN
108.00        NaN
41.00         NaN
225.00        NaN
53.00         NaN
58.00         NaN
45.00         NaN
68.00         NaN
233.00        NaN
86.00         NaN
88.00         NaN
91.00         NaN
NaN          Asia
117.00        NaN
122.00        NaN
123.00        NaN
138.00        NaN
153.00        NaN
151.00        NaN
174.00        NaN
175.00        NaN

NaN        Europe
198.00        NaN
200.00        NaN
227.00        NaN
241.00        NaN
240.00        NaN
Name: Country, dtype: str
```

We don't want to overwrite the entire series with this mapping.

`.fillna()` only fills in `NaN` values in `merged['Continent']` with the mapping, while leaving other values in the column unchanged

```
merged['Continent'] = merged['Continent'].fillna(merged['Country'].map(missing_
↪continents))

# Check for whether continents were correctly mapped

merged[merged['Country'] == 'Korea']
```

```
     2006-01-01 00:00:00  2007-01-01 00:00:00  2008-01-01 00:00:00  ...  \
NaN                 3.42                 3.74                 3.87  ...

     2016-01-01 00:00:00  Country  Continent
NaN                 5.28    Korea       Asia

[1 rows x 13 columns]
```

We will also combine the Americas into a single continent - this will make our visualization nicer later on.

To do this, we will use `.replace()` with a list of the continent values we want to replace.

```
replace = ['Central America', 'North America', 'South America']
merged['Continent'] = merged['Continent'].replace(to_replace=replace, value='America')
```

Now that we have all the data we want in a single `DataFrame`, we will reshape it back into panel form with a `MultiIndex`.

We should also ensure to sort the index using `.sort_index()` so that we can efficiently filter our dataframe later on.

By default, levels will be sorted top-down

```
merged = merged.set_index(['Continent', 'Country']).sort_index()
merged.head()
```

```
                     2006-01-01 00:00:00  2007-01-01 00:00:00  \
Continent Country
America   Brazil                    0.87                 0.92
          Canada                    6.89                 6.96
          Chile                     1.42                 1.45
          Colombia                  1.01                 1.02
          Costa Rica                 NaN                  NaN

                     2008-01-01 00:00:00  ...  2014-01-01 00:00:00  \
Continent Country                         ...
America   Brazil                    0.96  ...                 1.21
          Canada                    7.24  ...                 8.22
          Chile                     1.44  ...                 1.76
          Colombia                  1.01  ...                 1.13
          Costa Rica                 NaN  ...                 2.41

                     2015-01-01 00:00:00  2016-01-01 00:00:00
Continent Country
America   Brazil                    1.21                 1.24
          Canada                    8.35                 8.48
          Chile                     1.81                 1.91
          Colombia                  1.13                 1.12
          Costa Rica                2.56                 2.63

[5 rows x 11 columns]
```

While merging, we lost our `DatetimeIndex`, as we merged columns that were not in datetime format

```
merged.columns
```

```
Index([2006-01-01 00:00:00, 2007-01-01 00:00:00, 2008-01-01 00:00:00,
       2009-01-01 00:00:00, 2010-01-01 00:00:00, 2011-01-01 00:00:00,
       2012-01-01 00:00:00, 2013-01-01 00:00:00, 2014-01-01 00:00:00,
       2015-01-01 00:00:00, 2016-01-01 00:00:00],
      dtype='object')
```

Now that we have set the merged columns as the index, we can recreate a `DatetimeIndex` using `.to_datetime()`

```
merged.columns = pd.to_datetime(merged.columns)
merged.columns = merged.columns.rename('Time')
merged.columns
```

```
DatetimeIndex(['2006-01-01', '2007-01-01', '2008-01-01', '2009-01-01',
               '2010-01-01', '2011-01-01', '2012-01-01', '2013-01-01',
```

(continues on next page)

(continued from previous page)

```
               '2014-01-01', '2015-01-01', '2016-01-01'],
              dtype='datetime64[us]', name='Time', freq=None)
```

The `DatetimeIndex` tends to work more smoothly in the row axis, so we will go ahead and transpose `merged`

```
merged = merged.transpose()
merged.head()
```

```
Continent  America                ...   Europe
Country     Brazil Canada Chile   ... Slovenia Spain United Kingdom
Time                              ...
2006-01-01    0.87   6.89  1.42   ...     3.92  3.99           9.81
2007-01-01    0.92   6.96  1.45   ...     3.88  4.10          10.07
2008-01-01    0.96   7.24  1.44   ...     3.96  4.14          10.04
2009-01-01    1.03   7.67  1.52   ...     4.08  4.32          10.15
2010-01-01    1.08   7.94  1.56   ...     4.81  4.30           9.96

[5 rows x 32 columns]
```

144.4 Grouping and Summarizing Data

Grouping and summarizing data can be particularly useful for understanding large panel datasets.

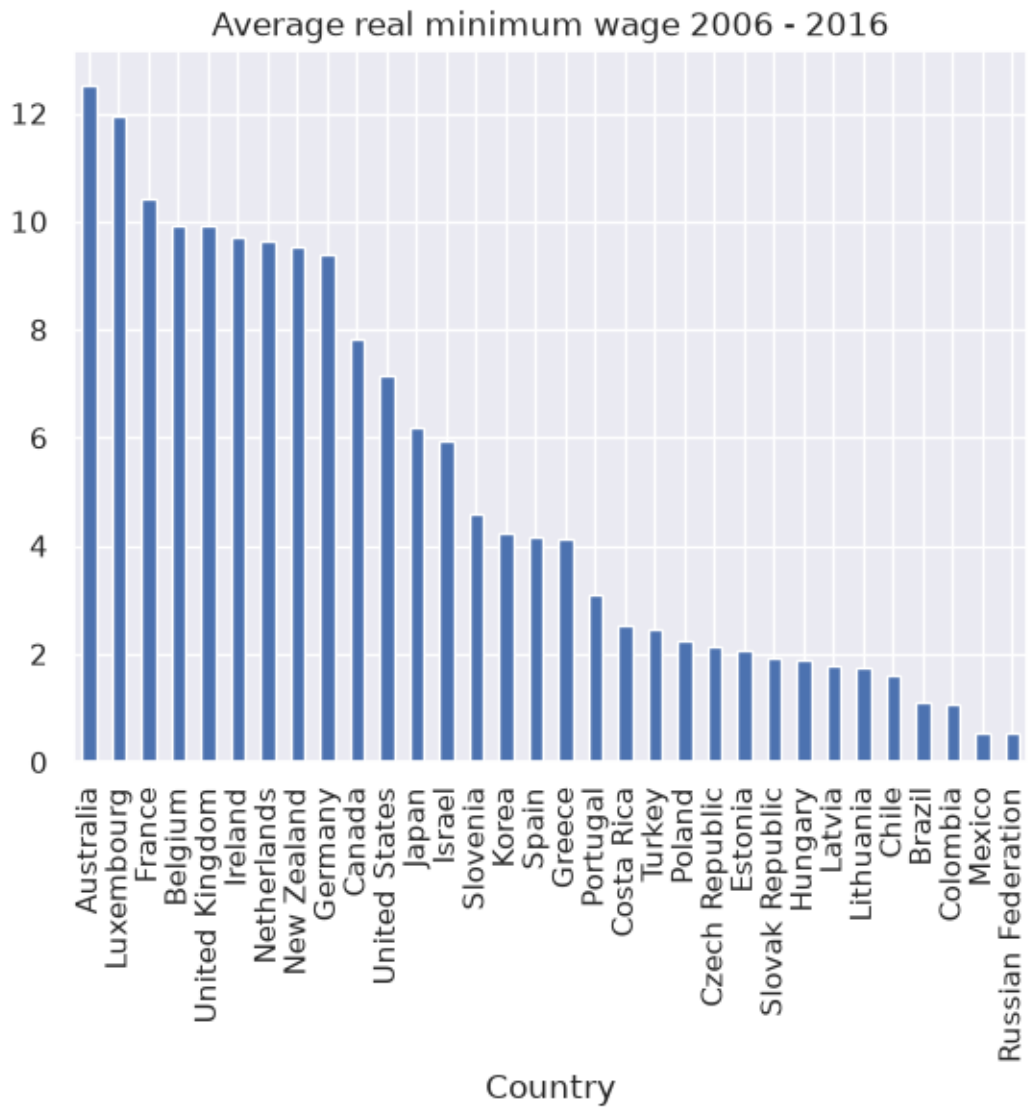
A simple way to summarize data is to call an aggregation method on the dataframe, such as `.mean()` or `.max()`.

For example, we can calculate the average real minimum wage for each country over the period 2006 to 2016 (the default is to aggregate over rows)

```
merged.mean().head(10)
```

```
Continent  Country
America    Brazil          1.09
           Canada          7.82
           Chile           1.62
           Colombia        1.07
           Costa Rica      2.53
           Mexico          0.53
           United States   7.15
Asia       Israel          5.95
           Japan           6.18
           Korea           4.22
dtype: float64
```

Using this series, we can plot the average real minimum wage over the past decade for each country in our data set



```
merged.mean().sort_values(ascending=False).plot(kind='bar',
                                                title="Average real minimum wage 2006
 ↪- 2016")

# Set country labels
country_labels = merged.mean().sort_values(ascending=False).index.get_level_values(
 ↪'Country').tolist()
plt.xticks(range(0, len(country_labels)), country_labels)
plt.xlabel('Country')
```

(continues on next page)

(continued from previous page)

```
plt.show()
```

Passing in `axis=1` to `.mean()` will aggregate over columns (giving the average minimum wage for all countries over time)

```
merged.mean(axis=1).head()
```

```
Time
2006-01-01   4.69
2007-01-01   4.84
2008-01-01   4.90
2009-01-01   5.08
2010-01-01   5.11
dtype: float64
```

We can plot this time series as a line graph

```
merged.mean(axis=1).plot()
plt.title('Average real minimum wage 2006 - 2016')
plt.ylabel('2015 USD')
plt.xlabel('Year')
plt.show()
```

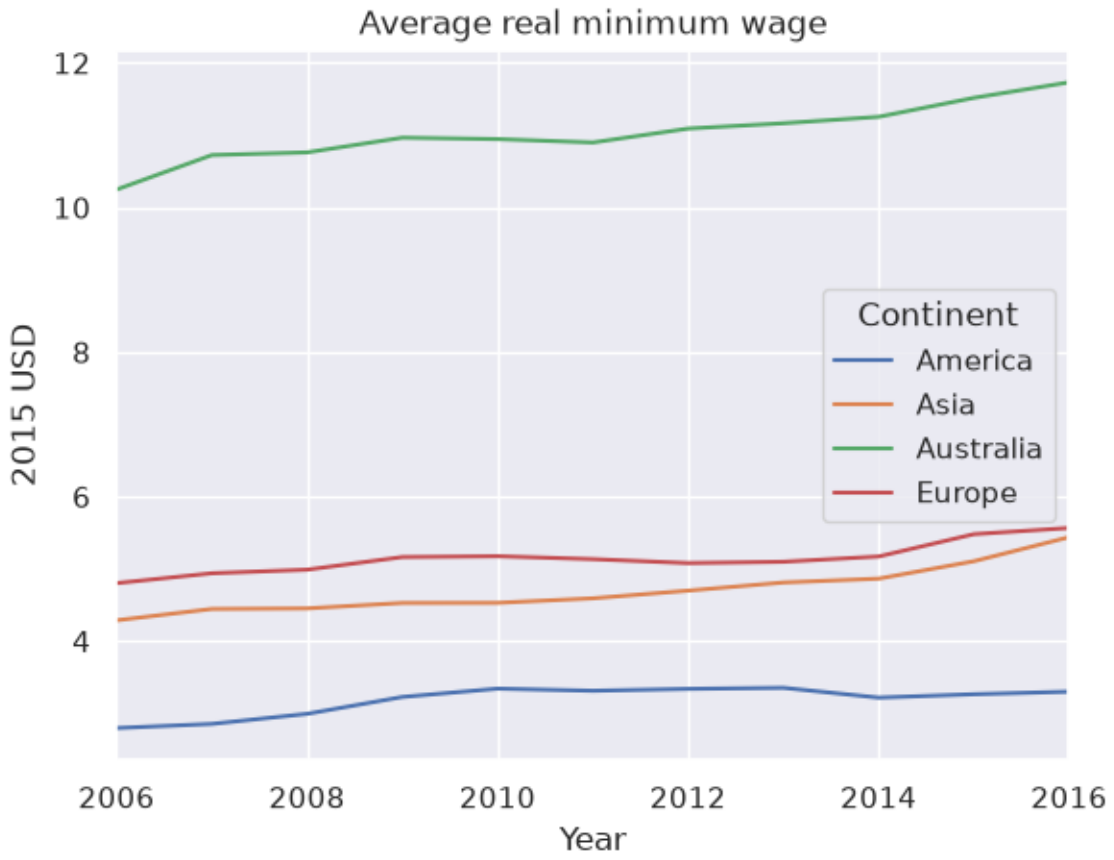
We can also specify a level of the `MultiIndex` (in the column axis) to aggregate over.

In the case of `groupby`, we need to use `.T` to transpose the columns into rows, as `pandas` has removed support for `axis=1` in the `groupby` method.

```
merged.T.groupby(level='Continent').mean().head()
```

```
Time       2006-01-01  2007-01-01  2008-01-01  ...  2014-01-01  2015-01-01  \
Continent                                      ...
America          2.80        2.85        2.99  ...        3.22        3.26
Asia             4.29        4.44        4.45  ...        4.86        5.10
Australia       10.25       10.73       10.76  ...       11.25       11.52
Europe           4.80        4.94        4.99  ...        5.17        5.48

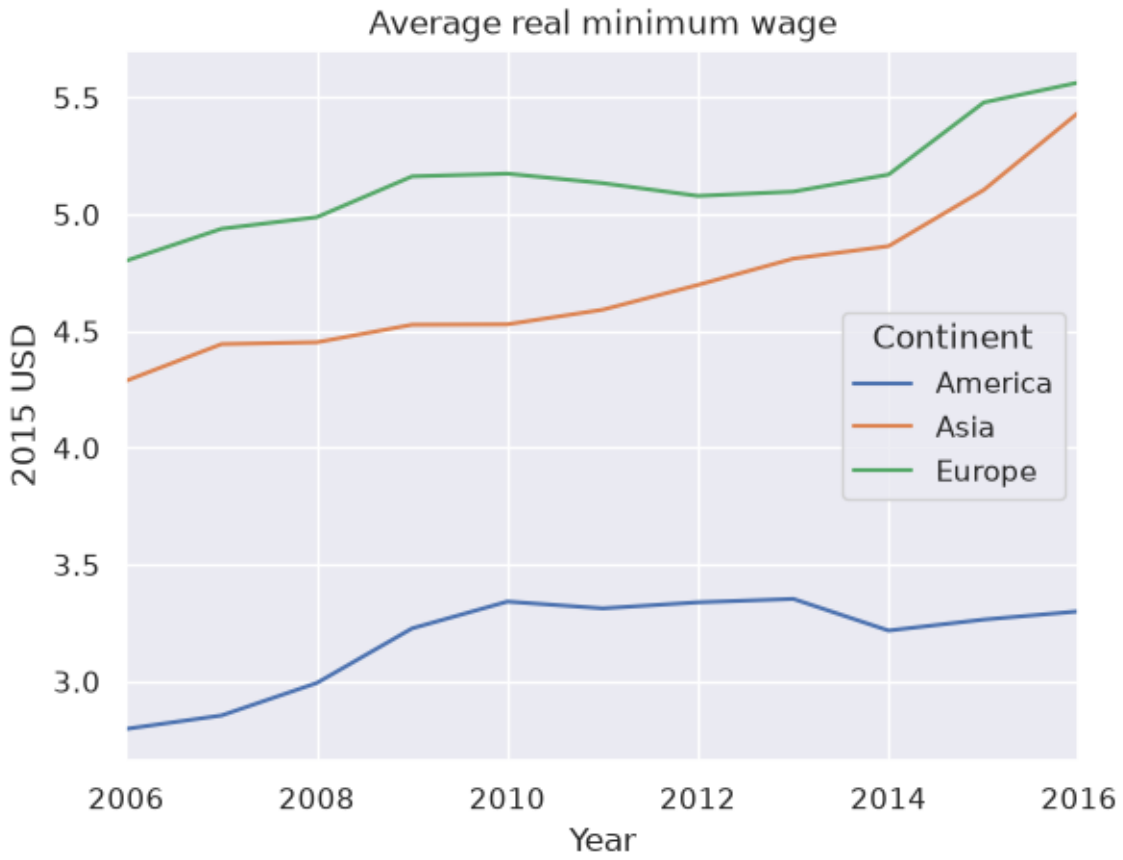
Time       2016-01-01
Continent
America          3.30
Asia             5.44
Australia       11.73
Europe           5.57
```



(continues on next page)

(continued from previous page)

```
[4 rows x 11 columns]
```



We can plot the average minimum wages in each continent as a time series

```
merged.T.groupby(level='Continent').mean().T.plot()
plt.title('Average real minimum wage')
plt.ylabel('2015 USD')
plt.xlabel('Year')
plt.show()
```

We will drop Australia as a continent for plotting purposes

```
merged = merged.drop('Australia', level='Continent', axis=1)
merged.T.groupby(level='Continent').mean().T.plot()
plt.title('Average real minimum wage')
plt.ylabel('2015 USD')
plt.xlabel('Year')
plt.show()
```

`.describe()` is useful for quickly retrieving a number of common summary statistics

```
merged.stack().describe()
```

```
Continent  America  Asia  Europe
count        69.00 44.00  200.00
mean          3.19  4.70    5.15
std           3.02  1.56    3.82
min           0.52  2.22    0.23
25%           1.03  3.37    2.02
50%           1.44  5.48    3.54
75%           6.96  5.95    9.70
max           8.48  6.65   12.39
```

This is a simplified way to use `groupby`.

Using `groupby` generally follows a 'split-apply-combine' process:

- split: data is grouped based on one or more keys
- apply: a function is called on each group independently
- combine: the results of the function calls are combined into a new data structure

The `groupby` method achieves the first step of this process, creating a new `DataFrameGroupBy` object with data split into groups.

Let's split `merged` by continent again, this time using the `groupby` function, and name the resulting object `grouped`

```
grouped = merged.T.groupby(level='Continent')
grouped
```

```
<pandas.api.typing.DataFrameGroupBy object at 0x780a610c1010>
```

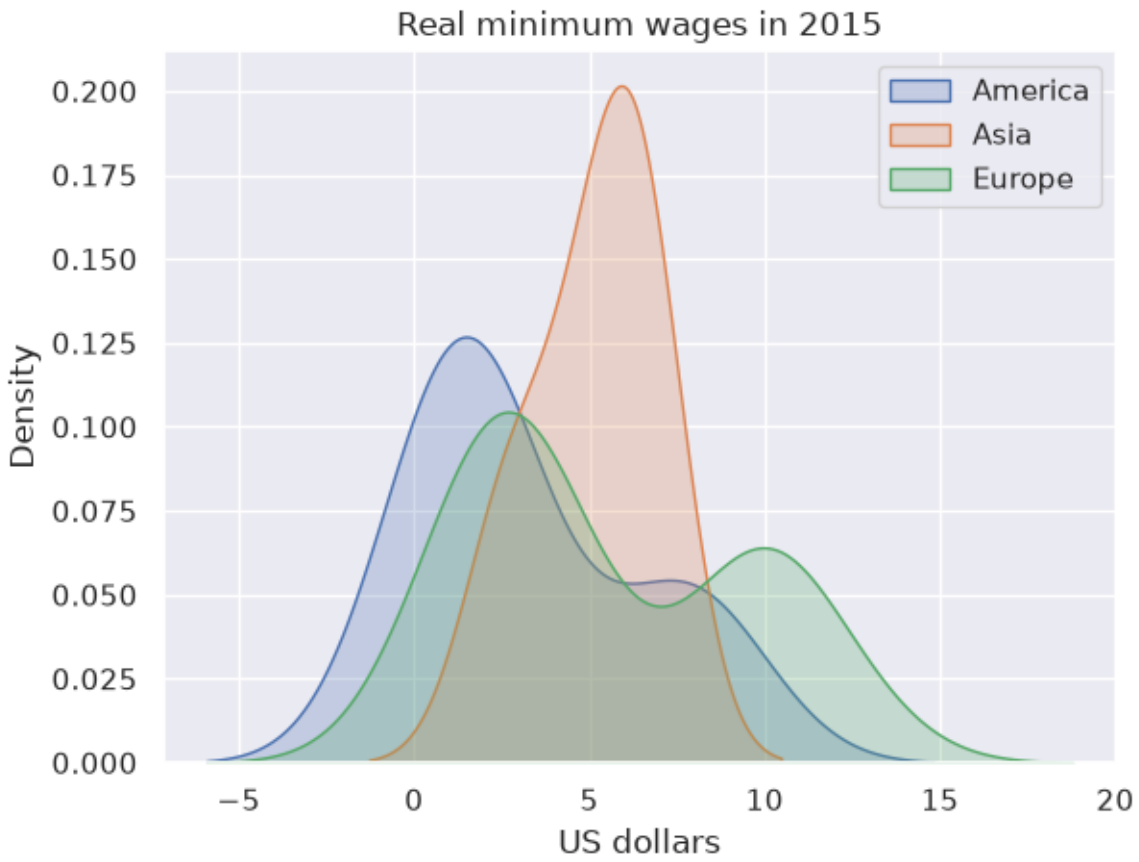
Calling an aggregation method on the object applies the function to each group, the results of which are combined in a new data structure.

For example, we can return the number of countries in our dataset for each continent using `.size()`.

In this case, our new data structure is a `Series`

```
grouped.size()
```

```
Continent
America     7
Asia        4
Europe     19
dtype: int64
```



Calling `.get_group()` to return just the countries in a single group, we can create a kernel density estimate of the distribution of real minimum wages in 2016 for each continent.

`grouped.groups.keys()` will return the keys from the `groupby` object

```
continents = grouped.groups.keys()

for continent in continents:
    sns.kdeplot(grouped.get_group(continent).T.loc['2015'].unstack(), label=continent,
 ↪ fill=True)

plt.title('Real minimum wages in 2015')
plt.xlabel('US dollars')
plt.legend()
plt.show()
```

144.5 Final Remarks

This lecture has provided an introduction to some of pandas' more advanced features, including multiindices, merging, grouping and plotting.

Other tools that may be useful in panel data analysis include xarray, a python package that extends pandas to N-dimensional data structures.

144.6 Exercises

Exercise 144.6.1

In these exercises, you'll work with a dataset of employment rates in Europe by age and sex from Eurostat.

The dataset can be accessed with the following link:

```
url3 = 'https://raw.githubusercontent.com/QuantEcon/data-lectures/main/lectures/
↪employ.csv'
```

Reading in the CSV file returns a panel dataset in long format. Use `.pivot_table()` to construct a wide format dataframe with a `MultiIndex` in the columns.

Start off by exploring the dataframe and the variables available in the `MultiIndex` levels.

Write a program that quickly returns all values in the `MultiIndex`.

Solution

```
employ = pd.read_csv(url3)
employ = employ.pivot_table(values='Value',
                            index=['DATE'],
                            columns=['UNIT','AGE', 'SEX', 'INDIC_EM', 'GEO'])
employ.index = pd.to_datetime(employ.index) # ensure that dates are datetime format
employ.head()
```

```
UNIT       Percentage of total population                   ...  \
AGE                    From 15 to 24 years                  ...

2011-01-01       4,164.00

[5 rows x 1440 columns]
```

This is a large dataset so it is useful to explore the levels and variables available

```
employ.columns.names
```

```
FrozenList(['UNIT', 'AGE', 'SEX', 'INDIC_EM', 'GEO'])
```

Variables within levels can be quickly retrieved with a loop

```
for name in employ.columns.names:
    print(name, employ.columns.get_level_values(name).unique())
```

```
UNIT Index(['Percentage of total population', 'Thousand persons'], dtype='str',␣
 ↪name='UNIT')
AGE Index(['From 15 to 24 years', 'From 25 to 54 years', 'From 55 to 64 years'],
 ↪ dtype='str', name='AGE')
SEX Index(['Females', 'Males', 'Total'], dtype='str', name='SEX')
INDIC_EM Index(['Active population', 'Total employment (resident population␣
 ↪concept - LFS)'], dtype='str', name='INDIC_EM')
GEO Index(['Austria', 'Belgium', 'Bulgaria', 'Croatia', 'Cyprus', 'Czech␣
 ↪Republic',
       'Denmark', 'Estonia', 'Euro area (17 countries)',
       'Euro area (18 countries)', 'Euro area (19 countries)',
       'European Union (15 countries)', 'European Union (27 countries)',
       'European Union (28 countries)', 'Finland',
       'Former Yugoslav Republic of Macedonia, the', 'France',
       'France (metropolitan)',
       'Germany (until 1990 former territory of the FRG)', 'Greece', 'Hungary',
       'Iceland', 'Ireland', 'Italy', 'Latvia', 'Lithuania', 'Luxembourg',
       'Malta', 'Netherlands', 'Norway', 'Poland', 'Portugal', 'Romania',
       'Slovakia', 'Slovenia', 'Spain', 'Sweden', 'Switzerland', 'Turkey',
       'United Kingdom'],
      dtype='str', name='GEO')
```

Exercise 144.6.2

Filter the above dataframe to only include employment as a percentage of 'active population'.

Create a grouped boxplot using `seaborn` of employment rates in 2015 by age group and sex.

Hint

`GEO` includes both areas and countries.

Solution

To easily filter by country, swap `GEO` to the top level and sort the `MultiIndex`

```
employ.columns = employ.columns.swaplevel(0,-1)
employ = employ.sort_index(axis=1)
```

We need to get rid of a few items in `GEO` which are not countries.

A fast way to get rid of the EU areas is to use a list comprehension to find the level values in `GEO` that begin with 'Euro'

```
geo_list = employ.columns.get_level_values('GEO').unique().tolist()
countries = [x for x in geo_list if not x.startswith('Euro')]
employ = employ[countries]
employ.columns.get_level_values('GEO').unique()
```

```
Index(['Austria', 'Belgium', 'Bulgaria', 'Croatia', 'Cyprus', 'Czech Republic',
       'Denmark', 'Estonia', 'Finland',
       'Former Yugoslav Republic of Macedonia, the', 'France',
       'France (metropolitan)',
       'Germany (until 1990 former territory of the FRG)', 'Greece', 'Hungary',
       'Iceland', 'Ireland', 'Italy', 'Latvia', 'Lithuania', 'Luxembourg',
       'Malta', 'Netherlands', 'Norway', 'Poland', 'Portugal', 'Romania',
       'Slovakia', 'Slovenia', 'Spain', 'Sweden', 'Switzerland', 'Turkey',
       'United Kingdom'],
      dtype='str', name='GEO')
```

Select only percentage employed in the active population from the dataframe

```
employ_f = employ.xs(('Percentage of total population', 'Active population'),
                     level=('UNIT', 'INDIC_EM'),
                     axis=1)
employ_f.head()
```

```
GEO                    Austria                ...      United Kingdom        \

LINEAR REGRESSION IN PYTHON

Contents

- *Linear Regression in Python*
  - *Overview*
  - *Simple Linear Regression*
  - *Extending the Linear Regression Model*
  - *Endogeneity*
  - *Summary*
  - *Exercises*

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install linearmodels
```

145.1 Overview

Linear regression is a standard tool for analyzing the relationship between two or more variables.

In this lecture, we'll use the Python package `statsmodels` to estimate, interpret, and visualize linear regression models.

Along the way, we'll discuss a variety of topics, including

- simple and multivariate linear regression
- visualization
- endogeneity and omitted variable bias
- two-stage least squares

As an example, we will replicate results from Acemoglu, Johnson and Robinson's seminal paper [Acemoglu *et al.*, 2001].

- You can download a copy here.

In the paper, the authors emphasize the importance of institutions in economic development.

The main contribution is the use of settler mortality rates as a source of *exogenous* variation in institutional differences.

Such variation is needed to determine whether it is institutions that give rise to greater economic growth, rather than the other way around.

Let's start with some imports:

```
import matplotlib.pyplot as plt
import numpy as np
import pandas as pd
import statsmodels.api as sm
from statsmodels.iolib.summary2 import summary_col
from linearmodels.iv import IV2SLS
import seaborn as sns
sns.set_theme()
```

145.1.1 Prerequisites

This lecture assumes you are familiar with basic econometrics.

For an introductory text covering these topics, see, for example, [Wooldridge, 2015].

145.2 Simple Linear Regression

[Acemoglu *et al.*, 2001] wish to determine whether or not differences in institutions can help to explain observed economic outcomes.

How do we measure *institutional differences* and *economic outcomes*?

In this paper,

- economic outcomes are proxied by log GDP per capita in 1995, adjusted for exchange rates.
- institutional differences are proxied by an index of protection against expropriation on average over 1985-95, constructed by the Political Risk Services Group.

These variables and other data used in the paper are available for download on Daron Acemoglu's webpage.

We will use pandas' `.read_stata()` function to read in data contained in the `.dta` files to dataframes

```
df1 = pd.read_stata('https://github.com/QuantEcon/data-lectures/raw/main/lectures/
↪maketable1.dta')
df1.head()
```

```
  shortnam    euro1900  excolony    avexpr  logpgp95  cons1  cons90  democ00a  \

2      NaN         NaN       NaN       NaN     NaN
3      3.0   68.900002  4.232656 -0.872274     1.0
4      NaN         NaN       NaN       NaN     NaN
```

Let's use a scatterplot to see whether any obvious relationship exists between GDP per capita and the protection against expropriation index

```
df1.plot(x='avexpr', y='logpgp95', kind='scatter')
plt.show()
```

The plot shows a fairly strong positive relationship between protection against expropriation and log GDP per capita.

Specifically, if higher protection against expropriation is a measure of institutional quality, then better institutions appear to be positively correlated with better economic outcomes (higher GDP per capita).

Given the plot, choosing a linear model to describe this relationship seems like a reasonable assumption.

We can write our model as

$$logpgp95_i = \beta_0 + \beta_1 avexpr_i + u_i$$

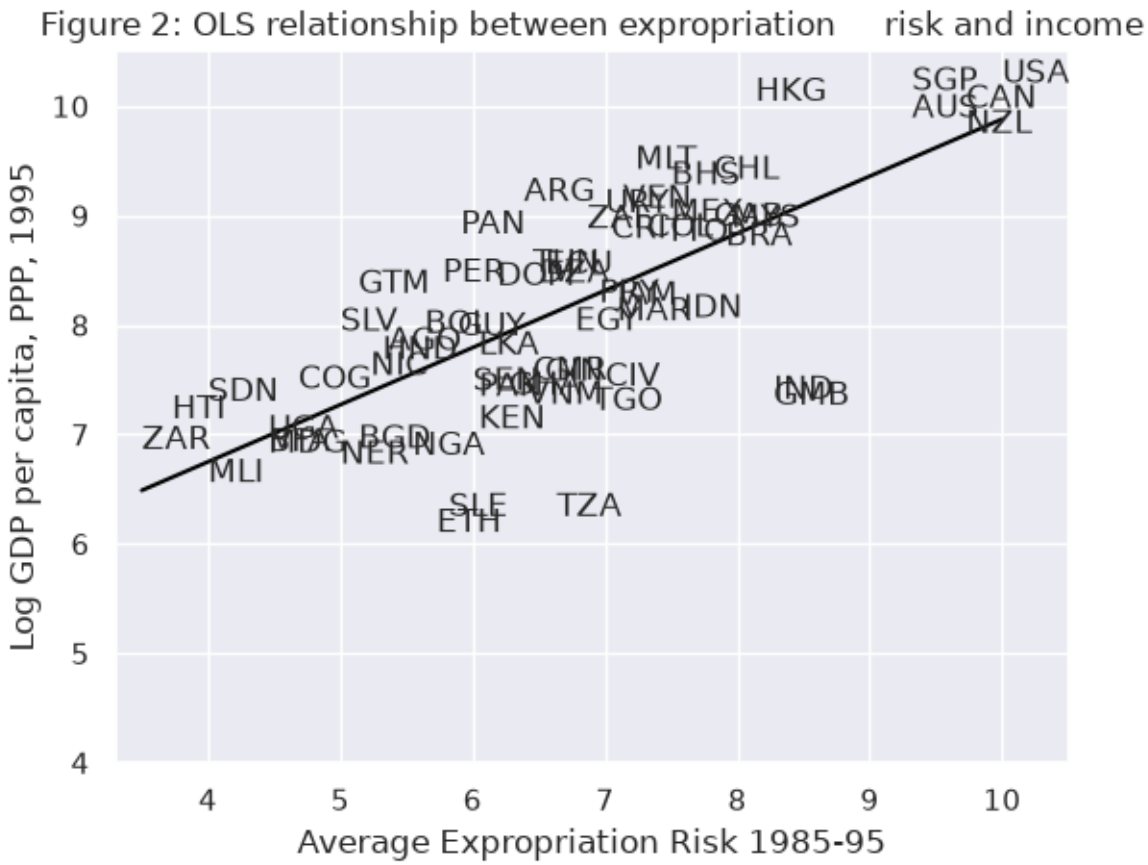
where:

- β_0 is the intercept of the linear trend line on the y-axis
- β_1 is the slope of the linear trend line, representing the *marginal effect* of protection against risk on log GDP per capita
- u_i is a random error term (deviations of observations from the linear trend due to factors not included in the model)

Visually, this linear model involves choosing a straight line that best fits the data, as in the following plot (Figure 2 in [Acemoglu *et al.*, 2001])

```
# Dropping NA's is required to use numpy's polyfit
df1_subset = df1.dropna(subset=['logpgp95', 'avexpr'])

# Use only 'base sample' for plotting purposes
df1_subset = df1_subset[df1_subset['baseco'] == 1]



X = df1_subset['avexpr']
y = df1_subset['logpgp95']
labels = df1_subset['shortnam']

# Replace markers with country labels
fig, ax = plt.subplots()
ax.scatter(X, y, marker='')

for i, label in enumerate(labels):
    ax.annotate(label, (X.iloc[i], y.iloc[i]))

# Fit a linear trend line
ax.plot(np.unique(X),
         np.poly1d(np.polyfit(X, y, 1))(np.unique(X)),
         color='black')

ax.set_xlim([3.3,10.5])
ax.set_ylim([4,10.5])
ax.set_xlabel('Average Expropriation Risk 1985-95')
ax.set_ylabel('Log GDP per capita, PPP, 1995')
ax.set_title('Figure 2: OLS relationship between expropriation \
    risk and income')
plt.show()
```

The most common technique to estimate the parameters (β's) of the linear model is Ordinary Least Squares (OLS).

As the name implies, an OLS model is solved by finding the parameters that minimize **the sum of squared residuals**, i.e.

$$\min_{\hat{\beta}} \sum_{i=1}^{N} \hat{u}_i^2$$

where $\hat{u}_i$ is the difference between the observation and the predicted value of the dependent variable.

To estimate the constant term β_0, we need to add a column of 1's to our dataset (consider the equation if β_0 was replaced with $\beta_0 x_i$ and $x_i = 1$)

```
df1['const'] = 1
```

Now we can construct our model in `statsmodels` using the OLS function.

We will use `pandas` dataframes with `statsmodels`, however standard arrays can also be used as arguments

```
reg1 = sm.OLS(endog=df1['logpgp95'], exog=df1[['const', 'avexpr']], \
    missing='drop')
type(reg1)
```

```
statsmodels.regression.linear_model.OLS
```

So far we have simply constructed our model.

We need to use `.fit()` to obtain parameter estimates $\hat{\beta}_0$ and $\hat{\beta}_1$

```
results = reg1.fit()
type(results)
```

```
statsmodels.regression.linear_model.RegressionResultsWrapper
```

We now have the fitted regression model stored in `results`.

To view the OLS regression results, we can call the `.summary()` method.

Note that an observation was mistakenly dropped from the results in the original paper (see the note located in `maketable2.do` from Acemoglu's webpage), and thus the coefficients differ slightly.

```
print(results.summary())
```

```

==============================================================================

Notes:
[1] Standard Errors assume that the covariance matrix of the errors is correctly␣
↪specified.
```

From our results, we see that

- The intercept $\hat{\beta}_0 = 4.63$.
- The slope $\hat{\beta}_1 = 0.53$.
- The positive $\hat{\beta}_1$ parameter estimate implies that. institutional quality has a positive effect on economic outcomes, as we saw in the figure.
- The p-value of 0.000 for $\hat{\beta}_1$ implies that the effect of institutions on GDP is statistically significant (using p < 0.05 as a rejection rule).
- The R-squared value of 0.611 indicates that around 61% of variation in log GDP per capita is explained by protection against expropriation.

Using our parameter estimates, we can now write our estimated relationship as

$$\widehat{logpgp95}_i = 4.63 + 0.53 \, avexpr_i$$

This equation describes the line that best fits our data, as shown in Figure 2.

We can use this equation to predict the level of log GDP per capita for a value of the index of expropriation protection.

For example, for a country with an index value of 7.07 (the average for the dataset), we find that their predicted level of log GDP per capita in 1995 is 8.38.

```
mean_expr = np.mean(df1_subset['avexpr'])
mean_expr
```

```
np.float32(6.515625)
```

```
predicted_logpdp95 = 4.63 + 0.53 * 7.07
predicted_logpdp95
```

```
8.3771
```

An easier (and more accurate) way to obtain this result is to use `.predict()` and set $constant = 1$ and $avexpr_i = mean_expr$

```
results.predict(exog=[1, mean_expr])
```

```
array([8.09156367])
```

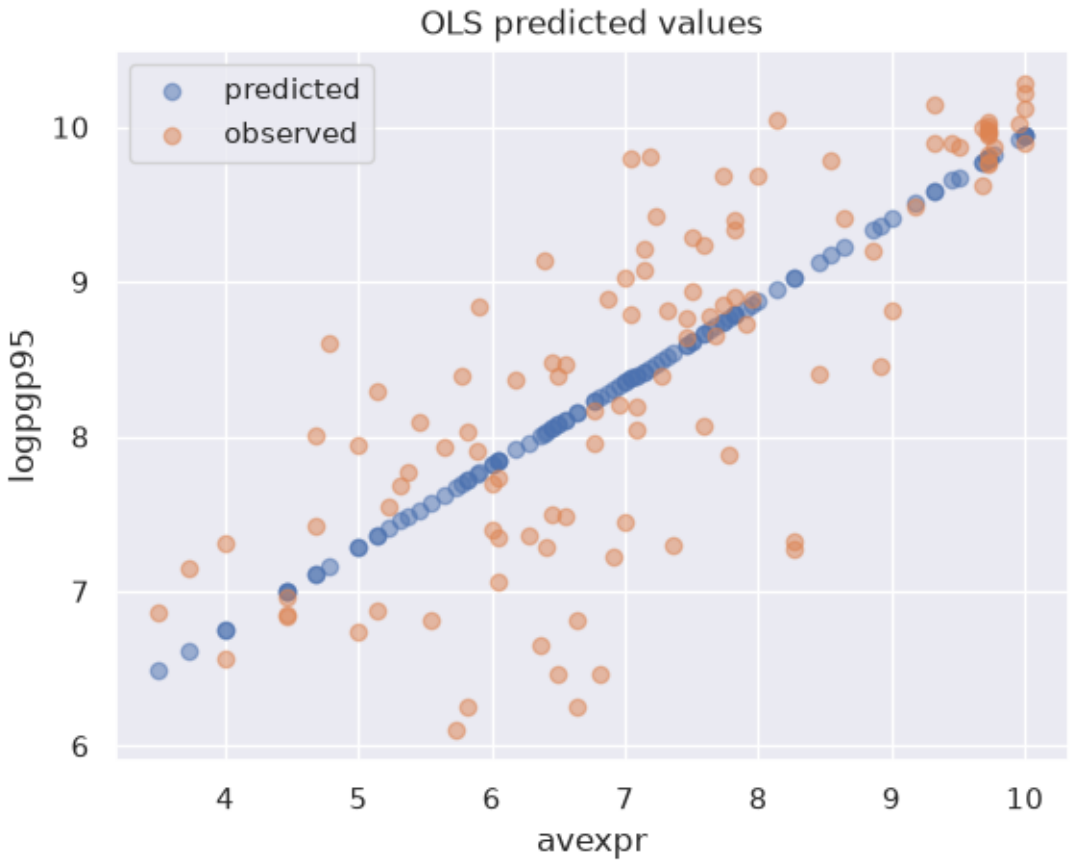
We can obtain an array of predicted $logpgp95_i$ for every value of $avexpr_i$ in our dataset by calling `.predict()` on our results.

Plotting the predicted values against $avexpr_i$ shows that the predicted values lie along the linear line that we fitted above.

The observed values of $logpgp95_i$ are also plotted for comparison purposes

```
# Drop missing observations from whole sample

df1_plot = df1.dropna(subset=['logpgp95', 'avexpr'])



# Plot predicted values

fix, ax = plt.subplots()
ax.scatter(df1_plot['avexpr'], results.predict(), alpha=0.5,
        label='predicted')

# Plot observed values

ax.scatter(df1_plot['avexpr'], df1_plot['logpgp95'], alpha=0.5,
        label='observed')

ax.legend()
ax.set_title('OLS predicted values')
ax.set_xlabel('avexpr')
ax.set_ylabel('logpgp95')
plt.show()
```

145.3 Extending the Linear Regression Model

So far we have only accounted for institutions affecting economic performance - almost certainly there are numerous other factors affecting GDP that are not included in our model.

Leaving out variables that affect $logpgp95_i$ will result in **omitted variable bias**, yielding biased and inconsistent parameter estimates.

We can extend our bivariate regression model to a **multivariate regression model** by adding in other factors that may affect $logpgp95_i$.

[Acemoglu *et al.*, 2001] consider other factors such as:

- the effect of climate on economic outcomes; latitude is used to proxy this
- differences that affect both economic performance and institutions, eg. cultural, historical, etc.; controlled for with the use of continent dummies

Let's estimate some of the extended models considered in the paper (Table 2) using data from `maketable2.dta`

```
df2 = pd.read_stata('https://github.com/QuantEcon/data-lectures/raw/main/lectures/
↪maketable2.dta')

# Add constant term to dataset
df2['const'] = 1
```

(continues on next page)

(continued from previous page)

```
# Create lists of variables to be used in each regression
X1 = ['const', 'avexpr']
X2 = ['const', 'avexpr', 'lat_abst']
X3 = ['const', 'avexpr', 'lat_abst', 'asia', 'africa', 'other']

# Estimate an OLS regression for each set of variables
reg1 = sm.OLS(df2['logpgp95'], df2[X1], missing='drop').fit()
reg2 = sm.OLS(df2['logpgp95'], df2[X2], missing='drop').fit()
reg3 = sm.OLS(df2['logpgp95'], df2[X3], missing='drop').fit()
```

Now that we have fitted our model, we will use `summary_col` to display the results in a single table (model numbers correspond to those in the paper)

```
info_dict={'R-squared' : lambda x: f"{x.rsquared:.2f}",
           'No. observations' : lambda x: f"{int(x.nobs):d}"}

results_table = summary_col(results=[reg1,reg2,reg3],
                            float_format='%0.2f',
                            stars = True,
                            model_names=['Model 1',
                                         'Model 3',
                                         'Model 4'],
                            info_dict=info_dict,
                            regressor_order=['const',
                                             'avexpr',
                                             'lat_abst',
                                             'asia',
                                             'africa'])

results_table.add_title('Table 2 - OLS Regressions')

print(results_table)
```

```

```

145.4 Endogeneity

As [Acemoglu *et al.*, 2001] discuss, the OLS models likely suffer from **endogeneity** issues, resulting in biased and inconsistent model estimates.

Namely, there is likely a two-way relationship between institutions and economic outcomes:

- richer countries may be able to afford or prefer better institutions
- variables that affect income may also be correlated with institutional differences
- the construction of the index may be biased; analysts may be biased towards seeing countries with higher income having better institutions

To deal with endogeneity, we can use **two-stage least squares (2SLS) regression**, which is an extension of OLS regression.

This method requires replacing the endogenous variable $avexpr_i$ with a variable that is:

1. correlated with $avexpr_i$
2. not correlated with the error term (ie. it should not directly affect the dependent variable, otherwise it would be correlated with u_i due to omitted variable bias)

The new set of regressors is called an **instrument**, which aims to remove endogeneity in our proxy of institutional differences.

The main contribution of [Acemoglu *et al.*, 2001] is the use of settler mortality rates to instrument for institutional differences.

They hypothesize that higher mortality rates of colonizers led to the establishment of institutions that were more extractive in nature (less protection against expropriation), and these institutions still persist today.

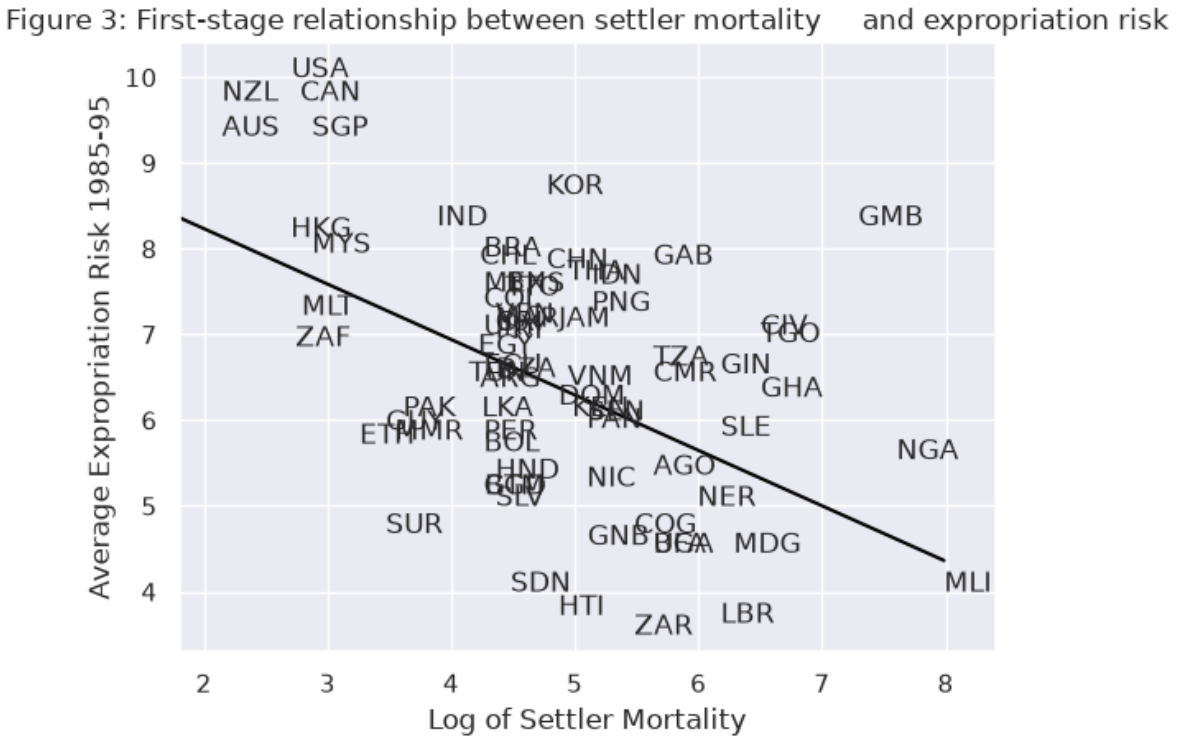
Using a scatterplot (Figure 3 in [Acemoglu *et al.*, 2001]), we can see protection against expropriation is negatively correlated with settler mortality rates, coinciding with the authors' hypothesis and satisfying the first condition of a valid instrument.

