Chow [1968] asks a fundamental question: if we build a macro model using only standard demand equations with simple distributed lags, can the system generate sustained oscillations?

He shows that, under natural sign restrictions, the answer is no.

Stock-adjustment demand for durable goods leads to investment equations where the coefficient on Y_{t-1} is negative.

This negative coefficient captures the **acceleration effect**: investment responds not just to the level of income, but to its rate of change.

This negative coefficient is also what makes complex roots possible in the characteristic equation.

Without it, Chow proves that demand systems with only positive coefficients have real positive roots, and hence no oscillatory dynamics.

The *Samuelson Multiplier-Accelerator* lecture explores this mechanism in detail through the Hansen-Samuelson multiplier-accelerator model.

Here we briefly illustrate the effect.

Take the multiplier–accelerator law of motion:

$$Y_t = cY_{t-1} + v(Y_{t-1} - Y_{t-2}),$$

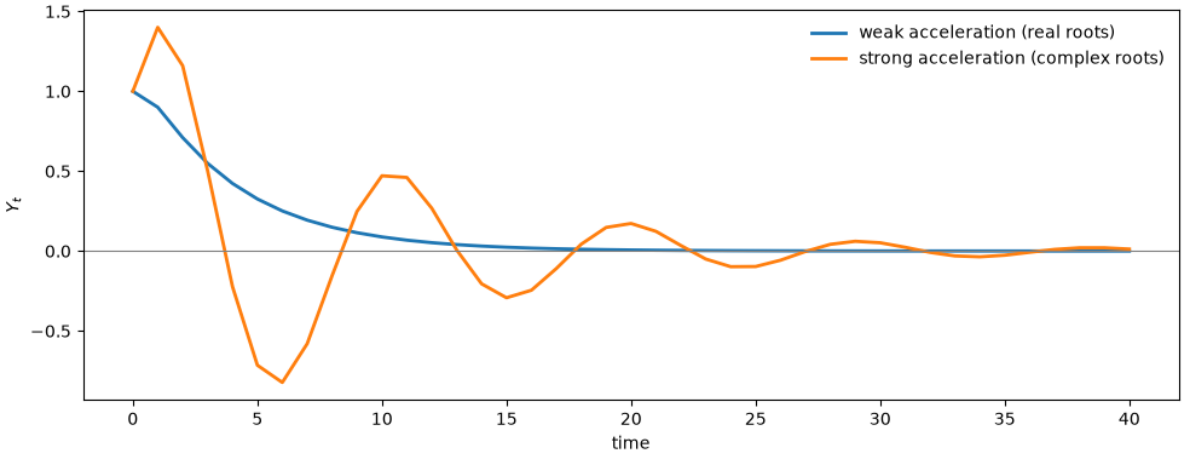
and rewrite it as a first-order system in (Y_t, Y_{t-1}).

```
def samuelson_transition(c, v):
    return np.array([[c + v, -v], [1.0, 0.0]])

# Compare weak vs strong acceleration
# Weak: c=0.8, v=0.1 gives real roots (discriminant > 0)
# Strong: c=0.6, v=0.8 gives complex roots (discriminant < 0)
cases = [("weak acceleration", 0.8, 0.1),
         ("strong acceleration", 0.6, 0.8)]
A_list = [samuelson_transition(c, v) for _, c, v in cases]

for (label, c, v), A in zip(cases, A_list):
    eig = np.linalg.eigvals(A)
    disc = (c + v)**2 - 4*v
    print(
        f"{label}: c={c}, v={v}, discriminant={disc:.2f}, eigenvalues={eig}")
```

```
weak acceleration: c=0.8, v=0.1, discriminant=0.41, eigenvalues=[0.77015621 0.
↪12984379]
strong acceleration: c=0.6, v=0.8, discriminant=-1.24, eigenvalues=[0.7+0.
↪55677644j 0.7-0.55677644j]
```



With weak acceleration ($v = 0.1$), the discriminant is positive and the roots are real.

With strong acceleration ($v = 0.8$), the discriminant is negative and the roots are complex conjugates that enable oscillatory dynamics.

Now let's see how these different eigenvalue structures affect the impulse responses to a one-time shock in Y

```
T = 40
s0 = np.array([1.0, 0.0])
irfs = []
for A in A_list:
    s = s0.copy()
    path = np.empty(T + 1)
    for t in range(T + 1):
        path[t] = s[0]
        s = A @ s
    irfs.append(path)

fig, ax = plt.subplots(figsize=(10, 4))
ax.plot(range(T + 1), irfs[0], lw=2,
                label="weak acceleration (real roots)")
ax.plot(range(T + 1), irfs[1], lw=2,
                label="strong acceleration (complex roots)")
ax.axhline(0.0, lw=0.8, color='gray')
ax.set_xlabel("time")
ax.set_ylabel(r"$Y_t$")
ax.legend(frameon=False)
plt.tight_layout()
plt.show()
```

With weak acceleration, the impulse response decays monotonically.

With strong acceleration, it oscillates.

We can ask how the eigenvalues change as we increase the accelerator v.

As we increase the accelerator v, the eigenvalues move further from the origin.

For this model, the eigenvalue modulus is $|\lambda| = \sqrt{v}$, so the stability boundary is $v = 1$.

```
v_grid = [0.2, 0.4, 0.6, 0.8, 0.95]
c = 0.6
T_irf = 40  # periods for impulse response

fig, axes = plt.subplots(1, 2, figsize=(12, 5))

for v in v_grid:
    A = samuelson_transition(c, v)
```

(continues on next page)

(continued from previous page)

```
    eig = np.linalg.eigvals(A)

    # Eigenvalues (left panel)
    axes[0].scatter(eig.real, eig.imag, s=40, label=f'$v={v}$')

    # Impulse response (right panel)
    s = np.array([1.0, 0.0])
    irf = np.empty(T_irf + 1)
    for t in range(T_irf + 1):
        irf[t] = s[0]
        s = A @ s
    axes[1].plot(range(T_irf + 1), irf, lw=2, label=f'$v={v}$')

# Visualize the eigenvalue locations and the unit circle
θ_circle = np.linspace(0, 2*np.pi, 100)
axes[0].plot(np.cos(θ_circle), np.sin(θ_circle),
             'k--', lw=0.8, label='unit circle')
axes[0].set_xlabel('real part')
axes[0].set_ylabel('imaginary part')
axes[0].set_aspect('equal')
axes[0].legend(frameon=False)

# impulse response panel
axes[1].axhline(0, lw=0.8, color='gray')
axes[1].set_xlabel('time')
axes[1].set_ylabel(r'$Y_t$')
axes[1].legend(frameon=False)

plt.tight_layout()
plt.show()
```

As v increases, eigenvalues approach the unit circle and oscillations become more persistent.

This illustrates that acceleration creates complex eigenvalues, which are necessary for oscillatory dynamics in deterministic systems.

But what happens when we add random shocks?

An insight of Ragnar Frisch [Frisch, 1933] was that damped oscillations can be "maintained" when the system is continuously perturbed by random disturbances.

To study this formally, we need to introduce the stochastic framework.

46.4 A linear system with shocks

We analyze a first-order linear stochastic system

$$y_t = Ay_{t-1} + u_t, \qquad \mathbb{E}[u_t] = 0, \qquad \mathbb{E}[u_t u_t^\top] = V, \qquad \mathbb{E}[u_t u_{t-k}^\top] = 0, \quad k \neq 0. \tag{46.4}$$

When the eigenvalues of A are strictly inside the unit circle, the process is covariance stationary and its autocovariances exist.

In the notation of *Linear State Space Models*, this is the same stability condition that guarantees a unique solution to a discrete Lyapunov equation.

Define the lag-k autocovariance matrices

$$\Gamma_k := \mathbb{E}[y_t y_{t-k}^\top]. \tag{46.5}$$

Standard calculations (also derived in [Chow, 1968]) give the recursion

$$\Gamma_k = A\Gamma_{k-1}, \quad k \geq 1, \qquad \text{and} \qquad \Gamma_0 = A\Gamma_0 A^\top + V. \tag{46.6}$$

The second equation is the discrete Lyapunov equation for Γ_0.

Chow [1968] motivates the stochastic analysis with a quote from Ragnar Frisch:

> The examples we have discussed … show that when a [deterministic] economic system gives rise to oscillations, these will most frequently be damped. But in reality the cycles … are generally not damped. How can the maintenance of the swings be explained? … One way which I believe is particularly fruitful and promising is to study what would become of the solution of a determinate dynamic system if it were exposed to a stream of erratic shocks … Thus, by connecting the two ideas: (1) the continuous solution of a determinate dynamic system and (2) the discontinuous shocks intervening and supplying the energy that may maintain the swings–we get a theoretical setup which seems to furnish a rational interpretation of those movements which we have been accustomed to see in our statistical time data.
>
> – Ragnar Frisch (1933) [Frisch, 1933]

Chow's main insight is that oscillations in the deterministic system are *neither necessary nor sufficient* for producing "cycles" in the stochastic system.

We have to bring the stochastic element into the picture.

We will show that even when eigenvalues are real (no deterministic oscillations), the stochastic system can exhibit cyclical patterns in its autocovariances and spectral densities.

46.4.1 Autocovariances in terms of eigenvalues

Let $\lambda_1, \ldots, \lambda_p$ be the distinct, possibly complex, eigenvalues of A, and let B be the matrix whose columns are the corresponding right eigenvectors:

$$AB = BD_\lambda, \quad \text{or equivalently} \quad A = BD_\lambda B^{-1} \tag{46.7}$$

where $D_\lambda = \text{diag}(\lambda_1, \ldots, \lambda_p)$.

Define canonical variables $z_t = B^{-1} y_t$.

These satisfy the decoupled dynamics:

$$z_t = D_\lambda z_{t-1} + \varepsilon_t \tag{46.8}$$

where $\varepsilon_t = B^{-1} u_t$ has covariance matrix $W = B^{-1} V (B^{-1})^\top$.

The autocovariance matrix of the canonical variables, denoted Γ_k^*, satisfies

$$\Gamma_k^* = D_\lambda^k \Gamma_0^*, \quad k = 1, 2, 3, \ldots \tag{46.9}$$

and

$$\Gamma_0^* = \left(\frac{w_{ij}}{1 - \lambda_i \lambda_j} \right) \tag{46.10}$$

where w_{ij} are elements of W.

The autocovariance matrices of the original variables are then

$$\Gamma_k = B \Gamma_k^* B^\top = B D_\lambda^k \Gamma_0^* B^\top, \quad k = 0, 1, 2, \ldots \tag{46.11}$$

The scalar autocovariance $\gamma_{ij,k} = \mathbb{E}[y_{it} y_{j,t-k}]$ is a *linear combination* of powers of the eigenvalues:

$$\gamma_{ij,k} = \sum_m \sum_n b_{im} b_{jn} \gamma^*_{mn,0} \lambda_m^k = \sum_m d_{ij,m} \lambda_m^k \tag{46.12}$$

Compare this to the deterministic time path from initial condition y_0:

$$y_{it} = \sum_j b_{ij} z_{j0} \lambda_j^t \tag{46.13}$$

Both the autocovariance function (46.12) and the deterministic path (46.13) are linear combinations of λ_m^k (or λ_j^t).

46.4.2 Complex roots and damped oscillations

When eigenvalues come in complex conjugate pairs $\lambda = re^{\pm i\theta}$ with $r < 1$, their contribution to the autocovariance function is a **damped cosine**:

$$2sr^k \cos(\theta k + \phi) \tag{46.14}$$

for appropriate amplitude s and phase ϕ determined by the eigenvector loadings.

In the deterministic model, such complex roots generate damped oscillatory time paths.

In the stochastic model, they generate damped oscillatory autocovariance functions.

It is in this sense that deterministic oscillations could be "maintained" in the stochastic model, but as we will see, the connection between eigenvalues and spectral peaks is more subtle than this suggests.

46.5 From autocovariances to spectra

Chow's key step is to translate the autocovariance sequence $\{\Gamma_k\}$ into a frequency-domain object.

The **spectral density matrix** is the Fourier transform of Γ_k:

$$F(\omega) := \frac{1}{2\pi} \sum_{k=-\infty}^{\infty} \Gamma_k e^{-i\omega k}, \qquad \omega \in [0, \pi]. \tag{46.15}$$

For the VAR(1) system (46.4), this sum has a closed form

$$F(\omega) = \frac{1}{2\pi} \left(I - Ae^{-i\omega}\right)^{-1} V \left(I - A^\top e^{i\omega}\right)^{-1}. \tag{46.16}$$

$F(\omega)$ tells us how much variation in y_t is associated with cycles of (angular) frequency ω.

Higher frequencies correspond to rapid oscillations, meaning short cycles where the series completes many up-and-down movements per unit of time.

Lower frequencies correspond to slower oscillations, meaning long cycles that unfold over extended periods.

The corresponding cycle length (or period) is

$$T(\omega) = \frac{2\pi}{\omega}. \tag{46.17}$$

Thus, a frequency of $\omega = \pi$ corresponds to the shortest possible cycle of $T = 2$ periods, while frequencies near zero correspond to very long cycles.

When the spectral density $F(\omega)$ is concentrated at particular frequencies, it indicates that the time series exhibits pronounced cyclical behavior at those frequencies.

The advanced lecture Estimation of Spectra explains how to estimate $F(\omega)$ from data.

Here we focus on the model-implied spectrum.

We saw earlier that acceleration creates complex eigenvalues, which enable oscillatory impulse responses.

But do complex roots guarantee a spectral peak?

Are they necessary for one?

Chow provides precise answers for the Hansen-Samuelson model.

46.6 Spectral peaks in the Hansen-Samuelson model

Chow [1968] provides a detailed spectral analysis of the Hansen-Samuelson multiplier-accelerator model, deriving exact conditions for when spectral peaks occur.

The analysis reveals that in this specific model, complex roots are *necessary* for a peak, but as we will see later, this is not true in general.

46.6.1 The model as a first-order system

The second-order Hansen-Samuelson equation can be written as a first-order system:

$$\begin{bmatrix} y_{1t} \\ y_{2t} \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} \\ 1 & 0 \end{bmatrix} \begin{bmatrix} y_{1,t-1} \\ y_{2,t-1} \end{bmatrix} + \begin{bmatrix} u_{1t} \\ 0 \end{bmatrix} \tag{46.18}$$

where $y_{2t} = y_{1,t-1}$ is simply the lagged value of y_{1t}.

This structure implies a special relationship among the autocovariances:

$$\gamma_{11,k} = \gamma_{22,k} = \gamma_{12,k-1} = \gamma_{21,k+1} \tag{46.19}$$

Using the autocovariance recursion, Chow shows that this leads to the condition

$$\gamma_{11,-1} = d_{11,1}\lambda_1^{-1} + d_{11,2}\lambda_2^{-1} = \gamma_{11,1} = d_{11,1}\lambda_1 + d_{11,2}\lambda_2 \tag{46.20}$$

which constrains the spectral density in a useful way.

46.6.2 The spectral density formula

From equations (46.12) and the scalar kernel $g_i(\omega) = (1-\lambda_i^2)/(1+\lambda_i^2-2\lambda_i\cos\omega)$, the spectral density of y_{1t} is:

$$f_{11}(\omega) = d_{11,1}g_1(\omega) + d_{11,2}g_2(\omega) \tag{46.21}$$

which can be written in the combined form:

$$f_{11}(\omega) = \frac{d_{11,1}(1-\lambda_1^2)(1+\lambda_2^2) + d_{11,2}(1-\lambda_2^2)(1+\lambda_1^2) - 2[d_{11,1}(1-\lambda_1^2)\lambda_2 + d_{11,2}(1-\lambda_2^2)\lambda_1]\cos\omega}{(1+\lambda_1^2-2\lambda_1\cos\omega)(1+\lambda_2^2-2\lambda_2\cos\omega)} \tag{46.22}$$

A key observation: due to condition (46.20), the *numerator is not a function of* $\cos\omega$.

Therefore, to find a maximum of $f_{11}(\omega)$, we need only find a minimum of the denominator.

46.6.3 Conditions for a spectral peak

The first derivative of the denominator with respect to ω is:

$$2[(1+\lambda_1^2)\lambda_2 + (1+\lambda_2^2)\lambda_1]\sin\omega - 8\lambda_1\lambda_2\cos\omega\sin\omega \tag{46.23}$$

For $0 < \omega < \pi$, we have $\sin\omega > 0$, so the derivative equals zero if and only if:

$$(1+\lambda_1^2)\lambda_2 + (1+\lambda_2^2)\lambda_1 = 4\lambda_1\lambda_2\cos\omega \tag{46.24}$$

For *complex conjugate roots* $\lambda_1 = re^{i\theta}$, $\lambda_2 = re^{-i\theta}$, substitution into (46.24) gives:

$$\cos\omega = \frac{1+r^2}{2r}\cos\theta \tag{46.25}$$

The second derivative confirms this is a maximum when $\omega < \frac{3\pi}{4}$.

The necessary condition for a valid solution is:

$$-1 < \frac{1+r^2}{2r}\cos\theta < 1 \tag{46.26}$$

We can interpret it as:

- When $r \approx 1$, the factor $(1+r^2)/2r \approx 1$, so $\omega \approx \theta$
- When r is small (e.g., 0.3 or 0.4), condition (46.26) can only be satisfied if $\cos\theta \approx 0$, meaning $\theta \approx \pi/2$ (cycles of approximately 4 periods)

If $\theta = 54^\circ$ (corresponding to cycles of 6.67 periods) and $r = 0.4$, then $(1+r^2)/2r = 1.45$, giving $\cos\omega = 1.45 \times 0.588 = 0.85$, or $\omega = 31.5^\circ$, corresponding to cycles of 11.4 periods, which is much longer than the deterministic cycle.

```
def peak_condition_factor(r):
    """Compute (1 + r^2) / (2r)"""
    return (1 + r**2) / (2 * r)

θ_deg = 54
θ = np.deg2rad(θ_deg)
r_grid = np.linspace(0.3, 0.99, 100)

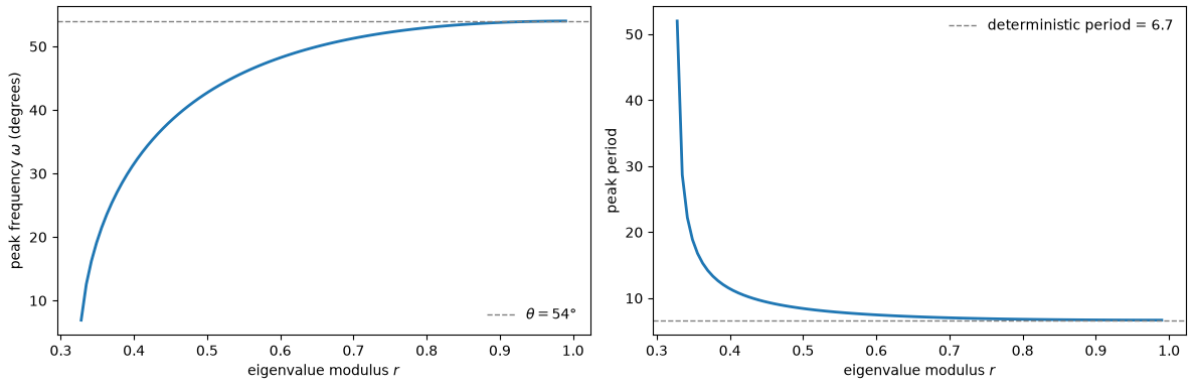
# For each r, compute the implied peak frequency
ω_peak = []
for r in r_grid:
```

(continues on next page)

(continued from previous page)

```
    factor = peak_condition_factor(r)
    cos_ω = factor * np.cos(θ)
    if -1 < cos_ω < 1:
        ω_peak.append(np.arccos(cos_ω))
    else:
        ω_peak.append(np.nan)

ω_peak = np.array(ω_peak)
period_peak = 2 * np.pi / ω_peak



fig, axes = plt.subplots(1, 2, figsize=(12, 4))

axes[0].plot(r_grid, np.rad2deg(ω_peak), lw=2)
axes[0].axhline(θ_deg, ls='--', lw=1.0, color='gray',
        label=rf'$\theta = {θ_deg}°$')
axes[0].set_xlabel('eigenvalue modulus $r$')
axes[0].set_ylabel(r'peak frequency $\omega$ (degrees)')
axes[0].legend(frameon=False)

axes[1].plot(r_grid, period_peak, lw=2)
axes[1].axhline(360/θ_deg, ls='--', lw=1.0, color='gray',
        label=rf'deterministic period = {360/θ_deg:.1f}')
axes[1].set_xlabel('eigenvalue modulus $r$')
axes[1].set_ylabel('peak period')
axes[1].legend(frameon=False)

plt.tight_layout()
plt.show()

r_example = 0.4
factor = peak_condition_factor(r_example)
cos_ω = factor * np.cos(θ)
ω_example = np.arccos(cos_ω)
print(f"Chow's example: r = {r_example}, θ = {θ_deg}°")
print(f"  cos(ω) = {cos_ω:.3f}")
print(f"  ω = {np.rad2deg(ω_example):.1f}°")
print(f"  Peak period = {360/np.rad2deg(ω_example):.1f}")
```

```
Chow's example: r = 0.4, θ = 54°
  cos(ω) = 0.852
  ω = 31.5°
  Peak period = 11.4
```

As $r \to 1$, the peak frequency converges to θ.

For smaller r, the peak frequency can differ substantially from the deterministic oscillation frequency.

46.6.4 Real positive roots cannot produce peaks

For *real and positive roots* $\lambda_1, \lambda_2 > 0$, the first-order condition (46.24) cannot be satisfied.

To see why, recall that a spectral peak at an interior frequency $\omega \in (0, \pi)$ requires

$$\cos\omega = \frac{(1+\lambda_1^2)\lambda_2 + (1+\lambda_2^2)\lambda_1}{4\lambda_1\lambda_2}.$$

For this to have a solution, we need the right-hand side to lie in $[-1, 1]$.

But for positive λ_1, λ_2, the numerator exceeds $4\lambda_1\lambda_2$:

$$(1+\lambda_1^2)\lambda_2 + (1+\lambda_2^2)\lambda_1 - 4\lambda_1\lambda_2 = \lambda_1(1-\lambda_2)^2 + \lambda_2(1-\lambda_1)^2. \tag{46.27}$$

The right-hand side is a sum of two non-negative terms (each is a positive number times a square).

It equals zero only if both $\lambda_1 = 1$ and $\lambda_2 = 1$, which violates the stability condition $|\lambda_i| < 1$.

For any stable system with real positive roots, this expression is strictly positive, so

$$\cos\omega = \frac{(1+\lambda_1^2)\lambda_2 + (1+\lambda_2^2)\lambda_1}{4\lambda_1\lambda_2} > 1, \tag{46.28}$$

which is impossible.

This is a key result: in the Hansen-Samuelson model, *complex roots are necessary* for a spectral peak at interior frequencies.

The following figure illustrates the difference in spectra between a case with complex roots and a case with real roots

```
ω_grid = np.linspace(1e-3, np.pi - 1e-3, 800)
V_hs = np.array([[1.0, 0.0], [0.0, 0.0]])  # shock only in first equation

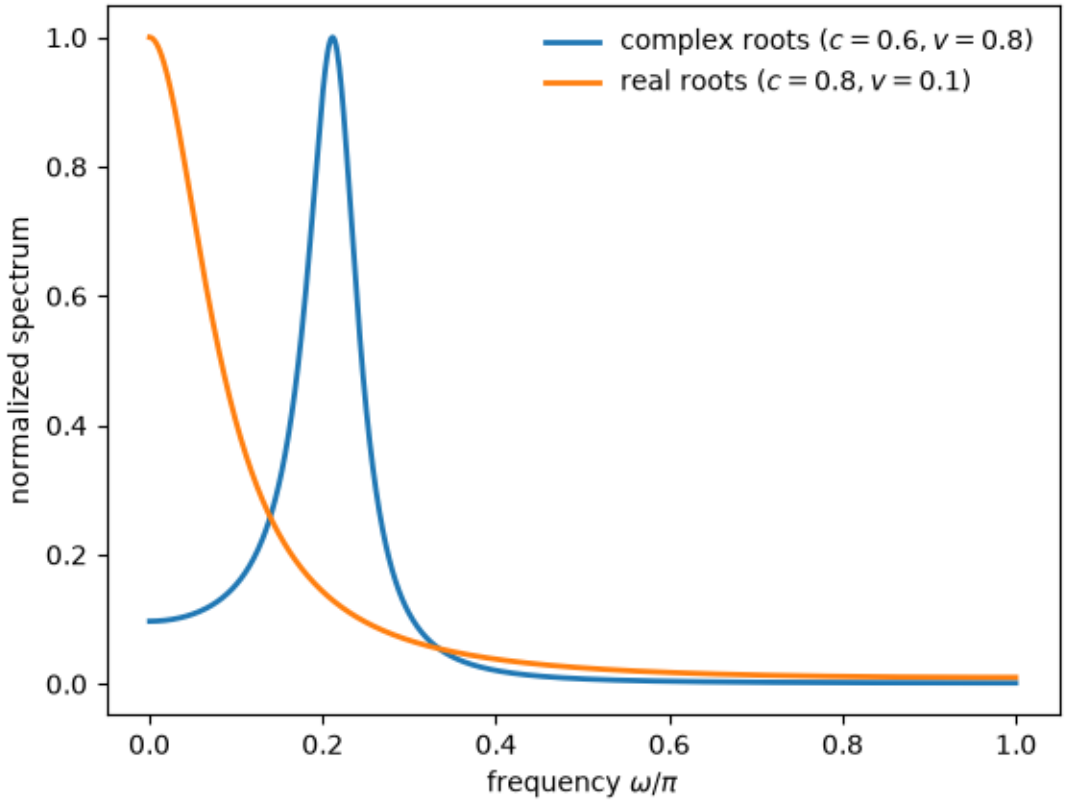
# Case 1: Complex roots (c=0.6, v=0.8)
c_complex, v_complex = 0.6, 0.8
A_complex = samuelson_transition(c_complex, v_complex)
eig_complex = np.linalg.eigvals(A_complex)

# Case 2: Real roots (c=0.8, v=0.1)
c_real, v_real = 0.8, 0.1
A_real = samuelson_transition(c_real, v_real)
eig_real = np.linalg.eigvals(A_real)

print(
    f"Complex case (c={c_complex}, v={v_complex}): eigenvalues = {eig_complex}")
print(
    f"Real case (c={c_real}, v={v_real}): eigenvalues = {eig_real}")

F_complex = spectral_density_var1(A_complex, V_hs, ω_grid)
F_real = spectral_density_var1(A_real, V_hs, ω_grid)

f11_complex = np.real(F_complex[:, 0, 0])
f11_real = np.real(F_real[:, 0, 0])



fig, ax = plt.subplots()
```

(continues on next page)

(continued from previous page)

```
ax.plot(ω_grid / np.pi, f11_complex / np.max(f11_complex), lw=2,
        label=fr'complex roots ($c={c_complex}, v={v_complex}$)')
ax.plot(ω_grid / np.pi, f11_real / np.max(f11_real), lw=2,
        label=fr'real roots ($c={c_real}, v={v_real}$)')
ax.set_xlabel(r'frequency $\omega/\pi$')
ax.set_ylabel('normalized spectrum')
ax.legend(frameon=False)
plt.show()
```

```
Complex case (c=0.6, v=0.8): eigenvalues = [0.7+0.55677644j 0.7-0.55677644j]
Real case (c=0.8, v=0.1): eigenvalues = [0.77015621 0.12984379]
```

With complex roots, the spectrum has a clear interior peak.

With real roots, the spectrum is monotonically decreasing and no interior peak is possible.

46.7 Real roots can produce peaks in general models

While real positive roots cannot produce spectral peaks in the Hansen-Samuelson model, Chow [1968] emphasizes that this is *not true in general*.

In multivariate systems, the spectral density of a linear combination of variables can have interior peaks even when all eigenvalues are real and positive.

46.7.1 Example

Chow constructs the following explicit example with two real positive eigenvalues:

$$\lambda_1 = 0.1, \quad \lambda_2 = 0.9 \tag{46.29}$$

$$w_{11} = w_{22} = 1, \quad w_{12} = 0.8 \tag{46.30}$$

$$b_{m1} = 1, \quad b_{m2} = -0.01 \tag{46.31}$$

The spectral density of the linear combination $x_t = b_m^\top y_t$ is:

$$f_{mm}(\omega) = \frac{0.9913}{1.01 - 0.2\cos\omega} - \frac{0.001570}{1.81 - 1.8\cos\omega} \tag{46.32}$$

Chow tabulates the values:

ω	0	$\pi/8$	$2\pi/8$	$3\pi/8$	$4\pi/8$	$5\pi/8$	$6\pi/8$	$7\pi/8$	π
$f_{mm}(\omega)$	1.067	1.183	1.191	1.138	1.061	0.981	0.912	0.860	0.829

The peak at ω slightly below $\pi/8$ (corresponding to periods around 11) is "quite pronounced."

In the following figure, we reproduce this table, but with Python, we can plot a finer grid to find the peak more accurately

```
λ1, λ2 = 0.1, 0.9
w11, w22, w12 = 1.0, 1.0, 0.8
bm1, bm2 = 1.0, -0.01

# Construct the system
A_chow_ex = np.diag([λ1, λ2])

# W is the canonical shock covariance; we need V = B W B^T
# For diagonal A with distinct eigenvalues, B = I, so V = W
V_chow_ex = np.array([[w11, w12], [w12, w22]])
b_chow_ex = np.array([bm1, bm2])

# Chow's formula
def chow_spectrum_formula(ω):
    term1 = 0.9913 / (1.01 - 0.2 * np.cos(ω))
    term2 = 0.001570 / (1.81 - 1.8 * np.cos(ω))
    return term1 - term2

# Compute via formula and via our general method
ω_table = np.array([0, np.pi/8, 2*np.pi/8, 3*np.pi/8, 4*np.pi/8,
                    5*np.pi/8, 6*np.pi/8, 7*np.pi/8, np.pi])
f_formula = np.array([chow_spectrum_formula(ω) for ω in ω_table])

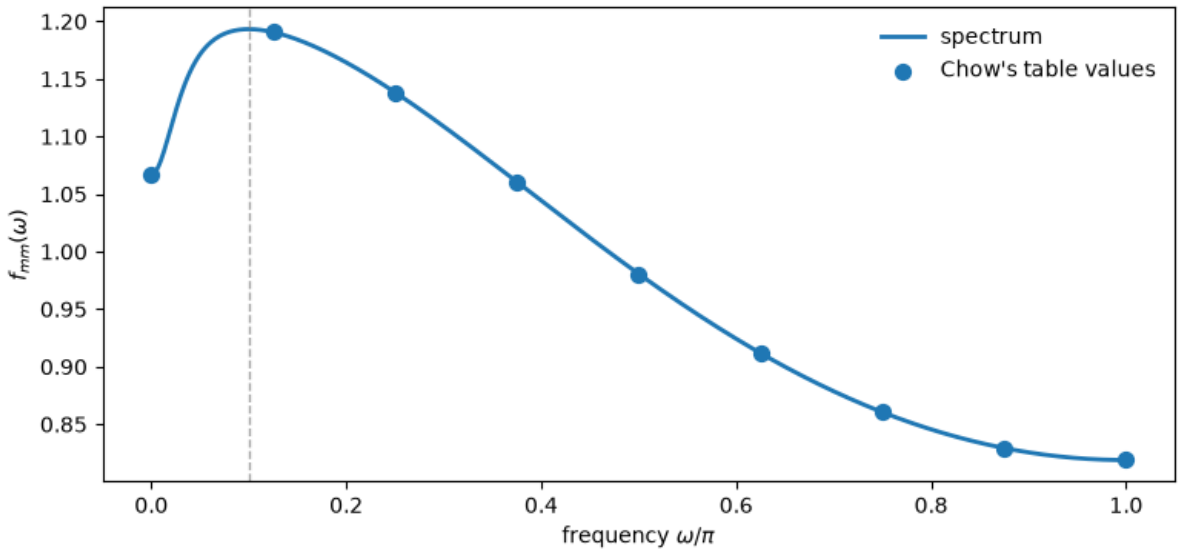
# General method
ω_grid_fine = np.linspace(1e-4, np.pi, 1000)
F_chow_ex = spectral_density_var1(A_chow_ex, V_chow_ex, ω_grid_fine)
f_general = spectrum_of_linear_combination(F_chow_ex, b_chow_ex)

# Normalize to match Chow's table scale
scale = f_formula[0] / spectrum_of_linear_combination(
    spectral_density_var1(
        A_chow_ex, V_chow_ex, np.array([0.0])), b_chow_ex)[0]
```

(continues on next page)

(continued from previous page)

```
print("Chow's Table (equation 67):")
print("ω/π:        ", "  ".join([f"{ω/np.pi:.3f}" for ω in ω_table]))
print("f_mm(ω):    ", "  ".join([f"{f:.3f}" for f in f_formula]))



fig, ax = plt.subplots(figsize=(9, 4))
ax.plot(ω_grid_fine / np.pi, f_general * scale, lw=2,
            label='spectrum')
ax.scatter(ω_table / np.pi, f_formula, s=50, zorder=3,
            label="Chow's table values")

# Mark the peak
i_peak = np.argmax(f_general)
ω_peak = ω_grid_fine[i_peak]
ax.axvline(ω_peak / np.pi, ls='--', lw=1.0, color='gray', alpha=0.7)
ax.set_xlabel(r'frequency $\omega/\pi$')
ax.set_ylabel(r'$f_{mm}(\omega)$')
ax.legend(frameon=False)
plt.show()

print(f"\nPeak at ω/π ≈ {ω_peak/np.pi:.3f}, period ≈ {2*np.pi/ω_peak:.1f}")
```

```
Chow's Table (equation 67):
ω/π:        0.000  0.125  0.250  0.375  0.500  0.625  0.750  0.875  1.000
f_mm(ω):    1.067  1.191  1.138  1.061  0.981  0.912  0.860  0.829  0.819

Peak at ω/π ≈ 0.100, period ≈ 20.0
```

The peak appears at $\omega/\pi \approx 0.10$, which corresponds to a cycle length of approximately 20 periods, again much longer than the deterministic cycles implied by the eigenvalues.

46.7.2 The Slutsky connection

Chow connects this result to Slutsky's [Slutzky, 1937] finding that moving averages of a random series have recurrent cycles.

The VAR(1) model can be written as an infinite moving average:

$$y_t = u_t + Au_{t-1} + A^2 u_{t-2} + \cdots \tag{46.33}$$

This amounts to taking an infinite moving average of the random vectors u_t with "geometrically declining" weights $A^0, A^1, A^2, ...$

For a scalar process with $0 < \lambda < 1$, no distinct cycles can emerge.

But for a matrix A with real roots between 0 and 1, cycles *can* emerge in linear combinations of the variables.

As Chow puts it: "When neither of two (canonical) variables has distinct cycles… a linear combination can have a peak in its spectral density."

46.7.3 The general lesson

The examples above illustrate the following central points:

1. In the *Hansen-Samuelson model specifically*, complex roots are necessary for a spectral peak
2. But in *general multivariate systems*, complex roots are neither necessary nor sufficient
3. The full spectral shape depends on:
    - The eigenvalues of A
    - The shock covariance structure V
    - How the observable of interest loads on the eigenmodes (the vector b)

46.8 A calibrated model in the frequency domain

Chow and Levitan [1969] use the frequency-domain objects from Chow [1968] to study a calibrated annual macroeconometric model.

They work with five annual aggregates:

- $y_1 = C$ (consumption),
- $y_2 = I_1$ (equipment plus inventories),
- $y_3 = I_2$ (construction),
- $y_4 = R_a$ (long rate),
- $y_5 = Y_1 = C + I_1 + I_2$ (private-domestic GNP),

and add $y_6 = y_{1,t-1}$ to rewrite the original system in first-order form.

Throughout this section, frequency is measured in cycles per year, $f = \omega/2\pi \in [0, 1/2]$.

Following the paper, we normalize each spectrum to have area 1 over $[0, 1/2]$ so plots compare shape rather than scale.

Our goal is to reconstruct the transition matrix A and then compute and interpret the model-implied spectra, gains/coherences, and phase differences.

46.8.1 The cycle subsystem

The paper starts from a reduced form with exogenous inputs,

$$y_t = Ay_{t-1} + Cx_t + u_t. \tag{46.34}$$

To study cycles, they remove the deterministic component attributable to x_t and focus on the zero-mean subsystem

$$y_t = Ay_{t-1} + u_t. \tag{46.35}$$

For second moments, the only additional ingredient is the covariance matrix $V = \mathbb{E}[u_t u_t^\top]$.

Chow and Levitan compute it from structural parameters via

$$V = M^{-1}\Sigma(M^{-1})^\top \tag{46.36}$$

where Σ is the covariance of structural residuals and M is the matrix of contemporaneous structural coefficients.

Here we take A and V as given and ask what they imply for spectra and cross-spectra.

The 6×6 reduced-form shock covariance matrix V (scaled by 10^{-7}) reported by Chow and Levitan is:

$$V = \begin{bmatrix} 8.250 & 7.290 & 2.137 & 2.277 & 17.68 & 0 \\ 7.290 & 7.135 & 1.992 & 2.165 & 16.42 & 0 \\ 2.137 & 1.992 & 0.618 & 0.451 & 4.746 & 0 \\ 2.277 & 2.165 & 0.451 & 1.511 & 4.895 & 0 \\ 17.68 & 16.42 & 4.746 & 4.895 & 38.84 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}. \tag{46.37}$$

The sixth row and column are zeros because y_6 is an identity (lagged y_1).

The transition matrix A has six characteristic roots:

$$\begin{aligned} &\lambda_1 = 0.9999725, \quad \lambda_2 = 0.9999064, \quad \lambda_3 = 0.4838, \\ &\lambda_4 = 0.0761 + 0.1125i, \quad \lambda_5 = 0.0761 - 0.1125i, \quad \lambda_6 = -0.00004142. \end{aligned} \tag{46.38}$$

Two roots are near unity because two structural equations are in first differences.

One root (λ_6) is theoretically zero because of the identity $y_5 = y_1 + y_2 + y_3$.

The complex conjugate pair $\lambda_{4,5}$ has modulus $|\lambda_4| = \sqrt{0.0761^2 + 0.1125^2} \approx 0.136$.

The right eigenvector matrix B (columns are eigenvectors corresponding to $\lambda_1, \ldots, \lambda_6$):

$$B = \begin{bmatrix} -0.008 & 1.143 & 0.320 & 0.283 + 0.581i & 0.283 - 0.581i & 0.000 \\ -0.000 & 0.013 & -0.586 & -2.151 + 0.742i & -2.151 - 0.742i & 2.241 \\ -0.001 & 0.078 & 0.889 & -0.215 + 0.135i & -0.215 - 0.135i & 0.270 \\ 1.024 & 0.271 & 0.069 & -0.231 + 0.163i & -0.231 - 0.163i & 0.307 \\ -0.009 & 1.235 & 0.623 & -2.082 + 1.468i & -2.082 - 1.468i & 2.766 \\ -0.008 & 1.143 & 0.662 & 4.772 + 0.714i & 4.772 - 0.714i & -4.399 \end{bmatrix}. \tag{46.39}$$

Together, V, $\{\lambda_i\}$, and B are sufficient to compute all spectral and cross-spectral densities.

46.8.2 Reconstructing A and computing $F(\omega)$

The paper reports (λ, B, V), which is enough to reconstruct $A = B\,\mathrm{diag}(\lambda_1, \ldots, \lambda_6)\,B^{-1}$ and then compute the model-implied spectral objects.

```
λ = np.array([
    0.9999725, 0.9999064, 0.4838,
    0.0761 + 0.1125j, 0.0761 - 0.1125j, -0.00004142
], dtype=complex)

B = np.array([
    [-0.008, 1.143, 0.320, 0.283+0.581j, 0.283-0.581j, 0.000],
    [-0.000, 0.013, -0.586, -2.151+0.742j, -2.151-0.742j, 2.241],
    [-0.001, 0.078, 0.889, -0.215+0.135j, -0.215-0.135j, 0.270],
    [1.024, 0.271, 0.069, -0.231+0.163j, -0.231-0.163j, 0.307],
    [-0.009, 1.235, 0.623, -2.082+1.468j, -2.082-1.468j, 2.766],
    [-0.008, 1.143, 0.662, 4.772+0.714j, 4.772-0.714j, -4.399]
], dtype=complex)

V = np.array([
    [8.250, 7.290, 2.137, 2.277, 17.68, 0],
    [7.290, 7.135, 1.992, 2.165, 16.42, 0],
    [2.137, 1.992, 0.618, 0.451, 4.746, 0],
    [2.277, 2.165, 0.451, 1.511, 4.895, 0],
    [17.68, 16.42, 4.746, 4.895, 38.84, 0],
    [0, 0, 0, 0, 0, 0]
]) * 1e-7

D_λ = np.diag(λ)
A_chow = B @ D_λ @ np.linalg.inv(B)
A_chow = np.real(A_chow)
print("eigenvalues of reconstructed A:")
print(np.linalg.eigvals(A_chow).round(6))
```

```
eigenvalues of reconstructed A:
[-4.10000e-05+0.j      7.61000e-02+0.1125j  7.61000e-02-0.1125j
  4.83800e-01+0.j      9.99906e-01+0.j      9.99973e-01+0.j    ]
```

46.8.3 Canonical coordinates

Chow and Levitan's canonical transformation uses $z_t = B^{-1} y_t$, giving dynamics $z_t = D_\lambda z_{t-1} + e_t$.