```
# Dropping NA's is required to use numpy's polyfit
df1_subset2 = df1.dropna(subset=['logem4', 'avexpr'])

X = df1_subset2['logem4']
y = df1_subset2['avexpr']
labels = df1_subset2['shortnam']

# Replace markers with country labels
fig, ax = plt.subplots()
ax.scatter(X, y, marker='')

for i, label in enumerate(labels):
    ax.annotate(label, (X.iloc[i], y.iloc[i]))



# Fit a linear trend line
ax.plot(np.unique(X),
         np.poly1d(np.polyfit(X, y, 1))(np.unique(X)),
         color='black')

ax.set_xlim([1.8,8.4])
ax.set_ylim([3.3,10.4])
ax.set_xlabel('Log of Settler Mortality')
ax.set_ylabel('Average Expropriation Risk 1985-95')
ax.set_title('Figure 3: First-stage relationship between settler mortality \
```

(continues on next page)

(continued from previous page)

```
    and expropriation risk')
plt.show()
```

The second condition may not be satisfied if settler mortality rates in the 17th to 19th centuries have a direct effect on current GDP (in addition to their indirect effect through institutions).

For example, settler mortality rates may be related to the current disease environment in a country, which could affect current economic performance.

[Acemoglu *et al.*, 2001] argue this is unlikely because:

- The majority of settler deaths were due to malaria and yellow fever and had a limited effect on local people.
- The disease burden on local people in Africa or India, for example, did not appear to be higher than average, supported by relatively high population densities in these areas before colonization.

As we appear to have a valid instrument, we can use 2SLS regression to obtain consistent and unbiased parameter estimates.

First stage

The first stage involves regressing the endogenous variable ($avexpr_i$) on the instrument.

The instrument is the set of all exogenous variables in our model (and not just the variable we have replaced).

Using model 1 as an example, our instrument is simply a constant and settler mortality rates $logem4_i$.

Therefore, we will estimate the first-stage regression as

$$avexpr_i = \delta_0 + \delta_1 logem4_i + v_i$$

The data we need to estimate this equation is located in `maketable4.dta` (only complete data, indicated by `baseco = 1`, is used for estimation)

```
# Import and select the data
df4 = pd.read_stata('https://github.com/QuantEcon/data-lectures/raw/main/lectures/
 ↪maketable4.dta')
df4 = df4[df4['baseco'] == 1]

# Add a constant variable
df4['const'] = 1

# Fit the first stage regression and print summary
results_fs = sm.OLS(df4['avexpr'],
                    df4[['const', 'logem4']],
                    missing='drop').fit()
print(results_fs.summary())
```

```

```

Second stage

We need to retrieve the predicted values of $avexpr_i$ using `.predict()`.

We then replace the endogenous variable $avexpr_i$ with the predicted values $\widehat{avexpr}_i$ in the original linear model.

Our second stage regression is thus

$$logpgp95_i = \beta_0 + \beta_1 \widehat{avexpr}_i + u_i$$

```
df4['predicted_avexpr'] = results_fs.predict()

results_ss = sm.OLS(df4['logpgp95'],
                    df4[['const', 'predicted_avexpr']]).fit()
print(results_ss.summary())
```

Notes:
[1] Standard Errors assume that the covariance matrix of the errors is correctly␣
↪specified.
```

The second-stage regression results give us an unbiased and consistent estimate of the effect of institutions on economic outcomes.

The result suggests a stronger positive relationship than what the OLS results indicated.

Note that while our parameter estimates are correct, our standard errors are not and for this reason, computing 2SLS 'manually' (in stages with OLS) is not recommended.

We can correctly estimate a 2SLS regression in one step using the linearmodels package, an extension of `statsmodels`

Note that when using `IV2SLS`, the exogenous and instrument variables are split up in the function arguments (whereas before the instrument included exogenous variables)

```
iv = IV2SLS(dependent=df4['logpgp95'],
            exog=df4['const'],
            endog=df4['avexpr'],
            instruments=df4['logem4']).fit(cov_type='unadjusted')

print(iv.summary)
```

```

```

Given that we now have consistent and unbiased estimates, we can infer from the model we have estimated that institutional differences (stemming from institutions set up during colonization) can help to explain differences in income levels across countries today.

[Acemoglu *et al.*, 2001] use a marginal effect of 0.94 to calculate that the difference in the index between Chile and Nigeria (ie. institutional quality) implies up to a 7-fold difference in income, emphasizing the significance of institutions in economic development.

145.5 Summary

We have demonstrated basic OLS and 2SLS regression in `statsmodels` and `linearmodels`.

If you are familiar with R, you may want to use the formula interface to `statsmodels`, or consider using r2py to call R from within Python.

145.6 Exercises

Exercise 145.6.1

In the lecture, we think the original model suffers from endogeneity bias due to the likely effect income has on institutional development.

Although endogeneity is often best identified by thinking about the data and model, we can formally test for endogeneity using the **Hausman test**.

We want to test for correlation between the endogenous variable, $avexpr_i$, and the errors, u_i

$$H_0 : Cov(avexpr_i, u_i) = 0 \quad (no\ endogeneity)$$
$$H_1 : Cov(avexpr_i, u_i) \neq 0 \quad (endogeneity)$$

This test is running in two stages.

First, we regress $avexpr_i$ on the instrument, $logem4_i$

$$avexpr_i = \pi_0 + \pi_1 logem4_i + \upsilon_i$$

Second, we retrieve the residuals $\hat{v}_i$ and include them in the original equation

$$logpgp95_i = \beta_0 + \beta_1 avexpr_i + \alpha\hat{v}_i + u_i$$

If α is statistically significant (with a p-value < 0.05), then we reject the null hypothesis and conclude that $avexpr_i$ is endogenous.

Using the above information, estimate a Hausman test and interpret your results.

Solution

```
# Load in data
df4 = pd.read_stata('https://github.com/QuantEcon/data-lectures/raw/main/lectures/
 ↪maketable4.dta')

# Add a constant term
df4['const'] = 1

# Estimate the first stage regression
reg1 = sm.OLS(endog=df4['avexpr'],
              exog=df4[['const', 'logem4']],
              missing='drop').fit()

# Retrieve the residuals
df4['resid'] = reg1.resid

# Estimate the second stage residuals
reg2 = sm.OLS(endog=df4['logpgp95'],
              exog=df4[['const', 'avexpr', 'resid']],
              missing='drop').fit()

print(reg2.summary())
```

```

Kurtosis:                       4.873   Cond. No.                         53.8
==============================================================================

Notes:
[1] Standard Errors assume that the covariance matrix of the errors is␣
 ↪correctly specified.
```

The output shows that the coefficient on the residuals is statistically significant, indicating $avexpr_i$ is endogenous.

Exercise 145.6.2

The OLS parameter β can also be estimated using matrix algebra and `numpy` (you may need to review the numpy lecture to complete this exercise).

The linear equation we want to estimate is (written in matrix form)

$$y = X\beta + u$$

To solve for the unknown parameter β, we want to minimize the sum of squared residuals

$$\min_{\hat{\beta}} \hat{u}'\hat{u}$$

Rearranging the first equation and substituting into the second equation, we can write

$$\min_{\hat{\beta}} (Y - X\hat{\beta})'(Y - X\hat{\beta})$$

Solving this optimization problem gives the solution for the $\hat{\beta}$ coefficients

$$\hat{\beta} = (X'X)^{-1}X'y$$

Using the above information, compute $\hat{\beta}$ from model 1 using `numpy` - your results should be the same as those in the `statsmodels` output from earlier in the lecture.

Solution

```
# Load in data
df1 = pd.read_stata('https://github.com/QuantEcon/data-lectures/raw/main/lectures/
↪maketable1.dta')
df1 = df1.dropna(subset=['logpgp95', 'avexpr'])

# Add a constant term
df1['const'] = 1

# Define the X and y variables
y = np.asarray(df1['logpgp95'])
X = np.asarray(df1[['const', 'avexpr']])

# Compute β_hat
β_hat = np.linalg.solve(X.T @ X, X.T @ y)

# Print out the results from the 2 x 1 vector β_hat
print(f'β_0 = {β_hat[0]:.2}')
print(f'β_1 = {β_hat[1]:.2}')
```

```
β_0 = 4.6
β_1 = 0.53
```

It is also possible to use `np.linalg.inv(X.T @ X) @ X.T @ y` to solve for β, however `.solve()` is

preferred as it involves fewer computations.

CHAPTER

SIX

MAXIMUM LIKELIHOOD ESTIMATION

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install jax
```

146.1 Overview

In *Linear Regression in Python*, we estimated the relationship between dependent and explanatory variables using linear regression.

But what if a linear relationship is not an appropriate assumption for our model?

One widely used alternative is maximum likelihood estimation, which involves specifying a class of distributions, indexed by unknown parameters, and then using the data to pin down these parameter values.

The benefit relative to linear regression is that it allows more flexibility in the probabilistic relationships between variables.

Here we illustrate maximum likelihood by replicating Daniel Treisman's (2016) paper, Russia's Billionaires, which connects the number of billionaires in a country to its economic characteristics.

The paper concludes that Russia has a higher number of billionaires than economic factors such as market size and tax rate predict.

We'll require the following imports:

```
import numpy as np
import jax.numpy as jnp
import jax
import pandas as pd
from typing import NamedTuple

from jax.scipy.special import factorial, gammaln
from jax.scipy.stats import norm

from statsmodels.api import Poisson
from statsmodels.iolib.summary2 import summary_col

import matplotlib.pyplot as plt
from mpl_toolkits.mplot3d import Axes3D
```

146.1.1 Prerequisites

We assume familiarity with basic probability and multivariate calculus.

146.2 Set up and assumptions

Let's consider the steps we need to go through in maximum likelihood estimation and how they pertain to this study.

146.2.1 Flow of ideas

The first step with maximum likelihood estimation is to choose the probability distribution believed to be generating the data.

More precisely, we need to make an assumption as to which *parametric class* of distributions is generating the data.

- e.g., the class of all normal distributions, or the class of all gamma distributions.

Each such class is a family of distributions indexed by a finite number of parameters.

- e.g., the class of normal distributions is a family of distributions indexed by its mean $\mu \in (-\infty, \infty)$ and standard deviation $\sigma \in (0, \infty)$.

We'll let the data pick out a particular element of the class by pinning down the parameters.

The parameter estimates so produced will be called **maximum likelihood estimates**.

146.2.2 Counting billionaires

Treisman [Treisman, 2016] is interested in estimating the number of billionaires in different countries.

The number of billionaires is integer-valued.

Hence we consider distributions that take values only in the nonnegative integers.

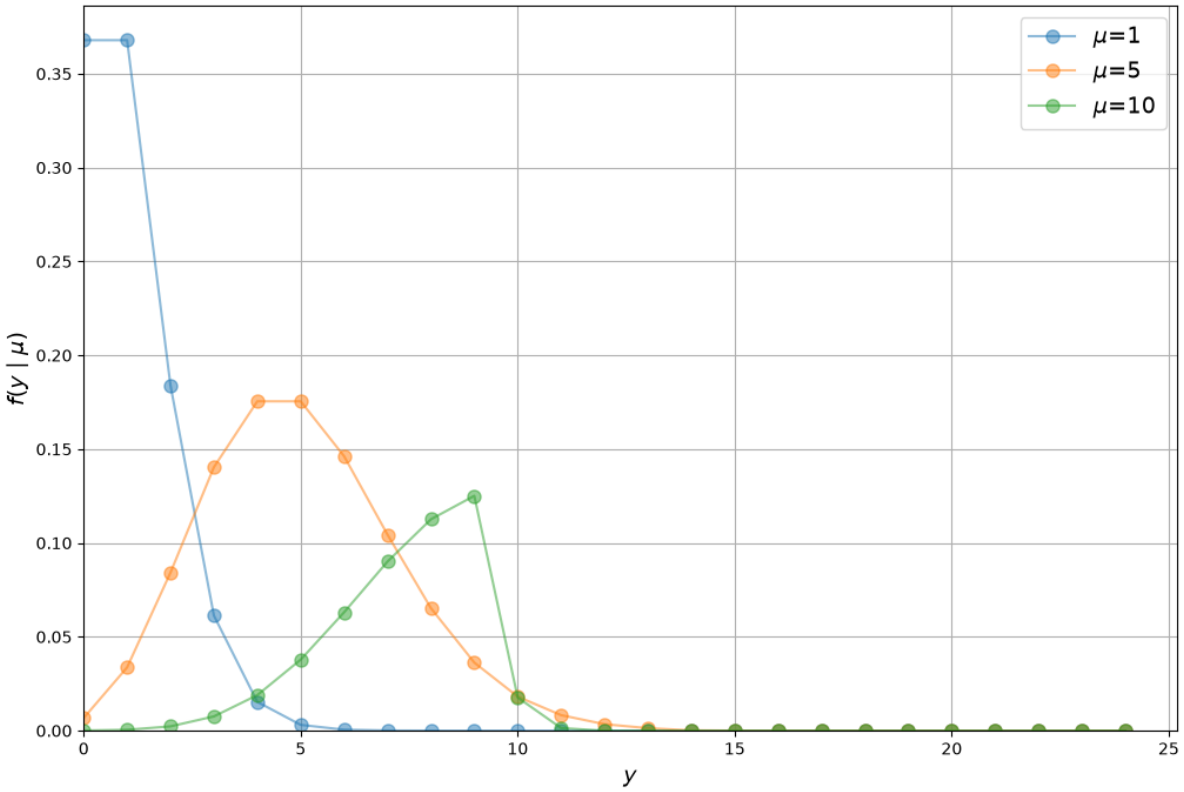
(This is one reason least squares regression is not the best tool for the present problem, since the dependent variable in linear regression is not restricted to integer values.)

One integer distribution is the Poisson distribution, the probability mass function (pmf) of which is

$$f(y) = \frac{\mu^y}{y!} e^{-\mu}, \qquad y = 0, 1, 2, \ldots, \infty$$

We can plot the Poisson distribution over y for different values of μ as follows

```
@jax.jit
def poisson_pmf(y, μ):
    return μ**y / factorial(y) * jnp.exp(-μ)
```



```
y_values = range(0, 25)

fig, ax = plt.subplots(figsize=(12, 8))

for μ in [1, 5, 10]:
    distribution = []
    for y_i in y_values:
        distribution.append(poisson_pmf(y_i, μ))
    ax.plot(
        y_values,
        distribution,
        label=rf"$\mu$={μ}",
        alpha=0.5,
        marker="o",
        markersize=8,
    )

ax.grid()
ax.set_xlabel(r"$y$", fontsize=14)
ax.set_ylabel(r"$f(y \mid \mu)$", fontsize=14)
ax.axis(xmin=0, ymin=0)
ax.legend(fontsize=14)

plt.show()
```

Notice that the Poisson distribution begins to resemble a normal distribution as the mean of y increases.

Let's have a look at the distribution of the data we'll be working with in this lecture.

Treisman's main source of data is *Forbes'* annual rankings of billionaires and their estimated net worth.

The dataset `fp.dta` can be downloaded from here or its AER page.

```
# Load in data and view
df = pd.read_stata(
    "https://github.com/QuantEcon/data-lectures/raw/main/lectures/fp.dta"
)
df.head()
```

```

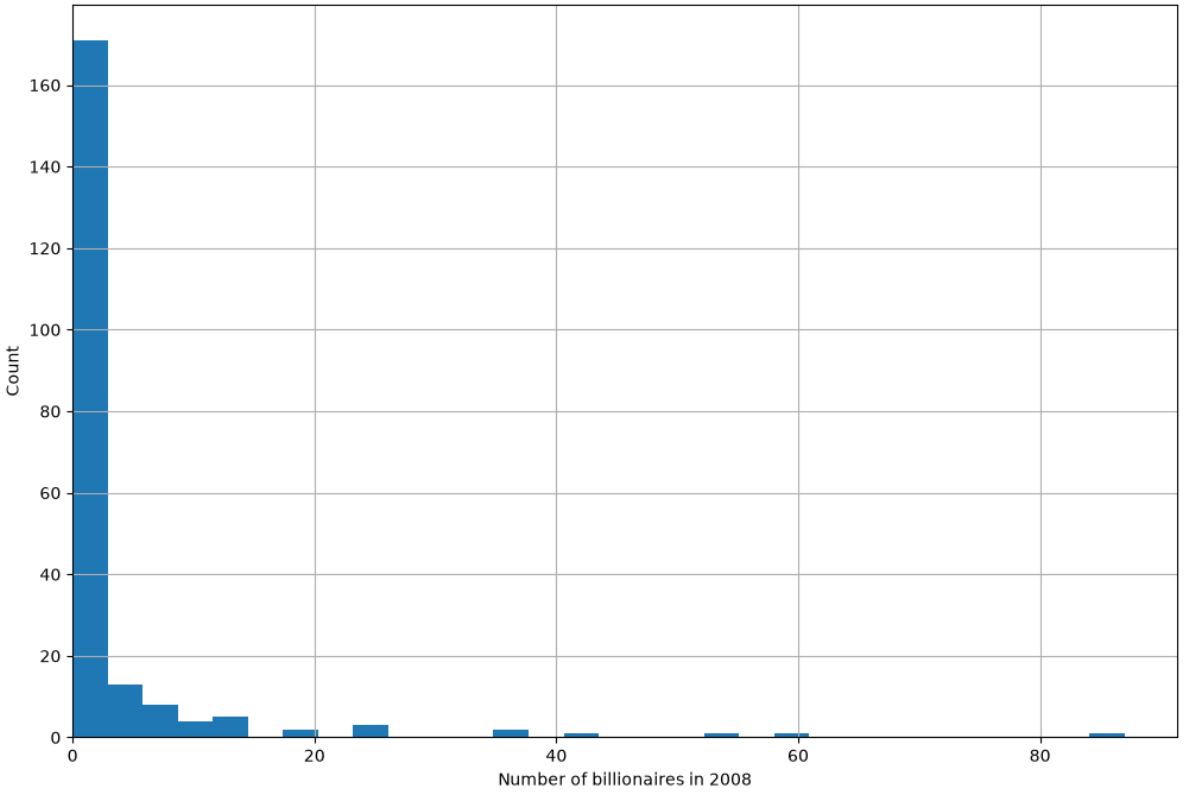
(continues on next page)

(continued from previous page)



```
2    39.799999  39.799999  4.988405   20.0    1.61      NaN
3    39.799999  39.799999  4.988405   20.0    1.61      NaN
4    39.799999  39.799999  4.988405   20.0    1.61      NaN

[5 rows x 36 columns]
```

Using a histogram, we can view the distribution of the number of billionaires per country, `numbil0`, in 2008 (the United States is dropped for plotting purposes)

```
numbil0_2008 = df[
    (df["year"] == 2008) & (df["country"] != "United States")
].loc[:, "numbil0"]

plt.subplots(figsize=(12, 8))
plt.hist(numbil0_2008, bins=30)
plt.xlim(left=0)
plt.grid()
plt.xlabel("Number of billionaires in 2008")
plt.ylabel("Count")
plt.show()
```

From the histogram, it appears that the Poisson assumption is not unreasonable (albeit with a very low μ and some outliers).

146.3 Conditional distributions

In Treisman's paper, the dependent variable — the number of billionaires y_i in country i — is modeled as a function of GDP per capita, population size, and years membership in GATT and WTO.

Hence, the distribution of y_i needs to be conditioned on the vector of explanatory variables $\mathbf{x}_i$.

The standard formulation — the so-called **Poisson regression** model — is as follows:

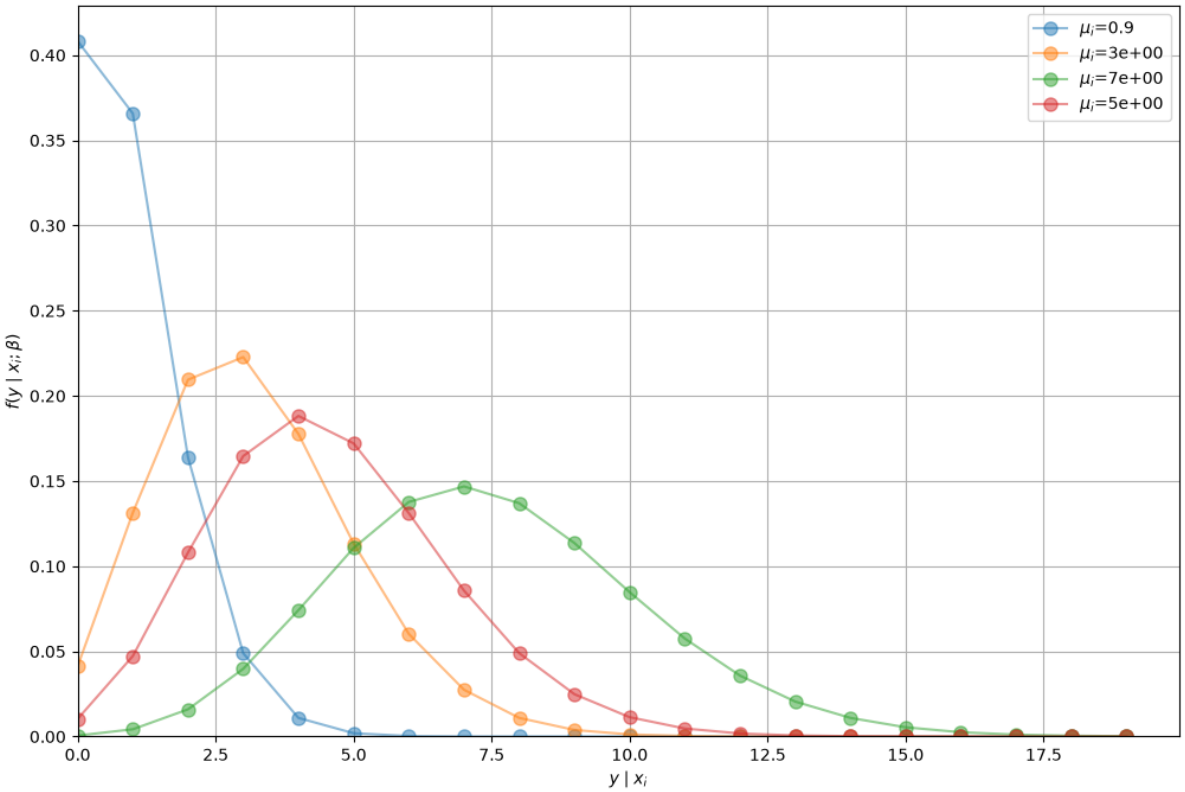
$$f(y_i \mid \mathbf{x}_i) = \frac{\mu_i^{y_i}}{y_i!} e^{-\mu_i}; \qquad y_i = 0, 1, 2, \ldots, \infty. \tag{146.1}$$

$$\text{where } \mu_i = \exp(\mathbf{x}_i'\beta) = \exp(\beta_0 + \beta_1 x_{i1} + \ldots + \beta_k x_{ik})$$

To illustrate the idea that the distribution of y_i depends on $\mathbf{x}_i$ let's run a simple simulation.

We use our `poisson_pmf` function from above and arbitrary values for β and $\mathbf{x}_i$

```
y_values = range(0, 20)



# Define a parameter vector with estimates
β = jnp.array([0.26, 0.18, 0.25, -0.1, -0.22])

# Create some observations X
datasets = [
    jnp.array([0, 1, 1, 1, 2]),
    jnp.array([2, 3, 2, 4, 0]),
    jnp.array([3, 4, 5, 3, 2]),
    jnp.array([6, 5, 4, 4, 7]),
]

fig, ax = plt.subplots(figsize=(12, 8))

for X in datasets:
    μ = jnp.exp(X @ β)
    distribution = []
    for y_i in y_values:
        distribution.append(poisson_pmf(y_i, μ))
    ax.plot(
        y_values,
        distribution,
        label=rf"$\mu_i$={μ:.1}",
        marker="o",
        markersize=8,
        alpha=0.5,
    )

ax.grid()
ax.legend()
ax.set_xlabel(r"$y \mid x_i$")
ax.set_ylabel(r"$f(y \mid x_i; \beta )$")
ax.axis(xmin=0, ymin=0)
plt.show()
```

We can see that the distribution of y_i is conditional on $\mathbf{x}_i$ (μ_i is no longer constant).

146.4 Maximum likelihood estimation

In our model for number of billionaires, the conditional distribution contains 4 ($k = 4$) parameters that we need to estimate.

We will label our entire parameter vector as β where

$$\beta = \begin{bmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \\ \beta_3 \end{bmatrix}$$

To estimate the model using MLE, we want to maximize the likelihood that our estimate $\hat{\beta}$ is the true parameter β.

Intuitively, we want to find the $\hat{\beta}$ that best fits our data.

First, we need to construct the likelihood function $\mathcal{L}(\beta)$, which is similar to a joint probability density function.

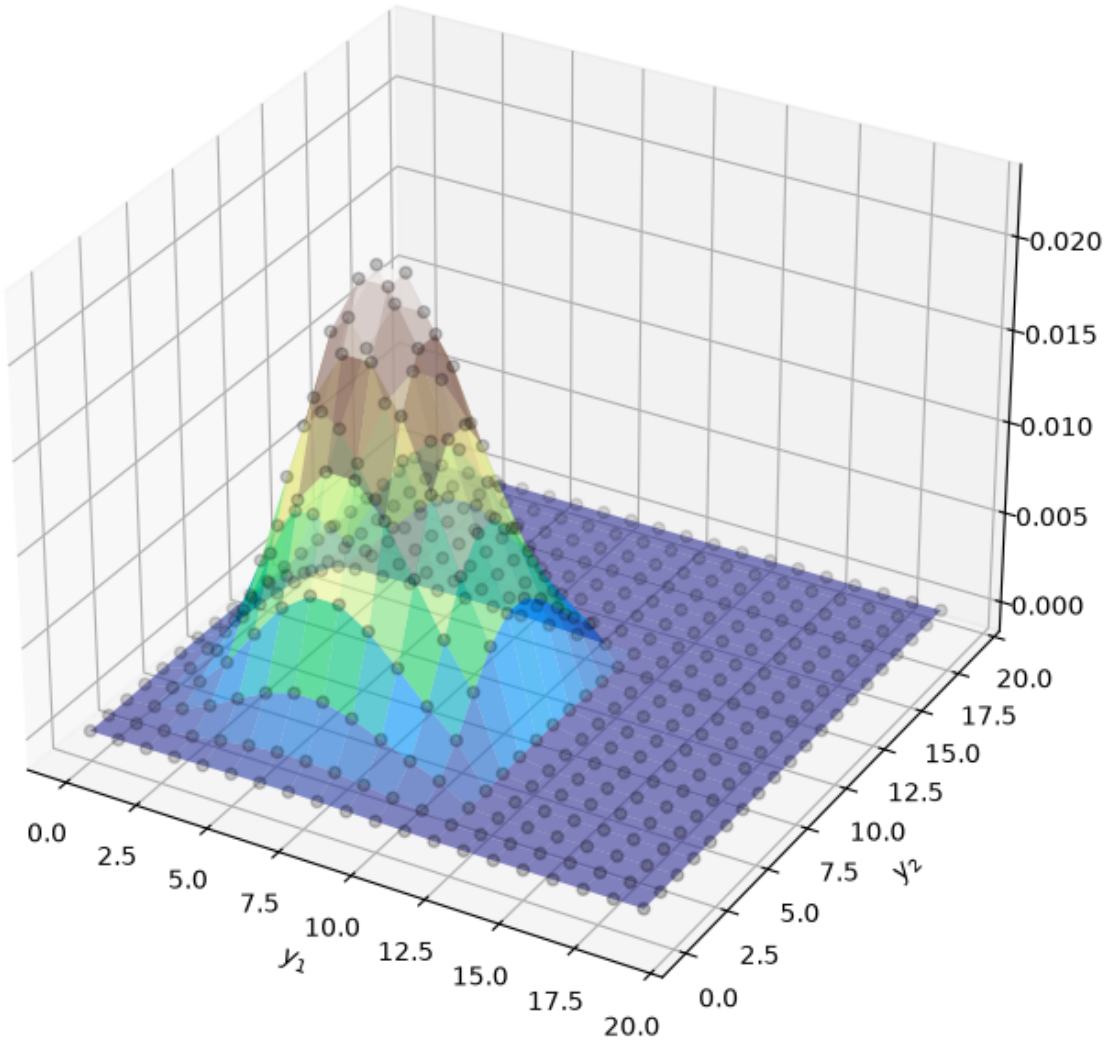
Assume we have some data $y_i = \{y_1, y_2\}$ and $y_i \sim f(y_i)$.

If y_1 and y_2 are independent, the joint pmf of these data is $f(y_1, y_2) = f(y_1) \cdot f(y_2)$.

If y_i follows a Poisson distribution with $\lambda = 7$, we can visualize the joint pmf like so

```
def plot_joint_poisson(μ=7, y_n=20):
    yi_values = jnp.arange(0, y_n, 1)
```

(continues on next page)



(continued from previous page)

```
    # Create coordinate points of X and Y
    X, Y = jnp.meshgrid(yi_values, yi_values)

    # Multiply distributions together
    Z = poisson_pmf(X, μ) * poisson_pmf(Y, μ)

    fig = plt.figure(figsize=(12, 8))
    ax = fig.add_subplot(111, projection="3d")
    ax.plot_surface(X, Y, Z.T, cmap="terrain", alpha=0.6)
    ax.scatter(X, Y, Z.T, color="black", alpha=0.5, linewidths=1)
    ax.set(xlabel=r"$y_1$", ylabel=r"$y_2$")
    ax.set_zlabel(r"$f(y_1, y_2)$", labelpad=10)
    plt.show()

plot_joint_poisson(μ=7, y_n=20)
```

Similarly, the joint pmf of our data (which is distributed as a conditional Poisson distribution) can be written as

$$f(y_1, y_2, \ldots, y_n \mid \mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n; \beta) = \prod_{i=1}^{n} \frac{\mu_i^{y_i}}{y_i!} e^{-\mu_i}$$

y_i is conditional on both the values of $\mathbf{x}_i$ and the parameters β.

The likelihood function is the same as the joint pmf, but treats the parameter β as a random variable and takes the observations $(y_i, \mathbf{x}_i)$ as given

$$\begin{aligned}\mathcal{L}(\beta \mid y_1, y_2, \ldots, y_n \; ; \; \mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n) &= \prod_{i=1}^{n} \frac{\mu_i^{y_i}}{y_i!} e^{-\mu_i} \\ &= f(y_1, y_2, \ldots, y_n \mid \; \mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n; \beta)\end{aligned}$$

Now that we have our likelihood function, we want to find the $\widehat{\beta}$ that yields the maximum likelihood value

$$\max_{\beta} \mathcal{L}(\beta)$$

In doing so it is generally easier to maximize the log-likelihood (consider differentiating $f(x) = x \exp(x)$ vs. $f(x) = \log(x) + x$).

Given that taking a logarithm is a monotone increasing transformation, a maximizer of the likelihood function will also be a maximizer of the log-likelihood function.

In our case the log-likelihood is

$$\begin{aligned}\log \mathcal{L}(\beta) &= \log \Big(f(y_1; \beta) \cdot f(y_2; \beta) \cdot \ldots \cdot f(y_n; \beta) \Big) \\ &= \sum_{i=1}^{n} \log f(y_i; \beta) \\ &= \sum_{i=1}^{n} \log \Big(\frac{\mu_i^{y_i}}{y_i!} e^{-\mu_i} \Big) \\ &= \sum_{i=1}^{n} y_i \log \mu_i - \sum_{i=1}^{n} \mu_i - \sum_{i=1}^{n} \log y_i!\end{aligned}$$

The MLE of the Poisson for $\widehat{\beta}$ can be obtained by solving

$$\max_{\beta} \Big(\sum_{i=1}^{n} y_i \log \mu_i - \sum_{i=1}^{n} \mu_i - \sum_{i=1}^{n} \log y_i! \Big)$$

However, no analytical solution exists to the above problem – to find the MLE we need to use numerical methods.

146.5 MLE with numerical methods

Many distributions do not have nice, analytical solutions and therefore require numerical methods to solve for parameter estimates.

One such numerical method is the Newton-Raphson algorithm.

Our goal is to find the maximum likelihood estimate $\widehat{\beta}$.

At $\widehat{\beta}$, the first derivative of the log-likelihood function will be equal to 0.

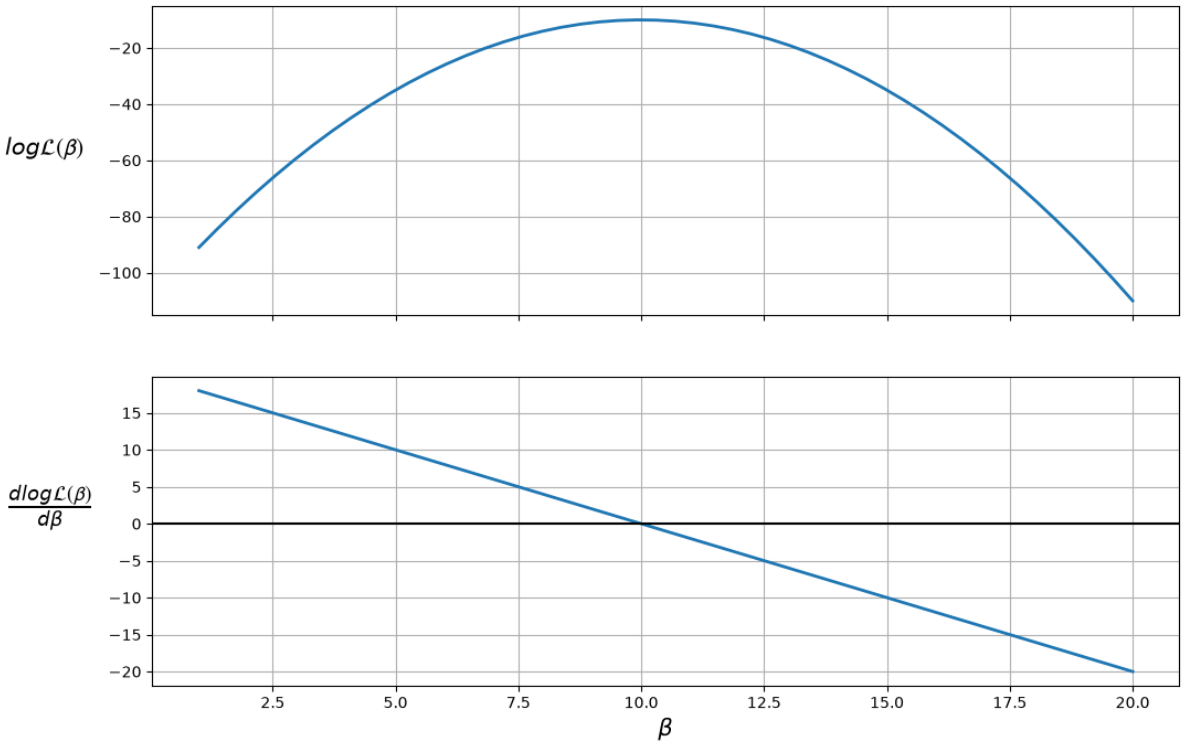
Let's illustrate this by supposing

$$\log \mathcal{L}(\beta) = -(\beta - 10)^2 - 10$$

```
@jax.jit
def logL(β):
    return -((β - 10) ** 2) - 10
```

To find the value of the gradient of the above function, we can use jax.grad which auto-differentiates the given function.

We further use jax.vmap which vectorizes the given function i.e. the function acting upon scalar inputs can now be used with vector inputs.



```
dlogL = jax.vmap(jax.grad(logL))
```

```
β = jnp.linspace(1, 20)

fig, (ax1, ax2) = plt.subplots(2, sharex=True, figsize=(12, 8))

ax1.plot(β, logL(β), lw=2)
ax2.plot(β, dlogL(β), lw=2)

ax1.set_ylabel(
    r"$log \mathcal{L(\beta)}$", rotation=0, labelpad=35, fontsize=15
)
ax2.set_ylabel(
    r"$\frac{dlog \mathcal{L(\beta)}}{d \beta}$ ",
    rotation=0,
    labelpad=35,
    fontsize=19,
)
ax2.set_xlabel(r"$\beta$", fontsize=15)
ax1.grid(), ax2.grid()
plt.axhline(c="black")
plt.show()
```

The plot shows that the maximum likelihood value (the top plot) occurs when $\frac{d \log \mathcal{L}(\beta)}{d\beta} = 0$ (the bottom plot).

Therefore, the likelihood is maximized when $\beta = 10$.

We can also ensure that this value is a *maximum* (as opposed to a minimum) by checking that the second derivative (slope of the bottom plot) is negative.

The Newton-Raphson algorithm finds a point where the first derivative is 0.

To use the algorithm, we take an initial guess at the maximum value, β_0 (the OLS parameter estimates might be a reasonable guess), then

1. Use the updating rule to iterate the algorithm

$$\beta_{(k+1)} = \beta_{(k)} - H^{-1}(\beta_{(k)})G(\beta_{(k)})$$

   where:

$$G(\beta_{(k)}) = \frac{d \log \mathcal{L}(\beta_{(k)})}{d\beta_{(k)}}$$
$$H(\beta_{(k)}) = \frac{d^2 \log \mathcal{L}(\beta_{(k)})}{d\beta_{(k)} d\beta'_{(k)}}$$

2. Check whether $\beta_{(k+1)} - \beta_{(k)} < tol$
   - If true, then stop iterating and set $\widehat{\beta} = \beta_{(k+1)}$
   - If false, then update $\beta_{(k+1)}$

As can be seen from the updating equation, $\beta_{(k+1)} = \beta_{(k)}$ only when $G(\beta_{(k)}) = 0$ i.e. where the first derivative is equal to 0.

(In practice, we stop iterating when the difference is below a small tolerance threshold.)

Let's have a go at implementing the Newton-Raphson algorithm.

First, we'll create a class called `PoissonRegression` so we can easily recompute the values of the log likelihood, gradient and Hessian for every iteration

```
class PoissonRegression(NamedTuple):
    X: jnp.ndarray
    y: jnp.ndarray
```

Now we can define the log likelihood function in Python

```
@jax.jit
def logL(β, model):
    y = model.y
    μ = jnp.exp(model.X @ β)
    return jnp.sum(model.y * jnp.log(μ) - μ - jnp.log(factorial(y)))
```

To find the gradient of the `poisson_logL`, we again use jax.grad.

According to the documentation,

- `jax.jacfwd` uses forward-mode automatic differentiation, which is more efficient for "tall" Jacobian matrices, while
- `jax.jacrev` uses reverse-mode, which is more efficient for "wide" Jacobian matrices.

(The documentation also states that when matrices that are near-square, `jax.jacfwd` probably has an edge over `jax.jacrev`.)

Therefore, to find the Hessian, we can directly use `jax.jacfwd`.

```
G_logL = jax.grad(logL)
H_logL = jax.jacfwd(G_logL)
```

Our function `newton_raphson` will take a `PoissonRegression` object that has an initial guess of the parameter vector β_0.

The algorithm will update the parameter vector according to the updating rule, and recalculate the gradient and Hessian matrices at the new parameter estimates.

Iteration will end when either:

- The difference between the parameter and the updated parameter is below a tolerance level.
- The maximum number of iterations has been achieved (meaning convergence is not achieved).

So we can get an idea of what's going on while the algorithm is running, an option `display=True` is added to print out values at each iteration.

```
def newton_raphson(model, β, tol=1e-3, max_iter=100, display=True):

    i = 0
    error = 100  # Initial error value

    # Print header of output
    if display:
        header = f'{"Iteration_k":<13}{"Log-likelihood":<16}{"θ":<60}'
        print(header)
        print("-" * len(header))

    # While loop runs while any value in error is greater
    # than the tolerance until max iterations are reached
    while jnp.any(error > tol) and i < max_iter:
        H, G = jnp.squeeze(H_logL(β, model)), G_logL(β, model)
        β_new = β - (jnp.dot(jnp.linalg.inv(H), G))
        error = jnp.abs(β_new - β)
        β = β_new

        if display:
            β_list = [f"{t:.3}" for t in list(β.flatten())]
            update = f"{i:<13}{logL(β, model):<16.8}{β_list}"
            print(update)

        i += 1

    print(f"Number of iterations: {i}")
    print(f"β_hat = {β.flatten()}")

    return β
```

Let's try out our algorithm with a small dataset of 5 observations and 3 variables in $\mathbf{X}$.

```
X = jnp.array([[1, 2, 5], [1, 1, 3], [1, 4, 2], [1, 5, 2], [1, 3, 1]])

y = jnp.array([1, 0, 1, 1, 0])
```

(continues on next page)

(continued from previous page)

```
# Take a guess at initial βs
init_β = jnp.array([0.1, 0.1, 0.1])

# Create an object with Poisson model values
poi = PoissonRegression(X=X, y=y)

# Use newton_raphson to find the MLE
β_hat = newton_raphson(poi, init_β, display=True)
```

```
Iteration_k  Log-likelihood  θ
--------------------------------------------------------------------------------
 ↪------
0             -4.3447633      ['-1.49', '0.265', '0.244']
1             -3.5742412      ['-3.38', '0.528', '0.474']
2             -3.3999527      ['-5.06', '0.782', '0.702']
3             -3.3788645      ['-5.92', '0.909', '0.82']
4             -3.3783557      ['-6.07', '0.933', '0.843']
5             -3.3783555      ['-6.08', '0.933', '0.843']
6             -3.3783555      ['-6.08', '0.933', '0.843']
Number of iterations: 7
β_hat = [-6.078486   0.9334028  0.8432968]
```

As this was a simple model with few observations, the algorithm achieved convergence in only 7 iterations.

You can see that with each iteration, the log-likelihood value increased.

Remember, our objective was to maximize the log-likelihood function, which the algorithm has worked to achieve.

Also, note that the increase in $\log \mathcal{L}(\beta_{(k)})$ becomes smaller with each iteration.

This is because the gradient is approaching 0 as we reach the maximum, and therefore the numerator in our updating equation is becoming smaller.

The gradient vector should be close to 0 at $\hat{\beta}$

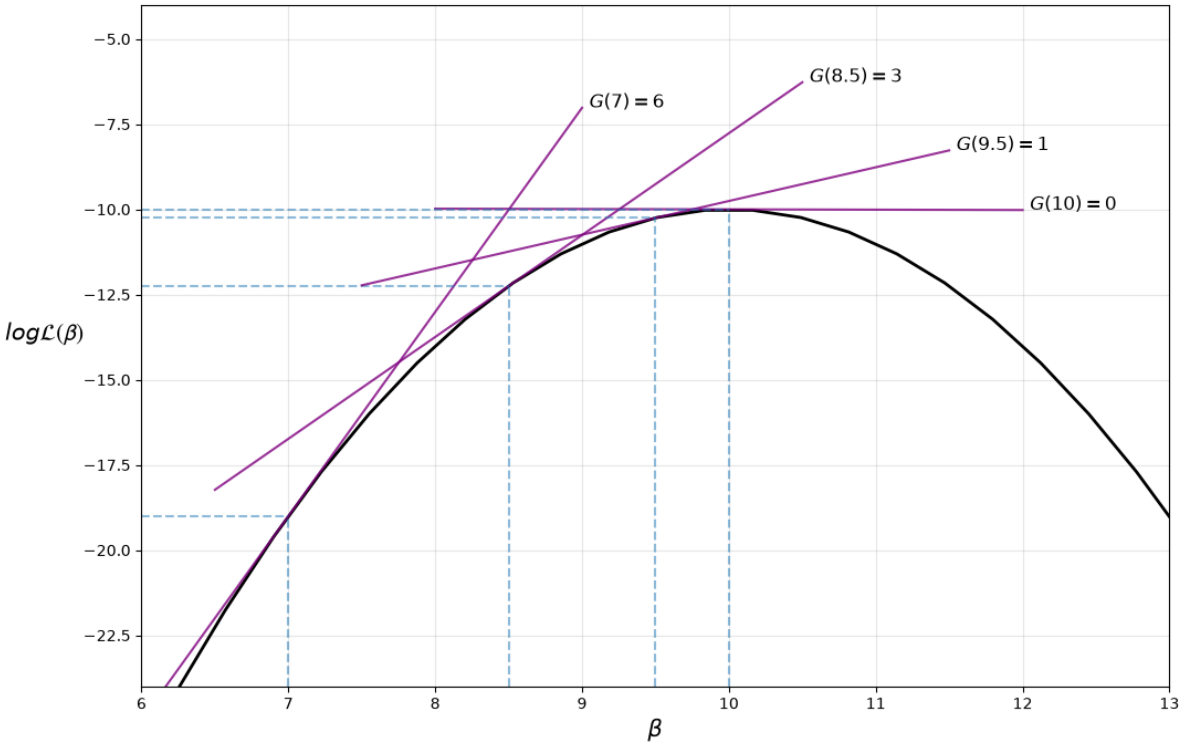
```
G_logL(β_hat, poi)
```

```
Array([ 7.4505806e-09, -2.9802322e-07,  3.7252903e-08], dtype=float32)
```

The iterative process can be visualized in the following diagram, where the maximum is found at $\beta = 10$

```
@jax.jit
def logL(x):
    return -((x - 10) ** 2) - 10

@jax.jit
def find_tangent(β, a=0.01):
    y1 = logL(β)
    y2 = logL(β + a)
    x = jnp.array([[β, 1], [β + a, 1]])
    m, c = jnp.linalg.lstsq(x, jnp.array([y1, y2]), rcond=None)[0]
    return m, c
```



```
β = jnp.linspace(2, 18)
fig, ax = plt.subplots(figsize=(12, 8))
ax.plot(β, logL(β), lw=2, c="black")
```

(continues on next page)

(continued from previous page)

```
for β in [7, 8.5, 9.5, 10]:
    β_line = jnp.linspace(β - 2, β + 2)
    m, c = find_tangent(β)
    y = m * β_line + c
    ax.plot(β_line, y, "-", c="purple", alpha=0.8)
    ax.text(β + 2.05, y[-1], rf"$G({β}) = {abs(m):.0f}$", fontsize=12)
    ax.vlines(β, -24, logL(β), linestyles="--", alpha=0.5)
    ax.hlines(logL(β), 6, β, linestyles="--", alpha=0.5)

ax.set(ylim=(-24, -4), xlim=(6, 13))
ax.set_xlabel(r"$\beta$", fontsize=15)
ax.set_ylabel(
    r"$log \mathcal{L(\beta)}$", rotation=0, labelpad=25, fontsize=15
)
ax.grid(alpha=0.3)
plt.show()
```

Note that our implementation of the Newton-Raphson algorithm is rather basic — for more robust implementations see, for example, scipy.optimize.