Accordingly, the canonical shock covariance is

$$W = B^{-1} V (B^{-1})^\top.$$

```
B_inv = np.linalg.inv(B)
W = B_inv @ V @ B_inv.T
print("diagonal of W:")
print(np.diag(W).round(10))
```

```
diagonal of W:
[ 8.560e-08-0.00e+00j  3.638e-07-0.00e+00j  1.300e-08-0.00e+00j
 -7.880e-08+6.26e-08j -7.880e-08-6.26e-08j -1.650e-08+0.00e+00j]
```

Chow and Levitan derive the following closed-form formula for the spectral density matrix:

$$F(\omega) = B \left[\frac{w_{ij}}{(1 - \lambda_i e^{-i\omega})(1 - \lambda_j e^{i\omega})} \right] B^\top, \tag{46.40}$$

where w_{ij} are elements of the canonical shock covariance W.

```
def spectral_density_chow(λ, B, W, ω_grid):
    """Spectral density via Chow's eigendecomposition formula."""
    p = len(λ)
    F = np.zeros((len(ω_grid), p, p), dtype=complex)
    for k, ω in enumerate(ω_grid):
        F_star = np.zeros((p, p), dtype=complex)
        for i in range(p):
            for j in range(p):
                denom = (1 - λ[i] * np.exp(-1j * ω)) \
                    * (1 - λ[j] * np.exp(1j * ω))
                F_star[i, j] = W[i, j] / denom
        F[k] = B @ F_star @ B.T
    return F / (2 * np.pi)

freq = np.linspace(1e-4, 0.5, 5000)      # cycles/year in [0, 1/2]
ω_grid = 2 * np.pi * freq                # radians in [0, π]
F_chow = spectral_density_chow(λ, B, W, ω_grid)
```

Let's plot the univariate spectra of consumption (y_1) and equipment plus inventories (y_2)

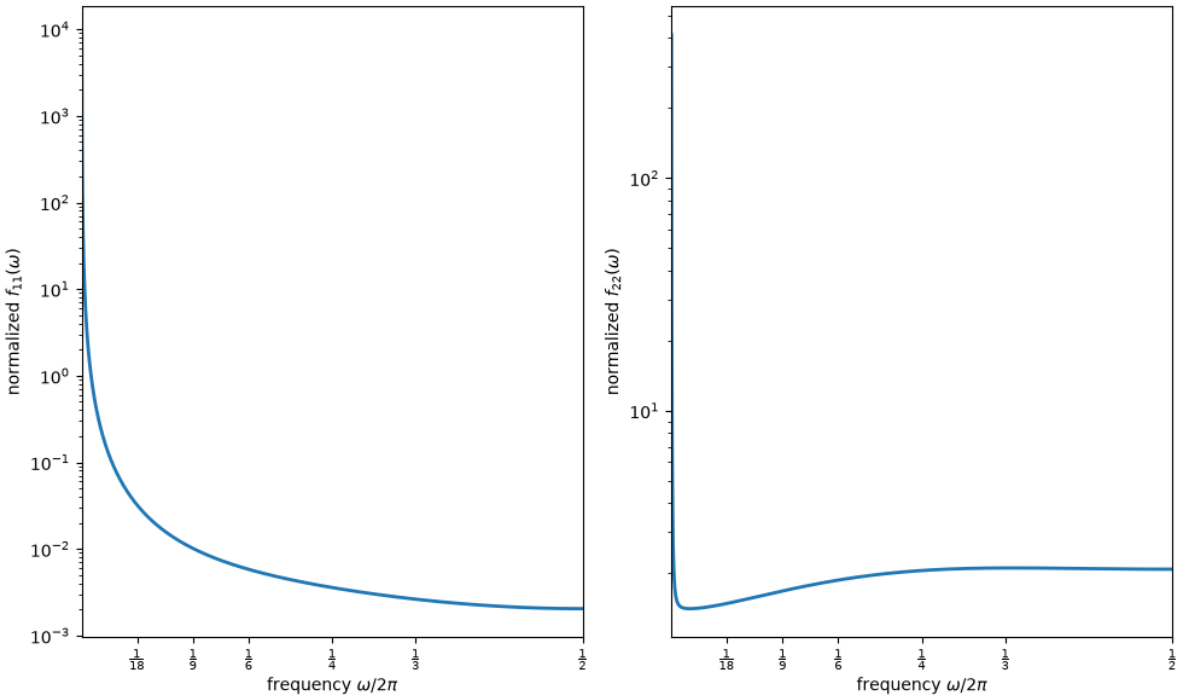
```
variable_names = ['$C$', '$I_1$', '$I_2$', '$R_a$', '$Y_1$']
freq_ticks = [1/18, 1/9, 1/6, 1/4, 1/3, 1/2]
freq_labels = [r'$\frac{1}{18}$', r'$\frac{1}{9}$', r'$\frac{1}{6}$',
               r'$\frac{1}{4}$', r'$\frac{1}{3}$', r'$\frac{1}{2}$']

def paper_frequency_axis(ax):
    ax.set_xlim([0.0, 0.5])
    ax.set_xticks(freq_ticks)
    ax.set_xticklabels(freq_labels)
    ax.set_xlabel(r'frequency $\omega/2\pi$')

# Normalized spectra (areas set to 1)
S = np.real(np.diagonal(F_chow, axis1=1, axis2=2))[:, :5]
df = np.diff(freq)
areas = np.sum(0.5 * (S[1:] + S[:-1]) * df[:, None], axis=0)
S_norm = S / areas
mask = freq >= 0.0

fig, axes = plt.subplots(1, 2, figsize=(10, 6))

# Figure I.1: consumption (log scale)
axes[0].plot(freq[mask], S_norm[mask, 0], lw=2)
axes[0].set_yscale('log')
paper_frequency_axis(axes[0])
axes[0].set_ylabel(r'normalized $f_{11}(\omega)$')



# Figure I.2: equipment + inventories (log scale)
axes[1].plot(freq[mask], S_norm[mask, 1], lw=2)
axes[1].set_yscale('log')
paper_frequency_axis(axes[1])
axes[1].set_ylabel(r'normalized $f_{22}(\omega)$')
```

(continues on next page)

(continued from previous page)

```
plt.tight_layout()
plt.show()

i_peak = np.argmax(S_norm[mask, 1])
f_peak = freq[mask][i_peak]
```

The left panel corresponds to consumption and declines monotonically with frequency.

It illustrates Granger's "typical spectral shape" for macroeconomic time series.

The right panel corresponds to equipment plus inventories and shows the clearest (but still very flat) interior-frequency bump.

Chow and Levitan associate the dominance of very low frequencies in both plots with strong persistence and long-run movements.

Very large low-frequency power can arise from eigenvalues extremely close to one, which occurs mechanically when some equations are written in first differences.

Local peaks are not automatic: complex roots may have small modulus, and multivariate interactions can generate peaks even when all roots are real.

The interior bump in the right panel corresponds to cycles of roughly three years, with the spectrum nearly flat over cycles between about two and four years.

(This discussion follows Section II of [Chow and Levitan, 1969].)

46.8.4 How variables move together across frequencies

Beyond univariate spectra, we can ask how pairs of variables covary at each frequency.

The **cross-spectrum** $f_{ij}(\omega) = c_{ij}(\omega) - i \cdot q_{ij}(\omega)$ decomposes into the cospectrum c_{ij} and the quadrature spectrum q_{ij}.

The **cross-amplitude** is $g_{ij}(\omega) = |f_{ij}(\omega)| = \sqrt{c_{ij}^2 + q_{ij}^2}$.

The **squared coherence** measures linear association at frequency ω:

$$R_{ij}^2(\omega) = \frac{|f_{ij}(\omega)|^2}{f_{ii}(\omega) f_{jj}(\omega)} \in [0, 1]. \tag{46.41}$$

Coherence measures how much of the variance of y_i at frequency ω can be "explained" by y_j at the same frequency.

High coherence means the two series move together tightly at that frequency.

The **gain** is the frequency-response coefficient when regressing y_i on y_j:

$$G_{ij}(\omega) = \frac{|f_{ij}(\omega)|}{f_{jj}(\omega)}. \tag{46.42}$$

It measures how much y_i responds to a unit change in y_j at frequency ω.

For instance, a gain of 0.9 at low frequencies means long-cycle movements in y_j translate almost one-for-one to y_i, and a gain of 0.3 at high frequencies means short-cycle movements are dampened.

The **phase** captures lead-lag relationships (in radians):

$$\Delta_{ij}(\omega) = \tan^{-1}\left(\frac{q_{ij}(\omega)}{c_{ij}(\omega)}\right). \tag{46.43}$$

```
def cross_spectral_measures(F, i, j):
    """Compute coherence, gain (y_i on y_j), and phase between variables i and j."""
    f_ij = F[:, i, j]
    f_ii, f_jj = np.real(F[:, i, i]), np.real(F[:, j, j])
    g_ij = np.abs(f_ij)
    coherence = (g_ij**2) / (f_ii * f_jj)
    gain = g_ij / f_jj
    phase = np.arctan2(-np.imag(f_ij), np.real(f_ij))
    return coherence, gain, phase
```

We now plot gain and coherence as in Figures II.1–II.4 of [Chow and Levitan, 1969].

```
gnp_idx = 4

fig, axes = plt.subplots(1, 2, figsize=(8, 6))

for idx, var_idx in enumerate([0, 1]):
    coherence, gain, phase = cross_spectral_measures(F_chow, var_idx, gnp_idx)
    ax = axes[idx]

    ax.plot(freq[mask], coherence[mask],
            lw=2, label=rf'$R^2_{{{var_idx+1}5}}(\omega)$')
    ax.plot(freq[mask], gain[mask],
            lw=2, label=rf'$G_{{{var_idx+1}5}}(\omega)$')
    paper_frequency_axis(ax)
    ax.set_ylim([0, 1.0])
    ax.set_ylabel('gain, coherence')
```

(continues on next page)

(continued from previous page)

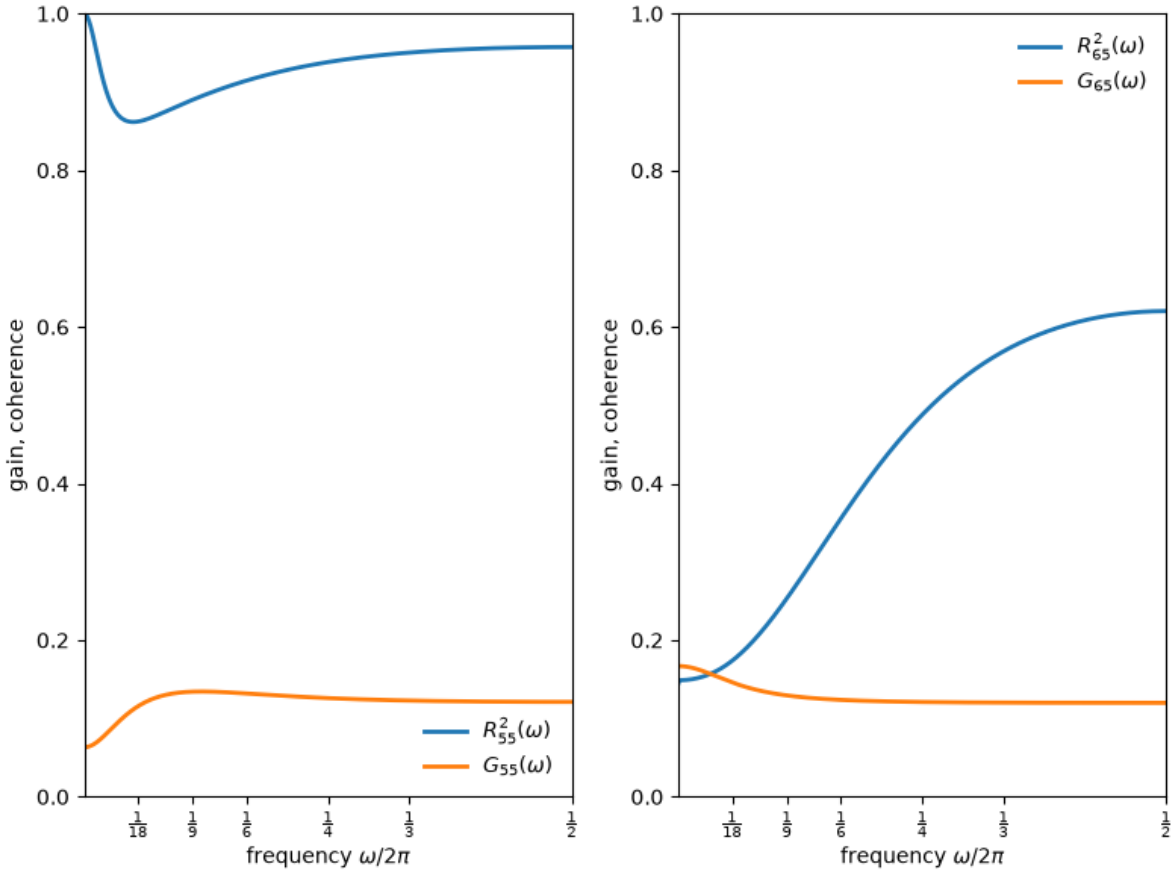
```
    ax.legend(frameon=False, loc='best')

plt.tight_layout()
plt.show()
```

The gain and coherence patterns differ across components (Figures II.1–II.2 of [Chow and Levitan, 1969]):

- Consumption vs private-domestic GNP (left panel):
  - Gain is about 0.9 at very low frequencies but falls below 0.4 for cycles shorter than four years.
  - This is evidence that short-cycle income movements translate less into consumption than long-cycle movements, consistent with permanent-income interpretations.
  - Coherence remains high throughout.
- Equipment plus inventories vs private-domestic GNP (right panel):
  - Gain *rises* with frequency, exceeding 0.5 for short cycles.
  - This is the frequency-domain signature of acceleration and volatile short-run inventory movements.

```
fig, axes = plt.subplots(1, 2, figsize=(8, 6))



for idx, var_idx in enumerate([2, 3]):
    coherence, gain, phase = cross_spectral_measures(F_chow, var_idx, gnp_idx)
    ax = axes[idx]
```

(continues on next page)

(continued from previous page)

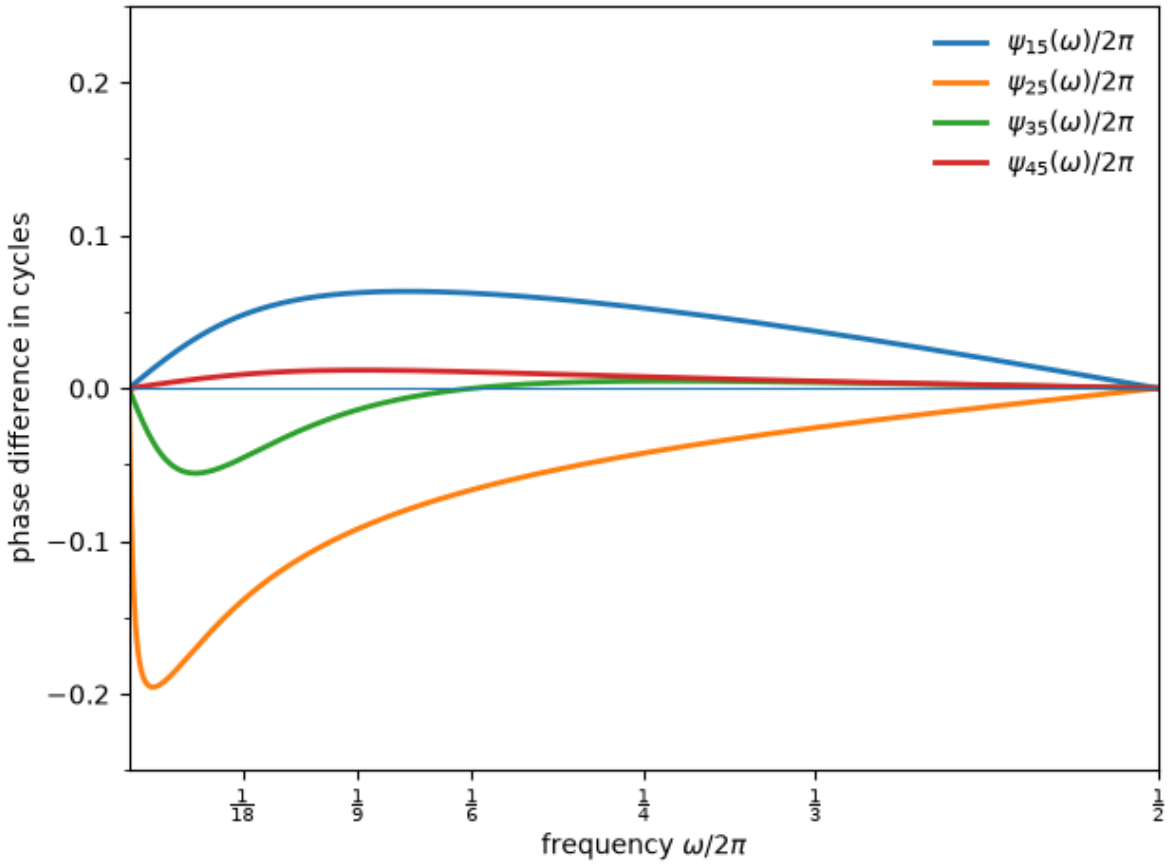
```
    ax.plot(freq[mask], coherence[mask],
            lw=2, label=rf'$R^2_{{{var_idx+3}5}}(\omega)$')
    ax.plot(freq[mask], gain[mask],
            lw=2, label=rf'$G_{{{var_idx+3}5}}(\omega)$')
    paper_frequency_axis(ax)
    ax.set_ylim([0, 1.0])
    ax.set_ylabel('gain, coherence')
    ax.legend(frameon=False, loc='best')

plt.tight_layout()
plt.show()
```

- New construction vs private-domestic GNP (left panel):
  - Gain peaks at medium cycle lengths (around 0.1 for short cycles).
  - Coherence for both investment series stays fairly high across frequencies.
- Long-bond yield vs private-domestic GNP (right panel):
  - Gain varies less across frequencies than real activity series.
  - Coherence with output is comparatively low at business-cycle frequencies, making it hard to explain interest-rate movements by inverting a money-demand equation.

46.8.5 Lead-lag relationships

The phase tells us which variable leads at each frequency.



Positive phase means output leads the component; negative phase means the component leads output.

```
fig, ax = plt.subplots()

labels = [r'$\psi_{15}(\omega)/2\pi$', r'$\psi_{25}(\omega)/2\pi$',
          r'$\psi_{35}(\omega)/2\pi$', r'$\psi_{45}(\omega)/2\pi$']

for var_idx in range(4):
    coherence, gain, phase = cross_spectral_measures(F_chow, var_idx, gnp_idx)
    phase_cycles = phase / (2 * np.pi)
    ax.plot(freq[mask], phase_cycles[mask], lw=2, label=labels[var_idx])

ax.axhline(0, lw=0.8)
paper_frequency_axis(ax)
ax.set_ylabel('phase difference in cycles')
ax.set_ylim([-0.25, 0.25])
ax.set_yticks(np.arange(-0.25, 0.3, 0.05), minor=True)
ax.legend(frameon=False)
plt.tight_layout()
plt.show()
```

The phase relationships reveal that:

- Output leads consumption by a small fraction of a cycle (about 0.06 cycles at a 6-year period, 0.04 cycles at a 3-year

period).

- Equipment plus inventories tends to lead output (by about 0.07 cycles at a 6-year period, 0.03 cycles at a 3-year period).
- New construction leads at low frequencies and is close to coincident at higher frequencies.
- The bond yield lags output slightly, remaining close to coincident in timing.

These implied leads and lags are broadly consistent with turning-point timing summaries reported elsewhere, and simulations of the same model deliver similar lead–lag ordering at turning points (Figure III of [Chow and Levitan, 1969]).

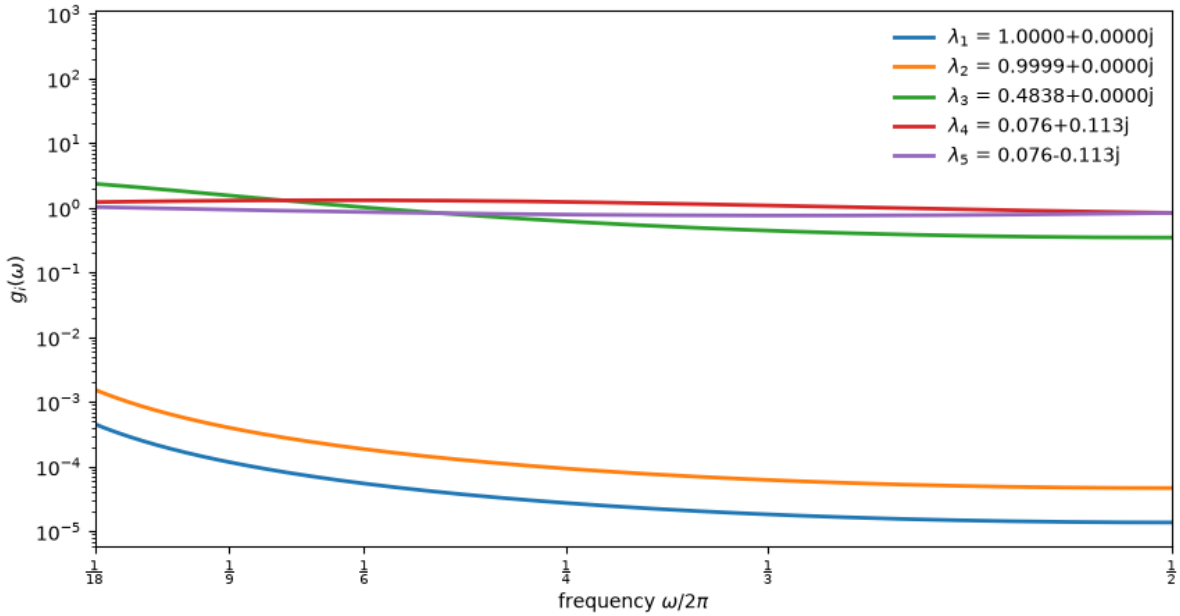
46.8.6 Building blocks of spectral shape

Each eigenvalue contributes a characteristic spectral shape through the *scalar kernel*

$$g_i(\omega) = \frac{1 - |\lambda_i|^2}{|1 - \lambda_i e^{-i\omega}|^2} = \frac{1 - |\lambda_i|^2}{1 + |\lambda_i|^2 - 2\mathrm{Re}(\lambda_i)\cos\omega + 2\mathrm{Im}(\lambda_i)\sin\omega}. \tag{46.44}$$

For real λ_i, this simplifies to

$$g_i(\omega) = \frac{1 - \lambda_i^2}{1 + \lambda_i^2 - 2\lambda_i \cos\omega}.$$



Each observable spectral density is a linear combination of these kernels (plus cross-terms).

Below, we plot the scalar kernels for each eigenvalue to see how they shape the overall spectra

```
def scalar_kernel(λ_i, ω_grid):
    """scalar spectral kernel g_i(ω)."""
    λ_i = complex(λ_i)
    mod_sq = np.abs(λ_i)**2
    return np.array(
        [(1 - mod_sq) / np.abs(1 - λ_i * np.exp(-1j * ω))**2
        for ω in ω_grid])

fig, ax = plt.subplots(figsize=(10, 5))
for i, λ_i in enumerate(λ):
    if np.abs(λ_i) > 0.01:
        g_i = scalar_kernel(λ_i, ω_grid)
        label = f'$\\lambda_{i+1}$ = {λ_i:.4f}' \
        if np.isreal(λ_i) else f'$\\lambda_{i+1}$ = {λ_i:.3f}'
        ax.semilogy(freq, g_i, label=label, lw=2)

ax.set_xlabel(r'frequency $\omega/2\pi$')
ax.set_ylabel('$g_i(\\omega)$')
ax.set_xlim([1/18, 0.5])
ax.set_xticks(freq_ticks)
ax.set_xticklabels(freq_labels)
ax.legend(frameon=False)
plt.show()
```

The figure reveals how eigenvalue magnitude shapes spectral contributions:

- *Near-unit eigenvalues* ($\lambda_1, \lambda_2 \approx 1$) produce kernels sharply peaked at low frequencies as these drive the strong low-frequency power seen in the spectra above.
- *The moderate eigenvalue* ($\lambda_3 \approx 0.48$) contributes a flatter component that spreads power more evenly across frequencies.
- *The complex pair* ($\lambda_{4,5}$) has such small modulus ($|\lambda_{4,5}| \approx 0.136$) that its kernel is nearly flat, which is too weak to generate a pronounced interior peak.

This decomposition explains why the spectra look the way they do: the near-unit eigenvalues dominate, concentrating variance at very low frequencies.

The complex pair, despite enabling oscillatory dynamics in principle, has insufficient modulus to produce a visible spectral peak.

46.9 Summary

Chow [1968] draws several conclusions that remain relevant for understanding business cycles.

The acceleration principle receives strong empirical support: the negative coefficient on lagged output in investment equations is a robust finding across datasets.

The relationship between eigenvalues and spectral peaks is more subtle than it first appears:

- Complex roots guarantee oscillatory autocovariances, but they are neither necessary nor sufficient for a pronounced spectral peak.
- In the Hansen–Samuelson model specifically, complex roots *are* necessary for a peak.
- But in general multivariate systems, even real roots can produce peaks through the interaction of shocks and eigenvector loadings.

Chow and Levitan [1969] demonstrate what these objects look like in a calibrated system: strong low-frequency power from near-unit eigenvalues, frequency-dependent gains and coherences, and lead–lag relations that vary with cycle length.

Their results are consistent with Granger's "typical spectral shape" for economic time series.

That is a monotonically decreasing function of frequency, driven by the near-unit eigenvalues that arise when some equations are specified in first differences.

Understanding whether this shape reflects the true data-generating process requires analyzing the spectral densities implied by structural econometric models.

46.10 Exercises

Exercise 46.10.1

Plot impulse responses and spectra side-by-side for several values of the accelerator v in the Hansen-Samuelson model, showing how acceleration strength affects both the time-domain and frequency-domain signatures.

Use the same v values as in the main text: $v \in \{0.2, 0.4, 0.6, 0.8, 0.95\}$ with $c = 0.6$.

Solution

Here is one solution:

```
v_grid_ex1 = [0.2, 0.4, 0.6, 0.8, 0.95]
c_ex1 = 0.6
freq_ex1 = np.linspace(1e-4, 0.5, 2000)
ω_grid_ex1 = 2 * np.pi * freq_ex1
V_ex1 = np.array([[1.0, 0.0], [0.0, 0.0]])
T_irf_ex1 = 40

fig, axes = plt.subplots(1, 2, figsize=(12, 5))

for v in v_grid_ex1:
    A = samuelson_transition(c_ex1, v)

    # impulse response (left panel)
    s = np.array([1.0, 0.0])
    irf = np.empty(T_irf_ex1 + 1)
    for t in range(T_irf_ex1 + 1):
        irf[t] = s[0]
        s = A @ s
    axes[0].plot(range(T_irf_ex1 + 1), irf, lw=2, label=f'$v={v}$')

    # spectrum (right panel)
    F = spectral_density_var1(A, V_ex1, ω_grid_ex1)
    f11 = np.real(F[:, 0, 0])
    df = np.diff(freq_ex1)
    area = np.sum(0.5 * (f11[1:] + f11[:-1]) * df)
    f11_norm = f11 / area
    axes[1].plot(freq_ex1, f11_norm, lw=2, label=f'$v={v}$')

axes[0].axhline(0, lw=0.8, color='gray')
axes[0].set_xlabel('time')
axes[0].set_ylabel(r'$Y_t$')
axes[0].legend(frameon=False)

axes[1].set_xlabel(r'frequency $\omega/2\pi$')
axes[1].set_ylabel('normalized spectrum')
```

```
axes[1].set_xlim([0, 0.5])
axes[1].set_yscale('log')
axes[1].legend(frameon=False)

plt.tight_layout()
plt.show()
```

As v increases, eigenvalues approach the unit circle: oscillations become more persistent in the time domain (left), and the spectral peak becomes sharper in the frequency domain (right).

Complex roots produce a pronounced peak at interior frequencies–the spectral signature of business cycles.

Exercise 46.10.2

Verify spectral peak condition (46.25) numerically for the Hansen-Samuelson model.

1. For a range of eigenvalue moduli $r \in [0.3, 0.99]$ with fixed $\theta = 60°$, compute:
   - The theoretical peak frequency from formula: $\cos\omega = \frac{1+r^2}{2r}\cos\theta$
   - The actual peak frequency by numerically maximizing the spectral density
2. Plot both on the same graph and verify they match.
3. Identify the range of r for which no valid peak exists (when the condition (46.26) is violated).

Solution

Here is one solution:

```
θ_ex = np.pi / 3  # 60 degrees
r_grid = np.linspace(0.3, 0.99, 50)
ω_grid_ex = np.linspace(1e-3, np.pi - 1e-3, 1000)
V_hs_ex = np.array([[1.0, 0.0], [0.0, 0.0]])

ω_theory = []
ω_numerical = []

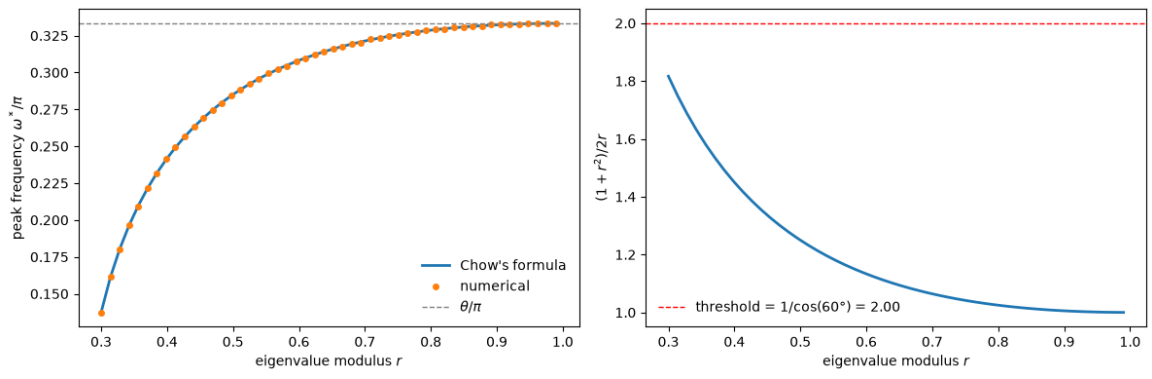
for r in r_grid:
    # Theoretical peak
```

```
    factor = (1 + r**2) / (2 * r)
    cos_ω = factor * np.cos(θ_ex)
    if -1 < cos_ω < 1:
        ω_theory.append(np.arccos(cos_ω))
    else:
        ω_theory.append(np.nan)

    # Numerical peak from spectral density
    # Construct Hansen-Samuelson with eigenvalues r*exp(+-iθ)
    # This corresponds to c + v = 2r*cos(θ), v = r^2
    v = r**2
    c = 2 * r * np.cos(θ_ex) - v
    A_ex = samuelson_transition(c, v)
    F_ex = spectral_density_var1(A_ex, V_hs_ex, ω_grid_ex)
    f11 = np.real(F_ex[:, 0, 0])
    i_max = np.argmax(f11)

    # Only count as a peak if it's not at the boundary
    if 5 < i_max < len(ω_grid_ex) - 5:
        ω_numerical.append(ω_grid_ex[i_max])
    else:
        ω_numerical.append(np.nan)

ω_theory = np.array(ω_theory)
ω_numerical = np.array(ω_numerical)



fig, axes = plt.subplots(1, 2, figsize=(12, 4))

# Plot peak frequencies
axes[0].plot(r_grid, ω_theory / np.pi, lw=2, label="Chow's formula")
axes[0].plot(r_grid, ω_numerical / np.pi, 'o', markersize=4, label='numerical')
axes[0].axhline(θ_ex / np.pi, ls='--', lw=1.0, color='gray', label=r'$\theta/\pi$')
axes[0].set_xlabel('eigenvalue modulus $r$')
axes[0].set_ylabel(r'peak frequency $\omega^*/\pi$')
axes[0].legend(frameon=False)

# Plot the factor (1+r^2)/2r to show when peaks are valid
axes[1].plot(r_grid, (1 + r_grid**2) / (2 * r_grid), lw=2)
axes[1].axhline(1 / np.cos(θ_ex), ls='--', lw=1.0, color='red',
                label=f'threshold = 1/cos({np.rad2deg(θ_ex):.0f}°) = {1/np.cos(θ_
 ↪ex):.2f}')
axes[1].set_xlabel('eigenvalue modulus $r$')
axes[1].set_ylabel(r'$(1+r^2)/2r$')
axes[1].legend(frameon=False)

plt.tight_layout()
plt.show()

# Find threshold r below which no peak exists
valid_mask = ~np.isnan(ω_theory)
if valid_mask.any():
    r_threshold = r_grid[valid_mask][0]
    print(f"Peak exists for r >= {r_threshold:.2f}")
```

```
Peak exists for r >= 0.30
```

The theoretical and numerical peak frequencies match closely.

As $r \to 1$, the peak frequency converges to θ.

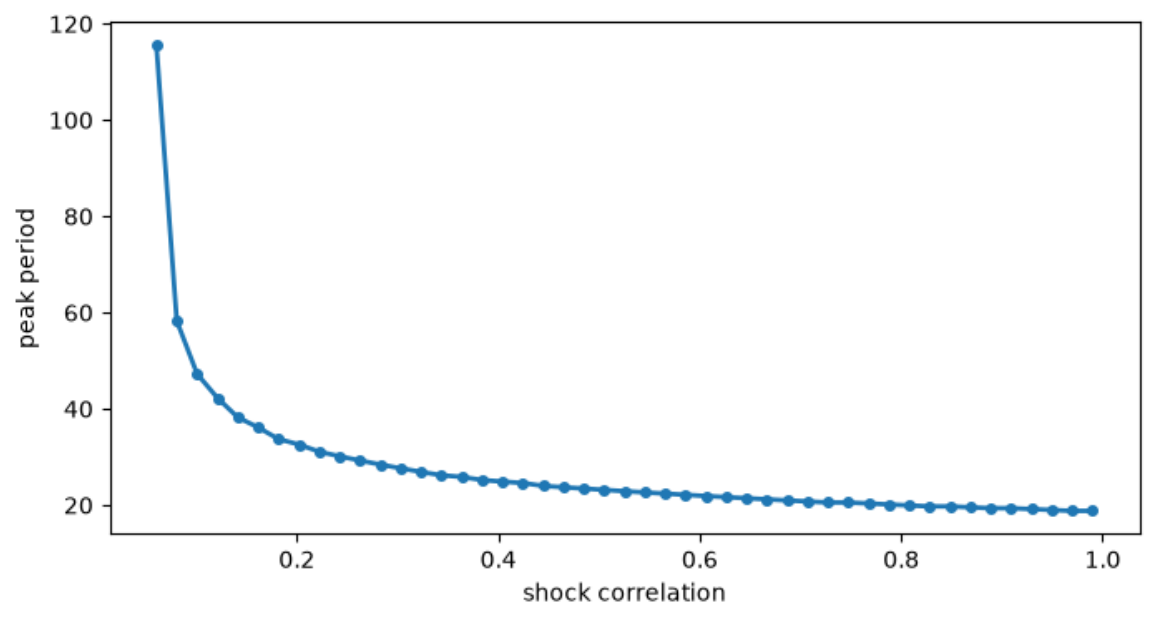
For smaller r, the factor $(1 + r^2)/2r$ exceeds the threshold, and no valid peak exists.

Exercise 46.10.3

In the "real roots but a peak" example, hold A fixed and vary the shock correlation (the off-diagonal entry of V) between 0 and 0.99.

When does the interior-frequency peak appear, and how does its location change?

Solution



Here is one solution:

```
A_ex3 = np.diag([0.1, 0.9])
b_ex3 = np.array([1.0, -0.01])
corr_grid = np.linspace(0, 0.99, 50)
peak_periods = []
for corr in corr_grid:
    V_ex3 = np.array([[1.0, corr], [corr, 1.0]])
    F_ex3 = spectral_density_var1(A_ex3, V_ex3, ω_grid_ex)
    f_x = spectrum_of_linear_combination(F_ex3, b_ex3)
    i_max = np.argmax(f_x)
    if 5 < i_max < len(ω_grid_ex) - 5:
        peak_periods.append(2 * np.pi / ω_grid_ex[i_max])
    else:
        peak_periods.append(np.nan)

fig, ax = plt.subplots(figsize=(8, 4))
ax.plot(corr_grid, peak_periods, marker='o', lw=2, markersize=4)
ax.set_xlabel('shock correlation')
ax.set_ylabel('peak period')
plt.show()

threshold_idx = np.where(~np.isnan(peak_periods))[0]
if len(threshold_idx) > 0:
    print(
```

```
    f"interior peak when correlation >= {corr_grid[threshold_idx[0]]:.2f}")
```

```
interior peak when correlation >= 0.06
```

The interior peak appears only when the shock correlation exceeds a threshold.

This illustrates that spectral peaks depend on the full system structure, not just eigenvalues.

Exercise 46.10.4

Using the calibrated Chow-Levitan parameters, compute the autocovariance matrices $\Gamma_0, \Gamma_1, \ldots, \Gamma_{10}$ using:

1. The recursion $\Gamma_k = A\Gamma_{k-1}$ with Γ_0 from the Lyapunov equation.
2. Chow's eigendecomposition formula $\Gamma_k = BD_\lambda^k \Gamma_0^* B^\top$ where Γ_0^* is the canonical covariance.

Verify that both methods give the same result.

Solution

Here is one solution:

```
from scipy.linalg import solve_discrete_lyapunov

Γ_0_lyap = solve_discrete_lyapunov(A_chow, V)
Γ_recursion = [Γ_0_lyap]
for k in range(1, 11):
    Γ_recursion.append(A_chow @ Γ_recursion[-1])

p = len(λ)
Γ_0_star = np.zeros((p, p), dtype=complex)
for i in range(p):
    for j in range(p):
        Γ_0_star[i, j] = W[i, j] / (1 - λ[i] * λ[j])
```

```
Γ_eigen = []
for k in range(11):
    D_k = np.diag(λ**k)
    Γ_eigen.append(np.real(B @ D_k @ Γ_0_star @ B.T))

print("Comparison of Γ_5 (first 3x3 block):")
print("\nRecursion method:")
print(np.real(Γ_recursion[5][:3, :3]).round(10))
print("\nEigendecomposition method:")
print(Γ_eigen[5][:3, :3].round(10))
print("\nMax absolute difference:",
        np.max(np.abs(np.real(Γ_recursion[5]) - Γ_eigen[5])))
```

```
Comparison of Γ_5 (first 3x3 block):

Recursion method:
[[2.5417901e-03 2.9310700e-05 1.7370210e-04]
 [2.8886900e-05 3.3220000e-07 1.9737000e-06]
 [1.7356020e-04 2.0028000e-06 1.1861700e-05]]

Eigendecomposition method:
[[2.5417901e-03 2.9310700e-05 1.7370210e-04]
 [2.8886900e-05 3.3220000e-07 1.9737000e-06]
 [1.7356020e-04 2.0028000e-06 1.1861700e-05]]

Max absolute difference: 9.500386588534582e-14
```

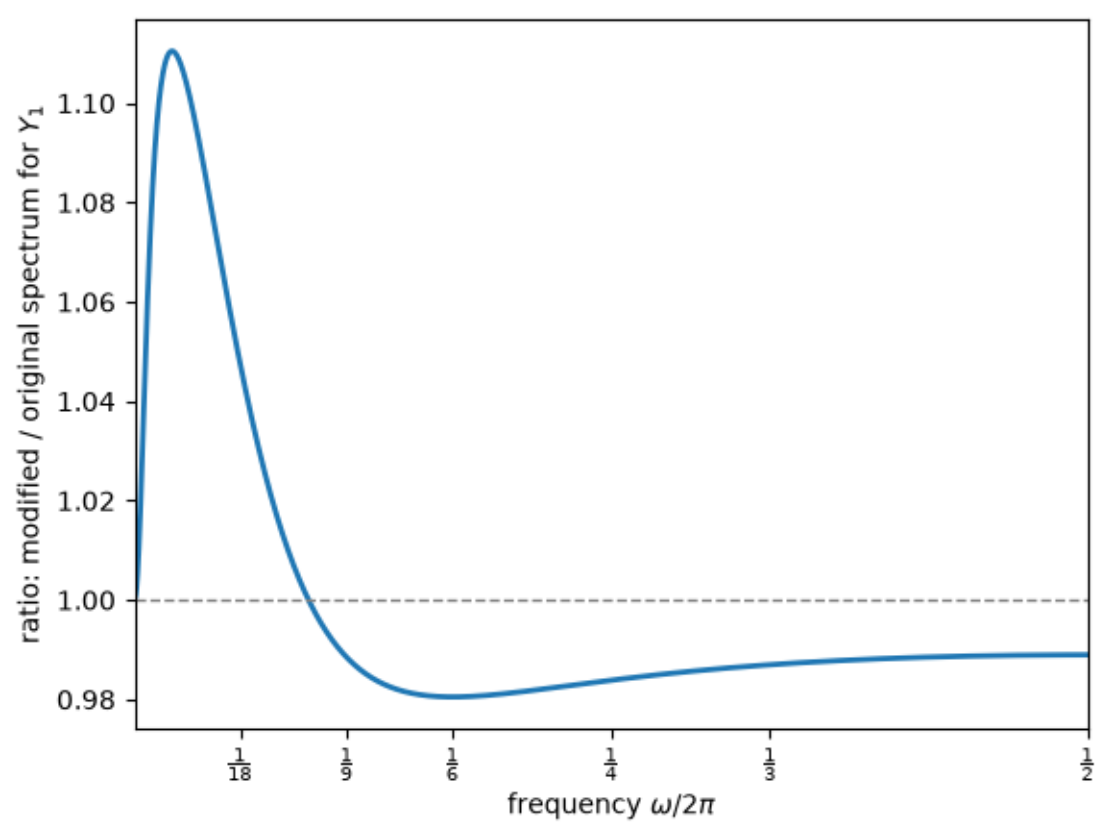
Both methods produce essentially identical results, up to numerical precision.

Exercise 46.10.5

Modify the Chow-Levitan model by changing λ_3 from 0.4838 to 0.95.

1. Recompute the spectral densities.
2. How does this change affect the spectral shape for each variable?
3. What economic interpretation might correspond to this parameter change?

Solution



Here is one solution:

```
# Modify λ_3 and reconstruct the transition matrix
λ_modified = λ.copy()
λ_modified[2] = 0.95
D_λ_mod = np.diag(λ_modified)
A_mod = np.real(B @ D_λ_mod @ np.linalg.inv(B))

# Compute spectra using the VAR(1) formula with original V
F_mod = spectral_density_var1(A_mod, V, ω_grid)
F_orig = spectral_density_var1(A_chow, V, ω_grid)

# Plot ratio of spectra for output (Y_1)
f_orig = np.real(F_orig[:, 4, 4])
f_mod = np.real(F_mod[:, 4, 4])
```

```
fig, ax = plt.subplots()
ax.plot(freq, f_mod / f_orig, lw=2)
ax.axhline(1.0, ls='--', lw=1, color='gray')
paper_frequency_axis(ax)
ax.set_ylabel(r"ratio: modified / original spectrum for $Y_1$")
plt.show()
```

The near-unit eigenvalues ($\lambda_1, \lambda_2 \approx 0.9999$) dominate the output spectrum so heavily that changing λ_3 from 0.48 to 0.95 produces only a small relative effect.

The ratio plot reveals the change: the modified spectrum has slightly more power at low-to-medium frequencies and slightly less at high frequencies.

Economically, increasing λ_3 adds persistence to the mode it governs.

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install --upgrade quantecon yfinance jax
```

47.1 Overview

Previously in AR(1) Processes, we learned about linear scalar-valued stochastic processes (AR(1) models).

Now we generalize these linear models slightly by allowing the multiplicative coefficient to be stochastic.

Such processes are known as Kesten processes after German–American mathematician Harry Kesten (1931–2019).

Although simple to write down, Kesten processes are interesting for at least two reasons:

1. A number of significant economic processes are or can be described as Kesten processes.

2. Kesten processes generate interesting dynamics, including, in some cases, heavy-tailed cross-sectional distributions.

We will discuss these issues as we go along.

Let's start with some imports:

```
import matplotlib.pyplot as plt
import numpy as np
import quantecon as qe
import yfinance as yf
```

Additional technical background related to this lecture can be found in the monograph by [Buraczewski *et al.*, 2016].

47.2 Kesten processes

A **Kesten process** is a stochastic process of the form

$$X_{t+1} = a_{t+1} X_t + \eta_{t+1} \tag{47.1}$$

where $\{a_t\}_{t \geq 1}$ and $\{\eta_t\}_{t \geq 1}$ are IID sequences.

We are interested in the dynamics of $\{X_t\}_{t \geq 0}$ when X_0 is given.

We will focus on the nonnegative scalar case, where X_t takes values in $\mathbb{R}_+$.

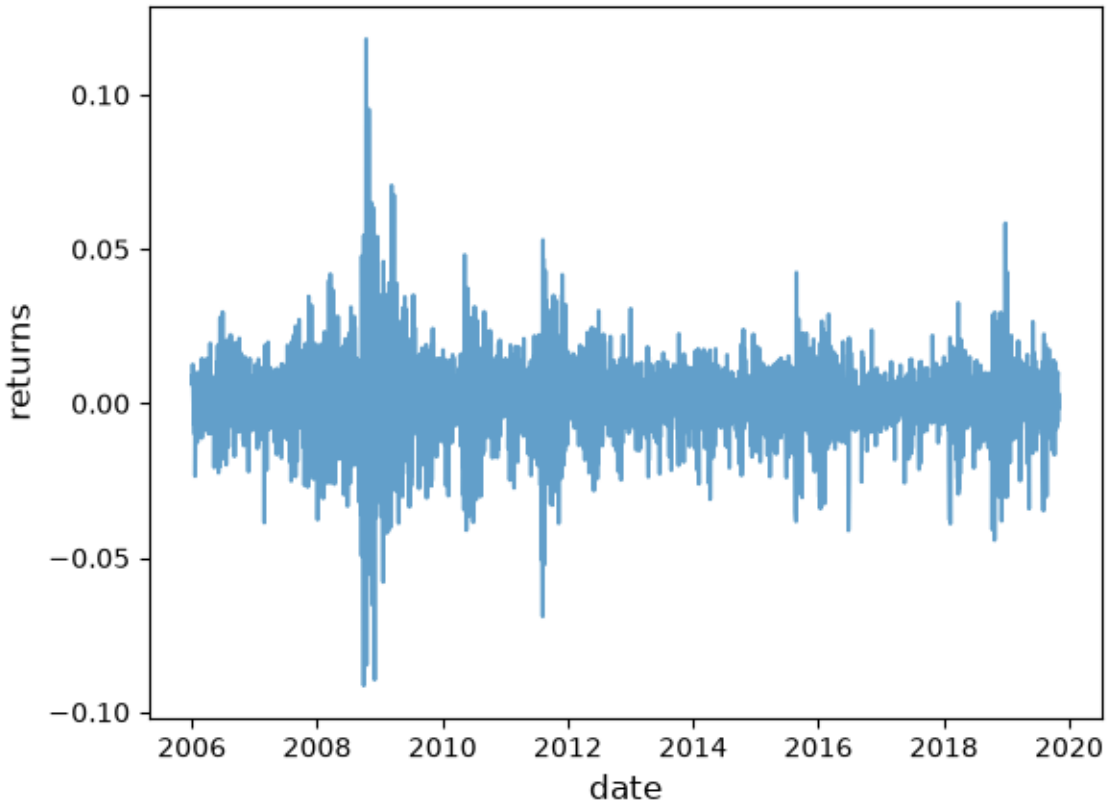
In particular, we will assume that

- the initial condition X_0 is nonnegative,
- $\{a_t\}_{t \geq 1}$ is a nonnegative IID stochastic process and
- $\{\eta_t\}_{t \geq 1}$ is another nonnegative IID stochastic process, independent of the first.

47.2.1 Example: GARCH volatility

The GARCH model is common in financial applications, where time series such as asset returns exhibit time varying volatility.

For example, consider the following plot of daily returns on the Nasdaq Composite Index for the period 1st January 2006 to 1st November 2019.