146.6 Maximum likelihood estimation with `statsmodels`

Now that we know what's going on under the hood, we can apply MLE to an interesting application.

We'll use the Poisson regression model in `statsmodels` to obtain a richer output with standard errors, test values, and more.

`statsmodels` uses the same algorithm as above to find the maximum likelihood estimates.

Before we begin, let's re-estimate our simple model with `statsmodels` to confirm we obtain the same coefficients and log-likelihood value.

Now, as `statsmodels` accepts only NumPy arrays, we can use `np.array` method to convert them to NumPy arrays.

```
X = jnp.array([[1, 2, 5], [1, 1, 3], [1, 4, 2], [1, 5, 2], [1, 3, 1]])

y = jnp.array([1, 0, 1, 1, 0])

y_numpy = np.array(y)
X_numpy = np.array(X)
stats_poisson = Poisson(y_numpy, X_numpy).fit()
print(stats_poisson.summary())
```

```
Optimization terminated successfully.

==============================================================================
```

Now let's replicate results from Daniel Treisman's paper, Russia's Billionaires, mentioned earlier in the lecture.

Treisman starts by estimating equation (146.1), where:

- y_i is $number\ of\ billionaires_i$
- x_{i1} is $\log GDP\ per\ capita_i$
- x_{i2} is $\log population_i$
- x_{i3} is $years\ in\ GATT_i$ – years membership in GATT and WTO (to proxy access to international markets)

The paper only considers the year 2008 for estimation.

We will set up our variables for estimation like so (you should have the data assigned to `df` from earlier in the lecture)

```
# Keep only year 2008
df = df[df["year"] == 2008]

# Add a constant
df["const"] = 1

# Variable sets
reg1 = ["const", "lngdppc", "lnpop", "gattwto08"]
reg2 = [
    "const",
    "lngdppc",
    "lnpop",
    "gattwto08",
    "lnmcap08",
    "rintr",
    "topint08",
]
reg3 = [
    "const",
    "lngdppc",
    "lnpop",
    "gattwto08",
    "lnmcap08",
    "rintr",
    "topint08",
    "nrrents",
    "roflaw",
]
```

Then we can use the `Poisson` function from `statsmodels` to fit the model.

We'll use robust standard errors as in the author's paper

```
# Specify model
poisson_reg = Poisson(df[["numbil0"]], df[reg1], missing="drop").fit(
    cov_type="HC0"
)
print(poisson_reg.summary())
```

```

```

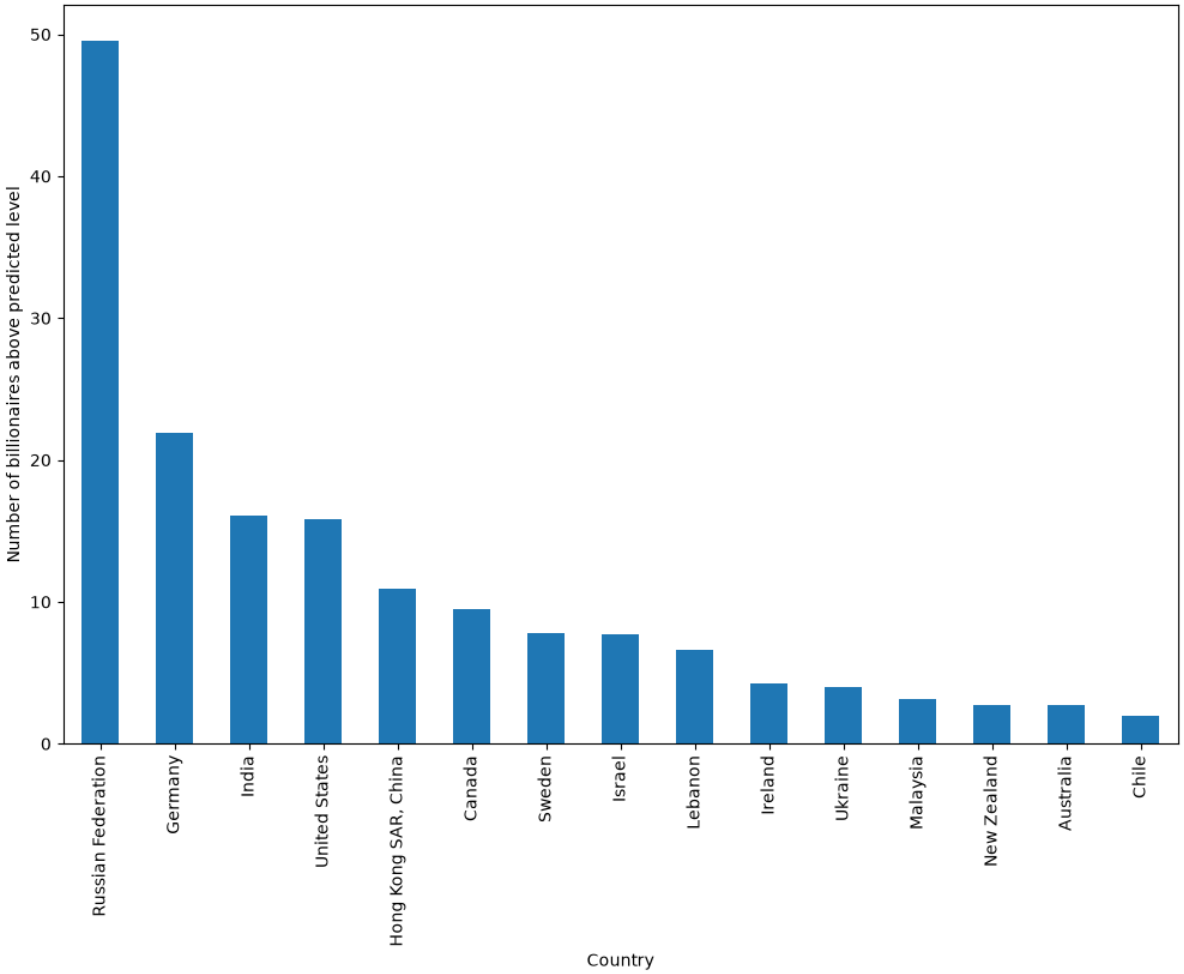
The output suggests that the frequency of billionaires is positively correlated with GDP per capita, population size, stock market capitalization, and negatively correlated with top marginal income tax rate.

To analyze our results by country, we can plot the difference between the predicted and actual values, then sort from highest to lowest and plot the first 15



```
data = [

results_df = df[data].dropna()

# Use last model (model 3)
results_df["prediction"] = results[-1].predict()

# Calculate difference
results_df["difference"] = results_df["numbil0"] - results_df["prediction"]

# Sort in descending order
results_df.sort_values("difference", ascending=False, inplace=True)

# Plot the first 15 data points
results_df[:15].plot(
    "country", "difference", kind="bar", figsize=(12, 8), legend=False
)
plt.ylabel("Number of billionaires above predicted level")
plt.xlabel("Country")
plt.show()
```

As we can see, Russia has by far the highest number of billionaires in excess of what is predicted by the model (around 50 more than expected).

Treisman uses this empirical result to discuss possible reasons for Russia's excess of billionaires, including the origination of wealth in Russia, the political climate, and the history of privatization in the years after the USSR.

146.7 Summary

In this lecture, we used Maximum Likelihood Estimation to estimate the parameters of a Poisson model.

`statsmodels` contains other built-in likelihood models such as Probit and Logit.

For further flexibility, `statsmodels` provides a way to specify the distribution manually using the `GenericLikelihoodModel` class - an example notebook can be found here.

146.8 Exercises

Exercise 146.8.1

Suppose we wanted to estimate the probability of an event y_i occurring, given some observations.

We could use a probit regression model, where the pmf of y_i is

$$f(y_i; \beta) = \mu_i^{y_i}(1-\mu_i)^{1-y_i}, \quad y_i = 0, 1$$
$$\text{where} \quad \mu_i = \Phi(\mathbf{x}_i'\beta)$$

Φ represents the **cumulative normal distribution** and constrains the predicted y_i to be between 0 and 1 (as required for a probability).

β is a vector of coefficients.

Following the example in the lecture, write a class to represent the Probit model.

To begin, find the log-likelihood function and derive the gradient and Hessian.

The `jax.scipy.stats` module `norm` contains the functions needed to compute the cdf and pdf of the normal distribution.

Solution

The log-likelihood can be written as

$$\log \mathcal{L} = \sum_{i=1}^{n} \left[y_i \log \Phi(\mathbf{x}_i'\beta) + (1-y_i) \log(1 - \Phi(\mathbf{x}_i'\beta)) \right]$$

Using the **fundamental theorem of calculus**, the derivative of a cumulative probability distribution is its marginal distribution

$$\frac{\partial}{\partial s}\Phi(s) = \phi(s)$$

where ϕ is the marginal normal distribution.

The gradient vector of the Probit model is

$$\frac{\partial \log \mathcal{L}}{\partial \beta} = \sum_{i=1}^{n} \left[y_i \frac{\phi(\mathbf{x}_i'\beta)}{\Phi(\mathbf{x}_i'\beta)} - (1-y_i)\frac{\phi(\mathbf{x}_i'\beta)}{1-\Phi(\mathbf{x}_i'\beta)} \right] \mathbf{x}_i$$

The Hessian of the Probit model is

$$\frac{\partial^2 \log \mathcal{L}}{\partial \beta \partial \beta'} = -\sum_{i=1}^{n} \phi(\mathbf{x}_i'\beta) \left[y_i \frac{\phi(\mathbf{x}_i'\beta) + \mathbf{x}_i'\beta\Phi(\mathbf{x}_i'\beta)}{[\Phi(\mathbf{x}_i'\beta)]^2} + (1-y_i)\frac{\phi(\mathbf{x}_i'\beta) - \mathbf{x}_i'\beta(1-\Phi(\mathbf{x}_i'\beta))}{[1-\Phi(\mathbf{x}_i'\beta)]^2} \right] \mathbf{x}_i\mathbf{x}_i'$$

Using these results, we can write a class for the Probit model as follows

```
class ProbitRegression(NamedTuple):
    X: jnp.ndarray
    y: jnp.ndarray
```

```
@jax.jit
def logL(β, model):
    y = model.y
    μ = norm.cdf(model.X @ β.T)
    return y @ jnp.log(μ) + (1 - y) @ jnp.log(1 - μ)
```

```
G_logL = jax.grad(logL)
H_logL = jax.jacfwd(G_logL)
```

Exercise 146.8.2

Use the following dataset and initial values of β to estimate the MLE with the Newton-Raphson algorithm developed earlier in the lecture

$$\mathbf{X} = \begin{bmatrix} 1 & 2 & 4 \\ 1 & 1 & 1 \\ 1 & 4 & 3 \\ 1 & 5 & 6 \\ 1 & 3 & 5 \end{bmatrix} \quad y = \begin{bmatrix} 1 \\ 0 \\ 1 \\ 1 \\ 0 \end{bmatrix} \quad \beta_{(0)} = \begin{bmatrix} 0.1 \\ 0.1 \\ 0.1 \end{bmatrix}$$

Verify your results with `statsmodels` - you can import the Probit function with the following import statement

```
from statsmodels.discrete.discrete_model import Probit
```

Note that the simple Newton-Raphson algorithm developed in this lecture is very sensitive to initial values, and therefore you may fail to achieve convergence with different starting values.

Solution

Here is one solution

```
X = jnp.array([[1, 2, 4], [1, 1, 1], [1, 4, 3], [1, 5, 6], [1, 3, 5]])

y = jnp.array([1, 0, 1, 1, 0])

# Take a guess at initial βs
β = jnp.array([0.1, 0.1, 0.1])

# Create a model of Probit regression
prob = ProbitRegression(y=y, X=X)

# Run Newton-Raphson algorithm
newton_raphson(prob, β)
```

```

CHAPTER

SEVEN

A LINEAR MODEL OF UNEMPLOYMENT

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

In addition to what's in Anaconda, this lecture needs the following libraries.

We first install `numpyro` and `jax`:

```
!pip install numpyro jax
```

We also install `pandas_datareader`, which we use to download data from FRED:

```
!pip install pandas_datareader
```

147.1 Overview

This lecture applies Bayesian estimation to a linear AR(1) model of the US unemployment rate.

We met the machinery in *Posterior Distributions for AR(1) Parameters*, but there the data were simulated and the focus was theoretical.

Here we work carefully through real data, organizing the lecture around a question that divided macroeconomists in the 1980s and 1990s: is unemployment a *random walk*?

In the process, we will observe an asymmetry the model cannot capture.

This will motivate a sequel lecture, titled *Unemployment Dynamics with Asymmetric Shocks*.

As in *Posterior Distributions for AR(1) Parameters* and *Non-Conjugate Priors*, we estimate by sampling posteriors with the NUTS sampler in NumPyro.

(See the *introduction to NUTS* in *Non-Conjugate Priors* for a brief account of how it works.)

Let's start with some imports.

```
import numpy as np
import matplotlib.pyplot as plt
import datetime as dt
from pandas_datareader import data as web

import jax.numpy as jnp
from jax import random
import numpyro
import numpyro.distributions as dist
from numpyro.infer import MCMC, NUTS
```

147.2 The natural rate versus hysteresis

In the early 1980s, Nelson and Plosser [1982] launched the unit-root literature.

They examined 14 macroeconomic time series and found that they could reject the random walk for only one of them.

Roughly speaking, this meant that, for most macroeconomic series, the effects of shocks looked permanent rather than transitory.

For unemployment, that view found expression in the **hysteresis hypothesis** of [Blanchard and Summers, 1986].

This hypothesis states that a shock to unemployment can be more or less permanent, because spells of joblessness erode skills and attachment to the labor force.

In contrast, the **natural rate hypothesis** of [Friedman, 1968] holds that unemployment fluctuates around a stable equilibrium rate — and hence shocks are transitory rather than permanent.

The debate matters because the two views imply different policies.

In particular, if shocks are permanent, a deep recession leaves a lasting scar, encouraging remedial action.

Here we reexamine the question with Bayesian estimation.

Note

There is an irony in the history described above.

While Nelson and Plosser [1982] fueled the unit root debate, and hence the hysteresis hypothesis, the one macroeconomic series they rejected the unit root for was the unemployment rate.

147.3 The data

We use the US civilian unemployment rate, series `UNRATE` from FRED, monthly and seasonally adjusted.

```
start, end = dt.datetime(1948, 1, 1), dt.datetime(2024, 12, 31)
unrate = web.DataReader("UNRATE", "fred", start, end)["UNRATE"]
```

The COVID-19 spike of 2020 is an extreme outlier driven by events our models know nothing about, so we drop it.

```
pre_covid = unrate[unrate.index < "2020-01-01"]
u_monthly = pre_covid.to_numpy()
print(f"{len(u_monthly)} monthly observations")
```

```
864 monthly observations
```

Here is the monthly series.

```
fig, ax = plt.subplots()
ax.plot(pre_covid.index, u_monthly, lw=2)
ax.set_xlabel('year')
ax.set_ylabel('unemployment rate (%)')
plt.show()
```

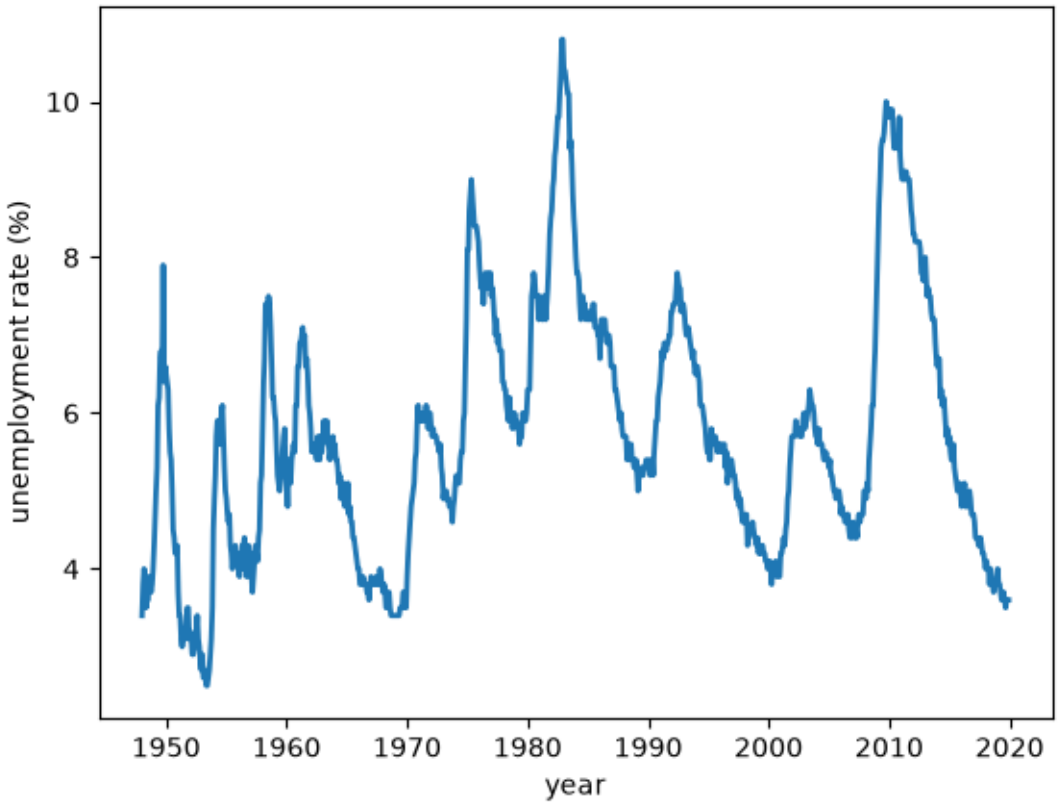

Fig. 147.1: US monthly unemployment rate, 1948–2019

As Fig. 147.1 shows, the rate rises sharply in recessions and drifts down in recoveries, but it always stays inside a band — roughly 3% to 11% over the whole post-war period.

(Keep that band in mind, since it connects back to the unit root debate, as we discuss below.)

147.4 A linear model of unemployment

Let's now set up and estimate our model, using monthly data.

147.4.1 The model

We let unemployment be pulled back toward a normal level $\bar{u}$:

$$u_{t+1} = \bar{u} + \phi\,(u_t - \bar{u}) + \varepsilon_{t+1}, \qquad \varepsilon_{t+1} \sim N(0, \sigma^2), \tag{147.1}$$

with $0 \leq \phi < 1$.

This is a linear AR(1) model, written so that $\bar{u}$ is the level the series reverts to and ϕ measures persistence.

The closer ϕ is to one, the more slowly the series returns to $\bar{u}$ after a shock; the random walk is the limiting case $\phi = 1$.

147.4.2 Priors

We treat $\bar{u}$, ϕ and σ as unknown and place weakly informative priors on them.

We give ϕ a uniform prior on $[0, 1)$.

The upper endpoint is excluded deliberately, since doing so confines us to the *stationary* region.

This is necessary, as we'll see below.

At the same time, the prior still lets ϕ approach one as closely as the data demand.

We center $\bar{u}$ on a plausible natural rate with a fairly wide normal prior, and give the shock scale σ a half-normal prior.

We write the model as a NumPyro function: each `numpyro.sample` introduces a random variable, and the keyword `obs=` ties the last one to the data, supplying the likelihood.

```
def linear_model(u):
    ubar = numpyro.sample("ubar",  dist.Normal(5.5, 2.0))      # Natural rate prior
    ψ    = numpyro.sample("phi",   dist.Uniform(0.0, 1.0))     # Persistence prior
    σ    = numpyro.sample("sigma", dist.HalfNormal(1.0))       # Volatility prior
    μ = ubar + ψ * (u[:-1] - ubar)
    numpyro.sample("u_obs", dist.Normal(μ, σ), obs=u[1:])
```

The vector `μ` holds the conditional means $\bar{u} + \phi(u_t - \bar{u})$, and `obs=u[1:]` says that each next value is drawn from $N(\mu_t, \sigma^2)$.

This one statement encodes the whole likelihood. (See *Non-Conjugate Priors* for more on writing NumPyro models.)

147.4.3 Estimation

We sample the posterior with NUTS, running four chains so that we can check convergence.

We use `chain_method="vectorized"`, which evaluates all chains together on a single device, so the same code runs unchanged on a CPU or a GPU.

```
def run_nuts(model, data, seed=0, num_warmup=1000, num_samples=2000, num_chains=4):
    "Sample a NumPyro model with the NUTS sampler."
    mcmc = MCMC(NUTS(model),
                num_warmup=num_warmup, num_samples=num_samples,
```

(continues on next page)

(continued from previous page)

```
                num_chains=num_chains, chain_method="vectorized",
                progress_bar=False)
    mcmc.run(random.key(seed), jnp.asarray(data))
    return mcmc
```

We fit the model to the monthly data.

```
mcmc_monthly = run_nuts(linear_model, u_monthly)
```

Now we inspect the output.

```
mcmc_monthly.print_summary()
```

```
                mean       std    median      5.0%     95.0%     n_eff     r_hat
       phi       0.99      0.00      0.99      0.99      1.00   2867.64      1.00
     sigma       0.21      0.01      0.21      0.20      0.22   4182.48      1.00
      ubar       5.64      1.16      5.66      3.81      7.62   3181.27      1.00

Number of divergences: 0
```

Each row summarizes the posterior for one parameter.

The `mean`, `median`, and `5.0%`/`95.0%` columns give the posterior mean, median, and a 90% credible interval; `std` is the posterior standard deviation.

The last two columns are convergence diagnostics: `n_eff` is the effective number of independent draws, and `r_hat` compares variation within and across chains — a value very close to 1.0 means the chains agree and the sampler has converged.

Here `r_hat` is essentially one and `n_eff` is large, so we can trust the draws.

The number that matters for us is the posterior for ϕ: its mass crowds right up against one.

In particular, the mean and median are very close to one, while the standard deviation is very small.

In other words, at a monthly frequency, US unemployment is *almost* a random walk.

This is the hysteresis boundary.

Thus, we find that the natural-rate and hysteresis views are nearly indistinguishable in the monthly data — the estimate is consistent with both.

This is why the unit-root tests of the era struggled to settle the debate [Røed, 1997].

147.5 A random walk would wander off

While the estimation above seems to give reasonable support to the unit root hypothesis, there is a good reason to view it as false.

To see the argument, suppose that unemployment really is a pure random walk, with $\phi = 1$:

$$u_{t+1} = u_t + \varepsilon_{t+1}, \qquad \varepsilon_{t+1} \sim N(0, \sigma^2).$$

Then $u_t = u_0 + \sum_{s=1}^{t} \varepsilon_s$, so its variance grows without bound: $\text{Var}(u_t) = t\sigma^2$.

The distribution spreads out forever, and eventually probability mass leaves *every* bounded interval.

We can see this by simulating many random-walk paths, using the observed one-month changes to set the shock size, and watching them fan out.

```
rng = np.random.default_rng(0)
T = len(u_monthly)
σ_rw = np.diff(u_monthly).std()
paths = u_monthly[0] + np.cumsum(rng.normal(0, σ_rw, size=(400, T)), axis=1)

u_min, u_max = u_monthly.min(), u_monthly.max()

fig, ax = plt.subplots()
ax.plot(paths[:60].T, color='C0', lw=0.5, alpha=0.3)
ax.axhspan(u_min, u_max, color='C1', alpha=0.15, label='observed range')
ax.axhline(u_min, color='C1', ls='--', lw=1.5)
ax.axhline(u_max, color='C1', ls='--', lw=1.5)
ax.set_xlabel('months since 1948')
ax.set_ylabel('unemployment rate (%)')
ax.legend()
plt.show()
```

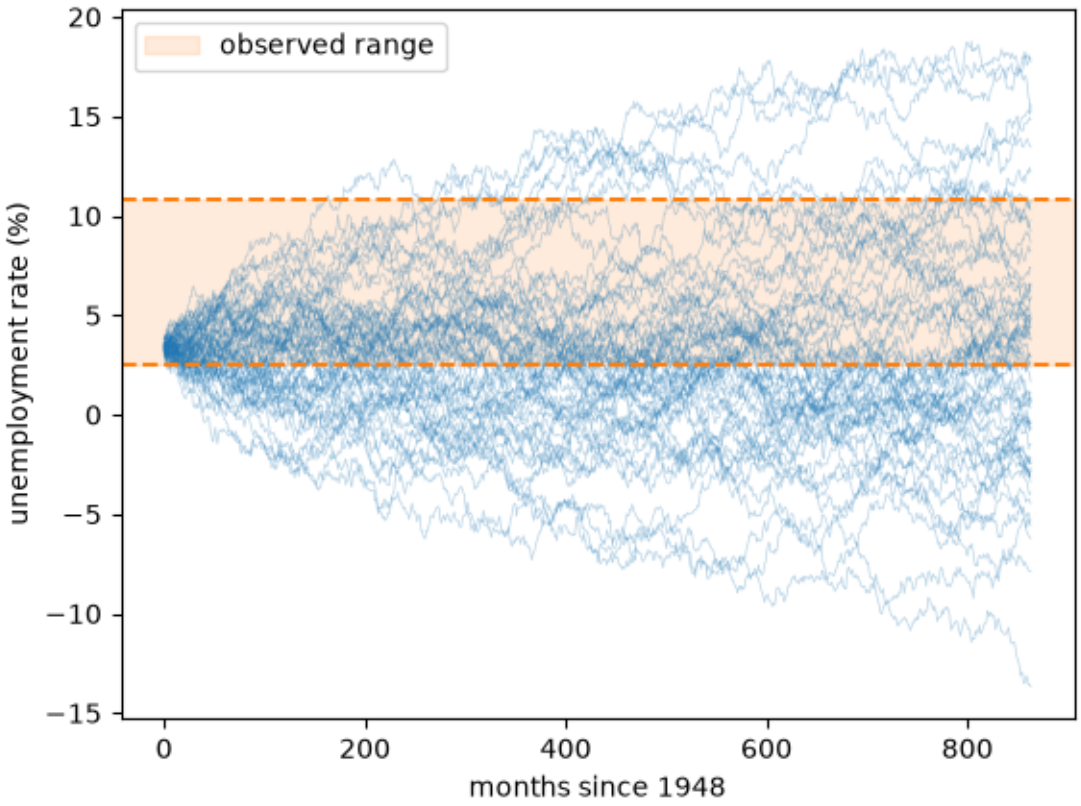

Fig. 147.2: Random walks leave the observed range

In Fig. 147.2 the dashed lines mark the lowest and highest unemployment rates ever seen in the data, and the shaded region is the band between them.

The simulated paths fan out like $\sqrt{t}$ and quickly spread far beyond this band, including into negative rates.

A random walk has no anchor, but unemployment clearly does — it has stayed inside a narrow band for seventy years.

So we can already rule out an exact random walk.

This will become even clearer when we examine annual data.

147.6 Monthly versus annual

The monthly data leave ϕ pinned against one.

Does a different frequency allow us to see something more?

We form an annual series from end-of-year values and fit the same model to it.

```
u_annual = pre_covid.resample("YE").last().to_numpy()
print(f"{len(u_annual)} annual observations")
```

```
72 annual observations
```

We fit the same model to this shorter series.

```
mcmc_annual = run_nuts(linear_model, u_annual)
```

Now we compare the posterior for ϕ across the two frequencies.

```
φ_m = np.asarray(mcmc_monthly.get_samples()["phi"])
φ_a = np.asarray(mcmc_annual.get_samples()["phi"])

fig, ax = plt.subplots()
ax.hist(φ_m, bins=50, density=True, alpha=0.6, label='monthly')
ax.hist(φ_a, bins=50, density=True, alpha=0.6, label='annual')
ax.set_xlabel('$\\phi$')
ax.legend()
plt.show()
```

Fig. 147.3 illustrates our main finding: the annual posterior for ϕ sits well below one, with clear reversion, while the monthly posterior pushes up against the boundary.

This is not a contradiction.

If the monthly persistence is ϕ, then for end-of-year values the persistence is about ϕ^{12}, and raising a number near one to the twelfth power pulls it appreciably below one — in line with our annual estimate.

147.7 What the model misses

Looking again at Fig. 147.1, we notice that unemployment jumps up quickly in recessions and drifts down slowly in recoveries.

This is an *asymmetry* that our current model cannot replicate.

To see why, we look closely at the one part of the model that is random — the shocks.

We proceed in three steps: state what the model assumes about the shocks, recover them from the data, and compare the two.

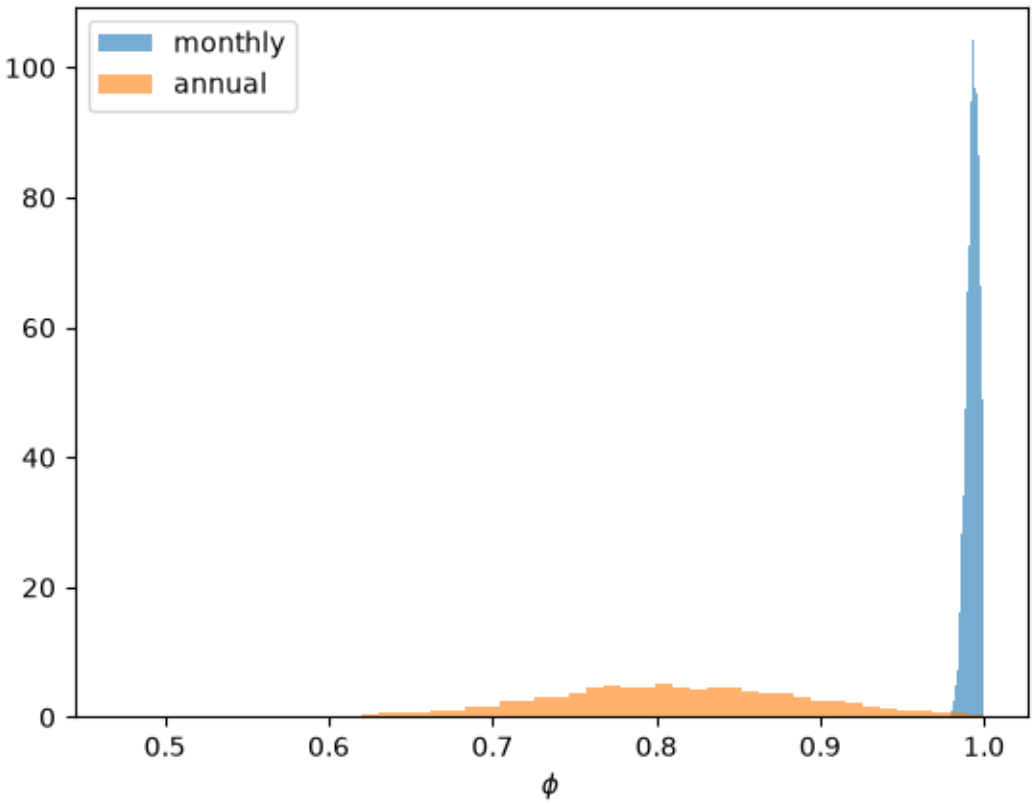

Fig. 147.3: Posterior for the persistence parameter

147.7.1 What the model assumes about the shocks

Given last period's rate u_t and the parameters, the next rate is a deterministic conditional mean plus a shock:

$$u_{t+1} = \underbrace{\bar{u} + \phi\,(u_t - \bar{u})}_{\text{conditional mean}} + \varepsilon_{t+1}, \qquad \varepsilon_{t+1} \sim N(0, \sigma^2).$$

Rearranging, the shock is just the gap between what happened and what the model expected:

$$\varepsilon_{t+1} = u_{t+1} - (\bar{u} + \phi\,(u_t - \bar{u})).$$

The model makes a strong and testable claim about these shocks: they are independent draws from a *symmetric* normal distribution.

If that claim holds, the shocks we recover from the data should look like a bell curve.

If it fails, the way it fails will tell us what the model is missing.

147.7.2 Recovering the shocks

We cannot read the shocks off directly, because we do not know the parameters $\bar{u}$ and ϕ.

So we estimate them, plugging a single representative value in for each.

We use the posterior medians — a reasonable choice for a quick diagnostic.

```
med = {k: np.median(np.asarray(mcmc_monthly.get_samples()[k]))
       for k in ("ubar", "phi", "sigma")}
resid = u_monthly[1:] - (med["ubar"] + med["phi"] * (u_monthly[:-1] - med["ubar"]))
```

The `resid` array holds our estimated shocks, one for each month-to-month transition — the model's **residuals**.

The slicing is what lines up each month with the one before it.

Each entry of `resid` is $u_{t+1} - (\hat{\bar{u}} + \hat{\phi}\,(u_t - \hat{\bar{u}}))$, the model's one-step-ahead forecast error, with hats denoting the median estimates.

(Because our estimate $\hat{\phi}$ is so close to one, this is nearly just the monthly change $u_{t+1} - u_t$.)

147.7.3 Comparing with the Gaussian

Now we ask whether these residuals look Gaussian.

We overlay a normal density whose standard deviation we set equal to that of the residuals themselves.

This is deliberate: the residuals already have mean near zero, so matching the variance makes the mean and the spread agree.

Anything left over is then a difference in *shape* — which is what we want to isolate.

One way to measure the shape is the **skewness**, the third standardized moment:

$$\text{skew} = \frac{\frac{1}{n}\sum_i (\varepsilon_i - \bar{\varepsilon})^3}{\left(\frac{1}{n}\sum_i (\varepsilon_i - \bar{\varepsilon})^2\right)^{3/2}}.$$

This measure is zero for any symmetric distribution and positive when the right tail is the longer one.

We now plot the residuals and compute their skewness:

```
def skewness(x):
    x = x - x.mean()
    return (x**3).mean() / x.std()**3

fig, ax = plt.subplots()
ax.hist(resid, bins=60, density=True, alpha=0.6, label='residuals')
grid = np.linspace(resid.min(), resid.max(), 200)
gauss = np.exp(-grid**2 / (2 * resid.std()**2)) / (resid.std() * np.sqrt(2 * np.pi))
ax.plot(grid, gauss, 'C1', lw=2, label='symmetric Gaussian')
ax.set_xlabel('one-month change not explained by the model')
ax.legend()
plt.show()

print(f"residual skewness = {skewness(resid):.2f}")
```

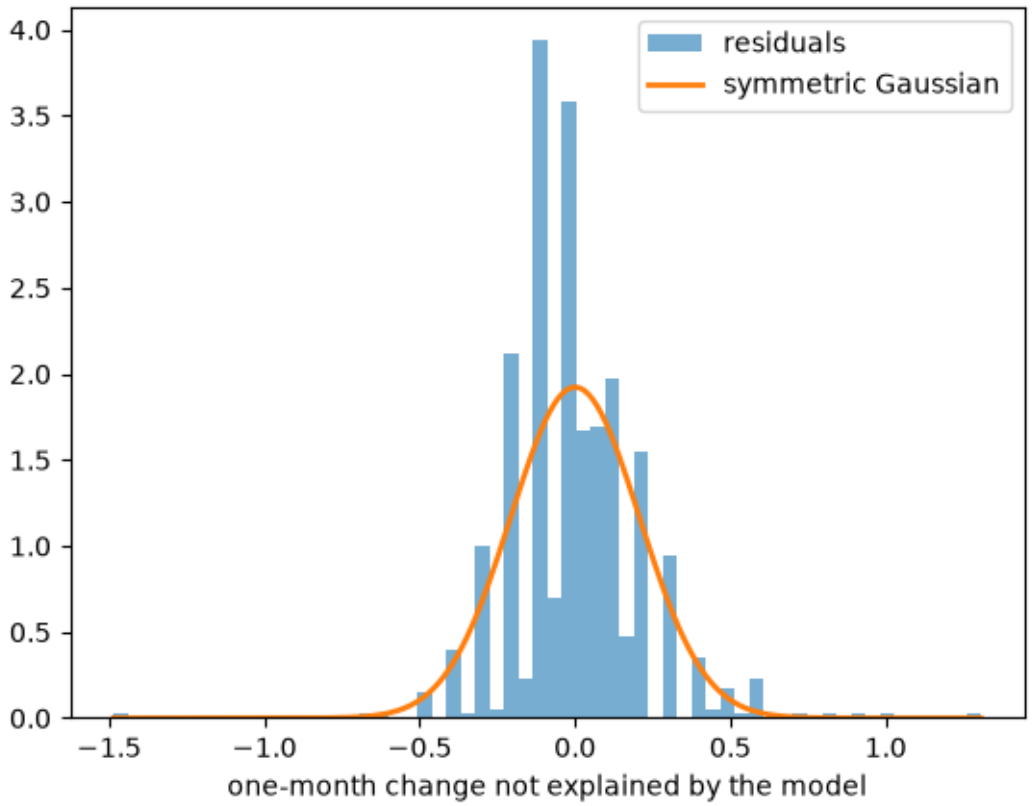

Fig. 147.4: Model residuals are right-skewed

```
residual skewness = 0.39
```

The residuals in Fig. 147.4 depart from the Gaussian in two ways.

They are *heavy-tailed* and *sharply peaked*: more tiny changes, and more large ones, than a bell curve allows.

Moreover, they are *right-skewed*, with the largest surprises on the upside (recessions).

The symmetric Gaussian (orange) can match neither feature: it treats upward and downward shocks as equally likely and has no room for the occasional very large jump.

So our model is bound to misread the data, seeing the rare jump up and the long gentle slide down as the *same* kind of

shock.

147.7.4 A note on the plug-in

A Bayesian purist would object that there is no single residual series here.

Every posterior draw of $(\bar{u}, \phi)$ implies its own, and we simply chose the medians.

That is fair, and the fully Bayesian version of this check — simulating whole datasets from the posterior and comparing a summary statistic — is what we do in *Unemployment Dynamics with Asymmetric Shocks*.

This plug-in check is a quick preview of that fuller test.

Capturing the asymmetry is the task of that next lecture, where we model the shocks themselves rather than the reversion curve.

147.8 Exercises

The lecture *Forecasting an AR(1) Process* forecasts an AR(1) process by simulating future paths, considering both a predictive distribution that **conditions on** fixed parameter values and one that **integrates over** their posterior uncertainty.

The following exercises apply these ideas to our fitted unemployment model.

Exercise 147.8.1

Using the fitted **annual** model, forecast unemployment over the next $H = 15$ years, starting from the last observed value, in two ways:

1. **plug-in**: hold the parameters at their posterior medians and simulate many future paths;
2. **extended**: for each future path, draw a fresh $(\bar{u}, \phi, \sigma)$ from the posterior.

Plot the 90% predictive band for each on the same axes and compare.

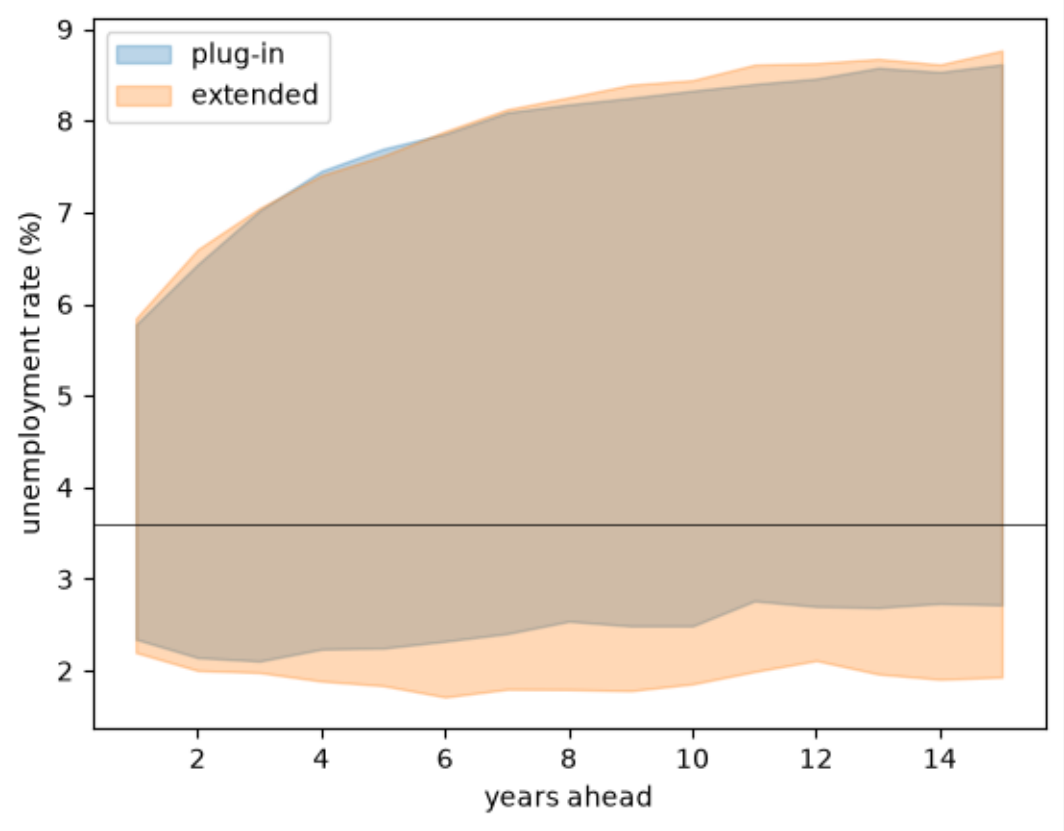
Which band is wider, and why?

Solution

We use the annual posterior draws and simulate forward from the last observation.

We work with the annual model because its persistence ϕ is far less certain than at the monthly frequency, so parameter uncertainty has more to say.

```
post = mcmc_annual.get_samples()
ubar_s = np.asarray(post["ubar"])
ψ_s = np.asarray(post["phi"])
σ_s = np.asarray(post["sigma"])



def sim_future(u_last, ubar, ψ, σ, H, rng):
    "Simulate H steps of the linear model forward from u_last."
    u = np.empty(H)
    prev = u_last
    for h in range(H):
        prev = ubar + ψ * (prev - ubar) + rng.normal(0, σ)
        u[h] = prev
    return u
```

```
H, N = 15, 2000
u_last = u_annual[-1]
rng = np.random.default_rng(0)

# plug-in: parameters fixed at posterior medians
ub0, φ0, σ0 = np.median(ubar_s), np.median(φ_s), np.median(σ_s)
plug = np.array([sim_future(u_last, ub0, φ0, σ0, H, rng) for _ in range(N)])

# extended: a fresh posterior draw for each path
idx = rng.integers(0, len(φ_s), N)
ext = np.array([sim_future(u_last, ubar_s[i], φ_s[i], σ_s[i], H, rng)
                for i in idx])

fig, ax = plt.subplots()
horizon = np.arange(1, H + 1)
for data, c, lab in [(plug, 'C0', 'plug-in'), (ext, 'C1', 'extended')]:
    lo, hi = np.percentile(data, [5, 95], axis=0)
    ax.fill_between(horizon, lo, hi, alpha=0.3, color=c, label=lab)
ax.axhline(u_last, color='k', lw=0.5)
ax.set_xlabel('years ahead')
ax.set_ylabel('unemployment rate (%)')
ax.legend()
plt.show()
```

Both forecasts drift up from the low starting value toward the reversion level $\bar{u}$, with bands that widen as we look further ahead.

The extended band is clearly wider, because it adds uncertainty about the parameters on top of the uncertainty from

future shocks — and here the persistence ϕ and the level $\bar{u}$ are both genuinely uncertain.

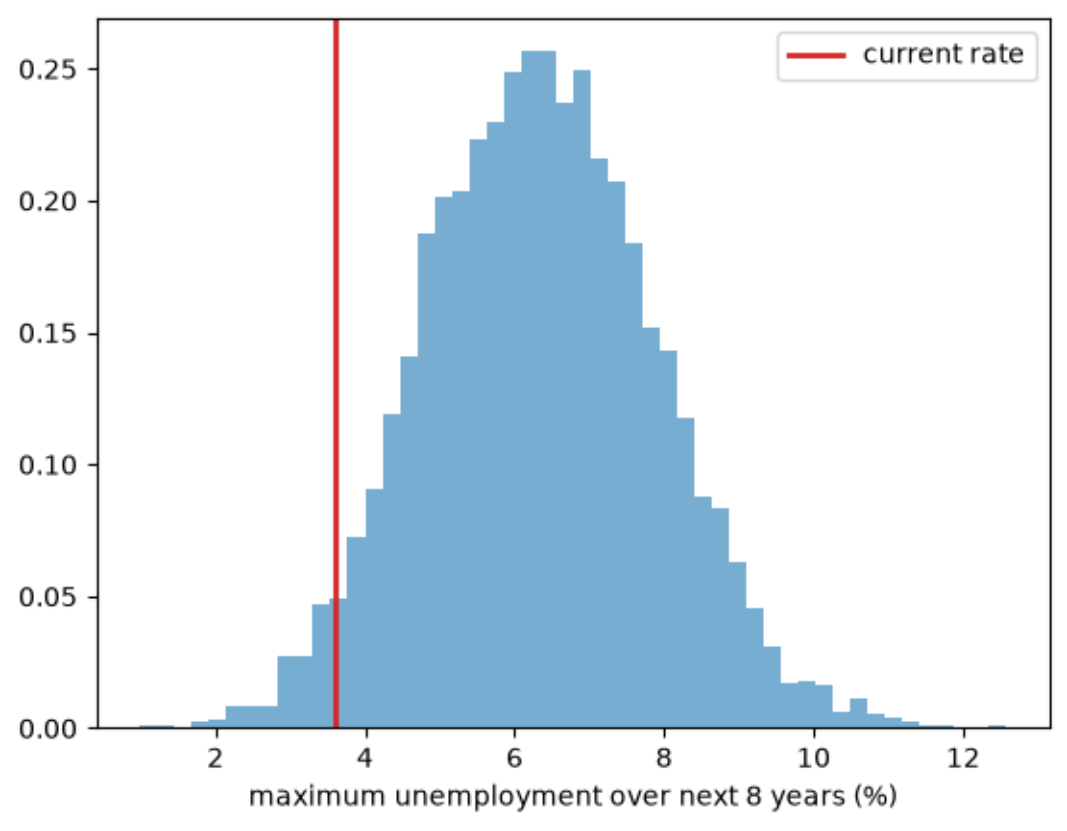
Exercise 147.8.2

Following Wecker (see *Forecasting an AR(1) Process*), we can also form a predictive distribution for a **path statistic** — a nonlinear function of the whole future path.

Take the **maximum unemployment rate over the next** $H = 8$ **years** as the statistic: a simple measure of how bad the next several years might get.

Using the extended simulation (a posterior draw per path), compute this maximum for each path and plot its predictive distribution.

What is the posterior predictive probability that unemployment reaches at least 7% — recession territory — at some point over the next eight years?



Solution

We reuse `sim_future` and the posterior draws from the previous exercise.