```
s = yf.download(
    "^IXIC", "2006-1-1", "2019-11-1", auto_adjust=False
)["Adj Close"]

r = s.pct_change()

fig, ax = plt.subplots()
ax.plot(r, alpha=0.7)
ax.set_ylabel("returns", fontsize=12)
ax.set_xlabel("date", fontsize=12)

plt.show()
```

```
[**********100%**********]  1 of 1 completed
```

Notice how the series exhibits bursts of volatility (high variance) and then settles down again.

GARCH models can replicate this feature.

The GARCH(1, 1) volatility process takes the form

$$\sigma_{t+1}^2 = \alpha_0 + \sigma_t^2(\alpha_1 \xi_{t+1}^2 + \beta) \tag{47.2}$$

where $\{\xi_t\}$ is IID with $\mathbb{E}\xi_t^2 = 1$ and all parameters are positive.

Returns on a given asset are then modeled as

$$r_t = \sigma_t \zeta_t \tag{47.3}$$

where $\{\zeta_t\}$ is again IID and independent of $\{\xi_t\}$.

The volatility sequence $\{\sigma_t^2\}$, which drives the dynamics of returns, is a Kesten process.

47.2.2 Example: wealth dynamics

Suppose that a given household saves a fixed fraction s of its current wealth in every period.

The household earns labor income y_t at the start of time t.

Wealth then evolves according to

$$w_{t+1} = R_{t+1} s w_t + y_{t+1} \tag{47.4}$$

where $\{R_t\}$ is the gross rate of return on assets.

If $\{R_t\}$ and $\{y_t\}$ are both IID, then (47.4) is a Kesten process.

47.2.3 Stationarity

In earlier lectures, such as the one on AR(1) Processes, we introduced the notion of a stationary distribution.

In the present context, we can define a stationary distribution as follows:

The distribution F^* on $\mathbb{R}$ is called **stationary** for the Kesten process (47.1) if

$$X_t \sim F^* \quad \Longrightarrow \quad a_{t+1} X_t + \eta_{t+1} \sim F^* \tag{47.5}$$

In other words, if the current state X_t has distribution F^*, then so does the next period state X_{t+1}.

We can write this alternatively as

$$F^*(y) = \int \mathbb{P}\{a_{t+1} x + \eta_{t+1} \leq y\} F^*(dx) \quad \text{for all } y \geq 0. \tag{47.6}$$

The left hand side is the distribution of the next period state when the current state is drawn from F^*.

The equality in (47.6) states that this distribution is unchanged.

47.2.4 Cross-sectional interpretation

There is an important cross-sectional interpretation of stationary distributions, discussed previously but worth repeating here.

Suppose, for example, that we are interested in the wealth distribution — that is, the current distribution of wealth across households in a given country.

Suppose further that

- the wealth of each household evolves independently according to (47.4),
- F^* is a stationary distribution for this stochastic process and
- there are many households.

Then F^* is a steady state for the cross-sectional wealth distribution in this country.

In other words, if F^* is the current wealth distribution then it will remain so in subsequent periods, *ceteris paribus*.

To see this, suppose that F^* is the current wealth distribution.

What is the fraction of households with wealth less than y next period?

To obtain this, we sum the probability that wealth is less than y tomorrow, given that current wealth is w, weighted by the fraction of households with wealth w.

Noting that the fraction of households with wealth in interval dw is $F^*(dw)$, we get

$$\int \mathbb{P}\{R_{t+1} sw + y_{t+1} \leq y\} F^*(dw)$$

By the definition of stationarity and the assumption that F^* is stationary for the wealth process, this is just $F^*(y)$.

Hence the fraction of households with wealth in $[0, y]$ is the same next period as it is this period.

Since y was chosen arbitrarily, the distribution is unchanged.

47.2.5 Conditions for stationarity

The Kesten process $X_{t+1} = a_{t+1}X_t + \eta_{t+1}$ does not always have a stationary distribution.

For example, if $a_t \equiv \eta_t \equiv 1$ for all t, then $X_t = X_0 + t$, which diverges to infinity.

To prevent this kind of divergence, we require that $\{a_t\}$ is strictly less than 1 most of the time.

In particular, if

$$\mathbb{E} \ln a_t < 0 \quad \text{and} \quad \mathbb{E}\eta_t < \infty \tag{47.7}$$

then a unique stationary distribution exists on $\mathbb{R}_+$.

- See, for example, theorem 2.1.3 of [Buraczewski *et al.*, 2016], which provides slightly weaker conditions.

As one application of this result, we see that the wealth process (47.4) will have a unique stationary distribution whenever labor income has finite mean and $\mathbb{E} \ln R_t + \ln s < 0$.

47.3 Heavy tails

Under certain conditions, the stationary distribution of a Kesten process has a Pareto tail.

(See our lecture Heavy-Tailed Distributions for background.)

This fact is significant for economics because of the prevalence of Pareto-tailed distributions.

47.3.1 The Kesten–Goldie theorem

To state the conditions under which the stationary distribution of a Kesten process has a Pareto tail, we first recall that a random variable is called **nonarithmetic** if its distribution is not concentrated on $\{\dots, -2t, -t, 0, t, 2t, \dots\}$ for any $t \geq 0$.

For example, any random variable with a density is nonarithmetic.

The famous Kesten–Goldie Theorem (see, e.g., [Buraczewski *et al.*, 2016], theorem 2.4.4) states that if

1. the stationarity conditions in (47.7) hold,
2. the random variable a_t is positive with probability one and nonarithmetic,
3. $\mathbb{P}\{a_t x + \eta_t = x\} < 1$ for all $x \in \mathbb{R}_+$ and
4. there exists a positive constant α such that

$$\mathbb{E}a_t^\alpha = 1, \quad \mathbb{E}\eta_t^\alpha < \infty, \quad \text{and} \quad \mathbb{E}[a_t^{\alpha+1}] < \infty$$

then the stationary distribution of the Kesten process has a Pareto tail with tail index α.

More precisely, if F^* is the unique stationary distribution and $X^* \sim F^*$, then

$$\lim_{x \to \infty} x^\alpha \mathbb{P}\{X^* > x\} = c$$

for some positive constant c.

47.3.2 Intuition

Later we will illustrate the Kesten–Goldie Theorem using rank-size plots.

Prior to doing so, we can give the following intuition for the conditions.

Two important conditions are that $\mathbb{E} \ln a_t < 0$, so the model is stationary, and $\mathbb{E} a_t^\alpha = 1$ for some $\alpha > 0$.

The first condition implies that the distribution of a_t has a large amount of probability mass below 1.

The second condition implies that the distribution of a_t has at least some probability mass at or above 1.

The first condition gives us existence of the stationary condition.

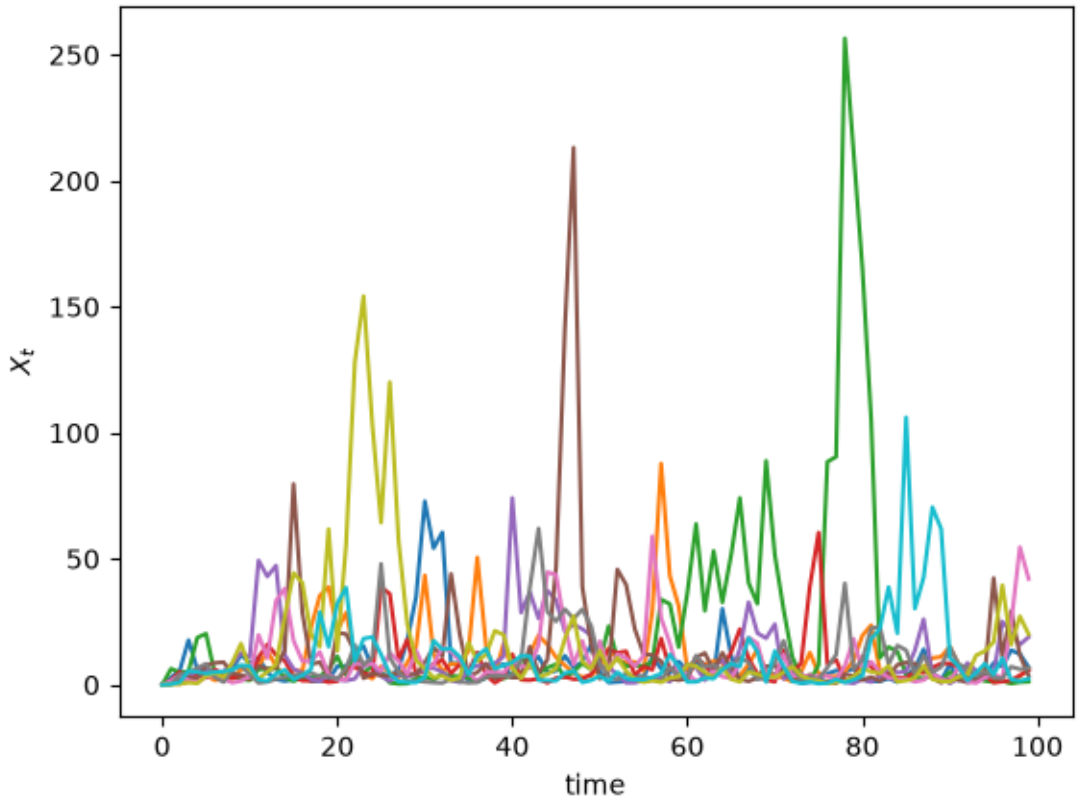
The second condition means that the current state can be expanded by a_t.

If this occurs for several concurrent periods, the effects compound each other, since a_t is multiplicative.

This leads to spikes in the time series, which fill out the extreme right hand tail of the distribution.

The spikes in the time series are visible in the following simulation, which generates 10 paths when a_t and b_t are lognormal.

```
μ = -0.5
σ = 1.0



def kesten_ts(rng, ts_length=100):
    x = np.zeros(ts_length)
    for t in range(ts_length - 1):
        a = np.exp(μ + σ * rng.standard_normal())
        b = np.exp(rng.standard_normal())
        x[t+1] = a * x[t] + b
    return x

fig, ax = plt.subplots()

num_paths = 10
rng = np.random.default_rng(12)

for i in range(num_paths):
    ax.plot(kesten_ts(rng))

ax.set(xlabel="time", ylabel="$X_t$")
plt.show()
```

47.4 Application: firm dynamics

As noted in our lecture Heavy-Tailed Distributions, for common measures of firm size such as revenue or employment, the US firm size distribution exhibits a Pareto tail (see, e.g., [Axtell, 2001], [Gabaix, 2016]).

Let us try to explain this rather striking fact using the Kesten–Goldie Theorem.

47.4.1 Gibrat's law

It was postulated many years ago by Robert Gibrat [Gibrat, 1931] that firm size evolves according to a simple rule whereby size next period is proportional to current size.

This is now known as Gibrat's law of proportional growth.

We can express this idea by stating that a suitably defined measure s_t of firm size obeys

$$\frac{s_{t+1}}{s_t} = a_{t+1} \tag{47.8}$$

for some positive IID sequence $\{a_t\}$.

One implication of Gibrat's law is that the growth rate of individual firms does not depend on their size.

However, over the last few decades, research contradicting Gibrat's law has accumulated in the literature.

For example, it is commonly found that, on average,

1. small firms grow faster than large firms (see, e.g., [Evans, 1987] and [Hall, 1987]) and

2. the growth rate of small firms is more volatile than that of large firms [Dunne *et al.*, 1989].

On the other hand, Gibrat's law is generally found to be a reasonable approximation for large firms [Evans, 1987].

We can accommodate these empirical findings by modifying (47.8) to

$$s_{t+1} = a_{t+1} s_t + b_{t+1} \tag{47.9}$$

where $\{a_t\}$ and $\{b_t\}$ are both IID and independent of each other.

In the exercises you are asked to show that (47.9) is more consistent with the empirical findings presented above than Gibrat's law in (47.8).

47.4.2 Heavy tails

So what has this to do with Pareto tails?

The answer is that (47.9) is a Kesten process.

If the conditions of the Kesten–Goldie Theorem are satisfied, then the firm size distribution is predicted to have heavy tails — which is exactly what we see in the data.

In the exercises below we explore this idea further, generalizing the firm size dynamics and examining the corresponding rank-size plots.

We also try to illustrate why the Pareto tail finding is significant for quantitative analysis.

47.5 Exercises

Exercise 47.5.1

Simulate and plot 15 years of daily returns (consider each year as having 250 working days) using the GARCH(1, 1) process in (47.2)–(47.3).

Take ξ_t and ζ_t to be independent and standard normal.

Set $\alpha_0 = 0.00001, \alpha_1 = 0.1, \beta = 0.9$ and $\sigma_0 = 0$.

Compare visually with the Nasdaq Composite Index returns *shown above*.

While the time path differs, you should see bursts of high volatility.

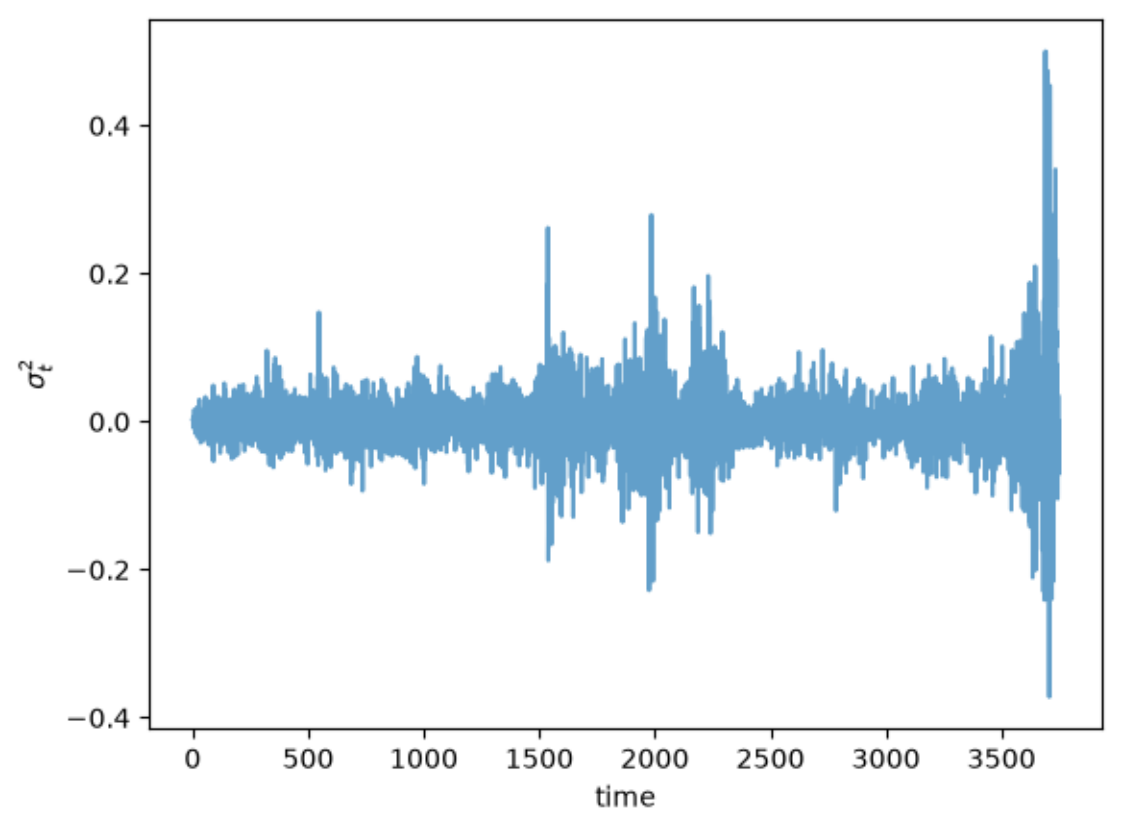
Solution

Here is one solution:

```
α_0 = 1e-5
α_1 = 0.1
β = 0.9

years = 15
days = years * 250

def garch_ts(rng, ts_length=days):
    σ2 = 0
    r = np.zeros(ts_length)
```



```
    for t in range(ts_length - 1):
        ξ = rng.standard_normal()
        σ2 = α_0 + σ2 * (α_1 * ξ**2 + β)
        r[t] = np.sqrt(σ2) * rng.standard_normal()
    return r

fig, ax = plt.subplots()

rng = np.random.default_rng(12)

ax.plot(garch_ts(rng), alpha=0.7)

ax.set(xlabel="time", ylabel="$\\sigma_t^2$")
plt.show()
```

Exercise 47.5.2

In our discussion of firm dynamics, it was claimed that (47.9) is more consistent with the empirical literature than Gibrat's law in (47.8).

(The empirical literature was reviewed immediately above (47.9).)

In what sense is this true (or false)?

Solution

The empirical findings are that

1. small firms grow faster than large firms and
2. the growth rate of small firms is more volatile than that of large firms.

Also, Gibrat's law is generally found to be a reasonable approximation for large firms than for small firms

The claim is that the dynamics in (47.9) are more consistent with points 1-2 than Gibrat's law.

To see why, we rewrite (47.9) in terms of growth dynamics:

$$\frac{s_{t+1}}{s_t} = a_{t+1} + \frac{b_{t+1}}{s_t} \tag{47.10}$$

Taking $s_t = s$ as given, the mean and variance of firm growth are

$$\mathbb{E}a + \frac{\mathbb{E}b}{s} \quad \text{and} \quad \mathbb{V}a + \frac{\mathbb{V}b}{s^2}$$

Both of these decline with firm size s, consistent with the data.

Moreover, the law of motion (47.10) clearly approaches Gibrat's law (47.8) as s_t gets large.

Exercise 47.5.3

Consider an arbitrary Kesten process as given in (47.1).

Suppose that $\{a_t\}$ is lognormal with parameters (μ, σ).

In other words, each a_t has the same distribution as $\exp(\mu + \sigma Z)$ when Z is standard normal.

Suppose further that $\mathbb{E}\eta_t^r < \infty$ for every $r > 0$, as would be the case if, say, η_t is also lognormal.

Show that the conditions of the Kesten–Goldie theorem are satisfied if and only if $\mu < 0$.

Obtain the value of α that makes the Kesten–Goldie conditions hold.

Solution

Since a_t has a density it is nonarithmetic.

Since a_t has the same density as $a = \exp(\mu + \sigma Z)$ when Z is standard normal, we have

$$\mathbb{E} \ln a_t = \mathbb{E}(\mu + \sigma Z) = \mu,$$

and since η_t has finite moments of all orders, the stationarity condition holds if and only if $\mu < 0$.

Given the properties of the lognormal distribution (which has finite moments of all orders), the only other condition in doubt is existence of a positive constant α such that $\mathbb{E} a_t^\alpha = 1$.

This is equivalent to the statement

$$\exp\left(\alpha\mu + \frac{\alpha^2\sigma^2}{2}\right) = 1.$$

Solving for α gives $\alpha = -2\mu/\sigma^2$.

Exercise 47.5.4

One unrealistic aspect of the firm dynamics specified in (47.9) is that it ignores entry and exit.

In any given period and in any given market, we observe significant numbers of firms entering and exiting the market.

Empirical discussion of this can be found in a famous paper by Hugo Hopenhayn [Hopenhayn, 1992].

In the same paper, Hopenhayn builds a model of entry and exit that incorporates profit maximization by firms and market clearing quantities, wages and prices.

In his model, a stationary equilibrium occurs when the number of entrants equals the number of exiting firms.

In this setting, firm dynamics can be expressed as

$$s_{t+1} = e_{t+1} \mathbb{1}\{s_t < \bar{s}\} + (a_{t+1} s_t + b_{t+1}) \mathbb{1}\{s_t \geq \bar{s}\} \tag{47.11}$$

Here

- the state variable s_t represents productivity (which is a proxy for output and hence firm size),
- the IID sequence $\{e_t\}$ is thought of as a productivity draw for a new entrant and
- the variable $\bar{s}$ is a threshold value that we take as given, although it is determined endogenously in Hopenhayn's model.

The idea behind (47.11) is that firms stay in the market as long as their productivity s_t remains at or above $\bar{s}$.

- In this case, their productivity updates according to (47.9).

Firms choose to exit when their productivity s_t falls below $\bar{s}$.

- In this case, they are replaced by a new firm with productivity e_{t+1}.

What can we say about dynamics?

Although (47.11) is not a Kesten process, it does update in the same way as a Kesten process when s_t is large.

So perhaps its stationary distribution still has Pareto tails?

Your task is to investigate this question via simulation and rank-size plots.

The approach will be to

1. generate M draws of s_T when M and T are large and
2. plot the largest 1,000 of the resulting draws in a rank-size plot.

(The distribution of s_T will be close to the stationary distribution when T is large.)

In the simulation, assume that

- each of a_t, b_t and e_t is lognormal,
- the parameters are

```
μ_a = -0.5        # location parameter for a
σ_a = 0.1         # scale parameter for a
μ_b = 0.0         # location parameter for b
σ_b = 0.5         # scale parameter for b
μ_e = 0.0         # location parameter for e
σ_e = 0.5         # scale parameter for e
s_bar = 1.0       # threshold
T = 500           # sampling date
M = 1_000_000     # number of firms
s_init = 1.0      # initial condition for each firm
```

Solution

Here's one solution.

We need to simulate a large cross-section of firms, so this is a good use case for JAX.

We store the firm parameters in a `NamedTuple` and write the update rule (47.11) for a single firm as a pure function.

```
import jax
import jax.numpy as jnp
from functools import partial
from typing import NamedTuple

class Firm(NamedTuple):
    μ_a: float
    σ_a: float
    μ_b: float
    σ_b: float
    μ_e: float
    σ_e: float
    s_bar: float

def update(s, key, firm):
    "Update a single firm's size s, given a fresh random key."
    a_key, b_key, e_key = jax.random.split(key, 3)
    a = jnp.exp(firm.μ_a + firm.σ_a * jax.random.normal(a_key))
    b = jnp.exp(firm.μ_b + firm.σ_b * jax.random.normal(b_key))
    e = jnp.exp(firm.μ_e + firm.σ_e * jax.random.normal(e_key))
    return jnp.where(s < firm.s_bar, e, a * s + b)
```

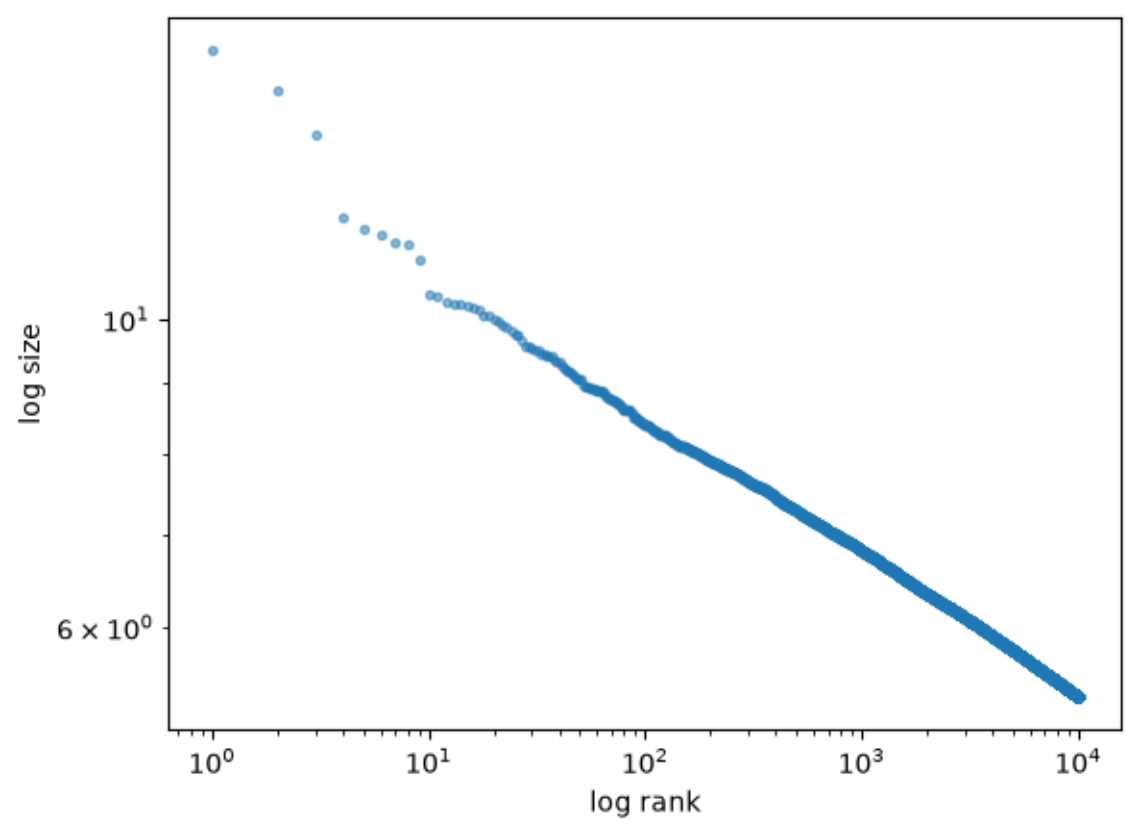
We simulate one firm for `T` periods with `lax.scan`, then use `vmap` to run all `M` firms in parallel.

```
@partial(jax.jit, static_argnames=("T", "M"))
def generate_draws(firm, s_init=1.0, T=500, M=1_000_000, seed=0):
    keys = jax.random.split(jax.random.PRNGKey(seed), M)

    def sim_firm(key):
        step_keys = jax.random.split(key, T)
        s_final, _ = jax.lax.scan(
            lambda s, k: (update(s, k, firm), None), s_init, step_keys
        )
        return s_final

    return jax.vmap(sim_firm)(keys)
```

Now we build the firm from the parameters above and generate the draws.



```
firm = Firm(μ_a, σ_a, μ_b, σ_b, μ_e, σ_e, s_bar)
data = generate_draws(firm, s_init=s_init, T=T, M=M)
```

Now we produce the rank-size plot:

```
fig, ax = plt.subplots()

rank_data, size_data = qe.rank_size(data, c=0.01)
ax.loglog(rank_data, size_data, "o", markersize=3.0, alpha=0.5)
ax.set_xlabel("log rank")
ax.set_ylabel("log size")

plt.show()
```

The plot produces a straight line, consistent with a Pareto tail.

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

48.1 Overview

This notebook gives an introduction to wealth distribution dynamics, with a focus on

- modeling and computing the wealth distribution via simulation,
- measures of inequality such as the Lorenz curve and Gini coefficient, and
- how inequality is affected by the properties of wage income and returns on assets.

One interesting property of the wealth distribution we discuss is Pareto tails.

The wealth distribution in many countries exhibits a Pareto tail

- See this lecture for a definition.
- For a review of the empirical evidence, see, for example, [Benhabib and Bisin, 2018].

This is consistent with high concentration of wealth amongst the richest households.

It also gives us a way to quantify such concentration, in terms of the tail index.

One question of interest is whether or not we can replicate Pareto tails from a relatively simple model.

48.1.1 A Note on Assumptions

The evolution of wealth for any given household depends on their savings behavior.

Modeling such behavior will form an important part of this lecture series.

However, in this particular lecture, we will be content with rather ad hoc (but plausible) savings rules.

We do this to more easily explore the implications of different specifications of income dynamics and investment returns.

At the same time, all of the techniques discussed here can be plugged into models that use optimization to obtain savings rules.

We will use the following imports.

```
import matplotlib.pyplot as plt
import numpy as np
import quantecon as qe
from numba import jit, float64, prange
from numba.experimental import jitclass
```

48.2 Lorenz Curves and the Gini Coefficient

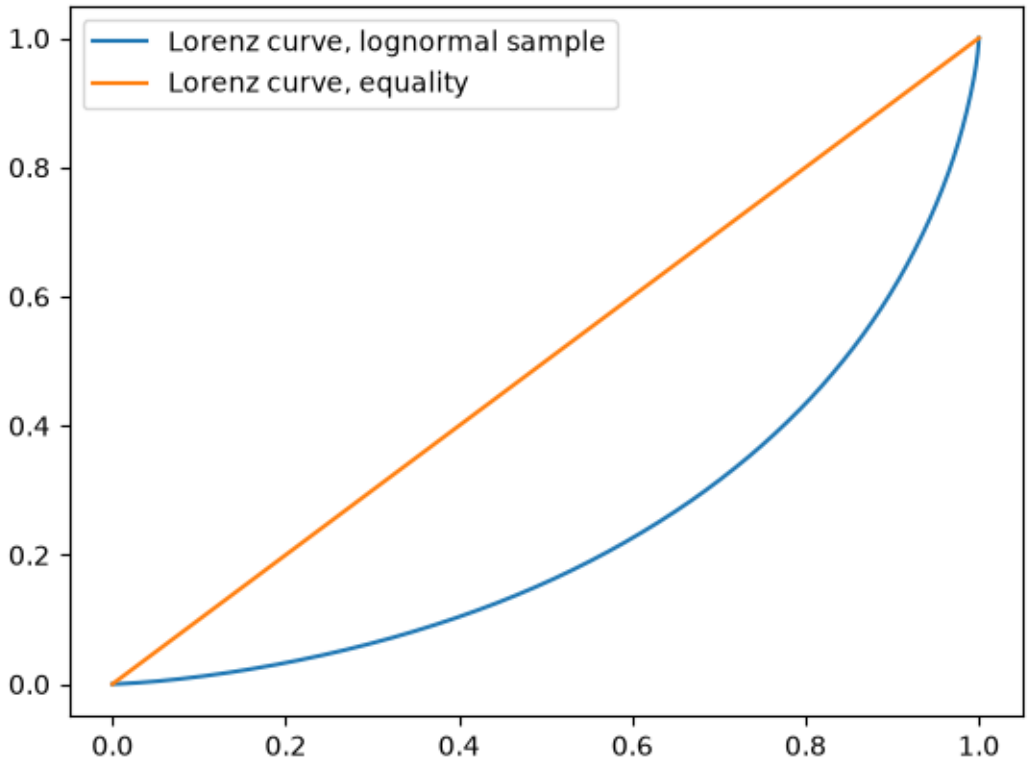
Before we investigate wealth dynamics, we briefly review some measures of inequality.

48.2.1 Lorenz Curves

One popular graphical measure of inequality is the Lorenz curve.

The package QuantEcon.py, already imported above, contains a function to compute Lorenz curves.

To illustrate, suppose that



```
rng = np.random.default_rng()
n = 10_000                       # size of sample
w = np.exp(rng.standard_normal(n))   # lognormal draws
```

is data representing the wealth of 10,000 households.

We can compute and plot the Lorenz curve as follows:

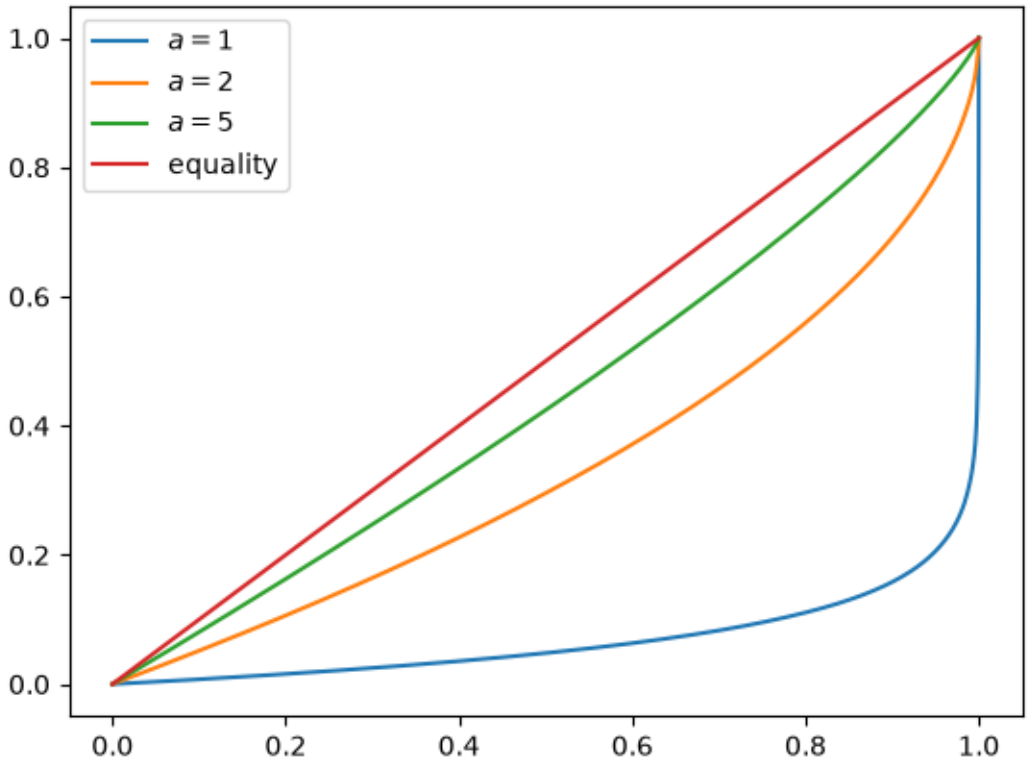
```
f_vals, l_vals = qe.lorenz_curve(w)

fig, ax = plt.subplots()
ax.plot(f_vals, l_vals, label='Lorenz curve, lognormal sample')
ax.plot(f_vals, f_vals, label='Lorenz curve, equality')
ax.legend()
plt.show()
```

This curve can be understood as follows: if point (x, y) lies on the curve, it means that, collectively, the bottom $(100x)\%$ of the population holds $(100y)\%$ of the wealth.

The "equality" line is the 45 degree line (which might not be exactly 45 degrees in the figure, depending on the aspect ratio).

A sample that produces this line exhibits perfect equality.



The other line in the figure is the Lorenz curve for the lognormal sample, which deviates significantly from perfect equality.

For example, the bottom 80% of the population holds around 40% of total wealth.

Here is another example, which shows how the Lorenz curve shifts as the underlying distribution changes.

We generate 10,000 observations using the Pareto distribution with a range of parameters, and then compute the Lorenz curve corresponding to each set of observations.

```
a_vals = (1, 2, 5)              # Pareto tail index
n = 10_000                      # size of each sample
fig, ax = plt.subplots()
for a in a_vals:
    u = rng.uniform(size=n)
    y = u**(-1/a)               # distributed as Pareto with tail index a
    f_vals, l_vals = qe.lorenz_curve(y)
    ax.plot(f_vals, l_vals, label=f'$a = {a}$')
ax.plot(f_vals, f_vals, label='equality')
ax.legend()
plt.show()
```

You can see that, as the tail parameter of the Pareto distribution increases, inequality decreases.

This is to be expected, because a higher tail index implies less weight in the tail of the Pareto distribution.

48.2.2 The Gini Coefficient

The definition and interpretation of the Gini coefficient can be found on the corresponding Wikipedia page.

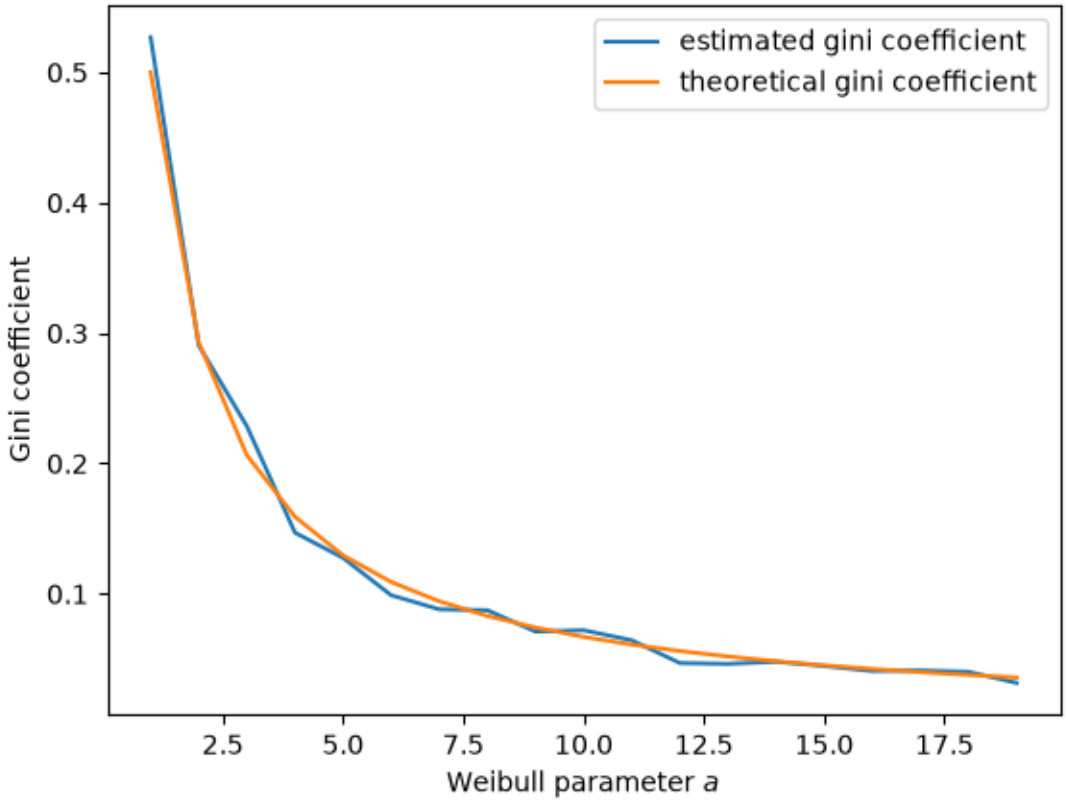
A value of 0 indicates perfect equality (corresponding the case where the Lorenz curve matches the 45 degree line) and a value of 1 indicates complete inequality (all wealth held by the richest household).

The QuantEcon.py library contains a function to calculate the Gini coefficient.

We can test it on the Weibull distribution with parameter a, where the Gini coefficient is known to be

$$G = 1 - 2^{-1/a}$$

Let's see if the Gini coefficient computed from a simulated sample matches this at each fixed value of a.



```
a_vals = range(1, 20)
ginis = []
ginis_theoretical = []
n = 100

fig, ax = plt.subplots()
for a in a_vals:
    y = rng.weibull(a, size=n)
    ginis.append(qe.gini_coefficient(y))
    ginis_theoretical.append(1 - 2**(-1/a))
ax.plot(a_vals, ginis, label='estimated gini coefficient')
```

(continues on next page)

(continued from previous page)

```
ax.plot(a_vals, ginis_theoretical, label='theoretical gini coefficient')
ax.legend()
ax.set_xlabel("Weibull parameter $a$")
ax.set_ylabel("Gini coefficient")
plt.show()
```

The simulation shows that the fit is good.

48.3 A Model of Wealth Dynamics

Having discussed inequality measures, let us now turn to wealth dynamics.

The model we will study is

$$w_{t+1} = (1 + r_{t+1})s(w_t) + y_{t+1} \tag{48.1}$$

where

- w_t is wealth at time t for a given household,
- r_t is the rate of return of financial assets,
- y_t is current non-financial (e.g., labor) income and
- $s(w_t)$ is current wealth net of consumption

Letting $\{z_t\}$ be a correlated state process of the form

$$z_{t+1} = az_t + b + \sigma_z \epsilon_{t+1}$$

we'll assume that

$$R_t := 1 + r_t = c_r \exp(z_t) + \exp(\mu_r + \sigma_r \xi_t)$$

and

$$y_t = c_y \exp(z_t) + \exp(\mu_y + \sigma_y \zeta_t)$$

Here $\{(\epsilon_t, \xi_t, \zeta_t)\}$ is IID and standard normal in $\mathbb{R}^3$.

The value of c_r should be close to zero, since rates of return on assets do not exhibit large trends.

When we simulate a population of households, we will assume all shocks are idiosyncratic (i.e., specific to individual households and independent across them).

Regarding the savings function s, our default model will be

$$s(w) = s_0 w \cdot \mathbb{1}\{w \geq \hat{w}\} \tag{48.2}$$

where s_0 is a positive constant.

Thus, for $w < \hat{w}$, the household saves nothing. For $w \geq \bar{w}$, the household saves a fraction s_0 of their wealth.

We are using something akin to a fixed savings rate model, while acknowledging that low wealth households tend to save very little.

48.4 Implementation

Here's some type information to help Numba.

```
wealth_dynamics_data = [
    ('w_hat',  float64),    # savings parameter
    ('s_0',    float64),    # savings parameter
    ('c_y',    float64),    # labor income parameter
    ('μ_y',    float64),    # labor income paraemter
    ('σ_y',    float64),    # labor income parameter
    ('c_r',    float64),    # rate of return parameter
    ('μ_r',    float64),    # rate of return parameter
    ('σ_r',    float64),    # rate of return parameter
    ('a',      float64),    # aggregate shock parameter
    ('b',      float64),    # aggregate shock parameter
    ('σ_z',    float64),    # aggregate shock parameter
    ('z_mean', float64),    # mean of z process
    ('z_var', float64),     # variance of z process
    ('y_mean', float64),    # mean of y process
    ('R_mean', float64)     # mean of R process
]
```

Here's a class that stores instance data and implements methods that update the aggregate state and household wealth.