```
H2, M = 8, 5000
idx = rng.integers(0, len(ψ_s), M)
peak = np.array([sim_future(u_last, ubar_s[i], ψ_s[i], σ_s[i], H2, rng).max()
                 for i in idx])

fig, ax = plt.subplots()
ax.hist(peak, bins=50, density=True, alpha=0.6)
ax.axvline(u_last, color='C3', lw=2, label='current rate')
ax.set_xlabel('maximum unemployment over next 8 years (%)')
ax.legend()
plt.show()

prob = (peak > 7.0).mean()
print(f"P(unemployment reaches 7% within 8 years) = {prob:.2f}")
```

```
P(unemployment reaches 7% within 8 years) = 0.33
```

The predictive distribution summarizes the plausible “worst case” over the next several years, integrating over both shocks and parameter uncertainty.

Starting from a cyclical low, the model sees a substantial chance of a return to recession-level unemployment within the horizon.

CHAPTER

EIGHT

UNEMPLOYMENT DYNAMICS WITH ASYMMETRIC SHOCKS

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

This lecture is a sequel to *A Linear Model of Unemployment*.

There we fit a linear AR(1) model to the US unemployment rate and examined persistence.

One thing we found but didn't address is that the model's residuals were both *heavy-tailed and right-skewed*.

Unemployment jumps up sharply in recessions and drifts down slowly in recoveries.

A model with symmetric Gaussian shocks cannot reproduce these features.

In this lecture we allow the innovations to be right-skewed and, to some degree, heavy-tailed.

We also use this lecture to develop a very useful Bayesian technique: *model comparison* by leave-one-out cross-validation.

We use this to decide whether one model really predicts better than another.

Our plan is to

1. build a model with a linear mean but asymmetric, occasionally-large shocks,
2. estimate it on the annual data, and
3. compare it to the original Gaussian model with cross-validation.

In addition to what's in Anaconda, this lecture needs the following libraries.

```
!pip install numpyro jax pandas_datareader arviz
```

We'll use the following imports.

```
import numpy as np
import matplotlib.pyplot as plt
import datetime as dt
from pandas_datareader import data as web

import jax.numpy as jnp
```

(continues on next page)

(continued from previous page)

```
from jax import random
import numpyro
import numpyro.distributions as dist
from numpyro.infer import MCMC, NUTS, log_likelihood
```

148.1 The data

We use the same series as in *A Linear Model of Unemployment* — the US unemployment rate (`UNRATE` from FRED), excluding the COVID-19 spike — and work at an annual frequency.

```
start, end = dt.datetime(1948, 1, 1), dt.datetime(2024, 12, 31)
unrate = web.DataReader("UNRATE", "fred", start, end)["UNRATE"]
pre_covid = unrate[unrate.index < "2020-01-01"]
u_annual = pre_covid.resample("YE").last().to_numpy()
years = pre_covid.resample("YE").last().index.year
```

The shape we want to capture is plain in the annual series.

```
fig, ax = plt.subplots()
ax.plot(years, u_annual, lw=2, marker='o', ms=3)
ax.set_xlabel('year')
ax.set_ylabel('unemployment rate (%)')
plt.show()
```

In Fig. 148.1 each recession is a sharp rise followed by a long, gradual decline — fast up, slow down.

148.2 A model with asymmetric shocks

We keep the linear structure from *A Linear Model of Unemployment*:

$$u_{t+1} = \bar{u} + \rho\,(u_t - \bar{u}) + \eta_{t+1}, \qquad 0 \le \rho < 1, \tag{148.1}$$

Here, however, the innovation η_{t+1} is drawn from a *mixture of two normals*:

$$\eta_{t+1} \sim \begin{cases} N(0, \sigma_s^2) & \text{with probability } 1-p \quad \text{(a quiet year)}, \\ N(\mu_J, \sigma_J^2) & \text{with probability } p \quad \text{(a recession jump)}, \end{cases} \qquad \mu_J > 0.$$

The model has six parameters:

symbol	name	role
$\bar{u}$	floor	the low level the series reverts to
ρ	persistence	speed of reversion (as in the linear lecture)
p	jump probability	how often a large shock arrives
μ_J	jump size	the average upward kick of a recession
σ_s, σ_J	shock spreads	the quiet and jumpy volatilities

The mechanism leads to a sawtooth dynamic for the unemployment rate.

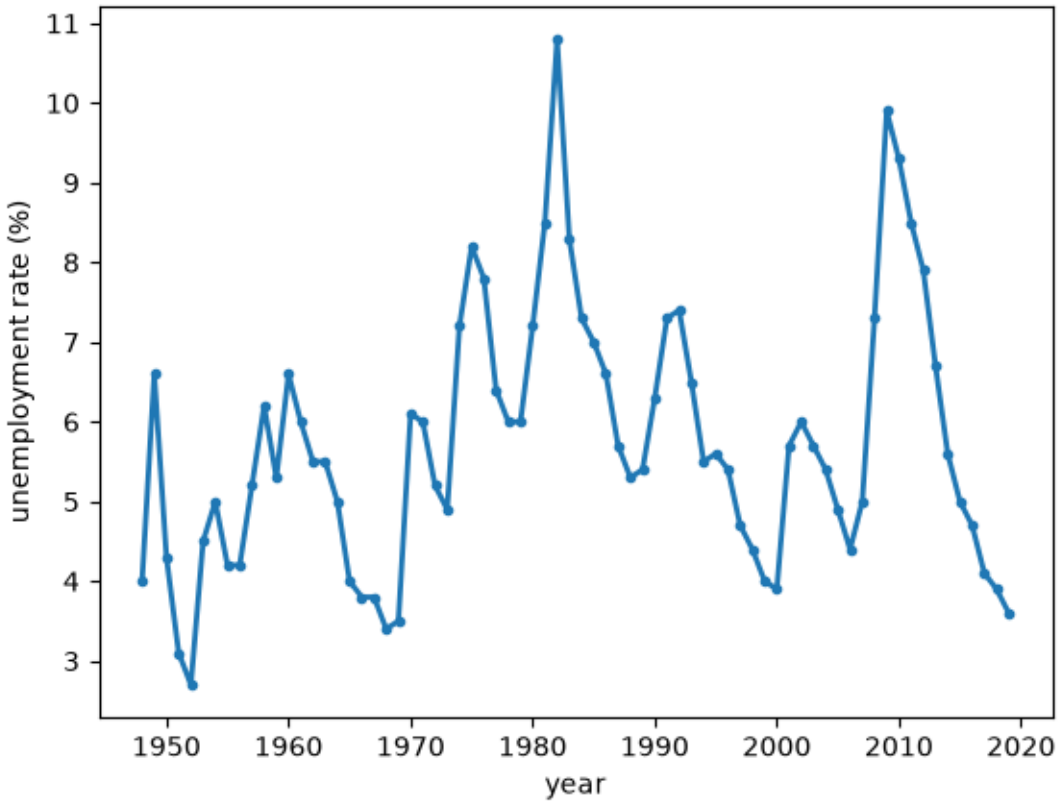


Fig. 148.1: Annual US unemployment

Most years are quiet, with small noise.

Occasionally a positive jump pushes unemployment up by a large amount.

Then, in most cases, the linear reversion pulls it slowly back down toward $\bar{u}$.

Thus, a spike arrives in one step, while the recovery takes time — the asymmetric dynamics we observe in the data.

This is, in spirit, Milton Friedman's "plucking model": a floor near full employment, from which bad shocks pluck the series upward.

The next cell shows the density of the shock and its two components.

```
def normal_pdf(x, m, s):
    return np.exp(-(x - m)**2 / (2 * s**2)) / (s * np.sqrt(2 * np.pi))

η = np.linspace(-3, 6, 400)
p_, μJ_, σs_, σJ_ = 0.25, 2.0, 0.4, 1.2
quiet = (1 - p_) * normal_pdf(η, 0.0, σs_)
jump  = p_ * normal_pdf(η, μJ_, σJ_)

fig, ax = plt.subplots()
ax.plot(η, quiet + jump, lw=2, label='shock density')
ax.fill_between(η, quiet, alpha=0.3, label='quiet years')
ax.fill_between(η, jump, alpha=0.3, label='recession jumps')
ax.set_xlabel('innovation $\\eta$')
ax.legend()
plt.show()
```

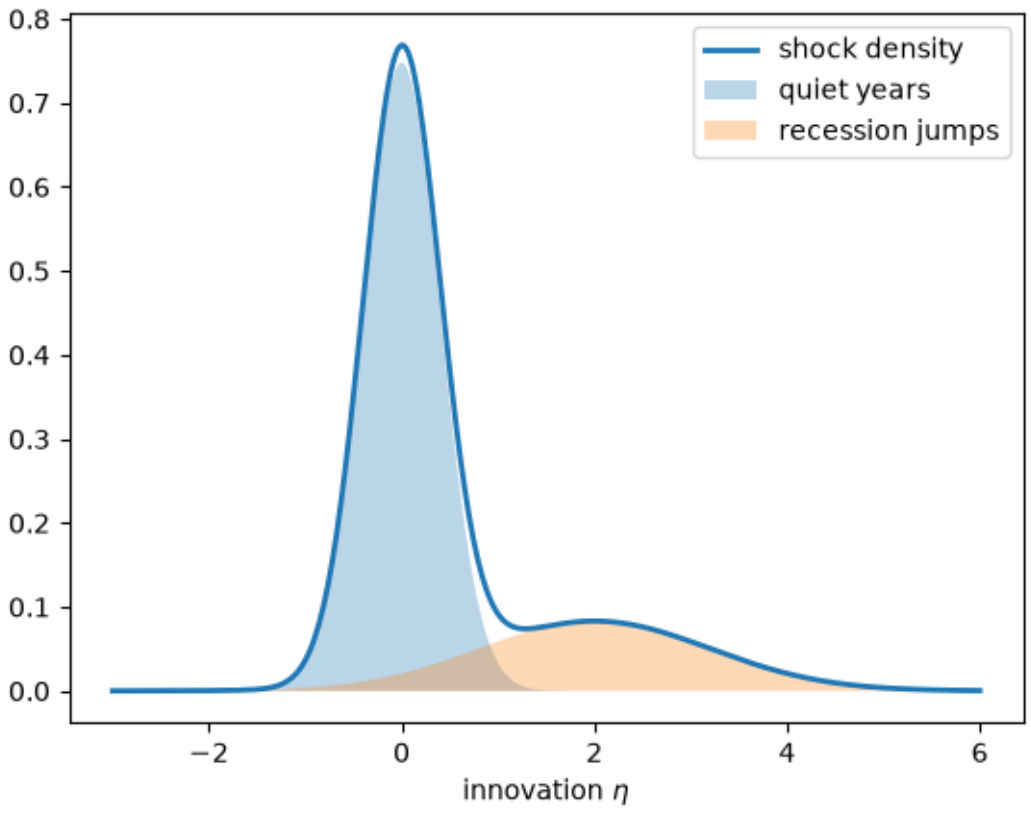

Fig. 148.2: Shock distribution as a mixture

Fig. 148.2 shows a tall, narrow peak at zero for ordinary years, plus a low, broad bump on the positive side for the recession jumps.

148.3 Bayesian estimation

We place weakly informative priors on the six parameters.

The mixture is written with NumPyro's `MixtureSameFamily`, which sums over the two components analytically.

```
def jump_model(u):
    # Set the priors
    ubar = numpyro.sample("ubar",    dist.Normal(4.5, 1.5))
    ρ    = numpyro.sample("rho",     dist.Uniform(0.0, 1.0))
    p    = numpyro.sample("p",       dist.Beta(2.0, 8.0))
    μ_J  = numpyro.sample("mu_J",    dist.HalfNormal(2.0))
    σ_s  = numpyro.sample("sigma_s", dist.HalfNormal(0.5))
    σ_J  = numpyro.sample("sigma_J", dist.HalfNormal(1.5))
    # Build the model
    n = u.shape[0] - 1
    base   = ubar + ρ * (u[:-1] - ubar)
    locs   = jnp.stack([base, base + μ_J], axis=-1)
    scales = jnp.stack([jnp.broadcast_to(σ_s, (n,)),
                        jnp.broadcast_to(σ_J, (n,))], axis=-1)
    probs  = jnp.broadcast_to(jnp.stack([1 - p, p]), (n, 2))
    mix = dist.MixtureSameFamily(dist.Categorical(probs=probs),
                                 dist.Normal(locs, scales))
    numpyro.sample("u_obs", mix, obs=u[1:])
```

We sample with NUTS, four chains, vectorized so the code runs on a CPU or a GPU.

```
def run_nuts(model, data, seed=0, num_warmup=2000, num_samples=4000, num_chains=4):
    "Sample a NumPyro model with the NUTS sampler."
    mcmc = MCMC(NUTS(model),
                num_warmup=num_warmup, num_samples=num_samples,
                num_chains=num_chains, chain_method="vectorized",
                progress_bar=False)
    mcmc.run(random.key(seed), jnp.asarray(data))
    return mcmc
```

We fit the model to the annual data.

```
mcmc_jump = run_nuts(jump_model, u_annual)
```

Let us look at the posterior.

```
mcmc_jump.print_summary()
```

```
                mean       std    median      5.0%     95.0%     n_eff     r_hat
      mu_J      1.25      0.42      1.20      0.58      1.96   3392.90      1.00
         p      0.35      0.09      0.35      0.20      0.50   4640.47      1.00
       rho      0.83      0.04      0.84      0.76      0.90   5896.66      1.00
   sigma_J      1.29      0.26      1.30      0.87      1.73   3866.36      1.00
   sigma_s      0.39      0.09      0.38      0.25      0.54   3978.27      1.00
      ubar      3.02      0.74      3.08      1.85      4.22   5563.53      1.00
```

(continues on next page)

(continued from previous page)

```
Number of divergences: 0
```

The `r_hat` values are essentially one, so the chains have converged.

Notice the distinct jump component: the normal year spread σ_s is small and the jump spread σ_J is large, with a positive mean μ_J.

Let's do a quick check by overlaying the fitted shock density on the model's actual residuals, as we did in *A Linear Model of Unemployment*.

```
m = {k: np.median(np.asarray(mcmc_jump.get_samples()[k]))
     for k in ("ubar", "rho", "p", "mu_J", "sigma_s", "sigma_J")}
resid = u_annual[1:] - (m["ubar"] + m["rho"] * (u_annual[:-1] - m["ubar"]))

η = np.linspace(resid.min() - 0.5, resid.max() + 0.5, 400)
quiet = (1 - m["p"]) * normal_pdf(η, 0.0, m["sigma_s"])
jump  = m["p"] * normal_pdf(η, m["mu_J"], m["sigma_J"])

fig, ax = plt.subplots()
ax.hist(resid, bins=25, density=True, alpha=0.5, label='residuals')
ax.plot(η, quiet + jump, lw=2, label='fitted density')
ax.fill_between(η, jump, alpha=0.3, color='C2', label='jump component')
ax.set_xlabel('innovation $\\eta$')
ax.legend()
plt.show()
```

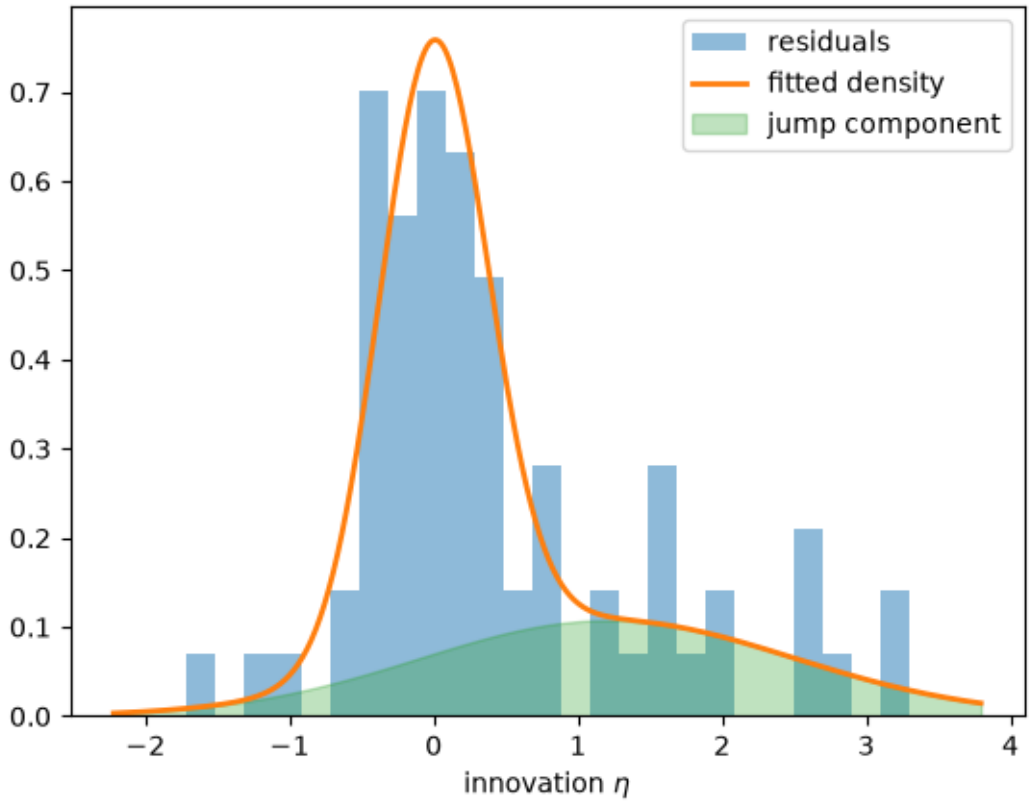

Fig. 148.3: Fitted shock density against the residuals

The fit looks quite good (although we are still struggling to capture some of the large shocks in the right tail).

148.4 Comparing models with cross-validation

The jump model looks reasonable, but is it actually better than the linear one?

To answer this question, we will use a form of *Bayesian model comparison*.

We build it up in stages: the guiding principle, the leave-one-out estimate, and how the computation is actually done.

148.4.1 The guiding principle: out-of-sample predictions

It is tempting to compare two models by asking which one fits the observed data better.

But this isn't the right criterion: more complex models can always be tuned to better match the data they are fitting.

The right question is instead: which model better predicts data it has not seen?

In other words, the criterion we care about is out-of-sample predictive accuracy.

We do not have new data for out-of-sample testing, so we manufacture some using *cross-validation*.

148.4.2 Leave-one-out cross-validation

The idea is to leave out one observation, fit the model to the rest, and then score the held-out point using a predictive distribution constructed from the rest of the data set.

The predictive distribution for data point u_i given the rest of the data u_{-i} is

$$p(u_i \mid u_{-i}) = \int p(u_i \mid \theta)\, p(\theta \mid u_{-i})\, d\theta.$$

Here $p(\theta \mid u_{-i})$ is the posterior obtained from the data in u_{-i}.

We score each held-out point by the *log* of this density.

This rewards a model for putting high probability on what actually happened.

Adding these scores over all data points gives the **expected log predictive density** (elpd), here in its leave-one-out (LOO) form,

$$\text{elpd}_{\text{loo}} = \sum_{i=1}^{n} \log p(u_i \mid u_{-i}).$$

148.4.3 Computational methods

The definition of elpd suggests that we need to refit the model n times, once for each omitted point.

This would be very time-consuming.

Here we discuss a method that removes all but the first fit, using the full posterior — which we have already sampled.

Regarding notation: let $u = (u_1, \ldots, u_n)$, and write u_{-i} for the sample with u_i deleted.

The method depends on the following independence-type assumption:

Assumption 148.4.1

Given θ, the observations are conditionally independent:

$$p(u \mid \theta) = \prod_{j=1}^{n} p(u_j \mid \theta).$$

For our autoregressive data this assumption is false, since each u_i is dependent on earlier observations through the transition dynamics.

We adopt it nonetheless, since

- it's what makes the leave-one-out computation tractable and
- it's a very standard procedure that needs to be understood.

We discuss the consequences in the section on time-series structure below.

Conditional on our assumption, the proposition that follows is exact.

Proposition 148.4.1

Under *Assumption 148.4.1*, we have

$$\frac{1}{p(u_i \mid u_{-i})} = \int \frac{1}{p(u_i \mid \theta)} p(\theta \mid u)\, d\theta \qquad (i = 1, \dots, n).$$

Proof. By Bayes' rule, $p(\theta \mid u) = p(u \mid \theta)\, p(\theta)/p(u)$ and $p(\theta \mid u_{-i}) = p(u_{-i} \mid \theta)\, p(\theta)/p(u_{-i})$.

By *Assumption 148.4.1*, $p(u \mid \theta) = p(u_i \mid \theta)\, p(u_{-i} \mid \theta)$.

Dividing the two posteriors and substituting this factorization,

$$\frac{p(\theta \mid u)}{p(\theta \mid u_{-i})} = \frac{p(u \mid \theta)}{p(u_{-i} \mid \theta)} \cdot \frac{p(u_{-i})}{p(u)} = p(u_i \mid \theta) \cdot \frac{p(u_{-i})}{p(u)},$$

so, rearranging,

$$\frac{p(\theta \mid u)}{p(u_i \mid \theta)} = \frac{p(u_{-i})}{p(u)}\, p(\theta \mid u_{-i}).$$

Now integrate both sides over θ.

On the right, $\int p(\theta \mid u_{-i})\, d\theta = 1$, leaving the constant factor $p(u_{-i})/p(u)$, so

$$\int \frac{1}{p(u_i \mid \theta)} p(\theta \mid u)\, d\theta = \frac{p(u_{-i})}{p(u)} = \frac{1}{p(u_i \mid u_{-i})},$$

the last equality by $p(u) = p(u_i \mid u_{-i})\, p(u_{-i})$.

The leave-i-out posterior has vanished; only the full posterior remains, and of it we have S draws $\theta^1, \dots, \theta^S$.

Replacing the integral in *Proposition 148.4.1* by the average over these draws gives

$$\frac{1}{p(u_i \mid u_{-i})} \;\approx\; \frac{1}{S}\sum_{s=1}^{S}\frac{1}{p(u_i \mid \theta^s)}, \qquad \text{so} \qquad p(u_i \mid u_{-i}) \;\approx\; \frac{S}{\sum_{s=1}^{S} 1/p(u_i \mid \theta^s)},$$

the harmonic mean of the per-draw likelihoods of u_i.

The integrand has finite mean, equal to $1/p(u_i \mid u_{-i})$ itself, so the law of large numbers applies.

The average therefore converges to that mean as $S \to \infty$, and the approximation becomes exact, with probability one, in the limit.

Its one ingredient is the likelihood of each observation under each draw — the **pointwise log-likelihood** — which is why we have been careful to keep it.

For numerical stability we compute on the log scale, where the harmonic mean becomes

$$\log p(u_i \mid u_{-i}) \;\approx\; \log S - \log \sum_{s=1}^{S} e^{-\ell_i^s}, \qquad \ell_i^s = \log p(u_i \mid \theta^s),$$

which is the `jnp.log(S) - logsumexp(-ll)` we use below.

To compare against the linear model, we first fit it on the same data.

```
def linear_model(u):
    ubar = numpyro.sample("ubar",  dist.Normal(5.5, 2.0))
    ρ    = numpyro.sample("rho",   dist.Uniform(0.0, 1.0))
    σ    = numpyro.sample("sigma", dist.HalfNormal(1.0))
    numpyro.sample("u_obs", dist.Normal(ubar + ρ * (u[:-1] - ubar), σ), obs=u[1:])
```

We sample it on the same annual data.

```
mcmc_lin = run_nuts(linear_model, u_annual)
```

Now we can do the whole leave-one-out calculation by hand in a few lines.

```
from jax.scipy.special import logsumexp

def pointwise_loo(mcmc, model):
    "Leave-one-out log predictive density for each observation."
    ll = log_likelihood(model, mcmc.get_samples(),
                        u=jnp.asarray(u_annual))["u_obs"]  # (draws, obs)
    S = ll.shape[0]
    # log of the harmonic mean of the per-draw likelihoods, per observation
    return jnp.log(S) - logsumexp(-ll, axis=0)

elpd_jump = pointwise_loo(mcmc_jump, jump_model)
elpd_lin  = pointwise_loo(mcmc_lin,  linear_model)

print(f"jump   elpd_loo = {elpd_jump.sum():.1f}")
print(f"linear elpd_loo = {elpd_lin.sum():.1f}")
```

```
jump   elpd_loo = -93.9
linear elpd_loo = -105.7
```

The jump model scores higher (closer to zero), so on out-of-sample prediction it wins.

To help understand whether the gap is real, we compute its standard error:

```
diff = elpd_jump - elpd_lin
n = diff.size
print(f"elpd difference = {diff.sum():.1f}")
print(f"standard error  = {jnp.sqrt(n) * diff.std():.1f}")
```

```
elpd difference = 11.8
standard error  = 5.7
```

The jump model is ahead by about twelve points, against a standard error near six — a bit over two standard errors, so a real improvement.

148.4.4 ArviZ implementation

In practice, most people do this calculation with a library like ArviZ.

We hand it the same pointwise log-likelihoods, packaged in its data format.

```
import arviz as az
import xarray as xr

def to_arviz(mcmc, model, u):
    "Package a NumPyro fit for ArviZ, with pointwise log-likelihoods."
    idata = az.from_numpyro(mcmc)
    ll = np.asarray(log_likelihood(model, mcmc.get_samples(),
                                   u=jnp.asarray(u))["u_obs"])
    ll = ll.reshape(mcmc.num_chains, -1, ll.shape[-1])
    idata["log_likelihood"] = xr.Dataset(
        {"u_obs": (("chain", "draw", "obs"), ll)})
    return idata

az.compare({
    "linear": to_arviz(mcmc_lin,  linear_model, u_annual),
    "jump":   to_arviz(mcmc_jump, jump_model,   u_annual),
})
```

```
        rank  elpd_diff  dse  p_worse diag_diff diag_elpd    p   elpd   se  \
jump       0        0.0  0.0      NaN                      6.5  -90.0  9.3
linear     1      -10.0  5.7     0.98   N < 100            3.5 -110.0  7.4

        weight
jump      0.86
linear    0.14
```

Here `az.compare` confirms the hand calculation and ranks the jump model first (its table rounds the scores for display).

148.4.5 Accommodating the time series structure

Leave-one-out drops one transition at a time, but it does not respect the order of time.

When it scores the step from u_t to u_{t+1}, the model doing the scoring was fit on data lying on *both* sides of that step — including the neighboring values u_t and u_{t+1} themselves.

So the held-out point was never truly unseen.

The formally correct measure is **leave-future-out** cross-validation.

It only ever predicts forward: fit the model on $u_1, \ldots, u_t$, score its one-step-ahead forecast of u_{t+1}, then expand the window by one step and repeat.

Now the model is genuinely blind to the future it is asked to predict, exactly as in real forecasting.

The price is computational.

Leave-one-out reused a single fit through its importance-sampling shortcut, but leave-future-out has no such trick.

For our short annual series leave-future-out cross-validation is still feasible but for a long series it can become prohibitive.

(We ran it without including it here and the conclusion holds: under leave-future-out the jump model still beats the linear one, by an even larger margin.)

148.5 Conclusion

In *A Linear Model of Unemployment* we applied a linear AR(1) model with Gaussian shocks to unemployment and found high levels of persistence in monthly data.

We also argued that the model is overly simplistic.

Here we found that the feature the linear model most conspicuously misses — the asymmetry of recessions — can be addressed by modeling the distribution of the shocks.

A linear reversion with large, one-sided innovations matches the right-skewed, heavy-tailed shocks that the Gaussian model could not.

Cross-validation prefers it.

An even better model than the one considered above would let the economy switch between persistent expansion and recession regimes.

This is the Markov-switching approach, which we leave to further reading.

148.6 Exercises

Exercise 148.6.1

The jump component here is symmetric within itself, $N(\mu_J, \sigma_J^2)$.

Replace the two-component mixture with a single **skew-normal** (or Student-t with a skew) innovation, refit, and compare to the mixture model with `az.compare`.

Does the simpler skewed shock do as well as the mixture?

  - *Estimating with Hamiltonian Monte Carlo*
  - *Concluding remarks*
  - *Exercises*

In addition to what's in Anaconda, this lecture uses `pandas_datareader` to download macroeconomic data and `jax`, `numpyro` and `arviz` for the Hamiltonian Monte Carlo section at the end:

```
!pip install pandas_datareader numpyro jax arviz
```

149.1 Overview

Lucas [1980] plotted long moving averages of U.S. inflation against long moving averages of U.S. money growth, and then long moving averages of a nominal interest rate against the same moving averages of money growth.

Both scatter plots hugged a 45 degree line.

Lucas read those two unit slopes as illustrating "two central implications of the quantity theory of money: that a given change in the rate of change in the quantity of money induces (i) an equal change in the rate of price inflation; and (ii) an equal change in nominal rates of interest."

He also warned that a theory tells us "conditions under which one might expect them to break down."

This lecture studies Sargent and Surico [2011], which takes that warning seriously.

The paper does three things.

First, it extends Lucas's sample and shows that his two slopes are *not* stable across subperiods.

Second, following Whiteman [1984], it interprets a Lucas slope as the sum of coefficients in a two-sided distributed lag regression, an object that a time series model delivers as a ratio of spectral densities at frequency zero.

Third, it estimates a small new Keynesian model on a pre-1984 sample and then perturbs *only* the monetary policy rule, showing that policy alone can move the two slopes across the range that the data display.

We do all of this from scratch in Python.

We write our own solver for linear rational expectations models, our own Kalman filter, and our own Metropolis-Hastings sampler, so that every step is visible.

A final section then uses the estimated model as a test bed for Hamiltonian Monte Carlo, which turns out to require replacing the model solver with a differentiable one.

Along the way we flag several places where the published paper's statement or implementation of its model needs care, and we check each of them numerically.

Most are corrections, and one turns out to sharpen the paper's message rather than weaken it.

Let's start with imports.

```
import datetime
import time
import warnings

import matplotlib.pyplot as plt
import numpy as np
import pandas as pd
import pandas_datareader.data as web
from scipy import optimize, stats
from scipy.linalg import ordqz, solve_discrete_lyapunov, svd
from scipy.stats import invwishart

warnings.filterwarnings('ignore')
plt.rcParams['figure.figsize'] = (10, 6)
plt.rcParams['axes.grid'] = True
plt.rcParams['grid.alpha'] = 0.3
```

149.2 Lucas's moving averages

For a scalar series x_t and $\beta \in [0, 1)$, Lucas [1980] formed the two-sided moving average

$$\bar{x}_t(\beta) = a \sum_{k=-n}^{n} \beta^{|k|} x_{t+k}, \qquad a = \frac{(1-\beta)^2}{1 - \beta^2 - 2\beta^{n+1}(1-\beta)}, \tag{149.1}$$

where a makes the weights sum to one.

Larger β means a smoother series and a longer window.

Setting $\beta = 0$ returns the raw data.

We apply the weights to whatever observations are available, renormalizing so that they always sum to one.

```
def lucas_filter(x, beta=0.95):
    """Two-sided exponentially weighted moving average of Lucas (1980)."""
    x = np.asarray(x, dtype=float)
    T = len(x)
    out = np.empty(T)
    for t in range(T):
        w = beta ** np.abs(np.arange(T) - t)
        out[t] = w @ x / w.sum()
    return out
```

149.3 Whiteman's reinterpretation

Whiteman [1984] observed that fitting a straight line through a scatter of moving averages is an informal way of computing the *sum* of coefficients in a long two-sided distributed lag regression.

Let $\{y_t, z_t\}$ be jointly covariance stationary with zero means, and project y_t on the entire history and future of z,

$$y_t = \sum_{j=-\infty}^{\infty} h_j z_{t-j} + \epsilon_t, \qquad \mathbb{E}\,\epsilon_t z_{t-j} = 0 \;\; \forall j. \tag{149.2}$$

Write $S_y(\omega)$, $S_z(\omega)$ and $S_{yz}(\omega)$ for the spectral and cross-spectral densities and $h(\omega) = \sum_j h_j e^{-i\omega j}$ for the transfer function.

Then

$$h(\omega) = \frac{S_{yz}(\omega)}{S_z(\omega)} \qquad \text{so} \qquad \sum_{j=-\infty}^{\infty} h_j = h(0) = \frac{S_{yz}(0)}{S_z(0)}. \tag{149.3}$$

Whiteman showed that as $\beta \to 1$ the regression coefficient of $\bar{y}_t(\beta)$ on $\bar{z}_t(\beta)$ converges to $h(0)$.

So Lucas's two illustrations are claims that

$$h_{\pi,\Delta m}(0) = 1 \qquad \text{and} \qquad h_{R,\Delta m}(0) = 1,$$

where π is inflation, Δm is money growth, and R is a nominal interest rate.

This is a useful reformulation because $h(0)$ is a *population* object that any time series model delivers.

149.3.1 From a state space model to $h(0)$

Suppose a model implies

$$X_{t+1} = AX_t + BW_{t+1}, \qquad Y_{t+1} = CX_t + DW_{t+1}, \tag{149.4}$$

with W_{t+1} a standard normal vector that is IID over time and A stable.

Iterating gives $X_t = \sum_{j \geq 0} A^j B W_{t-j}$, so the transfer function from W to Y is

$$H(\zeta) = D + \zeta\, C(I - A\zeta)^{-1} B, \qquad \zeta = e^{-i\omega},$$

and the spectral density matrix of Y is $S_Y(\omega) = H(\zeta)H(\zeta)^*/(2\pi)$, that is

$$2\pi S_Y(\omega) = C(I - Ae^{-i\omega})^{-1} BB' (I - A'e^{i\omega})^{-1} C' + DD' + e^{-i\omega} C(I - Ae^{-i\omega})^{-1} BD' + e^{i\omega} DB'(I - A'e^{i\omega})^{-1} C'. \tag{149.5}$$

Note

Equation (7) of Sargent and Surico [2011] reports only the first two terms of (149.5).

The two cross terms drop out exactly when $BD' = 0$, that is when the shocks that move the state are orthogonal to the shocks that hit the observation equation.

A one-line example shows that they matter otherwise: with scalars $A = 1/2$, $B = C = D = 1$, the correct $2\pi S_Y(0)$ is $(1 + 1/(1 - 1/2))^2 = 9$, while the truncated formula gives $1/(1 - 1/2)^2 + 1 = 5$.

Nothing in what follows turns on this, because we write both our VAR and our solved model with $D = 0$, which is the natural way to write each of them.

At $\omega = 0$ with $D = 0$ everything collapses to a long-run multiplier.

Writing $G = C(I - A)^{-1} B$,

$$2\pi S_Y(0) = GG', \qquad h_{y,z}(0) = \frac{[GG']_{yz}}{[GG']_{zz}}. \tag{149.6}$$

```
def h_zero_from_state_space(A, B, C, iy, iz):
    """h(0) for observable iy regressed on observable iz."""
    G = np.linalg.solve(np.eye(A.shape[0]) - A, B)
    S0 = C @ G @ G.T @ C.T
    return S0[iy, iz] / S0[iz, iz]
```

149.4 Data

Sargent and Surico [2011] splice FRED data onto the historical series of Balke and Gordon [1986] to reach back to 1900.

Those historical series are not on FRED, so we work with the post-1959 quarterly data that FRED does supply, and we extend the sample by twenty years beyond the paper's 2005 endpoint.

That extension is the interesting part: it covers the balance sheet expansions after 2008 and after 2020, and the inflation of 2021-2023.

We use M2 for money, the GDP deflator for prices, real GDP for output, and the three-month Treasury bill rate for the nominal interest rate.

The paper's benchmark is a six-month commercial paper rate, which FRED no longer carries; its Appendix Table A reports that the three-month bill gives similar answers.

Money growth, inflation, and output growth are 100 times quarterly log differences, and the interest rate is divided by four so that it too is a quarterly rate in percent.

```
start, end = datetime.datetime(1959, 1, 1), datetime.datetime(2030, 1, 1)
raw = web.DataReader(['M2SL', 'GDPDEF', 'GDPC1', 'TB3MS'], 'fred', start, end)

q = pd.DataFrame({'M2': raw['M2SL'].resample('QS').mean(),
                  'P': raw['GDPDEF'].resample('QS').mean(),
                  'Y': raw['GDPC1'].resample('QS').mean(),
                  'R': raw['TB3MS'].resample('QS').mean() / 4}).dropna()

data = pd.DataFrame({'dm': 100 * np.log(q['M2']).diff(),
                     'pi': 100 * np.log(q['P']).diff(),
                     'dy': 100 * np.log(q['Y']).diff(),
                     'R': q['R']}).dropna()

VARS = ['dm', 'pi', 'R', 'dy']
LABELS = {'dm': 'M2 growth', 'pi': 'inflation',
          'R': 'T-bill rate', 'dy': 'real GDP growth'}
print(f"sample: {data.index[0].date()} to {data.index[-1].date()},  T = {len(data)}")
data.describe().round(3)
```

```
sample: 1959-04-01 to 2026-07-01,  T = 270
```

	dm	pi	dy	R
count	270.000	270.000	270.000	270.000
mean	1.627	0.806	0.738	1.089
std	1.114	0.574	1.049	0.769
min	-1.770	-0.399	-8.204	0.003
25%	1.099	0.424	0.349	0.527
50%	1.600	0.627	0.764	1.099
75%	2.087	1.023	1.120	1.433
max	12.448	2.899	7.476	3.763

Here are the raw series and their $\beta = 0.95$ moving averages.

The shaded band marks 1959-1975, the closest we can come to Lucas's window.

```
filtered = pd.DataFrame({c: lucas_filter(data[c].values, 0.95) for c in VARS},
                        index=data.index)

fig, axes = plt.subplots(2, 2, figsize=(12, 7), sharex=True)
for ax, c in zip(axes.flat, VARS):
    ax.plot(data.index, data[c], lw=0.8, color='0.65', label='raw')
    ax.plot(filtered.index, filtered[c], lw=2.2, color='C0',
            label=r'$\beta = 0.95$ filter')
    ax.axvspan(pd.Timestamp('1959-01-01'), pd.Timestamp('1975-12-31'),
               color='C1', alpha=0.12)
    ax.set_title(LABELS[c])
    ax.legend(frameon=False, fontsize=9)
fig.suptitle('U.S. quarterly data and Lucas moving averages, percent per quarter')
plt.tight_layout()
plt.show()
```

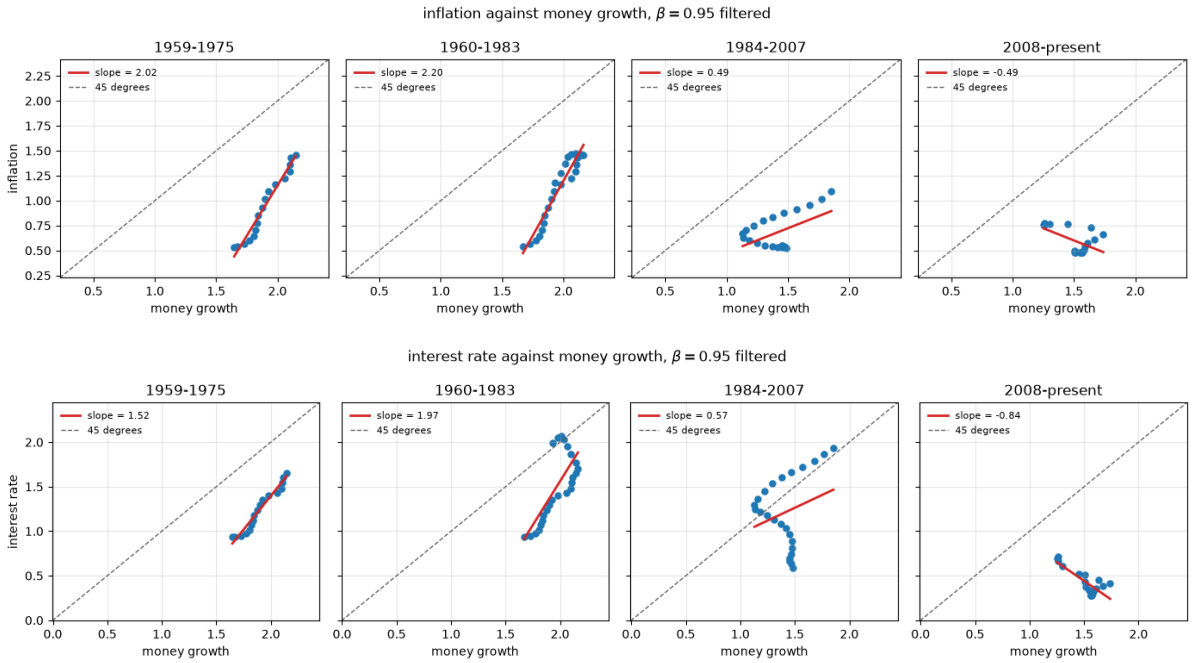
Money growth, inflation, and the interest rate rise together into the early 1980s and then fall together.

After 1984 that comovement is much harder to see, and the pandemic surge in M2 growth stands entirely apart from everything else.

149.5 Scatter plots

Following the paper we plot second quarter observations of each year, which reduces the overlap between neighboring filtered values.

```
PERIODS = [('1959-1975', 1959, 1975), ('1960-1983', 1960, 1983),
           ('1984-2007', 1984, 2007), ('2008-present', 2008, 2100)]



def scatter_panel(yvar, title):
    q2 = filtered[filtered.index.quarter == 2]
    pad = 0.15 * (q2[['dm', yvar]].values.max() - q2[['dm', yvar]].values.min())
    lim = np.array([q2[['dm', yvar]].values.min() - pad,
                    q2[['dm', yvar]].values.max() + pad])
    fig, axes = plt.subplots(1, 4, figsize=(14, 3.8), sharex=True, sharey=True)
    for ax, (name, lo, hi) in zip(axes, PERIODS):
        sub = q2[(q2.index.year >= lo) & (q2.index.year <= hi)]
        x, y = sub['dm'].values, sub[yvar].values
        ax.scatter(x, y, s=26, color='C0')
        b = np.polyfit(x, y, 1)
        xx = np.linspace(x.min(), x.max(), 2)
        ax.plot(xx, np.polyval(b, xx), color='C3', lw=2,
                label=f'slope = {b[0]:.2f}')
        ax.plot(lim, lim, color='0.4', ls='--', lw=1, label='45 degrees')
        ax.set(xlim=lim, ylim=lim, title=name, xlabel='money growth')
        ax.legend(frameon=False, fontsize=8, loc='upper left')
```

(continues on next page)

(continued from previous page)

```
    axes[0].set_ylabel(title)
    fig.suptitle(f'{title} against money growth, $\\beta = 0.95$ filtered')
    plt.tight_layout()
    plt.show()

scatter_panel('pi', 'inflation')
scatter_panel('R', 'interest rate')
```

Lucas's window and the pre-Volcker sample line up with the 45 degree line.

The great moderation and the period since 2008 do not.

149.6 Regressions on filtered data

Table 1 of the paper reports these slopes for a grid of β values.

```
def filtered_slopes(betas=(0.95, 0.8, 0.5, 0.0)):
    rows = {}
    for beta in betas:
        f = pd.DataFrame({c: lucas_filter(data[c].values, beta) for c in VARS},
                         index=data.index)
        for name, lo, hi in PERIODS + [('full sample', 1900, 2100)]:
            m = ((f.index.year >= lo) & (f.index.year <= hi)
                 & (f.index.quarter == 2))
            x = f.loc[m, 'dm'].values
            rows.setdefault(name, {})[('pi on dm', beta)] = np.polyfit(x, f.loc[m, 'pi
↪'], 1)[0]
            rows[name][('R on dm', beta)] = np.polyfit(x, f.loc[m, 'R'], 1)[0]
    tab = pd.DataFrame(rows).T
    order = [(v, b) for v in ['pi on dm', 'R on dm'] for b in betas]
```

(continues on next page)

(continued from previous page)

```
    return tab.reindex(columns=order)

filtered_slopes().round(2)
```

```
              pi on dm                    R on dm
                  0.95  0.80  0.50  0.00    0.95  0.80  0.50  0.00
1959-1975         2.02  1.06  0.24  0.01    1.52  0.54 -0.02 -0.12
1960-1983         2.20  1.14  0.23  0.04    1.97  0.94  0.15  0.05
1984-2007         0.49  0.02 -0.04 -0.03    0.57  0.23  0.21  0.08
2008-present     -0.49 -0.07 -0.05 -0.08   -0.84 -0.33 -0.15 -0.06
full sample       0.85  0.39  0.10 -0.04    0.90  0.30  0.04 -0.03
```

Two patterns stand out.

The closer β is to one, the larger the slopes, exactly as in Lucas's graphs and in the paper's Table 1.

And the slopes fall steadily as we move through the sample, from above one in Lucas's window to negative after 2008.

149.7 Estimates of $h(0)$ from a VAR

The filtered regressions are informal.

Equation (149.6) lets us compute $h(0)$ properly from a fitted VAR.

We fit a VAR(2) in money growth, inflation, the interest rate, and output growth, put it in companion form, and read $h(0)$ off the long-run multiplier matrix.

We use a diffuse prior so that we can report posterior bands, as the paper does in its Figure 5.

Draws whose companion matrix is explosive are discarded, since $h(0)$ is not defined for them.

```
def bvar_h0(Y, p=2, n_draws=500, seed=0):
    """Posterior draws of h(0) from a VAR(p) under a diffuse prior."""
    rng = np.random.default_rng(seed)
    T, n = Y.shape
    X = np.column_stack([np.ones(T - p)] + [Y[p - l - 1:T - l - 1] for l in range(p)])
    Z, k = Y[p:], 1 + n * p
    XXi = np.linalg.inv(X.T @ X)
    B_hat = XXi @ X.T @ Z
    E = Z - X @ B_hat
    S, nu = E.T @ E, T - p - k
    L_x = np.linalg.cholesky(XXi)
    J = np.vstack([np.eye(n), np.zeros((n * (p - 1), n))])

    out = np.full((n_draws, 2), np.nan)
    for d in range(n_draws):
        Sigma = invwishart.rvs(df=nu, scale=S, random_state=rng)
        B = B_hat + L_x @ rng.standard_normal((k, n)) @ np.linalg.cholesky(Sigma).T
        A = np.zeros((n * p, n * p))
        A[:n] = np.hstack([B[1 + l * n:1 + (l + 1) * n].T for l in range(p)])
        if p > 1:
            A[n:, :n * (p - 1)] = np.eye(n * (p - 1))
        if np.max(abs(np.linalg.eigvals(A))) >= 1:
            continue
        G = np.linalg.solve(np.eye(n * p) - A, J)
```

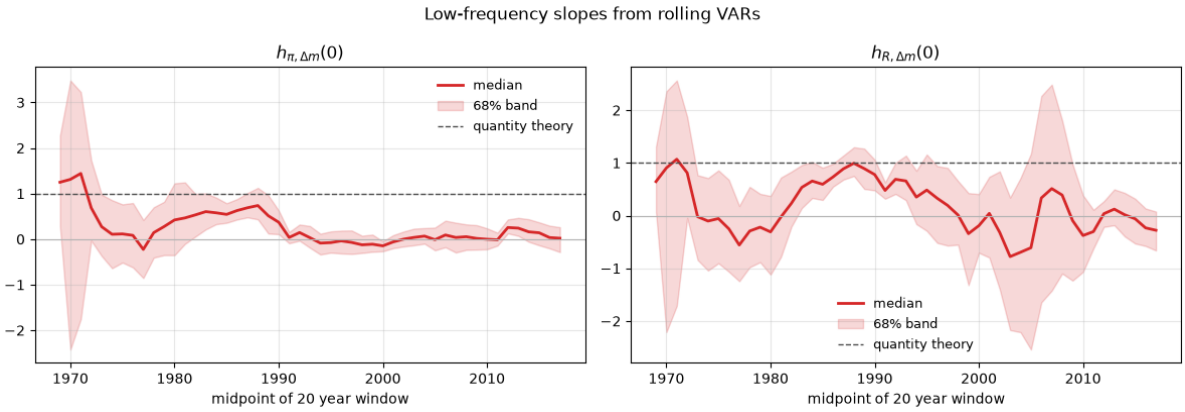
(continues on next page)

(continued from previous page)

```
        S0 = G @ Sigma @ G.T
        out[d] = [S0[1, 0] / S0[0, 0], S0[2, 0] / S0[0, 0]]
    return out
```

```
rows = []
for name, lo, hi in PERIODS + [('full sample', 1900, 2100)]:
    m = (data.index.year >= lo) & (data.index.year <= hi)
    o = bvar_h0(data.loc[m, VARS].values)
    qs = np.nanpercentile(o, [16, 50, 84], axis=0)
    rows.append(dict(period=name, T=int(m.sum()),
                     h_pi=qs[1, 0], h_pi_lo=qs[0, 0], h_pi_hi=qs[2, 0],
                     h_R=qs[1, 1], h_R_lo=qs[0, 1], h_R_hi=qs[2, 1]))
pd.DataFrame(rows).set_index('period').round(2)
```

period	T	h_pi	h_pi_lo	h_pi_hi	h_R	h_R_lo	h_R_hi
1959-1975	67	1.26	0.22	2.36	0.61	-0.04	1.31
1960-1983	96	0.74	-0.31	1.90	0.61	-0.63	1.91
1984-2007	96	-0.07	-0.30	0.14	0.27	-0.29	0.81
2008-present	75	-0.09	-0.50	0.42	-0.50	-1.10	0.28
full sample	270	0.72	0.44	1.08	0.99	0.45	1.61



The subperiods are chosen by hand, which is the objection that Boschen and Otrok [1994] raised against this style of evidence.

So we also run the VAR through rolling twenty year windows.

```
years = np.arange(data.index.year.min(), data.index.year.max() - 18)
mid, lo68, hi68 = {}, {}, {}
for y in years:
    m = (data.index.year >= y) & (data.index.year < y + 20)
    if m.sum() < 70:
        continue
    o = bvar_h0(data.loc[m, VARS].values, n_draws=300, seed=int(y))
    qs = np.nanpercentile(o, [16, 50, 84], axis=0)
    mid[y + 10], lo68[y + 10], hi68[y + 10] = qs[1], qs[0], qs[2]

mid = pd.DataFrame(mid).T
lo68, hi68 = pd.DataFrame(lo68).T, pd.DataFrame(hi68).T

fig, axes = plt.subplots(1, 2, figsize=(12, 4.2), sharex=True)
for j, (ax, ttl) in enumerate(zip(axes, [r'$h_{\pi,\Delta m}(0)$',
                                         r'$h_{R,\Delta m}(0)$'])):
    ax.plot(mid.index, mid[j], color='C3', lw=2, label='median')
    ax.fill_between(mid.index, lo68[j], hi68[j], color='C3', alpha=0.18,
                    label='68% band')
    ax.axhline(1, color='0.3', ls='--', lw=1, label='quantity theory')
    ax.axhline(0, color='0.7', lw=0.8)
    ax.set(title=ttl, xlabel='midpoint of 20 year window')
    ax.legend(frameon=False, fontsize=9)
fig.suptitle('Low-frequency slopes from rolling VARs')
plt.tight_layout()
plt.show()
```

The two low-frequency slopes are high early in the sample, when Lucas wrote, and drift toward zero afterwards.

One is rarely inside the 68 percent band after the mid 1980s.

This is the instability that the rest of the lecture tries to explain.

149.8 A model for monetary policy analysis

Section III of Sargent and Surico [2011] uses the log-linearized sticky price model of Ireland [2004], which has price indexation, habit formation, and a unit root technology shock.

The structure of the economy is

$$\pi_t = \theta(1-\alpha_\pi)\mathbb{E}_t\pi_{t+1} + \theta\alpha_\pi\pi_{t-1} + \kappa x_t - \tfrac{1}{\tau}e_t, \tag{149.7}$$

$$x_t = (1-\alpha_x)\mathbb{E}_t x_{t+1} + \alpha_x x_{t-1} - \sigma(R_t - \mathbb{E}_t\pi_{t+1}) + \sigma(1-\xi)(1-\rho_a)a_t, \tag{149.8}$$

$$\Delta m_t = \pi_t + z_t + \tfrac{1}{\sigma\gamma}\Delta x_t - \tfrac{1}{\gamma}\Delta R_t + \tfrac{1}{\gamma}(\Delta\chi_t - \Delta a_t), \tag{149.9}$$

$$\tilde{y}_t = x_t + \xi a_t, \qquad \Delta y_t = \tilde{y}_t - \tilde{y}_{t-1} + z_t. \tag{149.10}$$

Here π_t is inflation, x_t the output gap, Δm_t nominal money growth, R_t the short rate, $\tilde{y}_t$ detrended output, and z_t the growth rate of technology.

Equation (149.7) is a new Keynesian Phillips curve and (149.8) a new Keynesian IS curve.

Equation (149.9) is the money demand relation of McCallum and Nelson [1999] and Ireland [2003].

The discount factor is θ, α_π is indexation to past inflation, α_x is habit formation, κ is the slope of the Phillips curve, σ is the elasticity of intertemporal substitution, τ is the Rotemberg [1982] price adjustment cost, ξ is the inverse Frisch elasticity, and $1/\gamma$ is the interest semi-elasticity of money demand.

Four nonpolicy disturbances drive the economy: a markup shock e_t, a demand shock a_t, a money demand shock χ_t, and technology z_t,

$$e_t = \rho_e e_{t-1} + \varepsilon_{et}, \quad a_t = \rho_a a_{t-1} + \varepsilon_{at}, \quad \chi_t = \rho_\chi\chi_{t-1} + \varepsilon_{\chi t}, \quad z_t = \varepsilon_{zt}. \tag{149.11}$$

Monetary policy is either a money growth rule

$$\Delta m_t = \rho_m\Delta m_{t-1} + (1-\rho_m)(\phi_\pi\pi_t + \phi_x x_t) + \varepsilon_{mt} \tag{149.12}$$

or a Taylor rule

$$R_t = \rho_r R_{t-1} + (1-\rho_r)(\psi_\pi\pi_t + \psi_x x_t) + \varepsilon_{Rt}. \tag{149.13}$$

The observables are $[\Delta m_t, \pi_t, R_t, \Delta y_t]$.

149.9 Three things worth checking

Before estimating anything it pays to look at what this parameterization can and cannot deliver.

149.9.1 τ is not identified

The price adjustment cost τ enters the model in exactly one place, the term e_t/τ in (149.7).

Since e_t is an AR(1) with a freely estimated innovation standard deviation σ_e, the process e_t/τ is an AR(1) with innovation standard deviation σ_e/τ.

So the likelihood depends on (τ, σ_e) only through the ratio σ_e/τ.

We verify this numerically below.

Table 2 of the paper nevertheless reports a posterior for τ with mean 3.51 and a 5-95 interval of $[1.99, 4.99]$, against a prior with mean 4 and interval $[2.51, 5.77]$.

That posterior is not evidence about the Rotemberg adjustment cost.

Its leftward shift is what the prior on σ_e implies once the data pin down the ratio: the data want $\sigma_e/\tau \approx 0.31$, while the inverse gamma prior on σ_e has mean 0.3 and pulls σ_e down, dragging τ with it.

Because τ contributes nothing, we fix it at its prior mean and estimate one fewer parameter.

Nothing in the fit, or in $h(0)$, changes.

149.9.2 The first unit slope is an identity when money is exogenous

Group the terms of the money demand equation (149.9) as

$$\Delta m_t = \pi_t + z_t + \Delta v_t, \qquad v_t = \tfrac{1}{\sigma\gamma} x_t - \tfrac{1}{\gamma} R_t + \tfrac{1}{\gamma}(\chi_t - a_t). \tag{149.14}$$

Everything other than $\pi_t + z_t$ is a *first difference*.

The filter $1 - e^{-i\omega}$ vanishes at $\omega = 0$, so Δv_t contributes nothing to any spectral density or cross spectrum at frequency zero.

Therefore

$$h_{\pi,\Delta m}(0) = \frac{S_{\pi,\pi+z}(0)}{S_{\pi+z}(0)} = 1 - \frac{S_{z,\pi+z}(0)}{S_{\pi+z}(0)}. \tag{149.15}$$

This yields a proposition.

Proposition 149.9.1

Under the money growth rule (149.12) with $\phi_\pi = \phi_x = 0$,

$$h_{\pi,\Delta m}(0) = 1$$

exactly, whatever the values of the other parameters.

Proof. With $\phi_\pi = \phi_x = 0$ the rule reads $\Delta m_t = \rho_m \Delta m_{t-1} + \varepsilon_{mt}$, so money growth is driven by ε_m alone.

From (149.14), $\pi_t + z_t = \Delta m_t - \Delta v_t$, and Δv contributes nothing at frequency zero, so $S_{z,\pi+z}(0) = S_{z,\Delta m}(0)$.

Technology is exogenous and orthogonal to ε_m, so $S_{z,\Delta m}(\omega) \equiv 0$.

Now apply (149.15).

This is worth thinking about.

Lucas's *first* illustration prevails whenever money growth is econometrically exogenous, which is the case Whiteman [1984] assumed.

It is a property of the money demand specification, not of a deep monetary neutrality.

Departures from one arise only through $S_{z,\pi+z}(0)$, and that term is nonzero only when the policy rule makes money growth respond to the endogenous variables, so that technology becomes correlated with money growth at frequency zero.

The *second* illustration has no such backing.

The same argument gives $h_{R,\Delta m}(0) = S_{R,\pi+z}(0)/S_{\pi+z}(0)$, which equals one only if the low-frequency behavior of the ex ante real rate happens to cooperate.

So within this structural model, Lucas's two illustrations are not on the same footing.

149.9.3 The reported posterior for α_x stops at one half

Table 2 reports a posterior for the habit parameter α_x with mean 0.4775 and a 95th percentile of exactly 0.5000, under a beta prior on $[0, 1]$.

An interval that ends on a round number is usually a constraint rather than a finding.

It is not a determinacy constraint: we check below that the model has a unique stable solution on both sides of $\alpha_x = 0.5$.

We therefore let α_x range over the whole unit interval.

149.10 Solving the model

The model is a linear rational expectations system, which we solve with the method of Sims [2002].

Write it in the canonical form

$$\Gamma_0 y_t = \Gamma_1 y_{t-1} + \Psi \varepsilon_t + \Pi \eta_t, \tag{149.16}$$

where ε_t collects the structural shocks and η_t collects expectational errors, one for each variable whose expectation appears in the system.

The trick is to add $\mathbb{E}_t \pi_{t+1}$ and $\mathbb{E}_t x_{t+1}$ to the vector of variables, together with the identities

$$\pi_t = \mathbb{E}_{t-1}\pi_t + \eta^\pi_t, \qquad x_t = \mathbb{E}_{t-1} x_t + \eta^x_t.$$

The solution algorithm takes a generalized Schur decomposition of the matrix pencil (Γ_0, Γ_1), orders the stable generalized eigenvalues first, and then asks whether the expectational errors can be chosen to kill the explosive block.

If they can, a stable solution exists; if they can be chosen in only one way, it is unique.

```
SMALL = 1e-6

def gensys(g0, g1, psi, pi, div=1.01):
    """
    Solve  g0 @ y[t] = g1 @ y[t-1] + psi @ eps[t] + pi @ eta[t].

    Returns (G1, impact, eu) so that, when eu == (1, 1),

        y[t] = G1 @ y[t-1] + impact @ eps[t]

    is the unique stable solution.  eu[0] flags existence, eu[1] uniqueness.
    """
    n = g0.shape[0]
    S, T, alpha, beta, Q, Z = ordqz(g0, g1, output='complex',
                                    sort=lambda a, b: abs(b) < div * abs(a))
    nunstab = int(np.sum(abs(beta) >= div * abs(alpha)))
    ns = n - nunstab
    if np.any((abs(alpha) < SMALL) & (abs(beta) < SMALL)):
        return None, None, (-2, -2)

    q = Q.conj().T
    q1, q2 = q[:ns], q[ns:]

    def trimmed_svd(M):
        u, d, vh = svd(M)
        keep = d > SMALL
        r = len(d)
        return u[:, :r][:, keep], d[keep], vh.conj().T[:, :r][:, keep]

    u2, d2, v2 = trimmed_svd(q2 @ pi)        # can eta kill the explosive block?
    u1, d1, v1 = trimmed_svd(q1 @ pi)        # is the choice unique?

    exist = len(d2) >= nunstab
    if v1.shape[1] == 0:
        unique = True
    else:
        loose = v1 - v2 @ v2.conj().T @ v1
        unique = np.sum(svd(loose, compute_uv=False) > SMALL * n) == 0
    eu = (int(exist), int(unique))
    if not exist:
        return None, None, eu

    W = u2 @ np.diag(1 / d2) @ v2.conj().T @ v1 @ np.diag(d1) @ u1.conj().T
    tmat = np.hstack([np.eye(ns), -W.conj().T])
    G0 = np.vstack([tmat @ S,
                    np.hstack([np.zeros((nunstab, ns)), np.eye(nunstab)])])
    G0i = np.linalg.inv(G0)
    G1 = np.real(Z @ (G0i @ np.vstack([tmat @ T, np.zeros((nunstab, n))]))
                 @ Z.conj().T)
    impact = np.real(Z @ (G0i @ np.vstack([tmat @ q @ psi,
                                           np.zeros((nunstab, psi.shape[1]))])))
    return G1, impact, eu
```

Before trusting it, we check it against a model whose solution we can write down.

In the textbook three-equation new Keynesian model

$$\pi_t = \theta \mathbb{E}_t \pi_{t+1} + \kappa x_t, \quad x_t = \mathbb{E}_t x_{t+1} - \sigma(R_t - \mathbb{E}_t \pi_{t+1}) + g_t, \quad R_t = \phi_\pi \pi_t,$$

with g_t an AR(1), the equilibrium is $\pi_t = \pi_g g_t$ and $x_t = x_g g_t$ where (π_g, x_g) solves a two by two linear system, and the equilibrium is unique if and only if $\phi_\pi > 1$.

```
def toy_nk(phi_pi, theta=0.99, kappa=0.1, sigma=1.0, rho=0.8):
    """y = [pi, x, R, g, E pi(+1), E x(+1)]."""
    g0, g1 = np.zeros((6, 6)), np.zeros((6, 6))
    psi, pie = np.zeros((6, 1)), np.zeros((6, 2))
    g0[0, 0], g0[0, 4], g0[0, 1] = 1, -theta, -kappa
    g0[1, 1], g0[1, 5], g0[1, 2], g0[1, 4], g0[1, 3] = 1, -1, sigma, -sigma, -1
    g0[2, 2], g0[2, 0] = 1, -phi_pi
    g0[3, 3], g1[3, 3], psi[3, 0] = 1, rho, 1
    g0[4, 0], g1[4, 4], pie[4, 0] = 1, 1, 1
    g0[5, 1], g1[5, 5], pie[5, 1] = 1, 1, 1
    return g0, g1, psi, pie

for phi in [0.5, 1.5, 3.0]:
    G1, impact, eu = gensys(*toy_nk(phi))
    msg = 'unique stable solution' if eu == (1, 1) else 'indeterminate'
    print(f'phi_pi = {phi}:  eu = {eu}  ({msg})')

theta, kappa, sigma, rho, phi = 0.99, 0.1, 1.0, 0.8, 1.5
M = np.array([[1 - theta * rho, -kappa], [sigma * (phi - rho), 1 - rho]])
exact = np.linalg.solve(M, np.array([0.0, 1.0]))
G1, impact, _ = gensys(*toy_nk(phi))
print(f'\nanalytic (pi_g, x_g) = {np.round(exact, 8)}')
print(f'gensys   (pi_g, x_g) = {np.round(impact[:2, 0], 8)}')
```

```
phi_pi = 0.5:  eu = (1, 0)  (indeterminate)
phi_pi = 1.5:  eu = (1, 1)  (unique stable solution)
phi_pi = 3.0:  eu = (1, 1)  (unique stable solution)

analytic (pi_g, x_g) = [0.89605735 1.86379928]
gensys   (pi_g, x_g) = [0.89605735 1.86379928]
```

The solver reproduces the analytic solution to machine precision and correctly refuses to deliver one when $\phi_\pi < 1$.

149.11 The Sargent-Surico model in canonical form

Now we write (149.7) through (149.13) in the form (149.16).

The vector of variables is

$$y_t = [\pi_t,\ x_t,\ \Delta m_t,\ R_t,\ e_t,\ a_t,\ \chi_t,\ z_t,\ \mathbb{E}_t\pi_{t+1},\ \mathbb{E}_t x_{t+1}]',$$

and the shocks are $\varepsilon_t = [\varepsilon_{et}, \varepsilon_{at}, \varepsilon_{\chi t}, \varepsilon_{zt}, \varepsilon_{mt}]'$.

```
PI, X, DM, R, E, A_, CH, Z, EPI, EX = range(10)
NY = 10

def canonical(p, rule='money'):
    """Matrices g0, g1, psi, pi of equations (SS-NKPC) through (SS-Taylor)."""
    th, api, kap, tau = p['theta'], p['alpha_pi'], p['kappa'], p['tau']
    ax, sig, xi, gam = p['alpha_x'], p['sigma'], p['xi'], p['gamma']
    g0, g1 = np.zeros((NY, NY)), np.zeros((NY, NY))
```

(continues on next page)

(continued from previous page)

```
    psi, pie = np.zeros((NY, 5)), np.zeros((NY, 2))

    # Phillips curve
    g0[0, PI], g0[0, EPI], g0[0, X], g0[0, E] = 1, -th * (1 - api), -kap, 1 / tau
    g1[0, PI] = th * api
    # IS curve
    g0[1, X], g0[1, EX], g0[1, R], g0[1, EPI] = 1, -(1 - ax), sig, -sig
    g0[1, A_] = -sig * (1 - xi) * (1 - p['rho_a'])
    g1[1, X] = ax
    # money demand
    g0[2, DM], g0[2, PI], g0[2, Z] = 1, -1, -1
    for col, coef in [(X, -1 / (sig * gam)), (R, 1 / gam),
                      (CH, -1 / gam), (A_, 1 / gam)]:
        g0[2, col], g1[2, col] = coef, coef
    # policy rule
    if rule == 'money':
        rm = p['rho_m']
        g0[3, DM] = 1
        g0[3, PI], g0[3, X] = -(1 - rm) * p['phi_pi'], -(1 - rm) * p['phi_x']
        g1[3, DM] = rm
    else:
        rr = p['rho_r']
        g0[3, R] = 1
        g0[3, PI], g0[3, X] = -(1 - rr) * p['psi_pi'], -(1 - rr) * p['psi_x']
        g1[3, R] = rr
    psi[3, 4] = 1
    # exogenous shocks
    for row, (v, rho, k) in enumerate([(E, p['rho_e'], 0), (A_, p['rho_a'], 1),
                                       (CH, p['rho_chi'], 2), (Z, 0.0, 3)], 4):
        g0[row, v], g1[row, v], psi[row, k] = 1, rho, 1
    # expectational identities
    g0[8, PI], g1[8, EPI], pie[8, 0] = 1, 1, 1
    g0[9, X], g1[9, EX], pie[9, 1] = 1, 1, 1
    return g0, g1, psi, pie
```

Output growth in (149.10) needs x_{t-1} and a_{t-1}, so the state carries those two lags,

$$S_t = [y_t', \, x_{t-1}, \, a_{t-1}]', \qquad S_t = AS_{t-1} + B\varepsilon_t, \qquad Y_t = CS_t.$$

There is no measurement error, so $D = 0$ and (149.6) applies directly.

The following issue arises here.

The `div` argument of `gensys` splits stable from explosive generalized eigenvalues, and it has to sit a little above one for the split to be numerically reliable.

So a solution that `gensys` reports as unique and stable can still have a root of the transition matrix at or just above one.

Both $h(0)$ and the Kalman filter need covariance stationarity, so we test for it explicitly rather than trusting the flags.

```
def state_space(p, rule='money'):
    """
    Return A, B, C for S[t] = A S[t-1] + B eps[t] and Y[t] = C S[t],
    together with a status string that is 'ok' when the equilibrium is
    unique and covariance stationary.
    """
    G1, impact, eu = gensys(*canonical(p, rule))
    if eu[0] != 1:
```

(continues on next page)

(continued from previous page)

```
        return None, None, None, 'no stable solution'
    if eu[1] != 1:
        return None, None, None, 'indeterminate'
    sd = np.diag([p['sig_e'], p['sig_a'], p['sig_chi'], p['sig_z'], p['sig_m']])
    n = NY + 2
    A, B = np.zeros((n, n)), np.zeros((n, 5))
    A[:NY, :NY] = G1
    A[NY, X], A[NY + 1, A_] = 1, 1
    B[:NY] = impact @ sd
    C = np.zeros((4, n))                                # [dm, pi, R, dy]
    C[0, DM], C[1, PI], C[2, R] = 1, 1, 1
    C[3, X], C[3, NY] = 1, -1
    C[3, A_], C[3, NY + 1] = p['xi'], -p['xi']
    C[3, Z] = 1
    if np.max(np.abs(np.linalg.eigvals(A))) > 1 - 1e-9:
        return None, None, None, 'unit or explosive root'
    return A, B, C, 'ok'

def h_zero(p, rule='money'):
    """(h_pi,dm(0), h_R,dm(0)) implied by the model at parameters p."""
    A, B, C, status = state_space(p, rule)
    if status != 'ok':
        return np.nan, np.nan
    return (h_zero_from_state_space(A, B, C, 1, 0),
            h_zero_from_state_space(A, B, C, 2, 0))
```

This test matters.

Without it, a point like $\phi_\pi = 1$, $\phi_x = 0$ returns $h_{\pi,\Delta m}(0) = h_{R,\Delta m}(0) = 1.000$, an apparently perfect confirmation of both of Lucas's illustrations.

The transition matrix there has a root of exactly one, the spectral density at frequency zero does not exist, and those two numbers come from inverting a matrix whose condition number is about 10^{16}.

That point sits in the upper right corner of the range that Figure 6 of the paper plots.

We show below that at the paper's own Table 2 posterior means a whole strip of that range has no covariance stationary equilibrium.

We can now check our implementation against the paper.

At the posterior means of Table 2, Sargent and Surico [2011] report implied values $h_{\pi,\Delta m}(0) = 1.0068$ and $h_{R,\Delta m}(0) = 0.8163$.

```
PAPER = dict(theta=0.9901, alpha_pi=0.8815, kappa=0.0324, tau=3.5126,
             alpha_x=0.4775, sigma=0.0997, xi=3.0319, gamma=3.8128,
             phi_pi=0.2312, phi_x=-0.1971, rho_m=0.7428, rho_e=0.5645,
             rho_a=0.9241, rho_chi=0.5024, sig_e=1.0922, sig_a=0.7226,
             sig_chi=0.2388, sig_z=1.5845, sig_m=1.1457)

print('h at the posterior means of Table 2: %.4f, %.4f' % h_zero(PAPER))
print('reported in Table 2:                 1.0068, 0.8163')
```

```
h at the posterior means of Table 2: 1.0093, 0.8060
reported in Table 2:                 1.0068, 0.8163
```

Our independent implementation lands on the paper's numbers.

That gives us confidence that we have read equations (149.7) through (149.12) the way their authors intended.

149.11.1 Checking the three claims

Now we verify the three observations of the previous section.

```
print('scaling tau and sigma_e together leaves h(0) untouched:')
for f in [0.5, 1.0, 2.0, 8.0]:
    q = dict(PAPER, tau=PAPER['tau'] * f, sig_e=PAPER['sig_e'] * f)
    print(f'   tau, sigma_e scaled by {f:4.1f}:  h_pi = {h_zero(q)[0]:.10f}')

print('\nwith phi_pi = phi_x = 0, h_pi is exactly one for any other parameters:')
rng = np.random.default_rng(0)
for i in range(5):
    q = dict(PAPER, phi_pi=0.0, phi_x=0.0,
             kappa=rng.uniform(0.01, 0.3), alpha_pi=rng.uniform(0.1, 0.9),
             alpha_x=rng.uniform(0.1, 0.9), sigma=rng.uniform(0.05, 0.5),
             gamma=rng.uniform(1, 8), rho_m=rng.uniform(0, 0.95),
             sig_z=rng.uniform(0.2, 3.0), xi=rng.uniform(0.5, 5.0))
    print(f'   draw {i}:  h_pi = {h_zero(q)[0]:.12f}   h_R = {h_zero(q)[1]:.4f}')

for ax in [0.30, 0.45, 0.499, 0.501, 0.60, 0.80]:
    print(f'   alpha_x = {ax:5.3f}:  {state_space(dict(PAPER, alpha_x=ax))[3]}')
```

```
scaling tau and sigma_e together leaves h(0) untouched:
   tau, sigma_e scaled by  0.5:  h_pi = 1.0092936992
   tau, sigma_e scaled by  1.0:  h_pi = 1.0092936992
   tau, sigma_e scaled by  2.0:  h_pi = 1.0092936992
   tau, sigma_e scaled by  8.0:  h_pi = 1.0092936992

with phi_pi = phi_x = 0, h_pi is exactly one for any other parameters:
   draw 0:  h_pi = 1.000000000000   h_R = 0.4849
   draw 1:  h_pi = 1.000000000000   h_R = -0.0141
   draw 2:  h_pi = 1.000000000000   h_R = 0.2936
   draw 3:  h_pi = 1.000000000000   h_R = 0.7060
   draw 4:  h_pi = 1.000000000000   h_R = 0.7182

determinacy on both sides of alpha_x = 0.5:
   alpha_x = 0.300:  ok
   alpha_x = 0.450:  ok
   alpha_x = 0.499:  ok
   alpha_x = 0.501:  ok
   alpha_x = 0.600:  ok
   alpha_x = 0.800:  ok
```

All three claims hold.

The likelihood is invariant to scaling (τ, σ_e), the first unit slope is an identity under exogenous money growth, and the model is determinate on both sides of $\alpha_x = 1/2$.

Notice also that $h_{R,\Delta m}(0)$ moves all over the place across those same draws, which is the asymmetry between the two illustrations that *Proposition 149.9.1* predicts.

Finally, here is the strip of the Figure 6 policy grid on which, at the paper's own posterior means, no covariance stationary equilibrium exists.

```
for phi_x in [0.0, -0.25, -0.5]:
    bad = [round(g, 2) for g in np.linspace(-3, 1, 41)
           if state_space(dict(PAPER, phi_pi=g, phi_x=phi_x))[3] != 'ok']
    print(f'phi_x = {phi_x:5.2f}: no stationary equilibrium at phi_pi in '
          f'{bad if bad else "none of the grid"}')
```

```
phi_x =  0.00: no stationary equilibrium at phi_pi in [np.float64(-3.0), np.
↪float64(-2.9), np.float64(-2.8), np.float64(-2.7), np.float64(-2.6), np.float64(-
↪2.5), np.float64(-2.4), np.float64(-2.3), np.float64(-2.2), np.float64(-2.1), np.
↪float64(-2.0), np.float64(-1.9), np.float64(-1.8), np.float64(-1.7), np.float64(-
↪1.6), np.float64(1.0)]
phi_x = -0.25: no stationary equilibrium at phi_pi in none of the grid
phi_x = -0.50: no stationary equilibrium at phi_pi in none of the grid
```

The strip is far from the estimated policy rule, so the paper's conclusions are not at stake.

But an $h(0)$ reported over it would be a number computed from a spectral density that does not exist.

149.12 Bayesian estimation

We estimate the money growth rule version on 1960:I-1983:IV, the paper's sample.

The four observables are demeaned, since the model is written in deviations from a steady state.

```
mask = (data.index.year >= 1960) & (data.index.year <= 1983)
Y_est = data.loc[mask, VARS].values
Y_est = Y_est - Y_est.mean(0)
print(f'estimation sample: {mask.sum()} quarters, '
      f'{data.index[mask][0].date()} to {data.index[mask][-1].date()}')
```

```
estimation sample: 96 quarters, 1960-01-01 to 1983-10-01
```

149.12.1 The likelihood

Given (A, B, C) the likelihood follows from the Kalman filter.

We initialize the state at its unconditional mean and covariance, the latter solving the discrete Lyapunov equation $P = APA' + BB'$.

```
def loglik(p, Y, rule='money'):
    """Kalman filter log likelihood of Y (T x 4) at parameters p."""
    A, B, C, status = state_space(p, rule)
    if status != 'ok':
        return -np.inf
    Q = B @ B.T
    try:
        P = solve_discrete_lyapunov(A, Q)
    except Exception:
        return -np.inf
    s = np.zeros(A.shape[0])
    ll, const = 0.0, Y.shape[1] * np.log(2 * np.pi)
    for t in range(Y.shape[0]):
        s = A @ s
```

(continues on next page)

(continued from previous page)

```
        P = A @ P @ A.T + Q
        v = Y[t] - C @ s                                # forecast error
        PCt = P @ C.T
        F = C @ PCt                                     # its covariance
        try:
            L = np.linalg.cholesky(F)
        except np.linalg.LinAlgError:
            return -np.inf
        u = np.linalg.solve(L, v)
        ll -= 0.5 * (const + 2 * np.sum(np.log(np.diag(L))) + u @ u)
        K = np.linalg.solve(F, PCt.T).T                 # Kalman gain
        s, P = s + K @ v, P - K @ PCt.T
    return ll if np.isfinite(ll) else -np.inf
```

149.12.2 Priors

We use the prior means and standard deviations of Table 2, matching moments to pick the parameters of each family.

```
def beta_prior(m, s):
    nu = m * (1 - m) / s ** 2 - 1
    return stats.beta(m * nu, (1 - m) * nu)

def gamma_prior(m, s):
    return stats.gamma(m ** 2 / s ** 2, scale=s ** 2 / m)

def invgamma_prior(m, s):
    a = m ** 2 / s ** 2 + 2
    return stats.invgamma(a, scale=m * (a - 1))

PRIOR, SUPPORT = {}, {}
for n, (m, s) in [('theta', (0.99, 0.005)), ('alpha_pi', (0.5, 0.2)),
                  ('alpha_x', (0.5, 0.2)), ('rho_m', (0.5, 0.05)),
                  ('rho_e', (0.5, 0.1)), ('rho_a', (0.5, 0.1)),
                  ('rho_chi', (0.5, 0.1))]:
    PRIOR[n], SUPPORT[n] = beta_prior(m, s), (1e-6, 1 - 1e-6)
for n, (m, s) in [('kappa', (0.3, 0.1)), ('sigma', (0.1, 0.05)),
                  ('xi', (2.0, 1.0)), ('gamma', (4.0, 1.0))]:
    PRIOR[n], SUPPORT[n] = gamma_prior(m, s), (1e-8, np.inf)
for n in ['phi_pi', 'phi_x']:
    PRIOR[n], SUPPORT[n] = stats.norm(0, 0.5), (-np.inf, np.inf)
for n in ['sig_e', 'sig_a', 'sig_chi', 'sig_z', 'sig_m']:
    PRIOR[n], SUPPORT[n] = invgamma_prior(0.3, 1.0), (1e-8, np.inf)

FREE = ['theta', 'alpha_pi', 'kappa', 'alpha_x', 'sigma', 'xi', 'gamma',
        'phi_pi', 'phi_x', 'rho_m', 'rho_e', 'rho_a', 'rho_chi',
        'sig_e', 'sig_a', 'sig_chi', 'sig_z', 'sig_m']
TAU = 4.0                       # not identified; fixed at its prior mean

def unpack(v):
    return dict({n: float(x) for n, x in zip(FREE, v)}, tau=TAU)
```

(continues on next page)

(continued from previous page)

```
def log_post(v, Y):
    lp = 0.0
    for n, x in zip(FREE, v):
        lo, hi = SUPPORT[n]
        if not lo < x < hi:
            return -np.inf
        lp += PRIOR[n].logpdf(x)
    return lp + loglik(unpack(v), Y)
```

149.12.3 The posterior mode

We start the search at the paper's posterior means, use Powell's derivative free method, and polish with a gradient method.

```
v_start = np.array([PAPER[n] for n in FREE])
neg_log_post = lambda v: -log_post(v, Y_est)

res = optimize.minimize(neg_log_post, v_start, method='Powell',
                        options=dict(maxiter=20000, maxfev=20000))
res = optimize.minimize(neg_log_post, res.x, method='L-BFGS-B',
                        bounds=[SUPPORT[n] for n in FREE])
v_mode = res.x
print(f'log posterior at the paper\'s means: {log_post(v_start, Y_est):10.3f}')
print(f'log posterior at the mode:          {-res.fun:10.3f}')
print('h(0) at the mode: %.4f, %.4f' % h_zero(unpack(v_mode)))
```

```
log posterior at the paper's means:   -531.052
log posterior at the mode:            -320.204
h(0) at the mode: 0.9765, 0.7694
```

Note

Starting the search at the paper's estimates finds the mode nearest to them.

The Hamiltonian Monte Carlo section at the end of this lecture discovers that this is a *local* mode, and that the posterior has a second one with higher density.

149.12.4 Random walk Metropolis-Hastings

The standard proposal covariance is the inverse Hessian of the negative log posterior at the mode, which we compute by finite differences.

```
def numerical_hessian(f, v, rel=1e-4):
    n = len(v)
    h = rel * np.maximum(np.abs(v), 1e-2)
    H = np.zeros((n, n))
    for i in range(n):
        for j in range(i, n):
            ei, ej = np.zeros(n), np.zeros(n)
            ei[i], ej[j] = h[i], h[j]
            H[i, j] = H[j, i] = (f(v + ei + ej) - f(v + ei - ej)
```

(continues on next page)

(continued from previous page)

```
                                - f(v - ei + ej) + f(v - ei - ej)) / (4 * h[i] *␣
↪h[j])
    return H

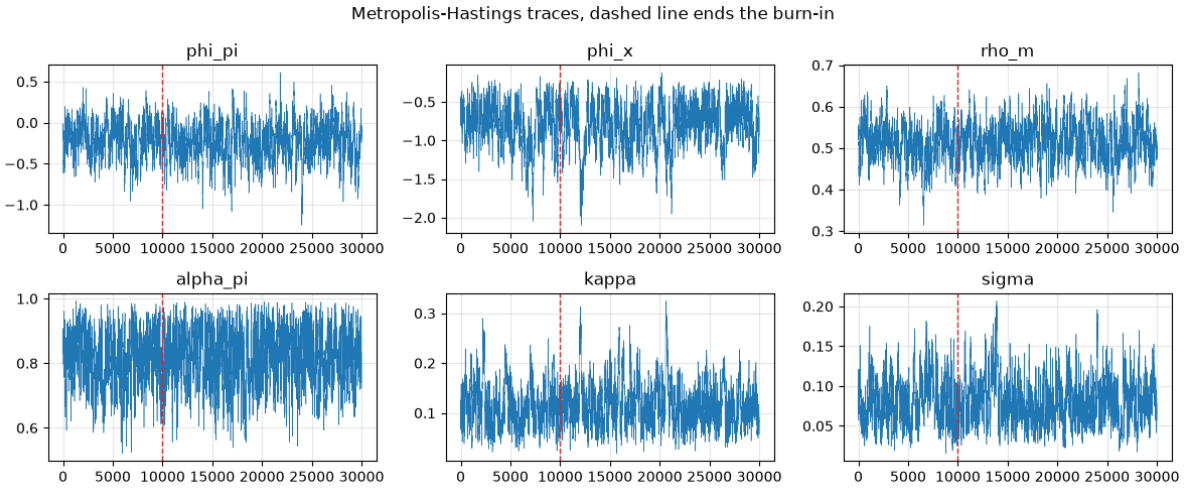
H = numerical_hessian(neg_log_post, v_mode)
Sigma_prop = np.linalg.inv(H)
print('proposal covariance is positive definite:',
      np.all(np.linalg.eigvalsh(H) > 0))
```

```
proposal covariance is positive definite: True
```

```
def rwmh(Y, v0, Sigma, n_draws, c=0.45, seed=42):
    """Random walk Metropolis-Hastings in the natural parameter space."""
    rng = np.random.default_rng(seed)
    L = np.linalg.cholesky(Sigma)
    v, lp = v0.copy(), log_post(v0, Y)
    draws, n_acc = np.empty((n_draws, len(v))), 0
    for i in range(n_draws):
        cand = v + c * (L @ rng.standard_normal(len(v)))
        lp_cand = log_post(cand, Y)
        if np.log(rng.random()) < lp_cand - lp:
            v, lp, n_acc = cand, lp_cand, n_acc + 1
        draws[i] = v
    return draws, n_acc / n_draws
```

Draws that fall outside the support of a prior get $-\infty$ and are rejected, so we can work in the natural parameter space and skip transformations.

The chain below is short enough to run while you read; a serious application would use many more draws.



```
N_DRAWS, BURN = 30_000, 10_000

t0 = time.time()
draws, acc_rate = rwmh(Y_est, v_mode, Sigma_prop, N_DRAWS)
rwmh_seconds = time.time() - t0

kept = draws[BURN::5]
print(f'acceptance rate {acc_rate:.3f},  {len(kept)} retained draws, '
      f'{rwmh_seconds:.0f} seconds')
```

```
acceptance rate 0.283,  4000 retained draws, 363 seconds
```

```

```

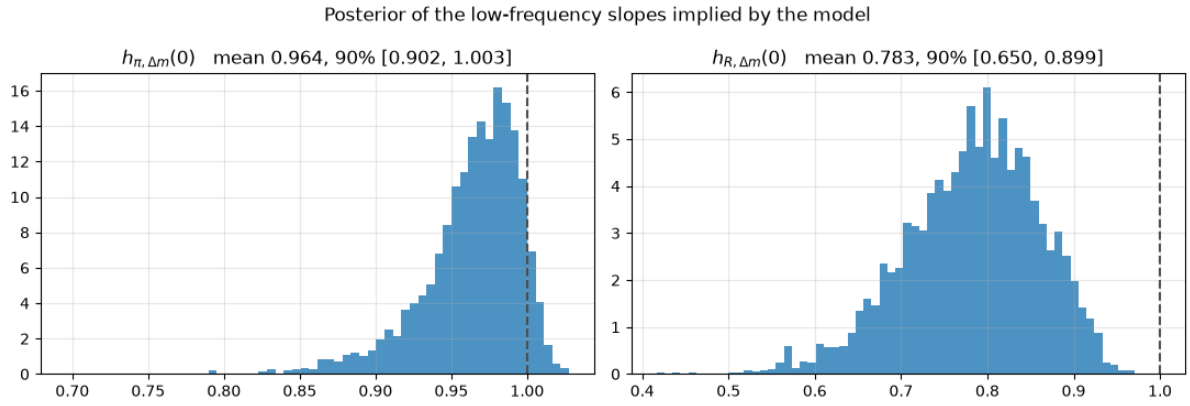
Our estimates are recognizably those of Table 2, with the differences one expects from a different interest rate series and different data vintages.

The Phillips curve is strongly backward looking and flat, the IS curve much less so.

Most important for what follows, the money growth rule responds weakly to inflation, with a posterior for ϕ_π that straddles zero, and it carries substantial smoothing.

That is the paper's central reading of the pre-1984 regime: the Federal Reserve put persistent, nearly exogenous, movement into money growth.



By *Proposition 149.9.1* that is precisely the configuration in which Lucas's first illustration holds, which is also why the paper's own posterior for $h_{\pi,\Delta m}(0)$ in Table 2 is so remarkably tight around one.

149.12.5 The posterior distribution of $h(0)$

Every draw of the structural parameters implies a pair of low-frequency slopes.

```
h_draws = np.array([h_zero(unpack(v)) for v in kept])

fig, axes = plt.subplots(1, 2, figsize=(11, 3.8))
for ax, j, ttl in zip(axes, [0, 1],
                      [r'$h_{\pi,\Delta m}(0)$', r'$h_{R,\Delta m}(0)$']):
    ax.hist(h_draws[:, j], bins=60, color='C0', alpha=0.8, density=True)
    ax.axvline(1, color='0.3', ls='--', lw=1.5)
    ax.set_title(f'{ttl}   mean {h_draws[:, j].mean():.3f}, '
                 f'90% [{np.percentile(h_draws[:, j], 5):.3f}, '
                 f'{np.percentile(h_draws[:, j], 95):.3f}]')
fig.suptitle('Posterior of the low-frequency slopes implied by the model')
plt.tight_layout()
plt.show()
```

The estimated model reproduces Lucas's two illustrations over a sample much like his.

Compare these with the VAR estimates for 1960-1983 that we computed earlier, and with the paper's reported posterior means of 1.0068 and 0.8163.

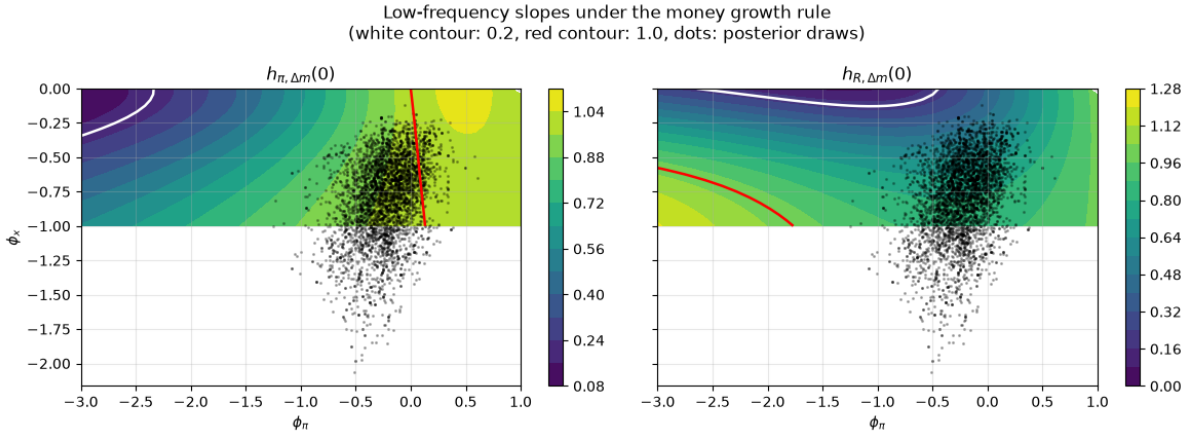
149.13 How monetary policy moves the low-frequency slopes

Now for the paper's main experiment.

We lock every structural parameter at its posterior mean, vary only the two policy coefficients, and recompute $h(0)$ at each point.