```
@jitclass(wealth_dynamics_data)
class WealthDynamics:

    def __init__(self,
                 w_hat=1.0,
                 s_0=0.75,
                 c_y=1.0,
```

(continues on next page)

(continued from previous page)

```
                μ_y=1.0,
                σ_y=0.2,
                c_r=0.05,
                μ_r=0.1,
                σ_r=0.5,
                a=0.5,
                b=0.0,
                σ_z=0.1):

        self.w_hat, self.s_0 = w_hat, s_0
        self.c_y, self.μ_y, self.σ_y = c_y, μ_y, σ_y
        self.c_r, self.μ_r, self.σ_r = c_r, μ_r, σ_r
        self.a, self.b, self.σ_z = a, b, σ_z

        # Record stationary moments
        self.z_mean = b / (1 - a)
        self.z_var = σ_z**2 / (1 - a**2)
        exp_z_mean = np.exp(self.z_mean + self.z_var / 2)
        self.R_mean = c_r * exp_z_mean + np.exp(μ_r + σ_r**2 / 2)
        self.y_mean = c_y * exp_z_mean + np.exp(μ_y + σ_y**2 / 2)

        # Test a stability condition that ensures wealth does not diverge
        # to infinity.
        α = self.R_mean * self.s_0
        if α >= 1:
            raise ValueError("Stability condition failed.")

    def parameters(self):
        """
        Collect and return parameters.
        """
        parameters = (self.w_hat, self.s_0,
                      self.c_y, self.μ_y, self.σ_y,
                      self.c_r, self.μ_r, self.σ_r,
                      self.a, self.b, self.σ_z)
        return parameters

    def update_states(self, w, z):
        """
        Update one period, given current wealth w and persistent
        state z.
        """

        # Simplify names
        params = self.parameters()
        w_hat, s_0, c_y, μ_y, σ_y, c_r, μ_r, σ_r, a, b, σ_z = params
        zp = a * z + b + σ_z * np.random.randn()

        # Update wealth
        y = c_y * np.exp(zp) + np.exp(μ_y + σ_y * np.random.randn())
        wp = y
        if w >= w_hat:
            R = c_r * np.exp(zp) + np.exp(μ_r + σ_r * np.random.randn())
            wp += R * s_0 * w
        return wp, zp
```

Here's function to simulate the time series of wealth for in individual households.

```
@jit
def wealth_time_series(wdy, w_0, n):
    """
    Generate a single time series of length n for wealth given
    initial value w_0.

    The initial persistent state z_0 for each household is drawn from
    the stationary distribution of the AR(1) process.

        * wdy: an instance of WealthDynamics
        * w_0: scalar
        * n: int

    """
    z = wdy.z_mean + np.sqrt(wdy.z_var) * np.random.randn()
    w = np.empty(n)
    w[0] = w_0
    for t in range(n-1):
        w[t+1], z = wdy.update_states(w[t], z)
    return w
```

Now here's function to simulate a cross section of households forward in time.

Note the use of parallelization to speed up computation.

```
@jit(parallel=True)
def update_cross_section(wdy, w_distribution, shift_length=500):
    """
    Shifts a cross-section of household forward in time

    * wdy: an instance of WealthDynamics
    * w_distribution: array_like, represents current cross-section

    Takes a current distribution of wealth values as w_distribution
    and updates each w_t in w_distribution to w_{t+j}, where
    j = shift_length.

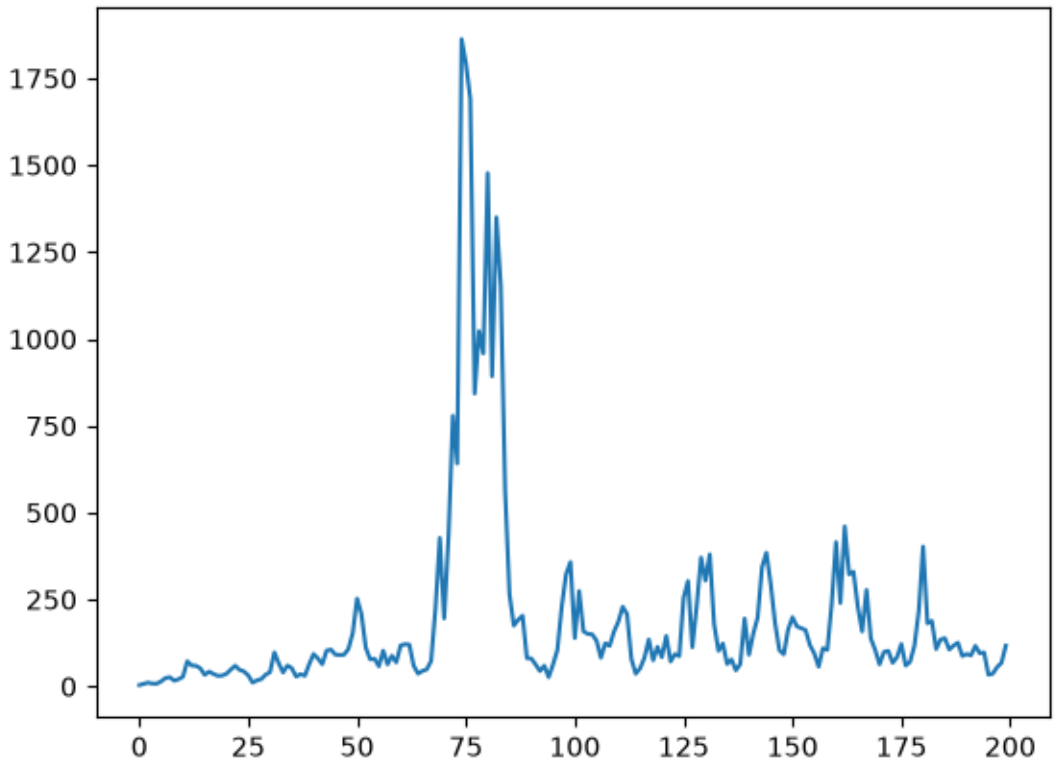
    Returns the new distribution.

    """
    new_distribution = np.empty_like(w_distribution)

    # Update each household
    for i in prange(len(new_distribution)):
        z = wdy.z_mean + np.sqrt(wdy.z_var) * np.random.randn()
        w = w_distribution[i]
        for t in range(shift_length-1):
            w, z = wdy.update_states(w, z)
        new_distribution[i] = w
    return new_distribution
```

Parallelization is very effective in the function above because the time path of each household can be calculated independently once the path for the aggregate state is known.

48.5 Applications



Let's try simulating the model at different parameter values and investigate the implications for the wealth distribution.

48.5.1 Time Series

Let's look at the wealth dynamics of an individual household.

```
wdy = WealthDynamics()
ts_length = 200
w = wealth_time_series(wdy, wdy.y_mean, ts_length)
```

```
fig, ax = plt.subplots()
ax.plot(w)
plt.show()
```

Notice the large spikes in wealth over time.

Such spikes are similar to what we observed in time series when *we studied Kesten processes*.

48.5.2 Inequality Measures

Let's look at how inequality varies with returns on financial assets.

The next function generates a cross section and then computes the Lorenz curve and Gini coefficient.

```
def generate_lorenz_and_gini(wdy, num_households=100_000, T=500):
    """
    Generate the Lorenz curve data and gini coefficient corresponding to a
    WealthDynamics mode by simulating num_households forward to time T.
    """
    ψ_0 = np.full(num_households, wdy.y_mean)
    z_0 = wdy.z_mean

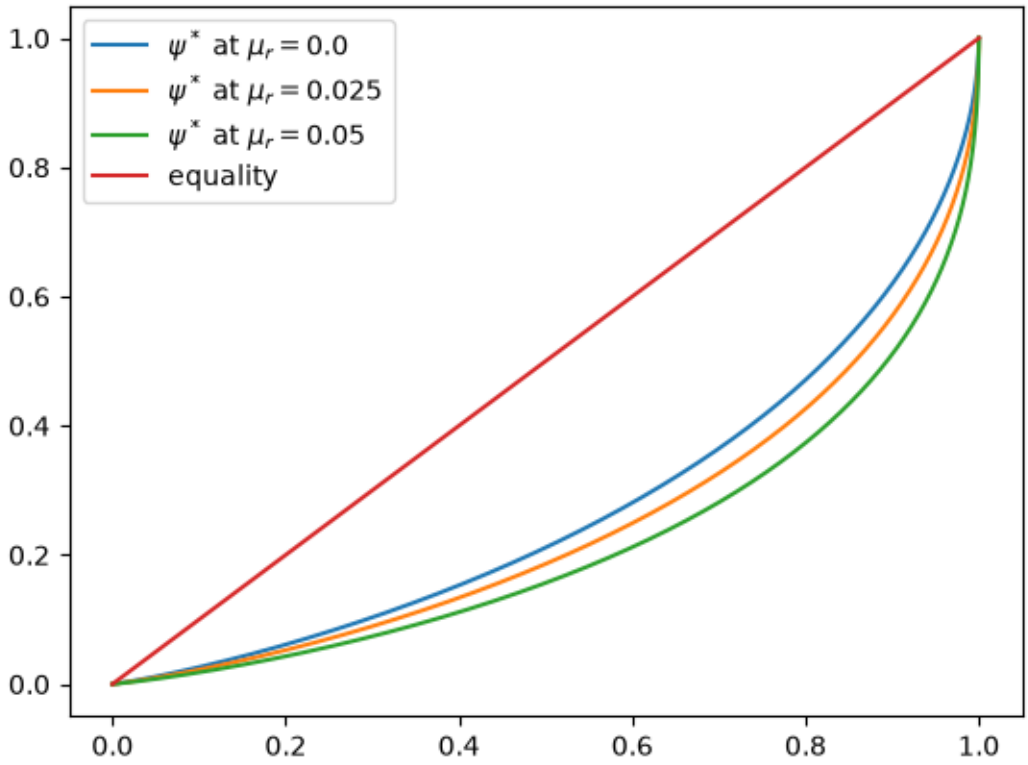
    ψ_star = update_cross_section(wdy, ψ_0, shift_length=T)
    return qe.gini_coefficient(ψ_star), qe.lorenz_curve(ψ_star)
```

Now we investigate how the Lorenz curves associated with the wealth distribution change as return to savings varies.

The code below plots Lorenz curves for three different values of μ_r.

If you are running this yourself, note that it will take one or two minutes to execute.

This is unavoidable because we are executing a CPU intensive task.



In fact the code, which is JIT compiled and parallelized, runs extremely fast relative to the number of computations.

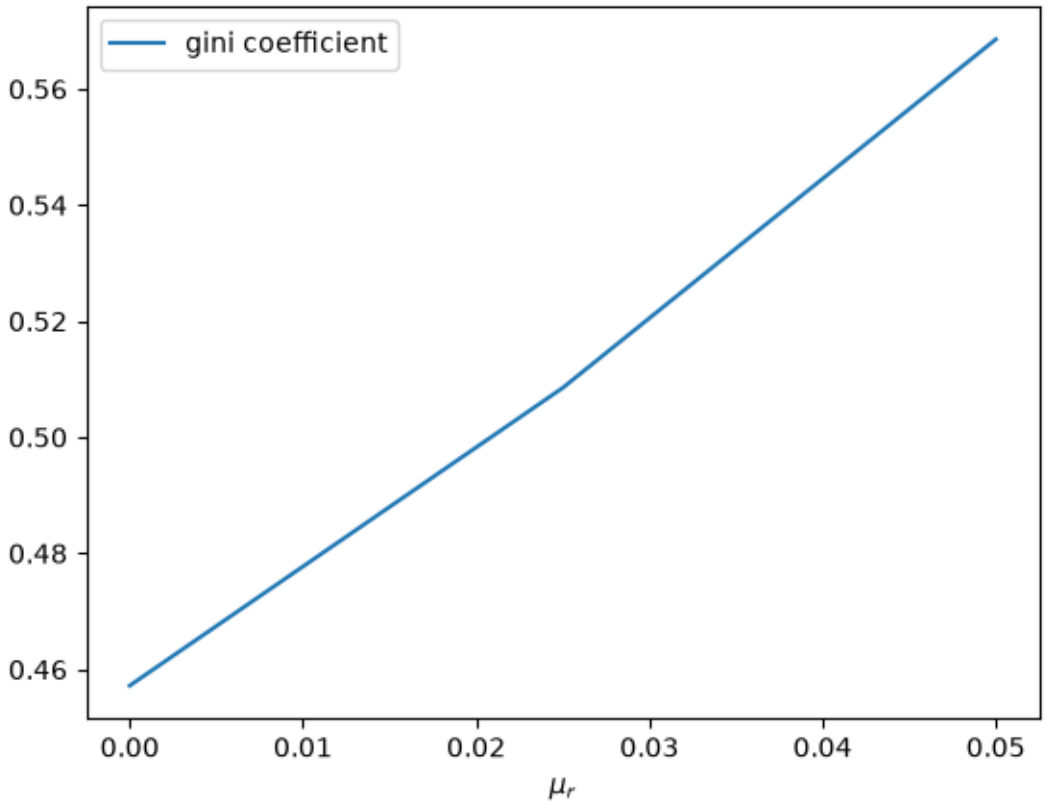
```
%%time

fig, ax = plt.subplots()
μ_r_vals = (0.0, 0.025, 0.05)
gini_vals = []

for μ_r in μ_r_vals:
    wdy = WealthDynamics(μ_r=μ_r)
    gv, (f_vals, l_vals) = generate_lorenz_and_gini(wdy)
    ax.plot(f_vals, l_vals, label=fr'$\psi^*$ at $\mu_r = {μ_r:0.2}$')
    gini_vals.append(gv)

ax.plot(f_vals, f_vals, label='equality')
ax.legend(loc="upper left")
plt.show()
```

```
CPU times: user 39.5 s, sys: 40.9 ms, total: 39.6 s
Wall time: 5.69 s
```



The Lorenz curve shifts downwards as returns on financial income rise, indicating a rise in inequality.

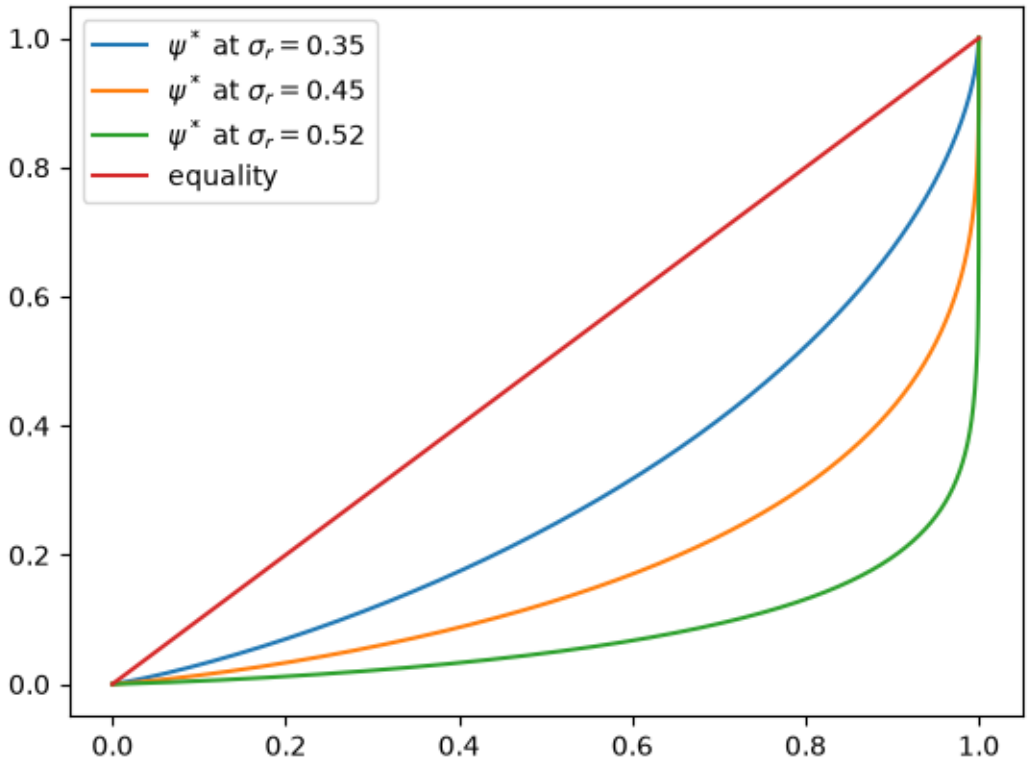
We will look at this again via the Gini coefficient immediately below, but first consider the following image of our system resources when the code above is executing:

Since the code is both efficiently JIT compiled and fully parallelized, it's close to impossible to make this sequence of tasks run faster without changing hardware.

Now let's check the Gini coefficient.

```
fig, ax = plt.subplots()
ax.plot(μ_r_vals, gini_vals, label='gini coefficient')
ax.set_xlabel(r"$\mu_r$")
ax.legend()
plt.show()
```

Once again, we see that inequality increases as returns on financial income rise.



Let's finish this section by investigating what happens when we change the volatility term σ_r in financial returns.

```
%%time

fig, ax = plt.subplots()
σ_r_vals = (0.35, 0.45, 0.52)
gini_vals = []

for σ_r in σ_r_vals:
    wdy = WealthDynamics(σ_r=σ_r)
    gv, (f_vals, l_vals) = generate_lorenz_and_gini(wdy)
    ax.plot(f_vals, l_vals, label=fr'$\psi^*$ at $\sigma_r = {σ_r:0.2}$')
    gini_vals.append(gv)

ax.plot(f_vals, f_vals, label='equality')
ax.legend(loc="upper left")
plt.show()
```

```
CPU times: user 39 s, sys: 28 ms, total: 39.1 s
Wall time: 5.12 s
```

We see that greater volatility has the effect of increasing inequality in this model.

48.6 Exercises

Exercise 48.6.1

For a wealth or income distribution with Pareto tail, a higher tail index suggests lower inequality.

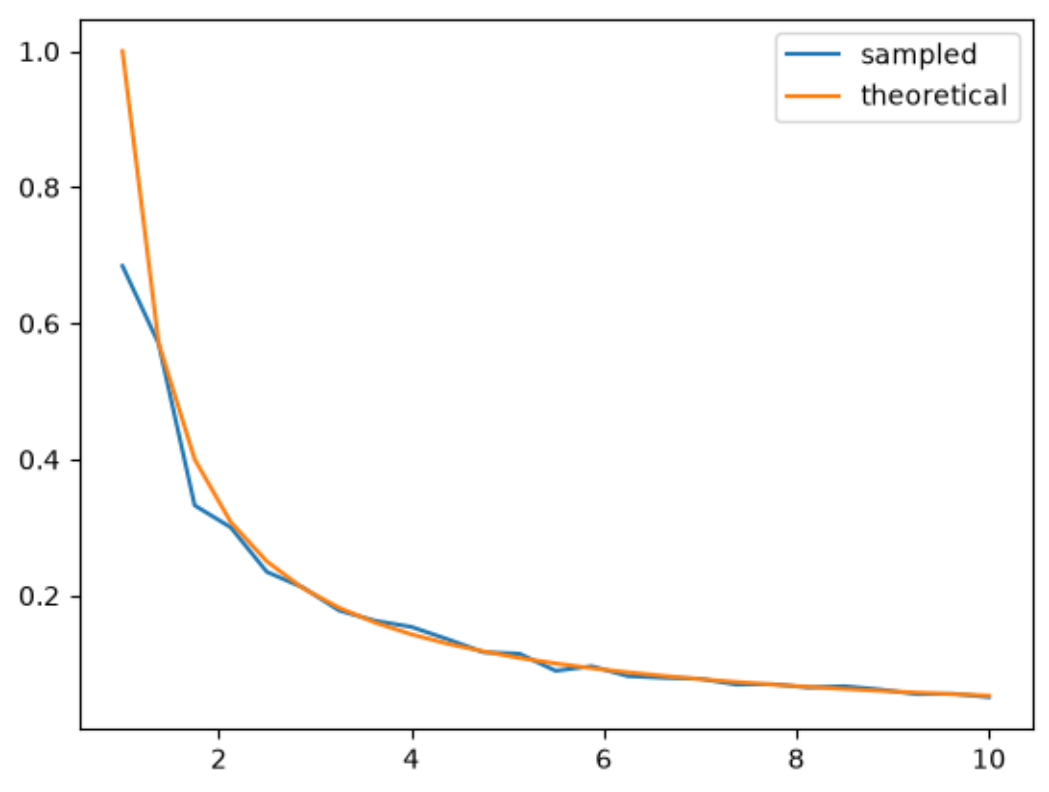
Indeed, it is possible to prove that the Gini coefficient of the Pareto distribution with tail index a is $1/(2a-1)$.

To the extent that you can, confirm this by simulation.

In particular, generate a plot of the Gini coefficient against the tail index using both the theoretical value just given and the value computed from a sample via `qe.gini_coefficient`.

For the values of the tail index, use `a_vals = np.linspace(1, 10, 25)`.

Use sample of size 1,000 for each a and the sampling method for generating Pareto draws employed in the discussion of Lorenz curves for the Pareto distribution.



To the extent that you can, interpret the monotone relationship between the Gini index and a.

Solution

Here is one solution, which produces a good match between theory and simulation.