```
p_bar = unpack(kept.mean(0))

def h_grid(p, rule, k1, k2, g1_vals, g2_vals):
    H1 = np.full((len(g2_vals), len(g1_vals)), np.nan)
    H2 = np.full_like(H1, np.nan)
    for i, b in enumerate(g2_vals):
        for j, a in enumerate(g1_vals):
            H1[i, j], H2[i, j] = h_zero(dict(p, **{k1: a, k2: b}), rule)
    return H1, H2
```



(continues on next page)

(continued from previous page)

```
phi_pi_grid = np.linspace(-3, 1, 49)
phi_x_grid = np.linspace(-1, 0, 25)
Hpi, HR = h_grid(p_bar, 'money', 'phi_pi', 'phi_x', phi_pi_grid, phi_x_grid)
```

```
def contour_panel(g1_vals, g2_vals, H1, H2, xlab, ylab, suptitle, scatter=None):
    fig, axes = plt.subplots(1, 2, figsize=(12, 4.4), sharey=True)
    for ax, Hm, ttl in zip(axes, [H1, H2],
                           [r'$h_{\pi,\Delta m}(0)$', r'$h_{R,\Delta m}(0)$']):
        cs = ax.contourf(g1_vals, g2_vals, Hm, levels=14, cmap='viridis')
        ax.contour(g1_vals, g2_vals, Hm, levels=[0.2, 1.0],
                   colors=['white', 'red'], linewidths=1.8)
        ax.contourf(g1_vals, g2_vals, np.isnan(Hm).astype(float),
                    levels=[0.5, 1.5], colors=['0.85'])
        if scatter is not None:
            ax.scatter(*scatter, s=1.5, color='k', alpha=0.25)
        fig.colorbar(cs, ax=ax)
        ax.set(title=ttl, xlabel=xlab)
    axes[0].set_ylabel(ylab)
    fig.suptitle(suptitle)
    plt.tight_layout()
    plt.show()

contour_panel(phi_pi_grid, phi_x_grid, Hpi, HR, r'$\phi_\pi$', r'$\phi_x$',
              'Low-frequency slopes under the money growth rule\n'
              '(white contour: 0.2, red contour: 1.0, dots: posterior draws)',
              scatter=(kept[:, FREE.index('phi_pi')],
                       kept[:, FREE.index('phi_x')]))
```

Three things come through, and they are the paper's three findings.

The low-frequency slopes are *not* policy invariant: moving (ϕ_π, ϕ_x) alone sweeps $h_{\pi,\Delta m}(0)$ across most of the range that the rolling VARs displayed.

The cloud of posterior draws sits in the region where both slopes are near one, which is where the 1960-1983 data put us.

And a much more aggressive anti-inflation stance, meaning a large *negative* ϕ_π so that money growth is cut hard when inflation rises, moves both slopes far below one, with the smallest values in the corner where ϕ_x is also near zero.

The red contour marks $h(0) = 1$ and, as *Proposition 149.9.1* requires, it passes exactly through $\phi_\pi = \phi_x = 0$.

Any gray region would be one with no unique covariance stationary equilibrium, where $h(0)$ does not exist.

Here is where the slopes bottom out, a slice through the grid at the posterior mean of ϕ_x, and the fraction of the grid the stationarity test removes.

```
print(f'no stationary equilibrium at {np.isnan(Hpi).mean():.0%} of grid points')
for name, Hm in [('h_pi', Hpi), ('h_R', HR)]:
    i, j = np.unravel_index(np.nanargmin(Hm), Hm.shape)
    print(f'   smallest {name:5s} = {Hm[i, j]:6.3f} at '
          f'phi_pi = {phi_pi_grid[j]:5.2f}, phi_x = {phi_x_grid[i]:5.2f}')

row = np.argmin(np.abs(phi_x_grid - p_bar['phi_x']))
print(f'\nslice at phi_x = {phi_x_grid[row]:.3f}')
for j in range(0, len(phi_pi_grid), 6):
    print(f'   phi_pi = {phi_pi_grid[j]:6.2f}:  '
          f'h_pi = {Hpi[row, j]:7.3f},  h_R = {HR[row, j]:7.3f}')
```

```
no stationary equilibrium at 0% of grid points
   smallest h_pi  =  0.097 at phi_pi = -3.00, phi_x =  0.00
   smallest h_R   =  0.059 at phi_pi = -1.25, phi_x =  0.00

slice at phi_x = -0.792
   phi_pi =  -3.00:  h_pi =   0.463,  h_R =   1.137
   phi_pi =  -2.50:  h_pi =   0.550,  h_R =   1.056

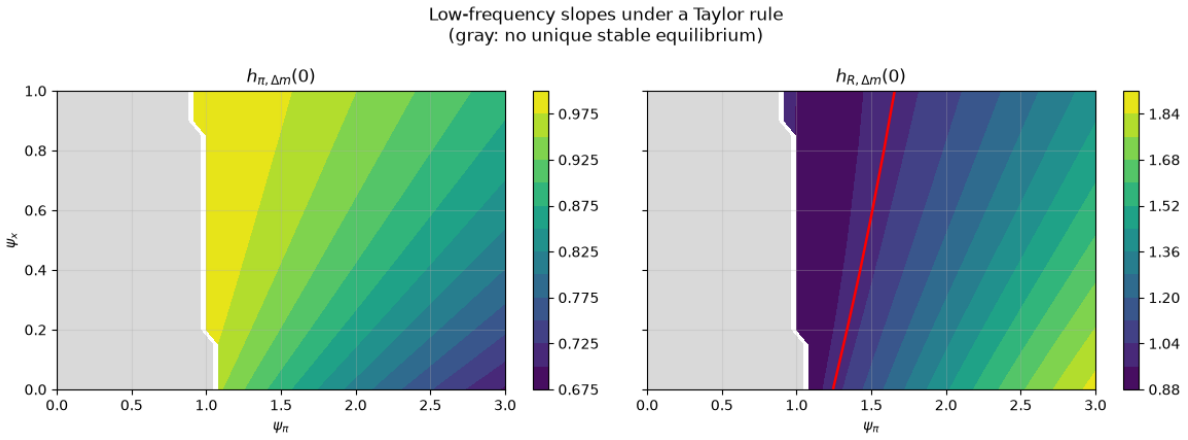
   phi_pi =  -0.50:  h_pi =   0.933,  h_R =   0.796
   phi_pi =   0.00:  h_pi =   0.992,  h_R =   0.808
   phi_pi =   0.50:  h_pi =   1.017,  h_R =   0.870
   phi_pi =   1.00:  h_pi =   1.005,  h_R =   0.980
```

149.13.1 The same exercise with a Taylor rule

The paper repeats the experiment with the interest rate rule (149.13).

We keep the smoothing coefficient and the policy shock standard deviation at their money rule estimates and vary (ψ_π, ψ_x).



Where the Taylor rule leaves the equilibrium indeterminate we simply record it, shading those regions in gray; the paper instead selects the orthogonality solution of Lubik and Schorfheide [2004].

```
p_taylor = dict(p_bar, rho_r=p_bar['rho_m'], psi_pi=1.5, psi_x=0.5)
psi_pi_grid = np.linspace(0, 3, 37)
psi_x_grid = np.linspace(0, 1, 21)
Tpi, TR = h_grid(p_taylor, 'taylor', 'psi_pi', 'psi_x',
                 psi_pi_grid, psi_x_grid)

print(f'indeterminate or nonexistent at {np.isnan(Tpi).mean():.0%} of grid points')
print(f'h_pi ranges over [{np.nanmin(Tpi):.2f}, {np.nanmax(Tpi):.2f}]')
print(f'h_R  ranges over [{np.nanmin(TR):.2f}, {np.nanmax(TR):.2f}]')

contour_panel(psi_pi_grid, psi_x_grid, Tpi, TR, r'$\psi_\pi$', r'$\psi_x$',
              'Low-frequency slopes under a Taylor rule\n'
              '(gray: no unique stable equilibrium)')
```

```
indeterminate or nonexistent at 33% of grid points
h_pi ranges over [0.70, 1.00]
h_R  ranges over [0.89, 1.87]
```

The dependence on policy survives, but it is much weaker.

Over the determinate region the Taylor rule cannot drive either slope anywhere near zero.

This is the paper's finding that the interest rate rule is "less able to replicate the estimates."

The decomposition (149.15) supplies a reason.

Driving $h_{\pi,\Delta m}(0)$ toward zero requires making the ratio $S_{z,\pi+z}(0)/S_{\pi+z}(0)$ close to one, which in practice means squeezing the zero-frequency power of inflation until $\pi_t + z_t$ is dominated by technology.

A money growth rule with a large negative ϕ_π does exactly that, because the central bank is choosing the left side of (149.14) directly.

A Taylor rule instead sets the interest rate and lets money growth be whatever money demand implies, so it never gets much purchase on low-frequency inflation relative to money growth, and $h_{\pi,\Delta m}(0)$ stays near one.

149.14 Estimating with Hamiltonian Monte Carlo

The random walk sampler that produced our posterior is the traditional workhorse of DSGE estimation.

It is also wasteful, and we can measure how wasteful.

This section takes the Sargent-Surico model as a guinea pig for a modern alternative.

149.14.1 What the random walk delivers

A correlated chain of length N is worth fewer than N independent draws, and the **effective sample size** says how many.

```
import arviz as az

rwmh_idata = az.from_dict(
    {'posterior': {n: kept[:, j][None, :] for j, n in enumerate(FREE)}})
rwmh_summary = az.summary(rwmh_idata, var_names=FREE)
print(rwmh_summary[['mean', 'sd', 'ess_bulk']].to_string())
print(f'\n{len(kept)} retained draws out of {N_DRAWS}, in {rwmh_seconds:.0f} seconds')
print(f'smallest effective sample size = {rwmh_summary["ess_bulk"].min():.0f}')
```

```
            mean      sd ess_bulk
theta     0.9887  0.0053      197
alpha_pi   0.816   0.085      415
kappa      0.117   0.045      195
alpha_x     0.38   0.039      112
sigma      0.082   0.029      165
xi           3.6       1      111
gamma       2.04     0.3      125
phi_pi     -0.24    0.24      220
phi_x       -0.8    0.31       91
rho_m      0.516   0.047      221
rho_e      0.258   0.065      328
rho_a       0.85   0.047       53
rho_chi     0.52   0.096      307
sig_e       1.16    0.17      279
sig_a       0.25   0.068       93
sig_chi    0.141   0.061      200
sig_z       0.71    0.12       96
sig_m       0.71   0.065      149

4000 retained draws out of 30000, in 363 seconds
smallest effective sample size = 53
```

Tens of thousands of iterations buy us on the order of a hundred independent draws for the worst-mixing parameter.

The reason is visible in the proposal.

A random walk perturbs all eighteen parameters in a direction that knows nothing about the local shape of the posterior, so the step size has to respect the most tightly constrained direction while the loosest direction is explored at that same crawl.

Our posterior is badly scaled.

```
w = np.linalg.eigvalsh(H)
print(f'condition number of the posterior Hessian     {w.max() / w.min():10.3g}')
print(f'ratio of longest to shortest posterior scale  {np.sqrt(w.max() / w.min()):10.
↪0f}')
```

```
condition number of the posterior Hessian        4.1e+04
ratio of longest to shortest posterior scale         202
```

149.14.2 Why Hamiltonian methods are awkward for DSGE models

Hamiltonian Monte Carlo [Duane *et al.*, 1987, Neal, 2011] treats the parameter vector as the position of a particle, gives it a random momentum, and simulates Hamiltonian dynamics in which the negative log posterior plays the role of potential energy.

Trajectories follow the contours of the distribution instead of blundering across them, so a proposal can travel a long way and still be accepted.

The **No-U-Turn sampler** [Hoffman and Gelman, 2014] removes the need to tune the trajectory length by extending each trajectory until it starts to double back on itself.

Betancourt [2017] gives a conceptual introduction.

The price of admission is the gradient $\nabla_\theta \log p(\theta \mid Y)$.

That is where DSGE models become awkward.

Our likelihood runs through `gensys`, whose first act is an *ordered* generalized Schur decomposition: it computes generalized eigenvalues, **sorts** them by modulus, and reorders the decomposition to match.

Sorting is a discrete operation, and no automatic differentiation library propagates derivatives through it.

This, rather than any statistical objection, is the reason Hamiltonian methods remain uncommon in DSGE estimation.

149.14.3 A differentiable solver

The obstacle is the *algorithm*, not the model, so we change algorithms.

Write the equilibrium conditions as

$$F_A \, \mathbb{E}_t y_{t+1} + F_B \, y_t + F_C \, y_{t-1} + F_E \, \varepsilon_t = 0, \tag{149.17}$$

where

$$y_t = [\pi_t, \; x_t, \; \Delta m_t, \; R_t, \; e_t, \; a_t, \; \chi_t, \; z_t, \; u_t]'$$

and $u_t = \varepsilon_{mt}$ carries the money rule shock.

The auxiliary expectation variables that `gensys` needs are not required here.

Conjecture a solution

$$y_t = G \, y_{t-1} + \Theta \, \varepsilon_t. \tag{149.18}$$

Then $\mathbb{E}_t y_{t+1} = G y_t$, and (149.17) becomes

$$(F_A G + F_B) \, y_t + F_C \, y_{t-1} + F_E \, \varepsilon_t = 0.$$

Solving for y_t and matching coefficients with (149.18) gives a fixed point in G alone,

$$G = -(F_A G + F_B)^{-1} F_C, \qquad \Theta = -(F_A G + F_B)^{-1} F_E. \tag{149.19}$$

Iterating (149.19) from $G = 0$ involves nothing but matrix products and linear solves, every one of them differentiable.

```
import jax
import jax.numpy as jnp
import numpyro
import numpyro.distributions as dist
from jax import lax
from numpyro.infer import MCMC, NUTS

jax.config.update('jax_enable_x64', True)
jax.config.update('jax_platform_name', 'cpu')

U, NJ = 8, 9          # y = [pi, x, dm, R, e, a, chi, z, u]

            .at[3, PI].set(-(1 - rm) * p['phi_pi'])
            .at[3, X].set(-(1 - rm) * p['phi_x']))
    FC = FC.at[3, DM].set(-rm)

    for row, (v, rho, k) in enumerate([(E, p['rho_e'], 0), (A_, ra, 1),
                                       (CH, p['rho_chi'], 2), (Z, 0.0, 3)], 4):
        FB = FB.at[row, v].set(1)
        FC = FC.at[row, v].set(-rho)
        FE = FE.at[row, k].set(-1)
    FB = FB.at[8, U].set(1)
    FE = FE.at[8, 4].set(-1)
    return FA, FB, FC, FE

def solve_fixed_point(p, n_iter=60):
    """Iterate (SS-fixedpoint) to convergence; differentiable throughout."""
    FA, FB, FC, FE = structural(p)

    def step(G, _):
        return -jnp.linalg.solve(FA @ G + FB, FC), None

    G, _ = lax.scan(step, jnp.zeros((NJ, NJ)), None, length=n_iter)
    return G, -jnp.linalg.solve(FA @ G + FB, FE)
```

Before trusting it we check it against `gensys` at the paper's posterior means.

The two algorithms share no code, so agreement to machine precision is a real test.

```
p_check = {n: float(PAPER[n]) for n in FREE}
G_fp, Theta_fp = solve_fixed_point(p_check)

A_gen, B_gen, C_gen, _ = state_space(dict(p_check, tau=TAU))
idx = [PI, X, DM, R, E, A_, CH, Z]
sd_check = np.array([p_check[n] for n in
                     ['sig_e', 'sig_a', 'sig_chi', 'sig_z', 'sig_m']])

print('fixed point versus gensys')
print(f'   transition matrix  max abs difference  '
      f'{np.abs(np.asarray(G_fp)[np.ix_(idx, idx)] - A_gen[:10, :10][np.ix_(idx,␣
 ↪idx)]).max():.2e}')
print(f'   shock loadings     max abs difference  '
```

(continues on next page)

(continued from previous page)

```
    f'{np.abs(np.asarray(Theta_fp * sd_check)[idx] - B_gen[:10][idx]).max():.2e}')
```

```
fixed point versus gensys
   transition matrix  max abs difference  1.20e-14
   shock loadings     max abs difference  3.50e-15
```

Note

The fixed point converges to the stable solution when there is one, but unlike `gensys` it returns no existence and uniqueness flags.

We therefore keep `gensys` for the determinacy map of the previous section and use the fixed point only where we need derivatives.

149.14.4 The likelihood in JAX

The Kalman filter carries over unchanged, written with `lax.scan` so that it too can be differentiated.

The only substantive change is the initial covariance: instead of calling a Lyapunov solver we use $\mathrm{vec}(P) = (I - A \otimes A)^{-1}\,\mathrm{vec}(Q)$, which is one linear solve.

```
def state_space_jax(p):
    G, Theta = solve_fixed_point(p)
    sd = jnp.array([p['sig_e'], p['sig_a'], p['sig_chi'], p['sig_z'], p['sig_m']])
    n = NJ + 2                                  # append x(-1) and a(-1)
    A = jnp.zeros((n, n)).at[:NJ, :NJ].set(G)
    A = A.at[NJ, X].set(1).at[NJ + 1, A_].set(1)
    B = jnp.zeros((n, 5)).at[:NJ].set(Theta * sd)
    C = jnp.zeros((4, n))
    C = C.at[0, DM].set(1).at[1, PI].set(1).at[2, R].set(1)
    C = C.at[3, X].set(1).at[3, NJ].set(-1)
    C = C.at[3, A_].set(p['xi']).at[3, NJ + 1].set(-p['xi'])
    C = C.at[3, Z].set(1)
    return A, B, C

def loglik_jax(p, Y):
    A, B, C = state_space_jax(p)
    n = A.shape[0]
    Q = B @ B.T
    P0 = jnp.linalg.solve(jnp.eye(n * n) - jnp.kron(A, A),
                          Q.reshape(-1)).reshape(n, n)
    const = Y.shape[1] * jnp.log(2 * jnp.pi)

    def step(carry, y):
        s, P = carry
        s, P = A @ s, A @ P @ A.T + Q
        v = y - C @ s
        PCt = P @ C.T
        F = C @ PCt
        L = jnp.linalg.cholesky(F)
        u = jax.scipy.linalg.solve_triangular(L, v, lower=True)
        ll = -0.5 * (const + 2 * jnp.sum(jnp.log(jnp.diag(L))) + u @ u)
        K = jnp.linalg.solve(F, PCt.T).T
```

(continues on next page)

(continued from previous page)

```
        return (s + K @ v, P - K @ PCt.T), ll

    _, lls = lax.scan(step, (jnp.zeros(n), P0), Y)
    return jnp.sum(lls)
```

Two checks: the new likelihood must agree with the one we used for the random walk, and its gradient must agree with finite differences.

```
Y_jax = jnp.asarray(Y_est)
print(f'log likelihood, JAX    {float(loglik_jax(p_check, Y_jax)):.8f}')
print(f'log likelihood, NumPy  {loglik(dict(p_check, tau=TAU), Y_est):.8f}')

grad_ll = jax.jit(jax.grad(lambda q: loglik_jax(q, Y_jax)))
g = grad_ll(p_check)

print('\n                  autodiff    finite difference')
for n in ['phi_pi', 'kappa', 'rho_m', 'sig_z']:
    step_n = 1e-5
    up = dict(p_check); up[n] = p_check[n] + step_n
    dn = dict(p_check); dn[n] = p_check[n] - step_n
    fd = (loglik_jax(up, Y_jax) - loglik_jax(dn, Y_jax)) / (2 * step_n)
    print(f'    {n:8s} {float(g[n]):12.5f} {float(fd):17.5f}')
```

```
log likelihood, JAX    -493.21564637
log likelihood, NumPy  -493.21564637

                  autodiff    finite difference
   phi_pi       -1.00005          -1.00005
   kappa        -0.68555          -0.68555
   rho_m         1.92667           1.92667
   sig_z       -56.71510         -56.71510
```

```
t0 = time.time()
for _ in range(20):
    gg = grad_ll(p_check)
jax.block_until_ready(gg)
grad_ms = 1000 * (time.time() - t0) / 20

t0 = time.time()
for _ in range(20):
    loglik(dict(p_check, tau=TAU), Y_est)
loglik_ms = 1000 * (time.time() - t0) / 20

print(f'one NumPy log likelihood         {loglik_ms:6.2f} ms')
print(f'one JAX gradient (18 partials)   {grad_ms:6.2f} ms')
```

```
one NumPy log likelihood          8.49 ms
one JAX gradient (18 partials)    5.79 ms
```

A full gradient costs about what a single likelihood evaluation costs, which is the whole point of reverse-mode differentiation.

A finite-difference gradient would need at least nineteen likelihood evaluations.

149.14.5 Sampling with NUTS

We hand the same priors to NumPyro [Phan *et al.*, 2019], which supplies NUTS and handles the transformations to unconstrained space that Hamiltonian dynamics require.

```
def beta_np(m, s):
    nu = m * (1 - m) / s ** 2 - 1
    return dist.Beta(m * nu, (1 - m) * nu)

def gamma_np(m, s):
    return dist.Gamma(m ** 2 / s ** 2, m / s ** 2)

def invgamma_np(m, s):
    a = m ** 2 / s ** 2 + 2
    return dist.InverseGamma(a, m * (a - 1))

PRIORS_NP = {
    'theta': beta_np(0.99, 0.005), 'alpha_pi': beta_np(0.5, 0.2),
    'alpha_x': beta_np(0.5, 0.2), 'rho_m': beta_np(0.5, 0.05),
    'rho_e': beta_np(0.5, 0.1), 'rho_a': beta_np(0.5, 0.1),
    'rho_chi': beta_np(0.5, 0.1),
    'kappa': gamma_np(0.3, 0.1), 'sigma': gamma_np(0.1, 0.05),
    'xi': gamma_np(2.0, 1.0), 'gamma': gamma_np(4.0, 1.0),
    'phi_pi': dist.Normal(0, 0.5), 'phi_x': dist.Normal(0, 0.5),
    'sig_e': invgamma_np(0.3, 1.0), 'sig_a': invgamma_np(0.3, 1.0),
    'sig_chi': invgamma_np(0.3, 1.0), 'sig_z': invgamma_np(0.3, 1.0),
    'sig_m': invgamma_np(0.3, 1.0)}

def ss_model(Y):
    p = {n: numpyro.sample(n, PRIORS_NP[n]) for n in FREE}
    numpyro.factor('loglik', loglik_jax(p, Y))
```

Three settings matter.

We ask for a **dense mass matrix**, because the condition number reported above says the posterior has correlations that a diagonal preconditioner cannot absorb.

We cap the trajectory length, since without a cap NUTS spends most of its time on very long trajectories in the flattest directions.

And we run **four chains** rather than one, all started from the posterior mode.

That last choice is the one that earns its keep.

```
kernel = NUTS(ss_model, target_accept_prob=0.8, dense_mass=True,
              max_tree_depth=8,
              init_strategy=numpyro.infer.init_to_value(
                  values={n: float(v) for n, v in zip(FREE, v_mode)}))
mcmc = MCMC(kernel, num_warmup=400, num_samples=400, num_chains=4,
            chain_method='sequential', progress_bar=False)

t0 = time.time()
mcmc.run(jax.random.PRNGKey(1), Y_jax, extra_fields=('num_steps', 'diverging'))
jax.block_until_ready(mcmc.get_samples())
nuts_seconds = time.time() - t0
```

(continues on next page)

(continued from previous page)

```
extra = mcmc.get_extra_fields()
print(f'{nuts_seconds:.0f} seconds for 4 chains of 400 draws')
print(f'mean leapfrog steps per iteration  '
      f'{np.asarray(extra["num_steps"]).mean():.0f}')

149.14.6 A warning sign in the diagnostics

Most parameters look excellent, with $\hat{R}$ at one and effective sample sizes in the hundreds or thousands.

A few do not, and it is worth asking which.

```
worst = nuts_summary['ess_bulk'].nsmallest(3).index.tolist()
print('weakest mixing:')
print(nuts_summary.loc[worst, ['mean', 'sd', 'ess_bulk', 'r_hat']])

by_chain = mcmc.get_samples(group_by_chain=True)
print('\nper-chain posterior means')
print(f'{"":10s}' + ''.join(f'{"chain " + str(c):>10s}' for c in range(4)))
for n in worst:
    v = np.asarray(by_chain[n])
    print(f'{n:10s}' + ''.join(f'{v[c].mean():10.4f}' for c in range(4)))
```

```
weakest mixing:
          mean   sd ess_bulk r_hat
sig_e      0.9  0.4       12  1.25
rho_e      0.4  0.3       12  1.25
alpha_pi   0.6  0.3       12  1.26

per-chain posterior means

alpha_pi      0.3025    0.6328    0.8050    0.8063
```

The chains started from a common point, so any disagreement between them means some of them have wandered somewhere the others have not.

The identity of the badly behaved parameters is a clue.

Inflation in the data is persistent, and equation (149.7) offers two ways to deliver that persistence.

Intrinsic persistence comes from indexation to past inflation, a large α_π, with the markup shock left transitory.

Inherited persistence comes from a persistent markup shock, a large ρ_e, with little indexation.

The parameters that mix worst are exactly the ones that distinguish these two stories.

That is a reason to suspect the posterior has more than one mode, and it tells us where to look for the second one.

149.14.7 Two modes

Sampler diagnostics are a noisy instrument, so we settle the question with the optimizer instead.

Our mode search in the estimation section started from the paper's posterior means and climbed to a high-indexation mode.

We now start the same optimizer from the opposite corner.

```
v_start_a = v_mode.copy()
for n, val in [('alpha_pi', 0.12), ('rho_e', 0.84), ('sig_e', 0.35)]:
    v_start_a[FREE.index(n)] = val

res_a = optimize.minimize(neg_log_post, v_start_a, method='Powell',
                          options=dict(maxiter=20000, maxfev=20000))
res_a = optimize.minimize(neg_log_post, res_a.x, method='L-BFGS-B',
                          bounds=[SUPPORT[n] for n in FREE])
v_mode_a = res_a.x

print(f'log posterior, low-indexation mode   {-res_a.fun:10.3f}')
print(f'log posterior, high-indexation mode  {log_post(v_mode, Y_est):10.3f}')
print('\n                low-index   high-index      paper')
for n in ['alpha_pi', 'rho_e', 'sig_e', 'kappa', 'phi_pi', 'phi_x']:
    i = FREE.index(n)
    print(f'   {n:9s}{v_mode_a[i]:10.4f}{v_mode[i]:13.4f}{PAPER[n]:11.4f}')
```

```
log posterior, low-indexation mode     -318.746
log posterior, high-indexation mode    -320.204

                low-index   high-index      paper
   alpha_pi        0.1096       0.8296     0.8815
```

(continues on next page)

(continued from previous page)

```
rho_e        0.8376       0.2359      0.5645
sig_e        0.3288       1.1516      1.0922
kappa        0.0817       0.0967      0.0324
phi_pi      -0.4359      -0.1957      0.2312
phi_x       -0.7975      -0.5739     -0.1971
```

There are two distinct modes, and the low-indexation one has the **higher** posterior density.

The mode we found earlier, the one nearest the paper's published estimates and the one our random walk explored for thirty thousand draws, is a *local* mode.

The pooled NUTS draws show the same thing from the sampling side.

```

fig.suptitle('The marginals spread across both modes rather than concentrating on one
↪')
fig.tight_layout()
plt.show()
```

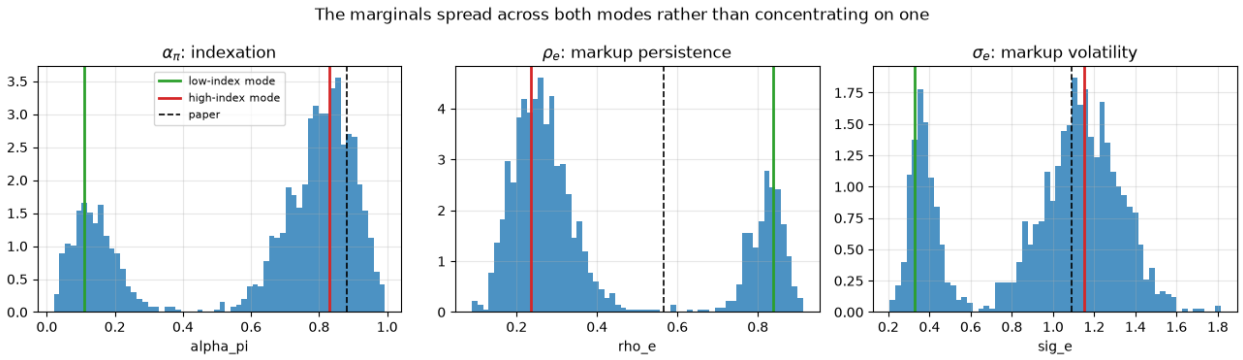

Fig. 149.1: Marginal posteriors for the parameters that separate the two modes

The marginals are wide and lumpy rather than the tidy bells that every other parameter produces.

The chains do move between the two regions, but slowly, and that slow movement is precisely what the poor effective sample sizes were reporting.

Thirty thousand random walk draws never made the trip at all.

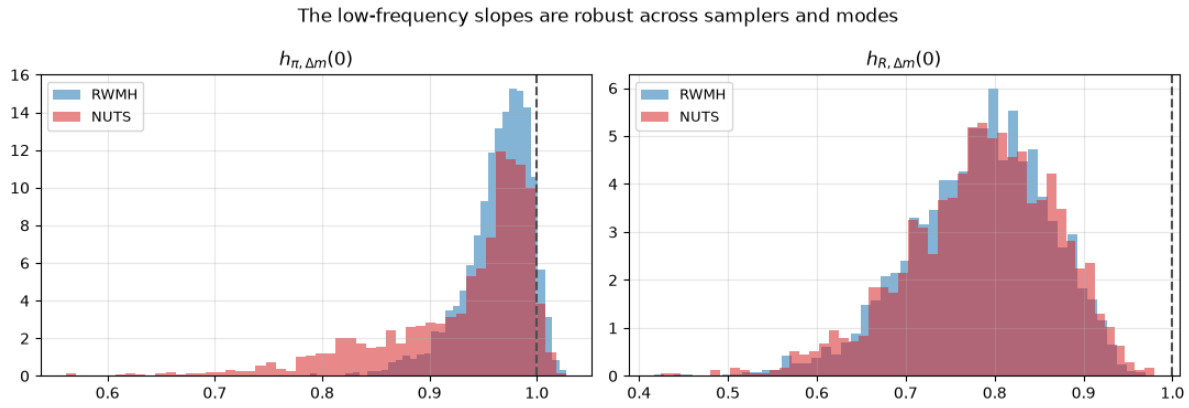
The economics behind the two modes is a familiar identification problem.

The data over 1960-1983 cannot tell us whether inflation is persistent because prices are indexed to past inflation or because the shocks pushing inflation around are themselves persistent.

Both stories fit, and the published estimates describe the one the data like slightly less.

149.14.8 Does the bimodality change the economics?

This is the question that matters for the rest of the lecture.



```
h_mode_a = h_zero(unpack(v_mode_a))
h_mode_b = h_zero(unpack(v_mode))
print(f'h(0) at the low-indexation mode   {h_mode_a[0]:.4f}, {h_mode_a[1]:.4f}')

    ax.set_title(ttl)
    ax.legend(fontsize=9)
fig.suptitle('The low-frequency slopes are robust across samplers and modes')
plt.tight_layout()
plt.show()
```

The reassuring answer is that it does not.

The two modes disagree sharply about *why* inflation is persistent and far less about the low-frequency slopes that this lecture is about.

Whether inflation persistence is intrinsic or inherited, $h_{\pi,\Delta m}(0)$ stays between about four fifths and one, and $h_{R,\Delta m}(0)$ sits near four fifths in both cases.

The paper's substantive conclusions survive the discovery that its parameter estimates describe a local mode.

149.14.9 Comparing the samplers

With that settled we can return to efficiency.

Effective sample sizes for the three parameters that separate the modes are not comparable across the two samplers, because for NUTS they partly measure movement *between* modes while for the random walk they measure movement within one.

We therefore compare medians rather than minima.

```
compare = pd.DataFrame({
    'RWMH mean': rwmh_summary['mean'], 'NUTS mean': nuts_summary['mean'],
    'RWMH ESS': rwmh_summary['ess_bulk'], 'NUTS ESS': nuts_summary['ess_bulk'],
    'NUTS r_hat': nuts_summary['r_hat']})
compare['ESS ratio'] = compare['NUTS ESS'] / compare['RWMH ESS']
compare.round(3)
```

	RWMH mean	NUTS mean	RWMH ESS	NUTS ESS	NUTS r_hat	ESS ratio

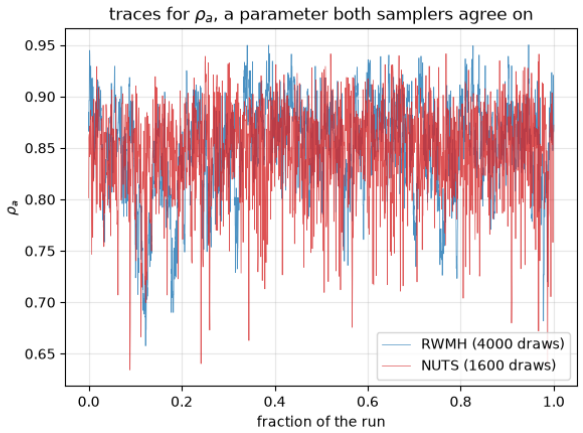
median ESS per second           0.41        2.76



speed-up in ESS per second      6.7x
```

Per draw the gap is very large, because each NUTS draw ends a trajectory that has travelled across the posterior rather than taking one small random step.

Cost claws some of that back, since a NUTS iteration needs many gradient evaluations where a random walk iteration needs one likelihood evaluation.

Effective draws per second is the ratio that matters, and it still favours NUTS by a wide margin.

149.14.10 What to take away

The obstacle to Hamiltonian methods in DSGE estimation is the model solver, not the statistics.

Replacing an eigenvalue-sorting solver by a fixed point that uses only linear algebra buys exact gradients for about the cost of one extra likelihood evaluation, and that is enough to put NUTS within reach.

The payoff was not only speed.

Cheap chains made it cheap to run several of them and inspect their diagnostics, and the parameters that mixed worst pointed straight at a second and better mode that thirty thousand random walk draws had never visited.

Two caveats are worth stating.

First, the fixed point returns something meaningless where no stable solution exists, so a sampler that wanders outside the determinacy region will produce nonsense rather than a rejection; the posterior here sits well inside that region, but a flatter one might not.

Second, the efficiency gain reported above is specific to this posterior, and a well-scaled posterior in fewer dimensions would narrow the gap considerably.

149.15 Concluding remarks

Lucas [1980] was careful to say that his two unit slopes should be expected to hold under some monetary policies and to break down under others.

Extending his sample by half a century confirms the breakdowns.

Estimating a small structural model on a sample like his, and then moving only the monetary policy rule, produces slopes that range over most of what the data display.

The lesson is the one Lucas, Sargent [1971], and Whiteman [1984] all drew, namely that low-frequency regression coefficients are not structural.

Working through the model from scratch adds something to the paper's account.

Lucas's first illustration, the unit slope of inflation on money growth, is an *identity* in this model whenever money growth is econometrically exogenous, because money demand is a quantity equation whose remaining terms are all first differences.

His second illustration, the unit slope of the interest rate on money growth, has no such support and moves around freely.

So the two illustrations, which look symmetric in a scatter plot, are quite different objects from the perspective of a structural model.

That asymmetry also marks the limit of the exercise, as Exercise 149.16.2 brings out.

Because $h_{\pi,\Delta m}(0)$ is anchored at one by money demand, driving it to the near-zero values that the post-1984 data display takes a money growth rule far more anti-inflationary than the one those same data select.

On the computational side, the model turned out to be a useful test bed for Hamiltonian Monte Carlo.

The barrier to using it on DSGE models is not statistical but algorithmic: the standard solvers sort eigenvalues, and sorting has no derivative.

Swapping in a fixed-point solver that uses only linear algebra restores exact gradients, and the sampler that becomes available is far more efficient per unit of computing time on a posterior as badly scaled as this one.

The larger dividend was a diagnostic one.

Cheap chains and their convergence diagnostics led us to a second mode, and the posterior turned out to be bimodal: the data cannot choose between intrinsic and inherited inflation persistence, and the mode nearest the published estimates is the *lower* of the two.

That the two modes nonetheless agree about $h_{\pi,\Delta m}(0)$ and $h_{R,\Delta m}(0)$ is a piece of good news for the paper that only the more thorough sampler could deliver.

149.16 Exercises

Exercise 149.16.1

The paper takes technology growth to be serially uncorrelated.

Replace $z_t = \varepsilon_{zt}$ by $z_t = \rho_z z_{t-1} + \varepsilon_{zt}$ and ask two questions.

Does *Proposition 149.9.1* survive, and does persistent technology growth offer a route to breaking the unit slope that has nothing to do with monetary policy?

Solution

The technology block is row 7 of the canonical form, where `g1[7, Z]` is currently zero.

```
def canonical_rho_z(p, rule='money'):
    g0, g1, psi, pie = canonical(p, rule)
    g1[7, Z] = p['rho_z']
    return g0, g1, psi, pie

def h_zero_rho_z(p):
    G1, impact, eu = gensys(*canonical_rho_z(p))
    if eu != (1, 1):
        return np.nan, np.nan
    sd = np.diag([p['sig_e'], p['sig_a'], p['sig_chi'], p['sig_z'], p['sig_m']])
    n = NY + 2
    A, B = np.zeros((n, n)), np.zeros((n, 5))
    A[:NY, :NY], A[NY, X], A[NY + 1, A_] = G1, 1, 1
    B[:NY] = impact @ sd
    C = np.zeros((4, n))
    C[0, DM], C[1, PI], C[2, R], C[3, Z] = 1, 1, 1, 1
    C[3, X], C[3, NY] = 1, -1
    C[3, A_], C[3, NY + 1] = p['xi'], -p['xi']
    if np.max(np.abs(np.linalg.eigvals(A))) > 1 - 1e-9:
        return np.nan, np.nan
    return (h_zero_from_state_space(A, B, C, 1, 0),
            h_zero_from_state_space(A, B, C, 2, 0))

   rho_z = 0.0:  h_pi = 0.4897, h_R = 0.7767
   rho_z = 0.3:  h_pi = 0.2340, h_R = 0.6392
   rho_z = 0.6:  h_pi = -0.1354, h_R = 0.3046
   rho_z = 0.9:  h_pi = -0.4584, h_R = -0.2820
```

Proposition 149.9.1 survives untouched, because its proof used only that technology is orthogonal to the policy shock, never how persistent it is.

Under exogenous money growth *both* slopes are invariant to ρ_z, and for a reason worth noticing: z_t enters the model only contemporaneously, through money demand, so ρ_z changes the dynamics of technology without changing anyone's response to a money shock.

Once policy feeds back the picture is different, and persistent technology growth pulls $h_{\pi,\Delta m}(0)$ well away from one.

So the answer to the second question is yes, and it points at a limitation of the paper's experiment: the technology process is held fixed while policy varies, but the two interact.

Exercise 149.16.2

The lecture estimates the model on 1960:I-1983:IV.

Find the posterior mode on 1984:I-2007:IV and compare the policy coefficients and the implied $h(0)$ with what we found for the earlier sample.

The VAR put $h_{\pi,\Delta m}(0)$ near zero over 1984-2007, so does the structural model, re-estimated, agree?

Solution

```
mask2 = (data.index.year >= 1984) & (data.index.year <= 2007)
Y2 = data.loc[mask2, VARS].values
Y2 = Y2 - Y2.mean(0)

res2 = optimize.minimize(lambda v: -log_post(v, Y2), v_mode, method='Powell',
                         options=dict(maxiter=20000, maxfev=20000))
res2 = optimize.minimize(lambda v: -log_post(v, Y2), res2.x, method='L-BFGS-B',
                         bounds=[SUPPORT[n] for n in FREE])
v2 = res2.x
print('                        1960-1983    1984-2007')
for n in ['phi_pi', 'phi_x', 'rho_m']:
    j = FREE.index(n)
    print(f'   {n:9s} {v_mode[j]:11.4f} {v2[j]:12.4f}')
print('   %-9s %5.3f, %.3f  %5.3f, %.3f'
      % (('model h(0)',) + h_zero(unpack(v_mode)) + h_zero(unpack(v2))))
for name, lo, hi in [('1960-1983', 1960, 1983), ('1984-2007', 1984, 2007)]:
    m = (data.index.year >= lo) & (data.index.year <= hi)
    med = np.nanmedian(bvar_h0(data.loc[m, VARS].values), axis=0)
    print(f'   VAR   h(0) on {name}: {med[0]:.3f}, {med[1]:.3f}')
```

```
                      1960-1983    1984-2007
phi_pi          -0.1957      -0.0399
phi_x           -0.5739      -1.5633
rho_m            0.5301       0.3080
model h(0) 0.976, 0.769  0.989, 0.858
VAR   h(0) on 1960-1983: 0.739, 0.607
VAR   h(0) on 1984-2007: -0.073, 0.268
```

The re-estimated model does *not* agree with the VAR.

The policy coefficients move, but the implied $h_{\pi,\Delta m}(0)$ stays close to one on both samples, while the VAR puts it near zero after 1984.

Proposition 149.9.1 explains why this had to be hard.

Within this model $h_{\pi,\Delta m}(0)$ is anchored at one and is dragged away from it only by policy feedback, so reaching values near zero needs a large negative ϕ_π, and the post-1984 data do not put the money growth rule anywhere near there.

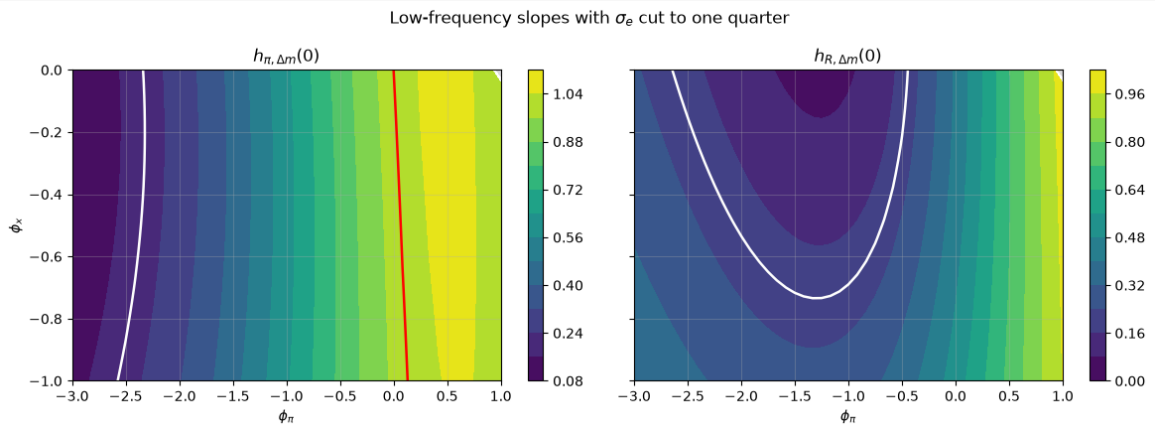
That is a genuine tension between the paper's Section II and its Section III: the contour plot shows a policy rule that *could* generate the low slopes, but the rule the later data actually select is not that rule.

A full comparison would run the sampler on both samples rather than compare modes.

Exercise 149.16.3

Figure 8 of the paper asks whether a fall in the variance of supply shocks, rather than a change in policy, could account for the decline in $h(0)$.

Redo the money rule contour plot with σ_e cut to one quarter of its posterior mean and report how much the picture moves.



Solution

```
p_small_e = dict(p_bar, sig_e=p_bar['sig_e'] / 4)
Hpi2, HR2 = h_grid(p_small_e, 'money', 'phi_pi', 'phi_x',
                   phi_pi_grid, phi_x_grid)

print('baseline    h_pi in [%.2f, %.2f],  h_R in [%.2f, %.2f]'
      % (np.nanmin(Hpi), np.nanmax(Hpi), np.nanmin(HR), np.nanmax(HR)))
print('small sig_e h_pi in [%.2f, %.2f],  h_R in [%.2f, %.2f]'
      % (np.nanmin(Hpi2), np.nanmax(Hpi2), np.nanmin(HR2), np.nanmax(HR2)))
print('largest change in h_pi across the grid: %.3f'
      % np.nanmax(np.abs(Hpi2 - Hpi)))

contour_panel(phi_pi_grid, phi_x_grid, Hpi2, HR2, r'$\phi_\pi$', r'$\phi_x$',
              r'Low-frequency slopes with $\sigma_e$ cut to one quarter')
```

```
baseline    h_pi in [0.10, 1.06],  h_R in [0.06, 1.21]
small sig_e h_pi in [0.10, 1.06],  h_R in [0.06, 1.00]
largest change in h_pi across the grid: 0.432
```

The range that $h_{\pi,\Delta m}(0)$ can reach is unchanged, and the mapping from policy to $h(0)$ keeps the same shape.

The contours do move within that range, by up to a few tenths at some grid points, so the claim is not that shock variances are irrelevant.

It is the weaker claim the paper makes, that a change in shock variances of this magnitude is not enough to substitute for a change in policy.

Part XVIII

Auctions

FIRST-PRICE AND SECOND-PRICE AUCTIONS

This lecture is designed to set the stage for a subsequent lecture about *Multiple Good Allocation Mechanisms*

In that lecture, a planner or auctioneer simultaneously allocates several goods to set of people.

In the present lecture, a single good is allocated to one person within a set of people.

Here we'll learn about and simulate two classic auctions :

- a First-Price Sealed-Bid Auction (FPSB)
- a Second-Price Sealed-Bid Auction (SPSB) created by William Vickrey [Vickrey, 1961]

We'll also learn about and apply a

- Revenue Equivalent Theorem

We recommend watching this video about second price auctions by Anders Munk-Nielsen:

https://youtu.be/qwWk_Bqtue8

and

https://youtu.be/eYTGQCGpmXI

Anders Munk-Nielsen put his code on GitHub.

Much of our Python code below is based on his.

150.1 First-price sealed-bid auction (FPSB)

Protocols:

- A single good is auctioned.
- Prospective buyers simultaneously submit sealed bids.
- Each bidder knows only his/her own bid.
- The good is allocated to the person who submits the highest bid.
- The winning bidder pays price she has bid.

Detailed Setting:

There are $n \geq 2$ prospective buyers named $i = 1, 2, \ldots, n$.

Buyer i attaches value v_i to the good being sold.

Buyer i wants to maximize the expected value of her **surplus** defined as $v_i - p$, where p is the price that she pays, conditional on her winning the auction.

Evidently,

- If i bids exactly v_i, she pays what she thinks it is worth and gathers no surplus value.
- Buyer i will never want to bid more than v_i.
- If buyer i bids $b < v_i$ and wins the auction, then she gathers surplus value $v_i - b > 0$.
- If buyer i bids $b < v_i$ and someone else bids more than b, buyer i loses the auction and gets no surplus value.
- To proceed, buyer i wants to know the probability that she wins the auction as a function of her bid v_i
  - this requires that she know a probability distribution of bids v_j made by prospective buyers $j \neq i$
- Given her idea about that probability distribution, buyer i wants to set a bid that maximizes the mathematical expectation of her surplus value.

Bids are sealed, so no bidder knows bids submitted by other prospective buyers.

This means that bidders are in effect participating in a game in which players do not know **payoffs** of other players.

This is a **Bayesian game**, a Nash equilibrium of which is called a **Bayesian Nash equilibrium**.

To complete the specification of the situation, we'll assume that prospective buyers' valuations are independently and identically distributed according to a probability distribution that is known by all bidders.

Bidder optimally chooses to bid less than v_i.

150.1.1 Characterization of FPSB auction

We assume throughout that

- valuations are **private** and **independent** across bidders
- bidders are **symmetric**: their valuations are drawn from a common distribution F that is continuous and strictly increasing on its support
- bidders are **risk neutral**

Under these assumptions a FPSB auction has a unique Bayesian Nash equilibrium in symmetric, strictly increasing bidding strategies.

Because the equilibrium bidding strategy is strictly increasing, the bidder with the highest valuation submits the highest bid, and so wins.

The optimal bid of buyer i is

$$\mathbb{E}[y_i | y_i < v_i] \tag{150.1}$$

where v_i is the valuation of bidder i and y_i is the maximum valuation of all other bidders:

$$y_i = \max_{j \neq i} v_j \tag{150.2}$$

For a derivation, see the Wikipedia page about first-price sealed-bid auctions, or Krishna [2009], chapter 2.

We'll verify this formula by simulation below, and Exercise 150.13.2 asks you to derive an equivalent expression that is easy to evaluate for any distribution F.

150.2 Second-price sealed-bid auction (SPSB)

Protocols: In a second-price sealed-bid (SPSB) auction, the winner pays the second-highest bid.

150.3 Characterization of SPSB auction

In a SPSB auction bidders optimally choose to bid their values.

Formally, in a SPSB auction with a single, indivisible item, bidding one's own value is a **weakly dominant** strategy.

It is *weakly* dominant because a bidder who bids something other than her value never does better, and sometimes does worse, whatever the other bidders do.

Notice how much stronger this is than the FPSB result: it requires no assumption at all about the distribution of other bidders' valuations, nor about how they bid.

A proof is provided at the Wikipedia page about Vickrey auctions

150.4 Uniform distribution of private values

We assume valuation v_i of bidder i is distributed $v_i \overset{\text{IID}}{\sim} U(0,1)$.

Under this assumption, we can analytically compute probability distributions of prices bid in both FPSB and SPSB.

We'll simulate outcomes and, by using a law of large numbers, verify that the simulated outcomes agree with analytical ones.

We can use our simulation to illustrate a **revenue equivalence theorem** that asserts that on average first-price and second-price sealed bid auctions provide a seller the same revenue.

The theorem requires hypotheses that both of our auctions satisfy:

- valuations are independent and private, and bidders are symmetric and risk neutral
- the two mechanisms award the good to the bidder with the highest valuation
- a bidder with the lowest possible valuation expects zero surplus

Under these hypotheses any two such mechanisms yield the same expected payment for each bidder, and therefore the same expected revenue for the seller.

Exercise 150.13.4 shows what happens when one of these hypotheses – risk neutrality – fails.

To read about the revenue equivalence theorem, see this Wikipedia page

150.5 Setup

There are n bidders.

Each bidder knows that there are $n-1$ other bidders.

150.6 First price sealed bid auction

An optimal bid for bidder i in a **FPSB** is described by equations (150.1) and (150.2).

When bids are IID draws from a uniform distribution, the CDF of y_i is

$$\begin{aligned}\tilde{F}_{n-1}(y) = \mathbb{P}\{y_i \leq y\} &= \mathbb{P}\{\max_{j \neq i} v_j \leq y\} \\ &= \prod_{j \neq i} \mathbb{P}\{v_j \leq y\} \\ &= y^{n-1}\end{aligned}$$

and the PDF of y_i is $\tilde{f}_{n-1}(y) = (n-1)y^{n-2}$.

Then bidder i's optimal bid in a **FPSB** auction is:

$$\begin{aligned}\mathbb{E}[y_i | y_i < v_i] &= \frac{\int_0^{v_i} y_i \tilde{f}_{n-1}(y_i) dy_i}{\int_0^{v_i} \tilde{f}_{n-1}(y_i) dy_i} \\ &= \frac{\int_0^{v_i} (n-1) y_i^{n-1} dy_i}{\int_0^{v_i} (n-1) y_i^{n-2} dy_i} \\ &= \frac{n-1}{n} y_i \Big|_0^{v_i} \\ &= \frac{n-1}{n} v_i\end{aligned}$$

150.7 Second price sealed bid auction

In a **SPSB**, it is optimal for bidder i to bid v_i.

150.8 Python code

```
import numpy as np
import matplotlib.pyplot as plt
import seaborn as sns
import scipy.stats as stats
import scipy.interpolate as interp

# for plots
plt.rcParams.update({'font.size': 14})
colors = plt.rcParams['axes.prop_cycle'].by_key()['color']

# ensure the notebook generates the same randomness
rng = np.random.default_rng(1337)
```

We repeat an auction with 5 bidders for 100,000 times.

The valuations of each bidder is distributed $U(0, 1)$.

```
N = 5
R = 100_000

v = rng.uniform(0, 1, (N, R))

# BNE in first-price sealed bid

b_star = lambda vi, N: ((N-1)/N) * vi
b = b_star(v,N)
```

We compute and sort bid price distributions that emerge under both FPSB and SPSB.

```
# Bidders' values are sorted in ascending order in each auction.
# We record the order because we want to apply it to bid price and their id.
idx = np.argsort(v, axis=0)

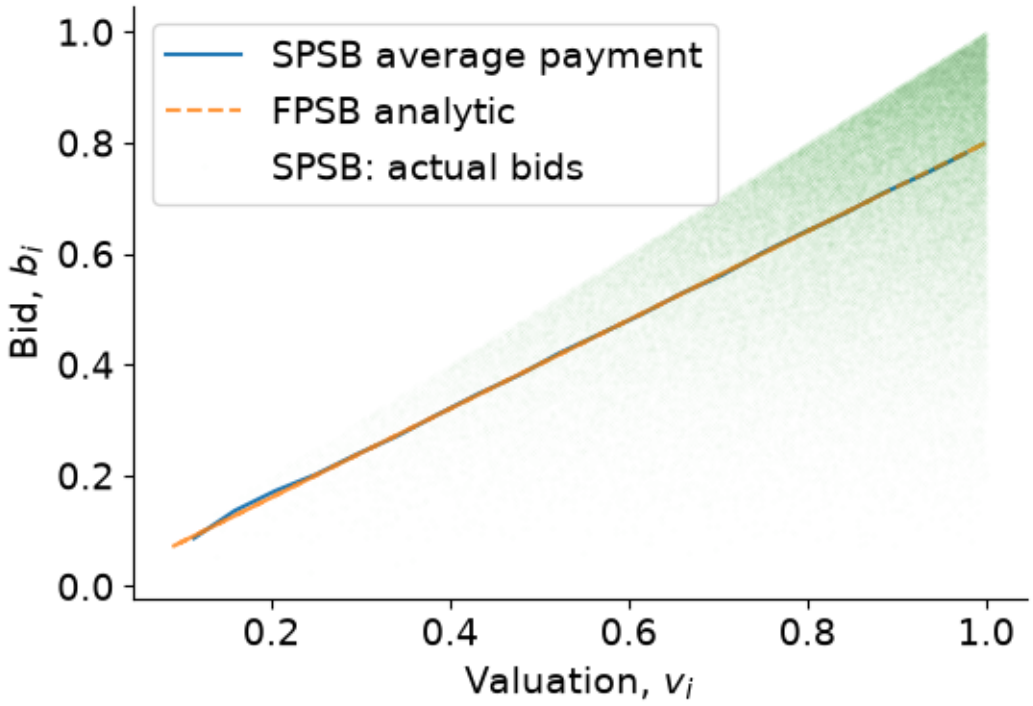
# same as np.sort(v, axis=0), except now we retain the idx
v = np.take_along_axis(v, idx, axis=0)
b = np.take_along_axis(b, idx, axis=0)

# In FPSB and SPSB the winner is the bidder with the highest valuation,
# which after sorting is the last row.

# highest bid
winner_pays_fpsb = b[-1, :]
# 2nd-highest valuation
winner_pays_spsb = v[-2, :]
```

Let's now plot the *winning* bids $b_{(n)}$ (i.e. the payment) against valuations, $v_{(n)}$ for both FPSB and SPSB.

Note that



- FPSB: There is a unique bid corresponding to each valuation
- SPSB: Because it equals the valuation of a second-highest bidder, what a winner pays varies even holding fixed the winner's valuation. So here there is a frequency distribution of payments for each valuation.

```
# We intend to compute average payments of different groups of bidders
binned = stats.binned_statistic(v[-1, :], v[-2, :], statistic='mean', bins=20)
xx = binned.bin_edges
xx = [(xx[ii]+xx[ii+1])/2 for ii in range(len(xx)-1)]
yy = binned.statistic

fig, ax = plt.subplots(figsize=(6, 4))

ax.plot(xx, yy, label='SPSB average payment')
ax.plot(v[-1, :], b[-1, :], '--', alpha=0.8, label='FPSB analytic')
ax.plot(v[-1, :], v[-2, :], 'o', alpha=0.05,
                markersize=0.1, label='SPSB: actual bids')

ax.legend(loc='best')
ax.set_xlabel('Valuation, $v_i$')
ax.set_ylabel('Bid, $b_i$')
sns.despine()
```

150.9 Revenue equivalence theorem

We now compare FPSB and a SPSB auctions from the point of view of the revenues that a seller can expect to acquire.

Expected Revenue FPSB:

The winner with valuation y pays $\frac{n-1}{n}y$, where n is the number of bidders.

Above we computed that the CDF is $F_n(y) = y^n$ and the PDF is $f_n = ny^{n-1}$.

Consequently, expected revenue is

$$R = \int_0^1 \frac{n-1}{n} v_i \times n v_i^{n-1} dv_i = \frac{n-1}{n+1}$$

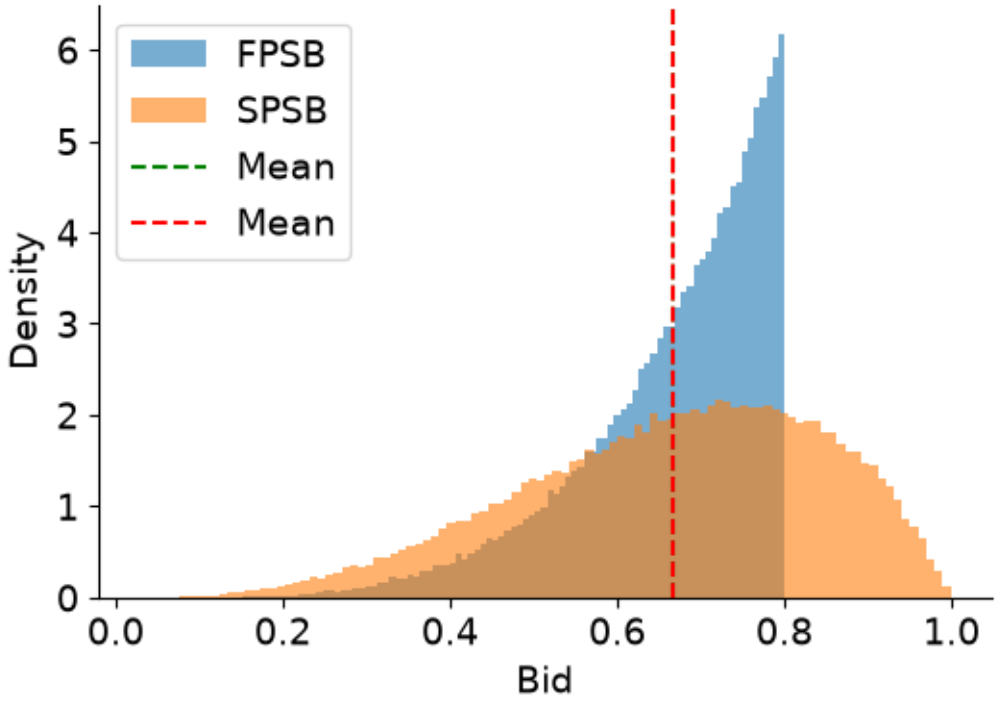
Expected Revenue SPSB:

The expected revenue equals n $\times$ expected payment of a bidder.

Computing this we get

$$\begin{aligned}
\text{TR} &= n\mathbb{E}_{v_i}\left[\mathbb{E}_{y_i}[y_i|y_i < v_i]\mathbb{P}\{y_i < v_i\} + 0 \times \mathbb{P}\{y_i > v_i\}\right] \\
&= n\mathbb{E}_{v_i}\left[\mathbb{E}_{y_i}[y_i|y_i < v_i]\tilde{F}_{n-1}(v_i)\right] \\
&= n\mathbb{E}_{v_i}[\frac{n-1}{n} \times v_i \times v_i^{n-1}] \\
&= (n-1)\mathbb{E}_{v_i}[v_i^n] \\
&= \frac{n-1}{n+1}
\end{aligned}$$

Thus, while probability distributions of winning bids typically differ across the two types of auction, we deduce that expected payments are identical in FPSB and SPSB.



```
fig, ax = plt.subplots(figsize=(6, 4))

for payment, label in zip([winner_pays_fpsb, winner_pays_spsb], ['FPSB', 'SPSB']):
    print('The average payment of %s: %.4f. Std.: %.4f. Median: %.4f' % (
        label, payment.mean(), payment.std(), np.median(payment)))
    ax.hist(payment, density=True, alpha=0.6, label=label, bins=100)

ax.axvline(winner_pays_fpsb.mean(), ls='--', c='g', label='Mean')
ax.axvline(winner_pays_spsb.mean(), ls='--', c='r', label='Mean')

ax.legend(loc='best')
ax.set_xlabel('Bid')
ax.set_ylabel('Density')
sns.despine()
```

```
The average payment of FPSB: 0.6670. Std.: 0.1122. Median: 0.6959
The average payment of SPSB: 0.6660. Std.: 0.1782. Median: 0.6850
```

Summary of FPSB and SPSB results with uniform distribution on $[0, 1]$

Auction: Sealed-Bid	First-Price	Second-Price
Winner	Agent with highest bid	Agent with highest bid
Winner pays	Winner's bid	Second-highest bid
Loser pays	0	0
Dominant strategy	No dominant strategy	Bidding truthfully is dominant strategy
Bayesian Nash equilibrium	Bidder i bids $\frac{n-1}{n} v_i$	Bidder i truthfully bids v_i
Auctioneer's revenue	$\frac{n-1}{n+1}$	$\frac{n-1}{n+1}$

Detour: Computing a Bayesian Nash Equibrium for FPSB

The revenue equivalence theorem lets us find an optimal bidding strategy for a FPSB auction from outcomes of a SPSB auction.

Let $b(v_i)$ be the optimal bid in a FPSB auction.

The revenue equivalence theorem tells us that a bidder agent with value v_i on average receives the same **payment** in the two types of auction.

Consequently,

$$b(v_i)\mathbb{P}\{y_i < v_i\} + 0 \cdot \mathbb{P}\{y_i \geq v_i\} = \mathbb{E}_{y_i}[y_i | y_i < v_i]\mathbb{P}\{y_i < v_i\} + 0 \cdot \mathbb{P}\{y_i \geq v_i\}$$

It follows that an optimal bidding strategy in a FPSB auction is $b(v_i) = \mathbb{E}_{y_i}[y_i | y_i < v_i]$.

150.10 Calculation of bid price in FPSB

In equations (150.1) and (150.2), we displayed formulas for optimal bids in a symmetric Bayesian Nash equilibrium of a FPSB auction.

$$\mathbb{E}[y_i | y_i < v_i]$$

where

- $v_i =$ value of bidder i
- $y_i =:$ maximum value of all bidders except i, i.e., $y_i = \max_{j \neq i} v_j$

Above, we computed an optimal bid price in a FPSB auction analytically for a case in which private values are uniformly distributed.

For most probability distributions of private values, analytical solutions aren't easy to compute.

Instead, we can compute bid prices in FPSB auctions numerically as functions of the distribution of private values.

```
def evaluate_largest(v_hat, array, order=1):
    """
    A method to estimate the largest (or certain-order largest) value of the other␣
↪biders,
    conditional on player 1 wins the auction.

    We estimate E[y | y < v_hat], where y is the highest valuation among the
    other bidders.  We do this by taking bidder 1 as the reference bidder
    (valuations are IID, so the choice does not matter), discarding her row,
    and averaging the highest remaining valuation over those auctions in which
    every other bidder's valuation falls below v_hat.

    Parameters:
    ----------
    v_hat : float, the valuation of the reference bidder.

    array: 2 dimensional array of bidders' values in shape of (N,R),
           where N: number of players, R: number of auctions

    order: int. Which order statistic of the losing bidders to average.
                order=1 gives the highest losing valuation,
                order=2 the second highest, and so on.

    """
```

(continues on next page)

(continued from previous page)

```
    N, R = array.shape

    # discard the reference bidder's row; condition on the rest losing
    array_residual = array[1:, :].copy()

    winning_auctions_mask = (array_residual < v_hat).all(axis=0)

    num_winning_auctions = np.sum(winning_auctions_mask)

    if num_winning_auctions == 0:
        return np.nan

    array_conditional = array_residual[:, winning_auctions_mask]

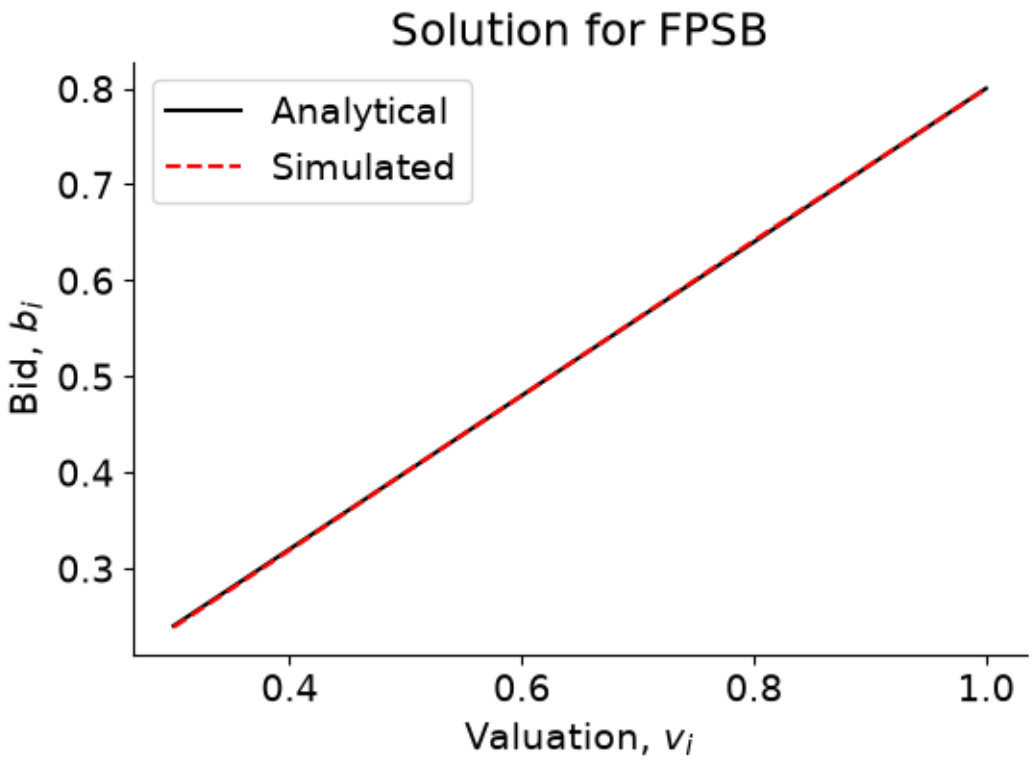
    array_conditional_sorted = np.sort(array_conditional, axis=0)

    order_largest_bids = array_conditional_sorted[-order, :]

    return np.mean(order_largest_bids)
```

We can check the accuracy of our `evaluate_largest` method by comparing it with an analytical solution.

We find that the `evaluate_largest` method functions well



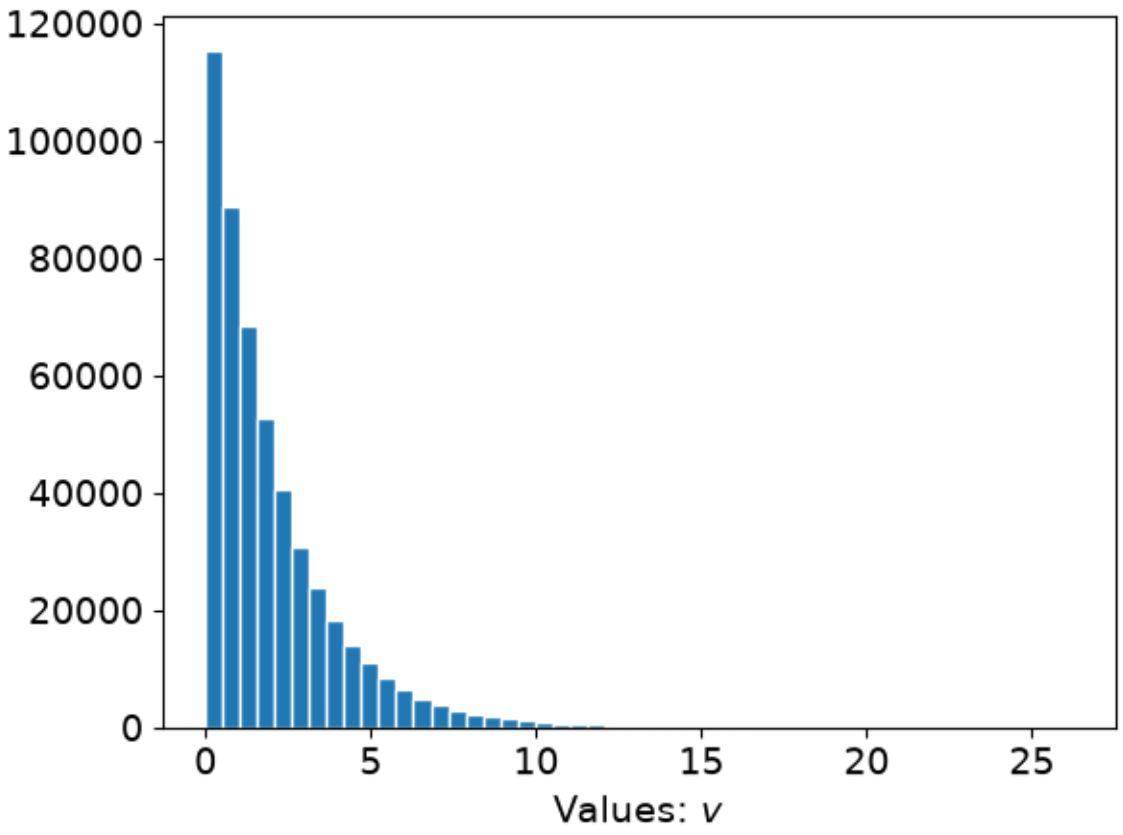
```
v_grid = np.linspace(0.3, 1, 8)
bid_analytical = b_star(v_grid, N)

# Redraw valuations
v = rng.uniform(0, 1, (N, R))
bid_simulated = [evaluate_largest(ii, v) for ii in v_grid]

fig, ax = plt.subplots(figsize=(6, 4))

ax.plot(v_grid, bid_analytical, '-', color='k', label='Analytical')
ax.plot(v_grid, bid_simulated, '--', color='r', label='Simulated')

ax.legend(loc='best')
ax.set_xlabel('Valuation, $v_i$')
ax.set_ylabel('Bid, $b_i$')
ax.set_title('Solution for FPSB')
sns.despine()
```



150.11 χ^2 Distribution

Let's try an example in which the distribution of private values is a χ^2 distribution.

We'll start by taking a look at a χ^2 distribution with the help of the following Python code:

```
rng = np.random.default_rng(1337)
v = rng.chisquare(df=2, size=(N * R,))

plt.hist(v, bins=50, edgecolor='w')
plt.xlabel('Values: $v$')
plt.show()
```

Now we'll get Python to construct a bid price function

```
rng = np.random.default_rng(1337)
v = rng.chisquare(df=2, size=(N, R))

# we compute the quantile of v as our grid
pct_quantile = np.linspace(0, 100, 101)[1:-1]
v_grid = np.percentile(v.flatten(), q=pct_quantile)

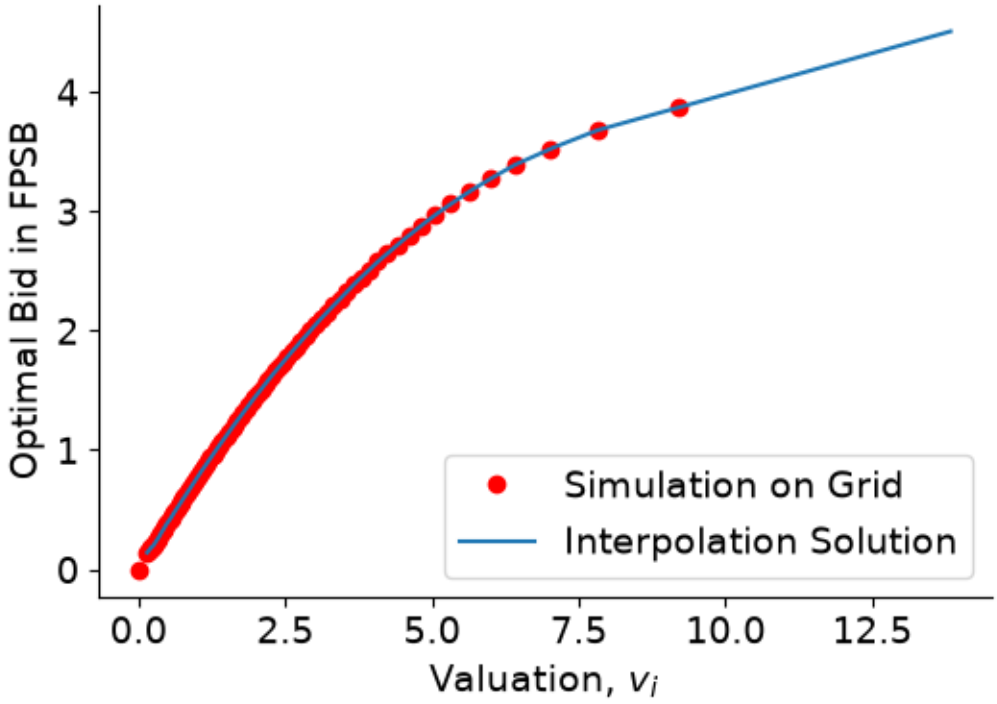
# nan values are returned for some low quantiles due to lack of observations
EV = [evaluate_largest(ii, v) for ii in v_grid]
```

```
# we insert 0 into our grid and bid price function as a complement
EV = np.insert(EV, 0, 0)
v_grid = np.insert(v_grid, 0, 0)

b_star_num = interp.interp1d(v_grid, EV, fill_value="extrapolate")
```

We check our bid price function by computing and visualizing the result.

```
pct_quantile_fine = np.linspace(0, 100, 1001)[1:-1]
v_grid_fine = np.percentile(v.flatten(), q=pct_quantile_fine)



fig, ax = plt.subplots(figsize=(6, 4))

ax.plot(v_grid, EV, 'or', label='Simulation on Grid')
ax.plot(v_grid_fine, b_star_num(v_grid_fine),
                '-', label='Interpolation Solution')
```

(continues on next page)

(continued from previous page)

```
ax.legend(loc='best')
ax.set_xlabel('Valuation, $v_i$')
ax.set_ylabel('Optimal Bid in FPSB')
sns.despine()
```

Now we can use Python to compute the probability distribution of the price paid by the winning bidder

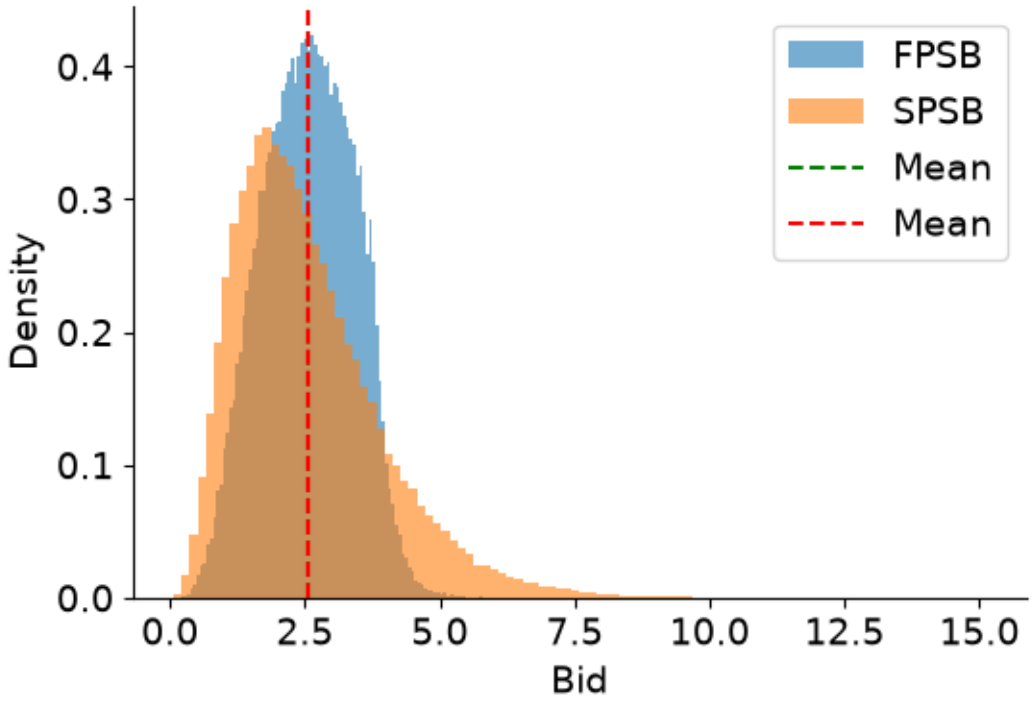
```
b = b_star_num(v)

idx = np.argsort(v, axis=0)
# same as np.sort(v, axis=0), except now we retain the idx
v = np.take_along_axis(v, idx, axis=0)
b = np.take_along_axis(b, idx, axis=0)

# highest bid
winner_pays_fpsb = b[-1, :]
# 2nd-highest valuation
winner_pays_spsb = v[-2, :]
```

```
fig, ax = plt.subplots(figsize=(6, 4))

for payment, label in zip([winner_pays_fpsb, winner_pays_spsb],
                          ['FPSB', 'SPSB']):
    print('The average payment of %s: %.4f. Std.: %.4f. Median: %.4f' % (
        label, payment.mean(), payment.std(), np.median(payment)))
    ax.hist(payment, density=True, alpha=0.6, label=label, bins=100)



ax.axvline(winner_pays_fpsb.mean(), ls='--', c='g', label='Mean')
ax.axvline(winner_pays_spsb.mean(), ls='--', c='r', label='Mean')
```

(continues on next page)

(continued from previous page)

```
ax.legend(loc='best')
ax.set_xlabel('Bid')
ax.set_ylabel('Density')
sns.despine()
```

```
The average payment of FPSB: 2.5672. Std.: 0.8373. Median: 2.5794
The average payment of SPSB: 2.5634. Std.: 1.3637. Median: 2.3075
```

150.12 Code summary

We assemble the functions that we have used into a Python class

```
class bid_price_solution:

    def __init__(self, array):
        """

150.13 Exercises

Exercise 150.13.1

Verify the revenue equivalence theorem by simulation.

For $n = 2, 3, 5, 10$ bidders with valuations drawn independently from $U(0, 1)$, simulate many auctions and compute

1. the average payment of the winner in a FPSB auction, in which each bidder bids $\frac{n-1}{n} v_i$
2. the average payment of the winner in a SPSB auction, in which each bidder bids v_i

Compare both with the theoretical expected revenue $\frac{n-1}{n+1}$, and comment on how the seller's revenue changes with the number of bidders.

Solution

```
R_ex = 200_000
rng_ex = np.random.default_rng(1234)

print(f"{'n':>4}{'FPSB':>12}{'SPSB':>12}{'(n-1)/(n+1)':>14}")
for n in (2, 3, 5, 10):
    v_ex = np.sort(rng_ex.uniform(0, 1, (n, R_ex)), axis=0)
```

```
    fpsb = (n - 1)/n * v_ex[-1, :]       # winner's own bid
    spsb = v_ex[-2, :]                   # second highest valuation
    print(f"{n:>4}{fpsb.mean():>12.4f}{spsb.mean():>12.4f}{(n-1)/(n+1):>14.4f}")
```

```
   n         FPSB         SPSB    (n-1)/(n+1)
   2       0.3335       0.3340         0.3333
   3       0.5000       0.5000         0.5000
   5       0.6671       0.6676         0.6667
  10       0.8185       0.8185         0.8182
```

The two auctions raise the same expected revenue, and both converge to the highest possible valuation as n grows.

With more bidders, competition pushes the winning payment toward the top of the support of valuations.

Notice that the two auctions raise the same revenue on average even though the *distributions* of the winner's payment differ: in a FPSB auction the payment is a deterministic function of the winner's valuation, while in a SPSB auction it is the second-highest valuation, which is random given the winner's valuation.

Exercise 150.13.2

Equation (150.1) says that an optimal bid in a FPSB auction is $\mathbb{E}[y_i \mid y_i < v_i]$.

1. Show that this can be written

$$b(v) = v - \frac{\int_0^v F(x)^{n-1} dx}{F(v)^{n-1}}$$

   where F is the distribution function of a valuation.

2. Verify that this reduces to $\frac{n-1}{n} v$ when F is uniform on $[0, 1]$.
3. Evaluate the formula for a $\chi^2(2)$ distribution of valuations and compare it with the simulation-based bid function computed in the lecture.

Solution

The distribution function of $y_i = \max_{j \neq i} v_j$ is $\tilde{F}_{n-1}(y) = F(y)^{n-1}$.

Hence

$$\mathbb{E}[y \mid y < v] = \frac{1}{F(v)^{n-1}} \int_0^v y \, d\left[F(y)^{n-1}\right].$$

Integrating by parts,

$$\int_0^v y \, d\left[F(y)^{n-1}\right] = vF(v)^{n-1} - \int_0^v F(y)^{n-1} dy,$$

which gives the formula.

For $F(x) = x$ on $[0, 1]$ we get $b(v) = v - \frac{v^n/n}{v^{n-1}} = \frac{n-1}{n} v$.

The formula has a nice reading: a bidder shades her bid below her valuation by an amount that shrinks as the number of competitors grows.

```
from scipy.integrate import quad

def b_closed_form(v, F, n):
    "Optimal FPSB bid for a bidder with valuation v when rivals' values ~ F."
    shading = quad(lambda x: F(x)**(n - 1), 0, v)[0] / F(v)**(n - 1)
    return v - shading

# check against the analytical solution for the uniform case
print("uniform check")
for v0 in (0.3, 0.6, 0.9):
    print(f"  v = {v0}:  closed form {b_closed_form(v0, lambda x: x, N):.4f}, "
          f"analytical {b_star(v0, N):.4f}")
```

```
uniform check
  v = 0.3:  closed form 0.2400, analytical 0.2400
  v = 0.6:  closed form 0.4800, analytical 0.4800
  v = 0.9:  closed form 0.7200, analytical 0.7200
```

```
# now the chi-squared case studied in the lecture
F_chi2 = stats.chi2(df=2).cdf
v_test = np.percentile(v.flatten(), [10, 30, 50, 70, 90])

print(f"{'v':>8}{'closed form':>14}{'simulated':>12}")
for v0 in v_test:
    print(f"{v0:>8.3f}{b_closed_form(v0, F_chi2, N):>14.4f}"
          f"{float(b_star_num(v0)):>12.4f}")
```

```
       v   closed form   simulated
   0.210        0.1663      0.1825
   0.711        0.5513      0.5544
   1.383        1.0370      1.0433
   2.397        1.6965      1.6984
   4.607        2.8055      2.7974
```

The closed form and the simulation agree closely, which is a useful check on both.

Exercise 150.13.3

This exercise asks you to see *why* truthful bidding is a weakly dominant strategy in a SPSB auction but not in a FPSB auction.

Fix $n = 5$ and consider a bidder whose valuation is $v = 0.75$, facing rivals whose valuations are $U(0, 1)$.

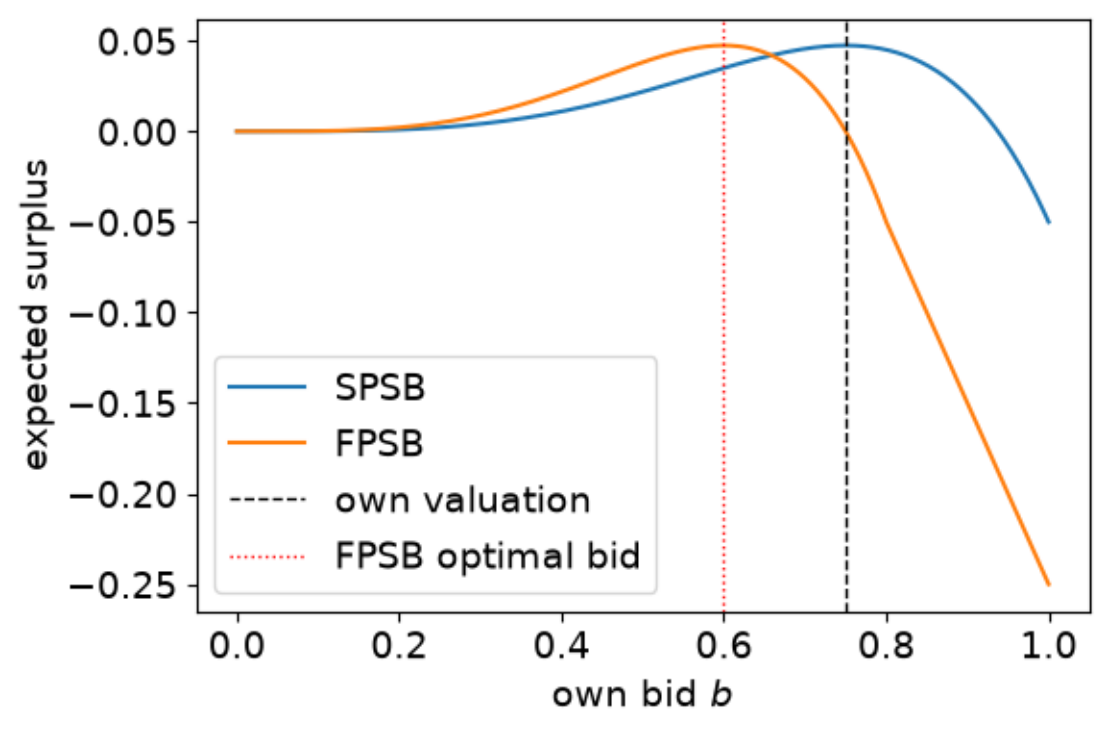
1. In a SPSB auction the rivals bid truthfully. Compute this bidder's expected surplus as a function of her own bid b and plot it.
2. In a FPSB auction the rivals bid $\frac{n-1}{n} v_j$. Compute and plot her expected surplus as a function of b.
3. Where does each curve peak? What surplus does she earn in the FPSB auction if she bids her valuation?

Solution

In the SPSB auction she wins when $y < b$ and then pays y, so her expected surplus is

$$\int_0^b (v - y)\,(n-1) y^{n-2} dy.$$

Differentiating with respect to b gives $(v-b)(n-1)b^{n-2}$, which is positive for $b < v$ and negative for $b > v$, so $b = v$ is optimal.



In the FPSB auction she wins when every rival's bid falls below b, which happens with probability $\left(\frac{nb}{n-1}\right)^{n-1}$, and then she pays b.

```
n_ex, v_own = 5, 0.75
bids = np.linspace(0, 1, 401)

spsb_surplus = [quad(lambda y: (v_own - y)*(n_ex - 1)*y**(n_ex - 2),
                     0, min(bb, 1))[0] for bb in bids]
fpsb_surplus = [(v_own - bb)*min(1, n_ex*bb/(n_ex - 1))**(n_ex - 1)
                for bb in bids]

fig, ax = plt.subplots(figsize=(6, 4))
ax.plot(bids, spsb_surplus, label='SPSB')
ax.plot(bids, fpsb_surplus, label='FPSB')
ax.axvline(v_own, ls='--', c='k', lw=1, label='own valuation')
ax.axvline((n_ex - 1)/n_ex*v_own, ls=':', c='r', lw=1, label='FPSB optimal bid')
ax.set_xlabel('own bid $b$')
ax.set_ylabel('expected surplus')
ax.legend()
plt.show()

print(f"SPSB surplus is maximized at b = {bids[int(np.argmax(spsb_surplus))]:.3f}")
print(f"FPSB surplus is maximized at b = {bids[int(np.argmax(fpsb_surplus))]:.3f}"
      f"  (theory: {(n_ex - 1)/n_ex*v_own:.3f})")
print(f"FPSB surplus from bidding one's valuation: {(v_own - v_own):.3f}")
```

```
SPSB surplus is maximized at b = 0.750
FPSB surplus is maximized at b = 0.600  (theory: 0.600)
FPSB surplus from bidding one's valuation: 0.000
```

The SPSB curve peaks exactly at the bidder's valuation.

The FPSB curve peaks strictly below it, and bidding one's valuation in a FPSB auction earns a surplus of exactly zero: the bidder wins more often, but pays her full valuation whenever she does.

Exercise 150.13.4

The revenue equivalence theorem requires bidders to be *risk neutral*.

Suppose instead that each bidder has utility $u(x) = x^\rho$ with $0 < \rho \leq 1$, so that $\rho < 1$ means risk aversion, and that valuations are $U(0, 1)$.

One can show that the symmetric equilibrium bid in a FPSB auction becomes

$$b(v) = \frac{n-1}{n-1+\rho} v.$$

1. Verify this numerically: for $n = 5$ and a bidder with $v = 0.8$, compute expected utility as a function of her own bid when rivals use this rule, and check where it is maximized.
2. Compute the seller's expected revenue in FPSB and SPSB for $\rho = 1, 0.6, 0.3$.
3. Explain the intuition.

Solution

```
def expected_utility(b, v_own, n, ρ):
    "Expected utility of bidding b when rivals bid (n-1)v/(n-1+ρ)."
    win_prob = np.minimum(1, b*(n - 1 + ρ)/(n - 1))**(n - 1)
    return win_prob * np.maximum(v_own - b, 0)**ρ

n_ex, v_own = 5, 0.8
grid = np.linspace(0.001, v_own, 2001)

print(f"{'ρ':>6}{'theory b*':>12}{'numerical':>12}")
for ρ in (1.0, 0.5, 0.2):
    theory = (n_ex - 1)*v_own/(n_ex - 1 + ρ)
    numerical = grid[int(np.argmax(expected_utility(grid, v_own, n_ex, ρ)))]
    print(f"{ρ:>6}{theory:>12.4f}{numerical:>12.4f}")
```

```
     ρ   theory b*   numerical
   1.0      0.6400      0.6398
   0.5      0.7111      0.7109
   0.2      0.7619      0.7620
```

```
rng_ra = np.random.default_rng(42)
v_ra = np.sort(rng_ra.uniform(0, 1, (n_ex, 200_000)), axis=0)

print(f"{'ρ':>6}{'FPSB revenue':>15}{'SPSB revenue':>15}")
for ρ in (1.0, 0.6, 0.3):
    fpsb = ((n_ex - 1)/(n_ex - 1 + ρ)) * v_ra[-1, :]
    print(f"{ρ:>6}{fpsb.mean():>15.4f}{v_ra[-2, :].mean():>15.4f}")
```

```
      ρ   FPSB revenue   SPSB revenue
    1.0          0.6666         0.6668
    0.6          0.7245         0.6668
    0.3          0.7751         0.6668
```

With risk neutrality ($\rho = 1$) the two auctions raise the same revenue, as the theorem says.

With risk aversion ($\rho < 1$) the FPSB auction raises *more*.

The intuition is that in a FPSB auction, shading one's bid is a gamble: it raises the surplus conditional on winning but lowers the probability of winning.

A risk-averse bidder dislikes that gamble and so shades less, which transfers revenue to the seller.

In a SPSB auction the winner's payment does not depend on her own bid, so risk aversion changes nothing: bidding one's valuation remains weakly dominant, and the seller's revenue is unaffected.

150.14 Further reading

The second-price sealed-bid auction was proposed by Vickrey [1961].

For textbook treatments of the material in this lecture, see Krishna [2009] and Milgrom [2004].

Klemperer [1999] surveys the literature.

The revenue equivalence theorem in the general form sketched above is due to Myerson [1981] and Riley and Samuelson [1981].

Both auctions studied here are naturally described in terms of order statistics of bidders' valuations, a subject treated at length by David and Nagaraja [2003].

CHAPTER

ONE

MULTIPLE GOOD ALLOCATION MECHANISMS

```
!pip install "prettytable<3.18"
```

151.1 Overview

This lecture describes two mechanisms for allocating n private goods ("houses") to m people ("buyers").

We assume that $m > n$ so that there are more potential buyers than there are houses.

Prospective buyers regard the houses as **substitutes**.

Buyer j attaches value v_{ij} to house i.

These values are **private**

- v_{ij} is known only to person j unless person j chooses to tell someone.

We require that a mechanism allocate **at most** one house to one prospective buyer.

We describe two distinct mechanisms

- A multiple rounds, ascending bid auction
- A sequential, "greedy" second-price mechanism administered by a benevolent social planner, inspired by the ideas of Groves [1973] and Clarke [1971]

Note

In 1994, the multiple rounds, ascending bid auction was actually used by Stanford University to sell leases to 9 lots on the Stanford campus to eligible faculty members.

We begin with overviews of the two mechanisms.

151.2 Ascending bids auction for multiple goods

An auction is administered by an **auctioneer**

The auctioneer has an $n \times 1$ vector r of reservation prices on the n houses.

The auctioneer sells house i only if the final price bid for it exceeds r_i

The auctioneer allocates all n houses **simultaneously**

The auctioneer does not know bidders' private values v_{ij}

There are multiple **rounds**

- during each round, active participants can submit bids on any of the n houses
- each bidder can bid on only one house during one round
- a person who was high bidder on a particular house in one round is understood to submit that same bid for the same house in the next round
- between rounds, a bidder who was not a high bidder can change the house on which he/she chooses to bid
- the auction ends when the price of no house changes from one round to the next
- all n houses are allocated after the final round
- house i is retained by the auctioneer if no prospective buyer offers more than r_i for the house

In this auction, person j never tells anyone else his/her private values v_{ij}

151.3 A benevolent planner

This mechanism is designed so that all prospective buyers voluntarily choose to reveal their private values to a **social planner** who uses them to construct a socially optimal allocation.

Among all feasible allocations, a **socially optimal allocation** maximizes the sum of private values across all prospective buyers.

The planner tells everyone in advance how he/she will allocate houses based on the matrix of values that prospective buyers report.

The mechanism is intended to give every prospective buyer an incentive to reveal his vector of private values to the planner.

After the planner receives everyone's vector of private values, the planner deploys a **sequential** algorithm to determine an **allocation** of houses and a set of **fees** that he charges awardees for the negative **externality** that their presence impose on other prospective buyers.

151.4 Comparing the two mechanisms

Remarkably, these two mechanisms can produce virtually identical allocations.

But "virtually identical" is not "identical", and the differences turn out to be instructive.

We'll discover that

- the ascending bid auction maximizes the total value of the allocation, and, as the bid increment ϵ becomes small, the prices that it sets converge to the payments prescribed by the **Vickrey-Clarke-Groves** (VCG) mechanism

- the greedy mechanism of the benevolent planner does *not* always maximize total value, and the prices that it charges are *not* VCG payments, so truthful reporting is not always in a buyer's interest

We construct Python code for both mechanisms.

We also work out some examples by hand or almost by hand.

Next, let's dive down into the details.

151.5 Ascending bid auction

151.5.1 Basic setting

We start with a more detailed description of the setting.

- A seller owns n houses that he wants to sell for the maximum possible amounts to a set of m prospective eligible buyers.
- The seller wants to sell at most one house to each potential buyer.
- There are m potential eligible buyers, identified by $j = [1, 2, \ldots, m]$
  - Each potential buyer is permitted to buy at most one house.
  - Buyer j would be willing to pay at most v_{ij} for house i.
  - Buyer j knows $v_{ij}, i = 1, \ldots, n$, but no one else does.
  - If buyer j pays p_i for house i, he enjoys surplus value $v_{ij} - p_i$.
  - Each buyer j wants to choose the i that maximizes his/her surplus value $v_{ij} - p_i$.
  - The seller wants to maximize $\sum_i p_i$.

The seller conducts a **simultaneous, multiple goods, ascending bid auction**.

Outcomes of the auction are

- An $n \times 1$ vector p of sales prices $p = [p_1, \ldots, p_n]$ for the n houses.
- An $n \times m$ matrix Q of 0's and 1's, where $Q_{ij} = 1$ if and only if person j bought house i.
- An $n \times m$ matrix S of surplus values consisting of all zeros unless person j bought house i, in which case $S_{ij} = v_{ij} - p_i$

We describe rules for the auction it terms of **pseudo code**.

The pseudo code will provide a road map for writing Python code to implement the auction.

151.6 Pseudocode

Here is a quick sketch of a possible simple structure for our Python code

Inputs:

- n, m.
- an $n \times m$ non-negative matrix v of private values
- an $n \times 1$ vector r of seller-specified reservation prices
- the seller will not accept a price less than r_i for house i

- we are free to think of these reservation prices as private values of a fictitious $m+1$ th buyer who does not actually participate in the auction
- initial bids can be thought of starting at r
- a scalar ϵ of seller-specified minimum price-bid increments

For each round of the auction, new bids on a house must be at least the prevailing highest bid so far **plus** ϵ

Auction Protocols

- the auction consists of a finite number of **rounds**
- in each round, a prospective buyer can bid on one and only one house
- after each round, a house is temporarily awarded to the person who made the highest bid for that house
  - temporarily winning bids on each house are announced
  - this sets the stage to move on to the next round
- a new round is held
  - bids for temporary winners from the previous round are again attached to the houses on which they bid; temporary winners of the last round leave their bids from the previous round unchanged
  - all other active prospective buyers must submit a new bid on some house
  - new bids on a house must be at least equal to the prevailing temporary price that won the last round **plus** ϵ
  - if a person does not submit a new bid and was also not a temporary winner from the previous round, that person must drop out of the auction permanently
  - for each house, the highest bid, whether it is a new bid or was the temporary winner from the previous round, is announced, with the person who made that new (temporarily) winning bid being (temporarily) awarded the house to start the next round
- rounds continue until no price on **any** house changes from the previous round
- houses are sold to the winning bidders from the final round at the prices that they bid

Outputs:

- an $n \times 1$ vector p of sales prices
- an $n \times m$ matrix S of surplus values consisting of all zeros unless person j bought house i, in which case $S_{ij} = v_{ij} - p_i$
- an $n \times (m+1)$ matrix Q of 0's and 1's that tells which buyer bought which house. (The last column accounts for unsold houses.)

Proposed buyer strategy:

In this pseudo code and the actual Python code below, we'll assume that all buyers choose to use the following strategy, often called **straightforward bidding**: in each round, bid on the house that currently offers the buyer the largest surplus.

Each buyer $j = 1, \ldots, m$ uses the same strategy.

Straightforward bidding is *myopic*: a buyer looks only at prevailing prices and ignores how his bid today might affect prices tomorrow.

That myopia is less restrictive than it might sound.

Our setting is an **assignment market** of the kind studied by Shapley and Shubik [1971]: each buyer wants at most one house, and values are private.

For such markets, Crawford and Knoer [1981] and Demange *et al.* [1986] showed that an ascending auction like ours, in which all buyers bid straightforwardly, converges to a competitive equilibrium of the assignment market.

It converges in particular to the *minimum* competitive equilibrium price vector, the one most favorable to buyers.

We'll return below to a striking consequence of this fact.

The strategy has the form:

- Let $\check{p}^t$ be the $n \times 1$ vector of prevailing highest-bid prices at the beginning of round t
- Let $\epsilon > 0$ be the minimum bid increment specified by the seller
- For each prospective buyer j, compute the index of the best house to bid on during round t, namely $\hat{i}_t = \text{argmax}_i\{[v_{ij} - \check{p}_i^t - \epsilon]\}$
- If $\max_i\{[v_{ij} - \check{p}_i^t - \epsilon]\} \leq 0$, person j permanently drops out of the auction at round t
- If $v_{\hat{i}_t,j} - \check{p}_{\hat{i}_t}^t - \epsilon > 0$, person j bids $\check{p}_{\hat{i}_t}^t + \epsilon$ on house $\hat{i}_t$

Resolving ambiguities: The protocols we have described so far leave open two possible sources of ambiguity.

(1) **The optimal bid choice for buyers in each round.** It is possible that a buyer has the same surplus value for multiple houses. The argmax function in Python always returns the first argmax element. We instead prefer to randomize among such houses. For that reason, we write our own argmax function below.

(2) **Seller's choice of winner if same price bid cast by several buyers.** To resolve this ambiguity, we use the np.random.choice function below.

Given the randomness in outcomes, it is possible that different allocations of houses could emerge from the same inputs.

However, this will happen only when the bid price increment ϵ is nonnegligible.

```
import numpy as np
import prettytable as pt

np.random.seed(100)
```

```
np.set_printoptions(precision=3, suppress=True)
```

151.7 An example

Before building a Python class, let's step by step solve things almost "by hand" to grasp how the auction proceeds.

A step-by-step procedure also helps reduce bugs, especially when the value matrix is peculiar (e.g. the differences between values are negligible, a column containing identical values or multiple buyers have the same valuation etc.).

Fortunately, our auction behaves well and robustly with various peculiar matrices.

We provide some examples later in this lecture.

```
v = np.array([[8, 5, 9, 4],
              [4, 11, 7, 4],
              [9, 7, 6, 4]])
n, m = v.shape
r = np.array([2, 1, 0])
ϵ = 1
p = r.copy()
buyer_list = np.arange(m)
house_list = np.arange(n)
```

```
v
```

```
array([[ 8,  5,  9,  4],
       [ 4, 11,  7,  4],
       [ 9,  7,  6,  4]])
```

Remember that column indexes j indicate buyers and row indexes i indicate houses.

The above value matrix v is peculiar in the sense that Buyer 3 (indexed from 0) puts the same value 4 on every house being sold.

Maybe buyer 3 is a bureaucrat who purchases these house simply by following instructions from his superior.

```
r
```

```
array([2, 1, 0])
```

```
def find_argmax_with_randomness(v):
    """
    We build our own version of argmax function such that the argmax index will be␣
 ↪returned randomly
    when there are multiple maximum values. This function is similar to np.argmax(v,

+--------------+-----+-----+-------+
|    Buyer     | [2] | [1] | [0 3] |
+--------------+-----+-----+-------+
```

check terminal condition

Notice that two buyers bid for house 2 (indexed from 0).

Because the auction protocol does not specify a selection rule in this case, we simply select a winner **randomly**.

This is reasonable because the seller can't distinguish these buyers and doesn't know the valuation of each buyer.

It is both convenient and practical for him to just pick a winner randomly.

There is a 50% probability that Buyer 3 is chosen as the winner for house 2, although he values it less than buyer 0.

In this case, buyer 0 has to bid one more time with a higher price, which crowds out Buyer 3.

Therefore, final price could be 3 or 4, depending on the winner in the last round.

```
def check_terminal_condition(bid_info, p, v, ϵ):
    """
    A function that checks whether the auction ends.
```

(continues on next page)

(continued from previous page)

```
    Recall that the auction ends when either losers have non-positive surplus values␣
↪for each house
    or there is no loser (every buyer gets a house).

    Parameters:
    ----------
    bid_info: a dictionary that contains bidding information of house numbers (as␣
↪keys) and buyers (as values).

    p: np.array. price array of houses

    v: value matrix

    ϵ: the minimum price increment in each round

    Returns:
    ----------
    allocation: a dictionary that describes how the houses bid are assigned.

    winner_list: a list of winners

    loser_list: a list of losers

    """

151.7.3 Later rounds

Every remaining round repeats exactly the same two steps, so rather than writing them out one at a time we iterate until no price changes.

Watch for two things as the rounds unfold: a buyer who is outbid switches to whichever house now offers him the largest surplus, and the auction stops as soon as a round passes in which no losing buyer is willing to raise any price.

```
round_number = 2

while True:
    round_number += 1

151.8 A Python class

Above we simulated an ascending bid auction step by step.

When defining functions, we repeatedly computed some intermediate objects because our Python function loses track of variables once the function is executed.

That of course led to redundancy in our code

It is much more efficient to collect all of the aforementioned code into a class that records information about all rounds.

```
class ascending_bid_auction:

    def __init__(self, v, r, ϵ):
        """
        A class that simulates an ascending bid auction for houses.

        Given buyers' value matrix, sellers' reservation prices and minimum increment␣
↪of bid prices,
        this class can execute an ascending bid auction and present information round␣
↪by round until the end.

        Parameters:
        ----------
        v: 2 dimensional value matrix

        r: np.array of reservation prices

        ϵ: minimum increment of bid price

        """

        self.v = v.copy()
        self.n,self.m = self.v.shape
        # prices are stored as floats so that a bid increment ϵ < 1 is allowed

The minimum increment of bid price is 1.00

The auction can not start because of high reservation prices
```

151.10 A Groves-Clarke mechanism

We now describe an alternative way for society to allocate n houses to m possible buyers in a way that maximizes total value across all potential buyers.

We continue to assume that each buyer can purchase at most one house.

The mechanism is a very special case of a Groves-Clarke mechanism [Groves, 1973], [Clarke, 1971].

Its special structure substantially simplifies writing Python code to find an optimal allocation.

Our mechanism works like this.

- The values V_{ij} are private information to person j
- The mechanism makes each person j willing to tell a social planner his private values $V_{i,j}$ for all $i = 1, \ldots, n$.
- The social planner asks all potential bidders to tell the planner their private values V_{ij}
- The social planner tells no one these, but uses them to allocate houses and set prices

- The mechanism is *intended* to make all prospective buyers want to tell the planner their private values
  - we shall put this intention to a test below, and find that it is not achieved
- The planner finds a house, bidder pair with highest private value by computing $(\tilde{i}, \tilde{j}) = \text{argmax}(V_{ij})$
- The planner assigns house $\tilde{i}$ to buyer $\tilde{j}$
- The planner charges buyer $\tilde{j}$ the price $\max_{-\tilde{j}} V_{\tilde{i},j}$, where $-\tilde{j}$ means all j's except $\tilde{j}$.
- The planner creates a matrix of private values for the remaining houses $-\tilde{i}$ by deleting row (i.e., house) $\tilde{i}$ and column (i.e., buyer) $\tilde{j}$ from V.
  - (But in doing this, the planner keeps track of the real names of the bidders and the houses).
- The planner returns to the original step and repeat it.
- The planner iterates until all n houses are allocated and the charges for all n houses are set.

151.11 An example solved by hand

Let's see how our Groves-Clarke algorithm would work for the following simple matrix V matrix of private values

$$V = \begin{bmatrix} 10 & 9 & 8 & 7 & 6 \\ 9 & 9 & 7 & 6 & 6 \\ 8 & 6 & 6 & 9 & 4 \\ 7 & 5 & 6 & 4 & 9 \end{bmatrix}$$

Remark: In the first step, when the highest private value corresponds to more than one house, bidder pairs, we choose the pair with the highest sale price. If a highest sale price corresponds to two or more pairs with highest private values, we randomly choose one.

```
np.random.seed(666)

V_orig = np.array([[10, 9, 8, 7, 6],  # record the original values
                   [9, 9, 7, 6, 6],
                   [8, 6, 6, 9, 4],
                   [7, 5, 6, 4, 9]])
V = np.copy(V_orig)  # used iteratively
n, m = V.shape
p = np.zeros(n) # prices of houses
Q = np.zeros((n, m)) # keep record the status of houses and buyers
```

First assignment

First, we find house, bidder pair with highest private value.

```
i, j = np.where(V==np.max(V))
i, j
```

```
(array([0]), array([0]))
```

So, house 0 will be sold to buyer 0 at a price of 9. We then update the sale price of house 0 and the status matrix Q.

```
p[i] = np.max(np.delete(V[i, :], j))
Q[i, j] = 1
p, Q
```

```
(array([9., 0., 0., 0.]),
 array([[1., 0., 0., 0., 0.],
        [0., 0., 0., 0., 0.],
        [0., 0., 0., 0., 0.],
        [0., 0., 0., 0., 0.]]))
```

Then we remove row 0 and column 0 from V. To keep the real number of houses and buyers, we set this row and this column to -1, which will have the same result as removing them since $V \geq 0$.

```
V[i, :] = -1
V[:, j] = -1
V
```

```
array([[-1, -1, -1, -1, -1],
       [-1,  9,  7,  6,  6],
       [-1,  6,  6,  9,  4],
       [-1,  5,  6,  4,  9]])
```

Second assignment

We find house, bidder pair with the highest private value again.

```
i, j = np.where(V==np.max(V))
i, j
```

```
(array([1, 2, 3]), array([1, 3, 4]))
```

In this special example, there are three pairs (1, 1), (2, 3) and (3, 4) with the highest private value. To solve this problem, we choose the one with highest sale price.

```
p_candidate = np.zeros(len(i))
for k in range(len(i)):
    p_candidate[k] = np.max(np.delete(V[i[k], :], j[k]))
k, = np.where(p_candidate==np.max(p_candidate))
i, j = i[k], j[k]
i, j
```

```
(array([1]), array([1]))
```

So, house 1 will be sold to buyer 1 at a price of 7. We update matrices.

```
p[i] = np.max(np.delete(V[i, :], j))
Q[i, j] = 1
V[i, :] = -1
V[:, j] = -1
p, Q, V
```

```
(array([9., 7., 0., 0.]),
 array([[1., 0., 0., 0., 0.],
        [0., 1., 0., 0., 0.],
        [0., 0., 0., 0., 0.],
        [0., 0., 0., 0., 0.]]),
 array([[-1, -1, -1, -1, -1],
        [-1, -1, -1, -1, -1],
        [-1, -1,  6,  9,  4],
        [-1, -1,  6,  4,  9]]))
```

Third assignment

```
i, j = np.where(V==np.max(V))
i, j
```

```
(array([2, 3]), array([3, 4]))
```

In this special example, there are two pairs (2, 3) and (3, 4) with the highest private value.

To resolve the assignment, we choose the one with highest sale price.

```
p_candidate = np.zeros(len(i))
for k in range(len(i)):
    p_candidate[k] = np.max(np.delete(V[i[k], :], j[k]))
k, = np.where(p_candidate==np.max(p_candidate))
i, j = i[k], j[k]
i, j
```

```
(array([2, 3]), array([3, 4]))
```

The two pairs even have the same sale price.

We randomly choose one pair.

```
k = np.random.choice(len(i))
i, j = i[k], j[k]
i, j
```

```
(np.int64(2), np.int64(3))
```

Finally, house 2 will be sold to buyer 3.

We update matrices accordingly.

```
p[i] = np.max(np.delete(V[i, :], j))
Q[i, j] = 1
V[i, :] = -1
V[:, j] = -1
p, Q, V
```

```
(array([9., 7., 6., 0.]),
 array([[1., 0., 0., 0., 0.],
        [0., 1., 0., 0., 0.],
        [0., 0., 0., 1., 0.],
        [0., 0., 0., 0., 0.]]),
 array([[-1, -1, -1, -1, -1],
        [-1, -1, -1, -1, -1],
        [-1, -1, -1, -1, -1],
        [-1, -1,  6, -1,  9]]))
```

Fourth assignment

```
i, j = np.where(V==np.max(V))
i, j
```

```
(array([3]), array([4]))
```

House 3 will be sold to buyer 4.

The final outcome follows.

```
p[i] = np.max(np.delete(V[i, :], j))
Q[i, j] = 1
V[i, :] = -1
V[:, j] = -1
S = V_orig*Q - np.diag(p)@Q
p, Q, V, S
```

```
(array([9., 7., 6., 6.]),
 array([[1., 0., 0., 0., 0.],
        [0., 1., 0., 0., 0.],
        [0., 0., 0., 1., 0.],
        [0., 0., 0., 0., 1.]]),
 array([[-1, -1, -1, -1, -1],
        [-1, -1, -1, -1, -1],
        [-1, -1, -1, -1, -1],
        [-1, -1, -1, -1, -1]]),
 array([[1., 0., 0., 0., 0.],
        [0., 2., 0., 0., 0.],

```

151.12.1 Elaborations

Here we use some additional notation designed to conform with standard notation in parts of the VCG literature.

We want to verify that our pseudo code is indeed a **pivot mechanism**, also called a **VCG** (Vickrey-Clarke-Groves) mechanism.

- The mechanism is named after Groves [1973], Clarke [1971], and Vickrey [1961].

To prepare for verifying this, we add some notation.

Let X be the set of feasible allocations of houses under the protocols above (i.e., at most one house to each person).

Let $X(v)$ be the allocation that the mechanism chooses for matrix v of private values.

The mechanism maps a matrix v of private values into an $x \in X$.

Let $v_j(x)$ be the value that person j attaches to allocation $x \in X$.

Let $\check{t}_j(v)$ the payment that the mechanism charges person j.

The VCG mechanism chooses the allocation

$$X(v) = \text{argmax}_{x \in X} \sum_{j=1}^{m} v_j(x) \tag{151.1}$$

and charges person j a "social cost"

$$\check{t}_j(v) = \max_{x \in X} \sum_{k \neq j} v_k(x) - \sum_{k \neq j} v_k(X(v)) \tag{151.2}$$

In our setting, equation (151.1) says that the VCG allocation allocates houses to maximize the total value of the successful prospective buyers.

In our setting, equation (151.2) says that the mechanism charges people for the externality that their presence in society imposes on other prospective buyers.

Thus, notice that according to equation (151.2):

- unsuccessful prospective buyers pay 0 because removing them from "society" would not affect the allocation chosen by the mechanism
- successful prospective buyers pay the difference between the total value society could achieve without them present and the total value that others present in society do achieve under the mechanism.

It is natural to ask whether the greedy mechanism that we coded above satisfies (151.1) and (151.2).

We shall compute $\check{t}_j$ for $j = 1, \ldots, m$ and compare it with the price p_j that the greedy mechanism actually charges.

The answer, which we develop in the next two sections, is that it satisfies neither requirement in general.

151.12.2 Social cost

Using the GC_Mechanism class, we can calculate the social cost of each buyer.

Let's see a simpler example with private value matrix

$$V = \begin{bmatrix} 10 & 9 & 8 & 7 & 6 \\ 9 & 8 & 7 & 6 & 6 \\ 8 & 7 & 6 & 5 & 4 \end{bmatrix}$$

To begin with, we implement the GC mechanism and see the outcome.

```
np.random.seed(666)

V_orig = np.array([[10, 9, 8, 7, 6],
                   [9, 8, 7, 6, 6],
                   [8, 7, 6, 5, 4]])
gc_mechanism = GC_Mechanism(V_orig)
gc_mechanism.start()
```

```
House 0 is sold to buyer 0 at price 9

House 1 is sold to buyer 1 at price 7

House 2 is sold to buyer 2 at price 5
```

(continues on next page)

(continued from previous page)

```
Prices of house:
 [9. 7. 5.]

The status matrix:
 [[1. 0. 0. 0. 0.]
 [0. 1. 0. 0. 0.]
 [0. 0. 1. 0. 0.]]

The surplus matrix:
 [[1. 0. 0. 0. 0.]
 [0. 1. 0. 0. 0.]
 [0. 0. 1. 0. 0.]]
```

We exclude buyer 0 and calculate the allocation.

```
V_exc_0 = np.copy(V_orig)
V_exc_0[:, 0] = -1
V_exc_0
gc_mechanism_exc_0 = GC_Mechanism(V_exc_0)
gc_mechanism_exc_0.start()
```

```
House 0 is sold to buyer 1 at price 8

House 1 is sold to buyer 2 at price 6

House 2 is sold to buyer 3 at price 4

Prices of house:
 [8. 6. 4.]

The status matrix:
 [[0. 1. 0. 0. 0.]
 [0. 0. 1. 0. 0.]
 [0. 0. 0. 1. 0.]]

The surplus matrix:
 [[-0.  1.  0.  0.  0.]
 [-0.  0.  1.  0.  0.]
 [-0.  0.  0.  1.  0.]]
```

Calculate the social cost of buyer 0.

```
print("The social cost of buyer 0:",
     np.sum(gc_mechanism_exc_0.Q*gc_mechanism_exc_0.V_orig)-np.sum(np.delete(gc_
 ↪mechanism.Q*gc_mechanism.V_orig, 0, axis=1)))
```

```
The social cost of buyer 0: 7.0
```

Repeat this process for buyer 1 and buyer 2

```
V_exc_1 = np.copy(V_orig)
V_exc_1[:, 1] = -1
V_exc_1
gc_mechanism_exc_1 = GC_Mechanism(V_exc_1)
gc_mechanism_exc_1.start()

print("\nThe social cost of buyer 1:",
     np.sum(gc_mechanism_exc_1.Q*gc_mechanism_exc_1.V_orig)-np.sum(np.delete(gc_
 ↪mechanism.Q*gc_mechanism.V_orig, 1, axis=1)))
```

```
House 0 is sold to buyer 0 at price 8

House 1 is sold to buyer 2 at price 6

House 2 is sold to buyer 3 at price 4

Prices of house:
 [8. 6. 4.]

The status matrix:
 [[1. 0. 0. 0. 0.]
 [0. 0. 1. 0. 0.]
 [0. 0. 0. 1. 0.]]

The surplus matrix:
 [[ 2. -0.  0.  0.  0.]
 [ 0. -0.  1.  0.  0.]
 [ 0. -0.  0.  1.  0.]]

The social cost of buyer 1: 6.0
```

```
V_exc_2 = np.copy(V_orig)
V_exc_2[:, 2] = -1
V_exc_2
gc_mechanism_exc_2 = GC_Mechanism(V_exc_2)
gc_mechanism_exc_2.start()

print("\nThe social cost of buyer 2:",
     np.sum(gc_mechanism_exc_2.Q*gc_mechanism_exc_2.V_orig)-np.sum(np.delete(gc_
 ↪mechanism.Q*gc_mechanism.V_orig, 2, axis=1)))
```

```
House 0 is sold to buyer 0 at price 9

House 1 is sold to buyer 1 at price 6

House 2 is sold to buyer 3 at price 4

Prices of house:
```

(continues on next page)

(continued from previous page)

```
 [9. 6. 4.]

The status matrix:
 [[1. 0. 0. 0. 0.]
 [0. 1. 0. 0. 0.]
 [0. 0. 0. 1. 0.]]

The surplus matrix:

 [ 0.  2. -0.  0.  0.]
 [ 0.  0. -0.  1.  0.]]

The social cost of buyer 2: 5.0
```

151.13 Is the greedy mechanism a VCG mechanism?

The mechanism that our benevolent planner runs is **greedy**: it repeatedly grabs the largest remaining entry of the value matrix.

A genuine VCG mechanism must do two things, namely, satisfy (151.1) and (151.2).

Let's check them one at a time.

We'll need a way to compute the value-maximizing allocation, which is a classic **assignment problem** that can be solved by linear programming.

```
from scipy.optimize import linear_sum_assignment

def optimal_assignment(V):
    """
    Solve the assignment problem: allocate at most one house to each buyer
    so as to maximize the total value.
    Returns the total value and a dictionary mapping buyer -> house.
    """
    rows, cols = linear_sum_assignment(-V)
    return V[rows, cols].sum(), {int(c): int(r) for r, c in zip(rows, cols)}

def greedy_outcome(V):
    "Run the planner's greedy mechanism quietly and report what it achieves."
    gc = GC_Mechanism(V.copy())
    gc.start(verbose=False)
    return (gc.Q * gc.V_orig).sum(), gc
```

151.13.1 Does the greedy allocation maximize total value?

Consider this simple matrix of private values for two houses and two buyers.

```
V_trap = np.array([[10, 9],
                   [9, 1]])

greedy_value, _ = greedy_outcome(V_trap)
best_value, best_alloc = optimal_assignment(V_trap)

print(f"greedy total value:  {greedy_value:.0f}")
print(f"optimal total value: {best_value:.0f}   (buyer -> house: {best_alloc})")
```

```
greedy total value:  11
optimal total value: 18   (buyer -> house: {1: 0, 0: 1})
```

The greedy rule starts from the largest entry, $V_{00} = 10$, and gives house 0 to buyer 0.

That leaves only $V_{11} = 1$, for a total of 11.

But assigning house 0 to buyer 1 and house 1 to buyer 0 yields $9 + 9 = 18$.

The largest entry was a trap: grabbing it destroyed a better pair of assignments.

So the greedy mechanism does *not* satisfy (151.1).

Exercise 151.14.1 asks you to investigate how often this happens.

The value matrices used earlier in this lecture happen to be ones for which greedy does find the best allocation, which is why the difficulty did not show up before.

151.13.2 Are the prices VCG payments?

Now let's compare the prices that the greedy mechanism charges with the social costs (151.2).

```
def vcg_payments(V):
    """
    The social cost of each buyer:
    the total value others could achieve without this buyer,
    minus the total value others do achieve when this buyer is present.
    """
    total, alloc = optimal_assignment(V)
    payments = np.zeros(V.shape[1])

    for j in range(V.shape[1]):
        total_without_j, _ = optimal_assignment(np.delete(V, j, axis=1))
        value_of_others = total - (V[alloc[j], j] if j in alloc else 0.0)
        payments[j] = total_without_j - value_of_others

    return payments
```

```
t_vcg = vcg_payments(V_orig)

print(f"{'buyer':>6}{'house':>7}{'greedy price':>15}{'VCG payment':>14}")
for j in range(V_orig.shape[1]):
    house = [i for i in range(V_orig.shape[0]) if gc_mechanism.Q[i, j] == 1]
    if house:
```

(continues on next page)

(continued from previous page)

```
        print(f"{j:>6}{house[0]:>7}{gc_mechanism.p[house[0]]:>15.1f}{t_vcg[j]:>14.1f}
↪")
```

```
 buyer  house   greedy price   VCG payment
     0      0            9.0           7.0
     1      1            7.0           6.0
     2      2            5.0           5.0
```

The prices differ from the VCG payments.

Notice that the VCG payments are exactly the social costs that we computed in the previous section by excluding one buyer at a time.

So the planner's mechanism collects *more* than the externality that a winning buyer imposes on others.

A mechanism that assigns objects greedily and charges each winner the best forgone offer for the same object is known as a **generalized second-price** mechanism.

Generalized second-price mechanisms are widely used – they are how search engines sell advertising slots – and it is well known that they are *not* VCG mechanisms [Edelman *et al.*, 2007].

151.13.3 Is truthful reporting a dominant strategy?

Because the mechanism is not VCG, the argument that makes truth telling a dominant strategy does not apply.

In fact truth telling is *not* a dominant strategy here, and Exercise 151.14.2 asks you to demonstrate that by finding a profitable lie.

151.13.4 What about the ascending bid auction?

Here is the striking fact promised earlier.

Our setting is an assignment market in which each buyer wants at most one house.

For such markets, Leonard [1983] and Demange *et al.* [1986] showed that the **minimum competitive equilibrium prices** coincide with the payments prescribed by the VCG mechanism.

Since an ascending auction with straightforward bidding converges to those minimum competitive equilibrium prices, it follows that our ascending bid auction implements the VCG outcome as the bid increment ϵ becomes small.

It is the auctioneer, not the benevolent planner, who runs a VCG mechanism here.

Exercise 151.14.3 asks you to verify this numerically.

151.14 Exercises

Exercise 151.14.1

We saw that the greedy mechanism can fail to maximize total value.

How often does it fail?

Draw many random value matrices with integer entries, run both the greedy mechanism and `optimal_assignment`, and report

1. the fraction of matrices for which greedy is suboptimal
2. the largest percentage shortfall that you find

Then explain in words why a greedy rule goes wrong.

Solution

```
rng_ha = np.random.default_rng(0)
trials = 200
failures, worst = 0, 0.0

for _ in range(trials):
    n_h, m_b = rng_ha.integers(2, 5), rng_ha.integers(2, 6)
    if m_b < n_h:
        n_h, m_b = m_b, n_h
    V_rand = rng_ha.integers(0, 12, size=(n_h, m_b))

    greedy_value, _ = greedy_outcome(V_rand)
    best_value, _ = optimal_assignment(V_rand)

    if greedy_value < best_value - 1e-9:
        failures += 1
        worst = max(worst, (best_value - greedy_value)/best_value)

print(f"greedy was suboptimal in {failures} of {trials} matrices")
print(f"largest shortfall: {100*worst:.1f} per cent of the attainable total value")
```

```
greedy was suboptimal in 66 of 200 matrices
largest shortfall: 43.8 per cent of the attainable total value
```

Greedy fails often, and sometimes badly.

The reason is that the largest entry of the value matrix need not belong to the best assignment.

Taking it removes a house *and* a buyer from further consideration, and that can destroy two good matches in order to secure one very good one.

Choosing the best assignment requires weighing all pairings simultaneously, which is what the linear programming routine does.

Exercise 151.14.2

Show that truthful reporting is not a dominant strategy under the planner's greedy mechanism.

Use the value matrix `V_orig` of the previous section, and consider buyer 0, whose true values for the three houses are $(10, 9, 8)$.

1. What surplus does buyer 0 receive when everyone reports truthfully?
2. Search over reports (a, b, c) with integer entries between 0 and 10 that buyer 0 might submit instead, holding fixed the reports of all other buyers, and find the report that maximizes buyer 0's *true* surplus.
3. Explain what the manipulation accomplishes.

Solution

```
def surplus_of_buyer_0(V_true, V_reported):
    "True surplus of buyer 0 when the mechanism is run on the reported values."
    gc = GC_Mechanism(V_reported.copy())
    gc.start(verbose=False)
    for i in range(V_true.shape[0]):
        if gc.Q[i, 0] == 1:
            return V_true[i, 0] - gc.p[i], i, gc.p[i]
    return 0.0, None, None      # buyer 0 wins nothing

np.random.seed(0)
truth_surplus, house, price = surplus_of_buyer_0(V_orig, V_orig)
print(f"truthful report: buyer 0 wins house {house} at price {price:.0f}, "
      f"surplus {truth_surplus:.0f}")

best = (truth_surplus, None)
for a in range(11):
    for b in range(11):
        for c in range(11):
            V_lie = V_orig.copy()
            V_lie[:, 0] = [a, b, c]
            surplus, h, pr = surplus_of_buyer_0(V_orig, V_lie)
            if surplus > best[0] + 1e-9:
                best = (surplus, (a, b, c, h, pr))

report = best[1]
print(f"best misreport found: {report[:3]} wins house {report[3]} "
      f"at price {report[4]:.0f}, surplus {best[0]:.0f}")
```

```
truthful report: buyer 0 wins house 0 at price 9, surplus 1
best misreport found: (0, 0, 5) wins house 2 at price 5, surplus 3
```

By reporting that he places no value on the two expensive houses, buyer 0 steps out of the competition for them.

The mechanism then awards him a cheaper house, and charges him the best forgone offer for *that* house, which is much less than what he paid when he told the truth.

His true value for the house he ends up with is high enough that this is a profitable deviation.

Under a genuine VCG mechanism this could not happen: a buyer's payment never depends on his own report, only on the harm he does to others.

Exercise 151.14.3

Verify that the ascending bid auction implements the VCG outcome.

Use the value matrix

$$v = \begin{bmatrix} 8 & 5 & 9 & 4 \\ 4 & 11 & 7 & 4 \\ 9 & 7 & 6 & 4 \end{bmatrix}$$

with reservation prices of zero, so that prices are free to settle at their competitive levels.

1. Compute the VCG payments and the value-maximizing allocation.
2. Run the ascending bid auction for $\epsilon = 1, 0.5, 0.25, 0.1, 0.05$ and record what each winning buyer pays.

3. Does the auction maximize total value? Do its payments approach the VCG payments?

Solution

```
v_ex = np.array([[8, 5, 9, 4],
                 [4, 11, 7, 4],
                 [9, 7, 6, 4]])

t_vcg_ex = vcg_payments(v_ex)
best_value_ex, best_alloc_ex = optimal_assignment(v_ex)

print(f"VCG payments by buyer: {t_vcg_ex}")
print(f"value-maximizing allocation (buyer -> house): {best_alloc_ex}")
print(f"maximum total value: {best_value_ex:.0f}\n")

print(f"{'ε':>7}{'total value':>14}   payments by buyer")
for ϵ_try in (1.0, 0.5, 0.25, 0.1, 0.05):
    np.random.seed(0)
    auction = ascending_bid_auction(v_ex, np.zeros(3), ϵ_try)
    auction.start_auction(verbose=False)

    payments = {j: round(float(auction.p[i]), 3)
                for i in range(v_ex.shape[0])
                for j in range(v_ex.shape[1]) if auction.Q[i, j] == 1}
    total_value = (auction.Q[:, :v_ex.shape[1]] * v_ex).sum()
    print(f"{ϵ_try:>7}{total_value:>14.0f}   {payments}")
```

```
VCG payments by buyer: [4. 4. 4. 0.]
value-maximizing allocation (buyer -> house): {2: 0, 1: 1, 0: 2}
maximum total value: 29

      ε   total value   payments by buyer
    1.0            29   {2: 4.0, 1: 3.0, 0: 3.0}
    0.5            29   {2: 4.0, 1: 3.5, 0: 3.5}
   0.25            29   {2: 4.0, 1: 3.75, 0: 3.75}
    0.1            29   {2: 4.0, 1: 3.9, 0: 3.9}
   0.05            29   {2: 4.0, 1: 4.05, 0: 4.05}
```

The auction always attains the maximum total value.

As ϵ shrinks, each winner's payment approaches that buyer's VCG payment.

This illustrates the theorem of Leonard [1983] and Demange *et al.* [1986]: in an assignment market, the minimum competitive equilibrium prices are exactly the VCG payments.

The auctioneer never asks anyone to reveal a private value, yet the ascending auction arrives at the outcome that a correctly designed planner would compute from full information.

TROUBLESHOOTING

Contents

- *Troubleshooting*
  - *Fixing Your Local Environment*
  - *Reporting an Issue*

This page is for readers experiencing errors when running the code from the lectures.

152.1 Fixing Your Local Environment

The basic assumption of the lectures is that code in a lecture should execute whenever

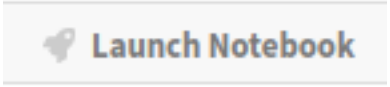
1. it is executed in a Jupyter notebook and
2. the notebook is running on a machine with the latest version of Anaconda Python.

You have installed Anaconda, haven't you, following the instructions in this lecture?

Assuming that you have, the most common source of problems for our readers is that their Anaconda distribution is not up to date.

Here's a useful article on how to update Anaconda.

Another option is to simply remove Anaconda and reinstall.



You also need to keep the external code libraries, such as QuantEcon.py up to date.

For this task you can either

- use `pip install --upgrade quantecon` on the command line, or
- execute `!pip install --upgrade quantecon` within a Jupyter notebook.

If your local environment is still not working you can do two things.

First, you can use a remote machine instead, by clicking on the Launch Notebook icon available for each lecture

Second, you can report an issue, so we can try to fix your local set up.

We like getting feedback on the lectures so please don't hesitate to get in touch.

152.2 Reporting an Issue

One way to give feedback is to raise an issue through our issue tracker.

Please be as specific as possible. Tell us where the problem is and as much detail about your local set up as you can provide.

Finally, you can provide direct feedback to contact@quantecon.org

INDEX

A

A Bayesian Formulation of Friedman and Wald's Problem, 599
A Problem that Stumped Milton Friedman, 565
An Introduction to Job Search, 1357, 1373
Arrow Securities
    competitive equilibrium, 3139
Asset Pricing
    GMM Estimation, 3119
    MLE Estimation, 3089
Asset Pricing: Finite State Models, 3067

B

Bewley Model, 1845, 1849
Blackwell
    and screening, 923
Bounded Rationality, 1925
    Exchange Rate Indeterminacy, 2015
    Genetic Algorithms, 2043
    Money as a Medium of Exchange, 2075
    Overlapping Generations, 1951
    Parameterized Expectations, 1989
    Prospects, 2121

C

Central Limit Theorem, 195, 200
    Intuition, 200
    Multivariate Case, 205
Certainty Equivalence
    Robustness, 1807, 1815
CLT, 195
Complete Markets, 1845
    Arrow securities, 1851
Consumption Smoothing, 1831
Cross-Section Distributions
    consumption, 1847

D

Detection Error Probabilities, 1876
Distorted Expectations
    Stackelberg multiplier game, 1867
Dynamic Programming
    Computation, 1582
    Theory, 1581
    Unbounded Utility, 1582

E

Eigenvalues, 21, 36
Eigenvectors, 21, 36
Ergodicity, 1043, 1057

F

Finite Markov Asset Pricing
    Lucas Tree, 3075
Finite Markov Chains, 1043, 1044
    Stochastic Matrices, 1044
Frequency Domain
    permanent income model, 1874

G

Gram-Schmidt process, 1241

H

Hansen Sargent Tallarini
    model, 1862
hidden Markov model, 1241
History Dependence, 1835

I

Information
    pricing, 923
    strategic experimentation, 951
Irreducibility and Aperiodicity, 1043, 1050

J

Job Search VIII: On-the-Job Search, 1453
Job Search VIII: On-the-Job Search, 1453

K

Kalman Filter, 1201, 1237
    and vector autoregressions, 1243, 1257

Programming Implementation, 1210
Recursive Procedure, 1209
Kalman Filter 2, 1219
Kesten processes
heavy tails, 1172

L

Lake Model, 2603
Lake Model, Endogenous, 2623
Law of Large Numbers, 195, 196
Illustration, 198
Multivariate Case, 205
Proof, 197
Learning
two-sided, 951
Linear Algebra, 21
Differentiating Linear and Quadratic Forms, 40
Eigenvalues, 36
Eigenvectors, 36
Matrices, 29
Matrix Norms, 39
Neumann's Theorem, 40
Positive Definite Matrices, 40
SciPy, 36
Series Expansions, 39
Spectral Radius, 40
Vectors, 22
Linear Markov Perfect Equilibria, 2757
Linear State Space Models, 1079, 1171
Distributions, 1086
Ergodicity, 1093
Martingale Difference Shocks, 1081
Moments, 1086
Moving Average Representations, 1085
Prediction, 1099
Seasonals, 1084
Stationarity, 1093
Time Trends, 1084
Univariate Autoregressive Processes, 1082
Vector Autoregressions, 1084
LLN, 195
LQ Control, 1705
Infinite Horizon, 1717
Optimality (*Finite Horizon*), 1709
Permanent Income, 1807, 1815
LQ Permanent Income Model, 1831
cross section, 1845
standard, 1832

M

Marginal Distributions, 1043, 1048
Markov Asset Pricing
Overview, 3067
Markov Chains, 1044
Calculating Stationary Distributions, 1055
Convergence to Stationarity, 1056
Cross-Sectional Distributions, 1050
Ergodicity, 1057
Forecasting Future Values, 1058
Future Probabilities, 1050
Irreducibility, Aperiodicity, 1050
Marginal Distributions, 1048
Simulation, 1046
Stationary Distributions, 1053
Markov Perfect Equilibrium, 2755
Applications, 2760
Background, 2756
Overview, 2755
Markov process, inventory, 1067
Matrix
Determinants, 34
Inverse, 34
Maps, 31
NumPy, 30
Operations, 29
Solving Systems of Equations, 31
Modeling
Career Choice, 1439
Modeling COVID-19, 9
Modeling COVID-19, 9
Models
Harrison Kreps, 3181
Linear State Space, 1080
Markov Asset Pricing, 3067
McCall, 1334
Morris Learning, 3193
On-the-Job Search, 1453
Permanent Income, 1753, 1769
Pricing, 3068
Sequential analysis, 565, 599

N

Neumann's Theorem, 40

O

Observational Equivalence
heterogeneous agents, 1885
robustness and discounting, 1862
Theorem 1, 1865
Theorem 2, 1868
On-the-Job Search
Model, 1454
Model Features, 1454
Parameterization, 1455
Programming Implementation, 1456

Solving for Policies, 1458
Optimal Savings
Computation, 1650, 1690
Model, 1578
Policy Function, 1589
Policy Function Approach, 1579
Problem, 1648, 1666
Programming Implementation, 1654, 1671
Optimal Savings III: Stochastic Returns, 1577
Optimal Savings IV: Time Iteration, 1593
Optimal Savings V: The Endogenous Grid Method, 1605
Optimal Savings VI: EGM with JAX, 1613
Organization Capital, 1279
Bayesian Screening, 1289
Human Capital, 1293
Industry Equilibrium, 1287
Personnel Information, 1280
Team Information, 1291
Transfer Costs, 1294

P

Pandas for Panel Data, 3405
Permanent Income Hypothesis
Friedman, 1832
Permanent Income II: LQ Techniques, 1769
Permanent Income Model
examples, 1835
Hall's Representation, 1761
Savings Problem, 1754
Phillips Curve
Adaptive Expectations, 2229
Adaptive Learning and Escape Dynamics, 2285
Credibility Problem, 2179
Credible Policies, 2199
Drifts and Volatilities, 2403
Drifts and Volatilities after 2000, 2447
Econometric Policy Evaluation, 2379
Escaping Nash Inflation, 2317
Fed Policy in the 2020s, 2467
Optimal Misspecified Beliefs, 2245
Priors and Learning Cycles, 2347
Rise and Fall of U.S. Inflation, 2149
Self-Confirming Equilibria, 2261
Positive Definite Matrices, 40
Precautionary Savings
robustness, 1859
robustness vs convex marginal utility, 1866
Pricing Models, 3067, 3068
Risk Aversion, 3068
Risk-Neutral, 3068
Python
Pandas, 3405
python, 114, 1022

Q

Quantity Theory of Money, 3493

R

Rational Expectations Equilibrium, 2637
Competitive Equilbrium (*w. Adjustment Costs*), 2640
Computation, 2643
Definition, 2640
Planning Problem Approach, 2644
Riccati equation
matrix difference, 1240
Robust Bewley Model, 1885
Robust Control
breakdown point, 1870
permanent income, 1859
Robustness
payoff evaluation, 1879

S

spectral factorization identity, 1243
Spectral Radius, 40
Stability in Linear Rational Expectations Models, 2735
Stationary Distributions, 1043, 1053
Stochastic Matrices, 1044
Survival
Recursive Preferences, 891

T

The Income Fluctuation Problem III: The Endogenous Grid Method, 1647
The Income Fluctuation Problem IV: Transient Income Shocks, 1665
The Income Fluctuation Problem V: Stochastic Returns on Assets, 1687
The Permanent Income Model, 1753

U

Unbounded Utility, 1582

V

Vector Autoregression
and Kalman filter, 1237
subsystems, 1257
vector autoregression, 1243
Vectors, 21, 22
Inner Product, 25

Linear Independence, 28