```
rng = np.random.default_rng()
a_vals = np.linspace(1, 10, 25)  # Pareto tail index
ginis = np.empty_like(a_vals)

n = 1000                         # size of each sample
fig, ax = plt.subplots()
for i, a in enumerate(a_vals):
    y = rng.uniform(size=n)**(-1/a)
    ginis[i] = qe.gini_coefficient(y)
ax.plot(a_vals, ginis, label='sampled')
ax.plot(a_vals, 1/(2*a_vals - 1), label='theoretical')
ax.legend()
plt.show()
```

In general, for a Pareto distribution, a higher tail index implies less weight in the right hand tail.

This means less extreme values for wealth and hence more equality.

More equality translates to a lower Gini index.

Exercise 48.6.2

The wealth process (48.1) is similar to a *Kesten process*.

This is because, according to (48.2), savings is constant for all wealth levels above $\hat{w}$.

When savings is constant, the wealth process has the same quasi-linear structure as a Kesten process, with multiplicative and additive shocks.

The Kesten–Goldie theorem tells us that Kesten processes have Pareto tails under a range of parameterizations.

The theorem does not directly apply here, since savings is not always constant and since the multiplicative and additive terms in (48.1) are not IID.

At the same time, given the similarities, perhaps Pareto tails will arise.

To test this, run a simulation that generates a cross-section of wealth and generate a rank-size plot.

If you like, you can use the function `rank_size` from the `quantecon` library (documentation here).

In viewing the plot, remember that Pareto tails generate a straight line. Is this what you see?

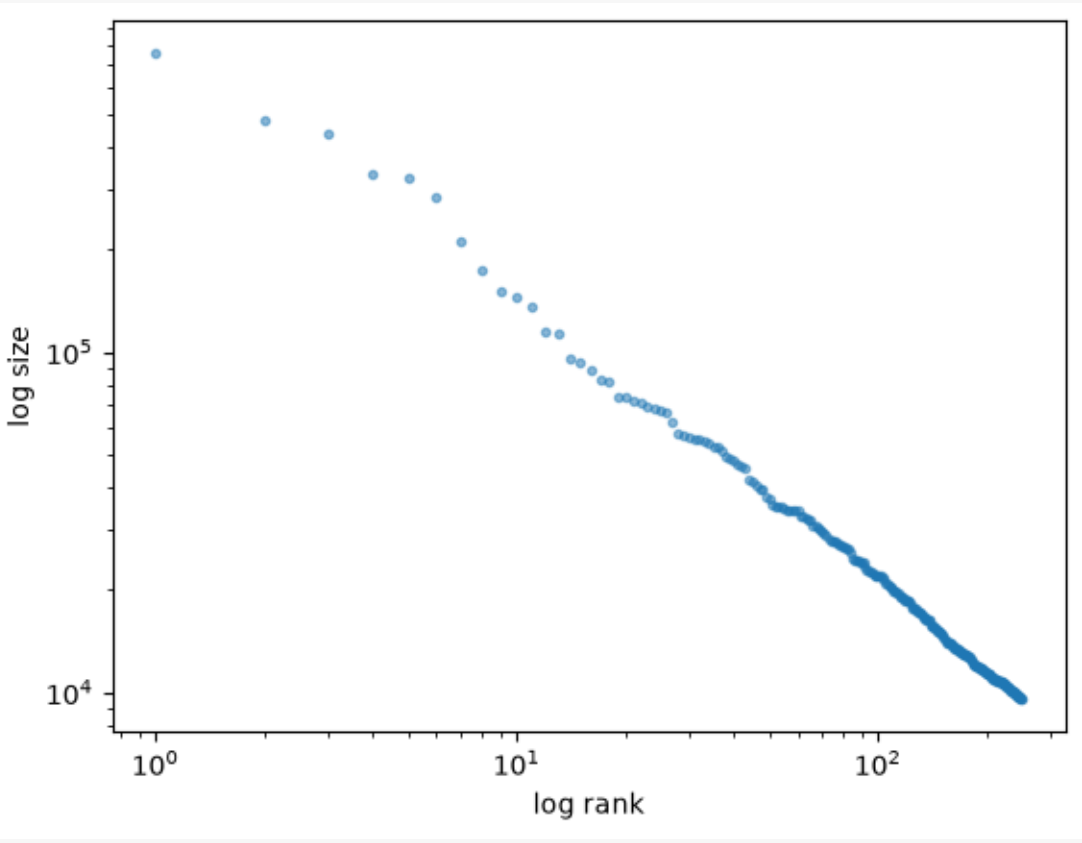
For sample size and initial conditions, use

```
num_households = 250_000
T = 500                                          # shift forward T periods
ψ_0 = np.full(num_households, wdy.y_mean)    # initial distribution
z_0 = wdy.z_mean
```

Solution

First let's generate the distribution:

```
num_households = 250_000
T = 500  # how far to shift forward in time
wdy = WealthDynamics()
ψ_0 = np.full(num_households, wdy.y_mean)
z_0 = wdy.z_mean



ψ_star = update_cross_section(wdy, ψ_0, shift_length=T)
```

Now let's see the rank-size plot:

```
fig, ax = plt.subplots()

rank_data, size_data = qe.rank_size(ψ_star, c=0.001)
ax.loglog(rank_data, size_data, 'o', markersize=3.0, alpha=0.5)
ax.set_xlabel("log rank")
ax.set_ylabel("log size")

plt.show()
```

log size
10^5
10^4
10^0
10^1
10^2
log rank

CHAPTER

FORTYNINE

A FIRST LOOK AT THE KALMAN FILTER

Contents

- *A First Look at the Kalman Filter*
  - *Overview*
  - *The basic idea*
  - *Convergence*
  - *Implementation*
  - *Exercises*

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

49.1 Overview

This lecture provides a simple and intuitive introduction to the Kalman filter

It is aimed at readers who either

- have heard of the Kalman filter but don't know how it works, or
- know the Kalman filter equations, but don't know where they come from

Subsequent lectures use the same recursive logic in more applied and more econometric settings.

See *Another Look at the Kalman Filter* for an economic application in which a firm infers a worker's hidden human capital and effort.

See *The Kalman Filter and Vector Autoregressions* for a derivation of the innovations representation and its connection to vector autoregressions.

Priors, Escapes, and Learning Cycles gives a government that tracks drifting regression coefficients with this filter, and *Drifts and Volatilities* gives an econometrician who does the same for a vector autoregression.

For additional (more advanced) reading on the Kalman filter, see

- [Ljungqvist and Sargent, 2018], section 2.7
- [Anderson and Moore, 2005]

The second reference presents a comprehensive treatment of the Kalman filter.

Required knowledge: Familiarity with matrix manipulations, multivariate normal distributions, covariance matrices, etc.

We'll need the following imports:

```
import matplotlib.pyplot as plt
from scipy import linalg
import numpy as np
from quantecon import Kalman, LinearStateSpace
from scipy.stats import norm, multivariate_normal
from scipy.integrate import quad
from scipy.linalg import eigvals
```

49.2 The basic idea

The Kalman filter has many applications in economics, but for now let's pretend that we are rocket scientists.

A missile has been launched from a hostile country and our mission is to track it.

Let $X_t \in \mathbb{R}^2$ denote the current location of the missile—a pair indicating latitude-longitude coordinates on a map.

At the present moment in time, the location X_t is unknown, but we do have some beliefs about it.

We could certainly produce a point prediction.

For example, it could mark a point on the globe somewhere in northern Mongolia.

But the fact is that we are uncertain.

And the President wants to know: what is the probability that the missile is within 500km of Manhattan?

A point prediction doesn't address that question.

Hence it's best if we can express our current understanding via a bivariate probability density p.

- Now $\int_E p(x)dx$ indicates the probability that the missile is in region E.

We will call p our **prior** for the random variable X.

To keep things tractable, we assume for now that our prior is Gaussian.

In particular, we take

$$p = N(\mu, \Sigma) \tag{49.1}$$

where μ is the (vector) mean of the distribution—a natural point prediction—and Σ is a 2×2 covariance matrix.

In our simulations, we will suppose that

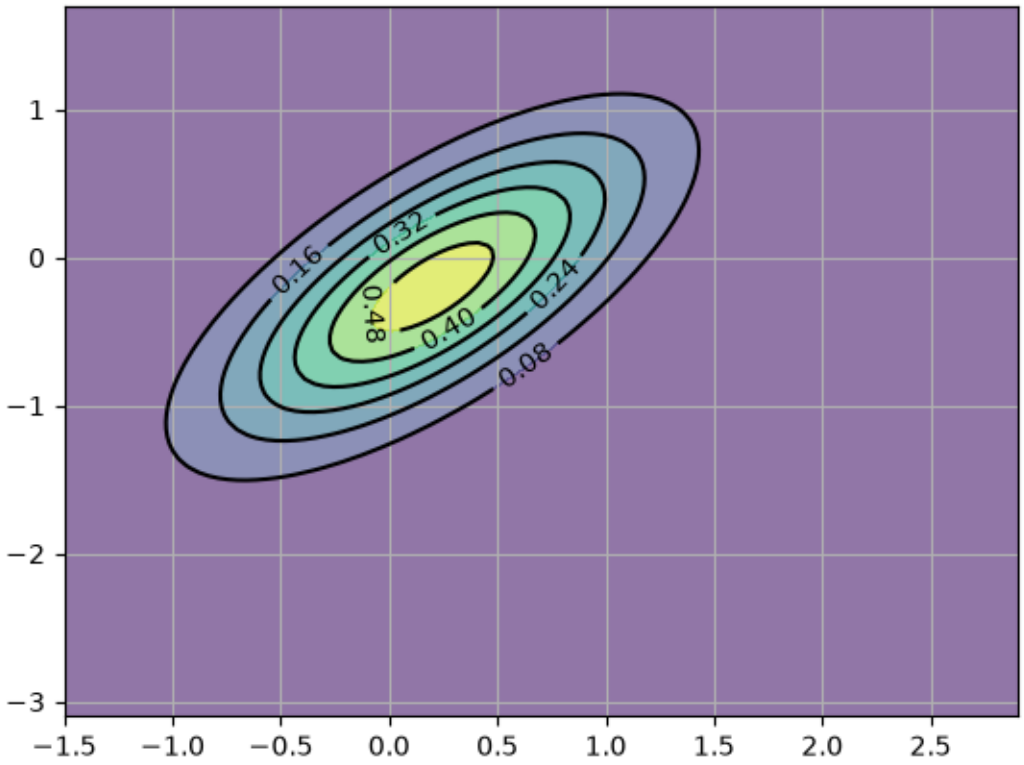
$$\mu = \begin{pmatrix} 0.2 \\ -0.2 \end{pmatrix}, \qquad \Sigma = \begin{pmatrix} 0.4 & 0.3 \\ 0.3 & 0.45 \end{pmatrix} \tag{49.2}$$

This density p is shown below as a contour map, with the center of the red ellipse being equal to μ.

```
# Set up the Gaussian prior density p
Σ = np.array([[0.4, 0.3],
              [0.3, 0.45]])
μ = np.array([[0.2],
              [-0.2]])
# Define the matrices G and R from the measurement equation Y = G X + v
```

(continues on next page)

(continued from previous page)



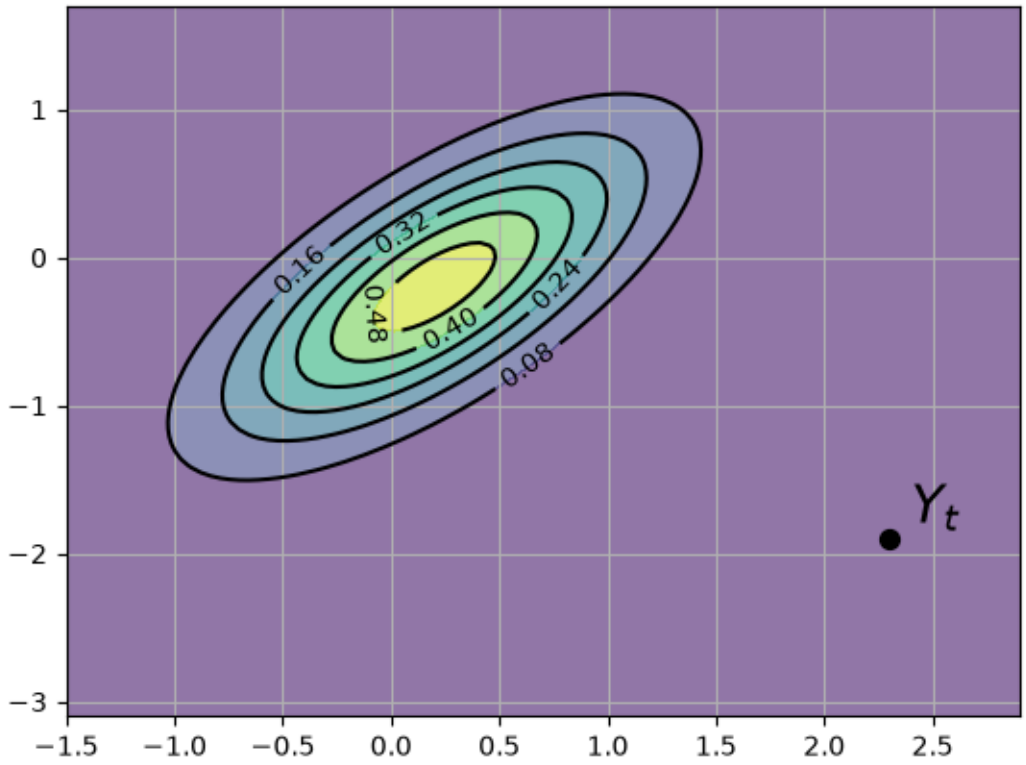
```
G = np.array([[1, 0],
              [0, 1]])
R = 0.5 * Σ
# The matrices A and Q
A = np.array([[1.2, 0],
              [0, -0.2]])
Q = 0.3 * Σ
# The observed value of y
y = np.array([[2.3],
              [-1.9]])

# Set up grid for plotting
x_grid = np.linspace(-1.5, 2.9, 100)
y_grid = np.linspace(-3.1, 1.7, 100)
X, Y = np.meshgrid(x_grid, y_grid)

def gen_gaussian_plot_vals(μ, C):
    "Z values for plotting the bivariate Gaussian N(μ, C)"
    pos = np.dstack((X, Y))
    return multivariate_normal(μ.ravel(), C).pdf(pos)

# Plot the figure

fig, ax = plt.subplots()
ax.grid()
Z = gen_gaussian_plot_vals(μ, Σ)
ax.contourf(X, Y, Z, 6, alpha=0.6, cmap="viridis")
cs = ax.contour(X, Y, Z, 6, colors="black")
ax.clabel(cs, inline=1, fontsize=10)
plt.show()
```



49.2.1 The filtering step

We are now presented with some good news and some bad news.

The good news is that the missile has been located by our sensors, which report that the current location is $Y_t = (2.3, -1.9)$.

The next figure shows the original prior p and the new reported signal Y_t

```
fig, ax = plt.subplots()
ax.grid()
Z = gen_gaussian_plot_vals(μ, Σ)
ax.contourf(X, Y, Z, 6, alpha=0.6, cmap="viridis")
cs = ax.contour(X, Y, Z, 6, colors="black")
ax.clabel(cs, inline=1, fontsize=10)
y_1, y_2 = y[0].item(), y[1].item()
ax.scatter(y_1, y_2, marker="o", s=50, color="black", zorder=3)
ax.text(y_1 + 0.1, y_2 + 0.1, "$Y_t$", fontsize=20, color="black")
plt.show()
```

The bad news is that our sensors are imprecise.

The sensor report is a noisy signal distorted by measurement error.

In particular, we should interpret the output of our sensor not as $Y_t = X_t$, but rather as

$$Y_t = GX_t + v_t, \quad \text{where} \quad v_t \sim N(0, R) \tag{49.3}$$

Here G and R are 2×2 matrices, with R being symmetric and positive definite.

We assume that

- G and R are known
- the noise term v_t is unobservable and independent of X_t

How then should we combine our prior $X_t \sim N(\mu, \Sigma)$ and this new information Y_t to improve our understanding of the location of the missile?

As you may have guessed, the answer is to use Bayes' theorem.

It tells us how to update the prior density $p(x)$ for X_t to the posterior density $p(x \mid y)$ after observing Y_t:

$$p(x \mid Y_t) = \frac{p(Y_t \mid x)\, p(x)}{p(Y_t)}$$

where $p(Y_t) = \int p(Y_t \mid x)\, p(x) dx$.

In solving for $p(x \mid Y_t)$, we observe that

- $p(x)$ is the prior density $N(\mu, \Sigma)$.
- $p(Y_t \mid x)$ is the conditional density of Y_t given $X_t = x$.
- In view of (49.3), this conditional density is $N(Gx, R)$.

Due to our linear Gaussian framework, the updated density turns out to be Gaussian as well.

In particular, the solution is known to be

$$p(x \mid Y_t) = N(\mu^F, \Sigma^F)$$

where

$$\mu^F := \mu + \Sigma G^\top (G \Sigma G^\top + R)^{-1} (y - G\mu) \tag{49.4}$$

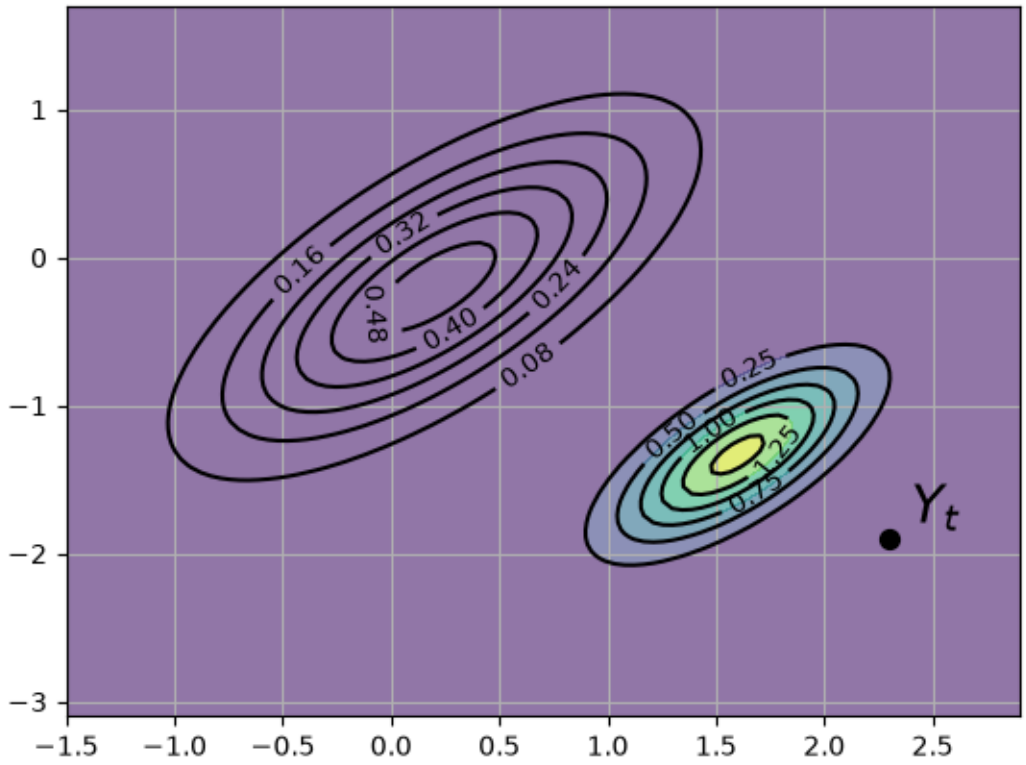
and

$$\Sigma^F := \Sigma - \Sigma G^\top (G \Sigma G^\top + R)^{-1} G \Sigma \tag{49.5}$$

Note

A proof can be found in [Bishop, 2006].

To get from his expressions to the ones used above, you will also need to apply the Woodbury matrix identity.



Here $\Sigma G^\top (G \Sigma G^\top + R)^{-1}$ is the matrix of population regression coefficients of the hidden state deviation $X_t - \mu$ on the *signal surprise* $Y_t - G\mu$.

This new density $p(x \mid Y_t) = N(\mu^F, \Sigma^F)$ is shown in the next figure via contour lines and the color map.

The original density is left in as contour lines for comparison

```
fig, ax = plt.subplots()
ax.grid()

Z = gen_gaussian_plot_vals(μ, Σ)
cs1 = ax.contour(X, Y, Z, 6, colors="black")
ax.clabel(cs1, inline=1, fontsize=10)
M = Σ @ G.T @ linalg.inv(G @ Σ @ G.T + R)
μ_F = μ + M @ (y - G @ μ)
Σ_F = Σ - M @ G @ Σ
new_Z = gen_gaussian_plot_vals(μ_F, Σ_F)
cs2 = ax.contour(X, Y, new_Z, 6, colors="black")
ax.clabel(cs2, inline=1, fontsize=10)
ax.contourf(X, Y, new_Z, 6, alpha=0.6, cmap="viridis")
y_1, y_2 = y[0].item(), y[1].item()
ax.scatter(y_1, y_2, marker="o", s=50, color="black", zorder=3)
ax.text(y_1 + 0.1, y_2 + 0.1, "$Y_t$", fontsize=20, color="black")
plt.show()
```

Our new density twists the prior $p(x)$ in a direction determined by the new information $Y_t - G\mu$.

In generating the figure, we set G to the identity matrix and $R = 0.5\Sigma$ for Σ defined in (49.2).

49.2.2 The forecast step

What have we achieved so far?

We have obtained probabilities for the current location of the state (missile) given prior and current information.

This is called "filtering" rather than forecasting because we are filtering out noise rather than looking into the future.

The posterior $p(x \mid Y_t) = N(\mu^F, \Sigma^F)$ is called the **filtering distribution** for X_t after observing Y_t

But now let's suppose that we are given another task: to predict the location of the missile after one unit of time (whatever that may be) has elapsed.

To do this we need a model of how the state evolves.

Let's suppose that we have one, and that it's linear and Gaussian.

In particular,

$$X_{t+1} = AX_t + W_{t+1}, \quad \text{where} \quad W_t \sim N(0, Q) \tag{49.6}$$

Our aim is to combine this law of motion and our current filtering distribution $N(\mu^F, \Sigma^F)$ to come up with a new **predictive** distribution for the location in one unit of time.

In view of (49.6), all we have to do is introduce a random vector $X^F \sim N(\mu^F, \Sigma^F)$ and work out the distribution of $AX^F + W$ where W is independent of X^F and has distribution $N(0, Q)$.

Since linear combinations of Gaussians are Gaussian, $AX^F + W$ is Gaussian.

Standard calculations and the expressions in (49.4)–(49.5) tell us that

$$\begin{aligned}\mathbb{E}[AX^F + W] &= A\mathbb{E}[X^F] + \mathbb{E}[W] \\ &= A\mu^F \\ &= A\mu + A\Sigma G^\top (G\Sigma G^\top + R)^{-1}(Y_t - G\mu)\end{aligned}$$

and

$$\begin{aligned}\text{Var}[AX^F + W] &= A\,\text{Var}[X^F]A^\top + Q \\ &= A\Sigma^F A^\top + Q \\ &= A\Sigma A^\top + Q - A\Sigma G^\top (G\Sigma G^\top + R)^{-1} G\Sigma A^\top\end{aligned}$$

The matrix $A\Sigma G^\top (G\Sigma G^\top + R)^{-1}$ is often written as K_Σ and called the **Kalman gain**.

- The subscript Σ has been added to remind us that K_Σ depends on Σ, but not Y_t or μ.

Using this notation, we can summarize our results as follows.

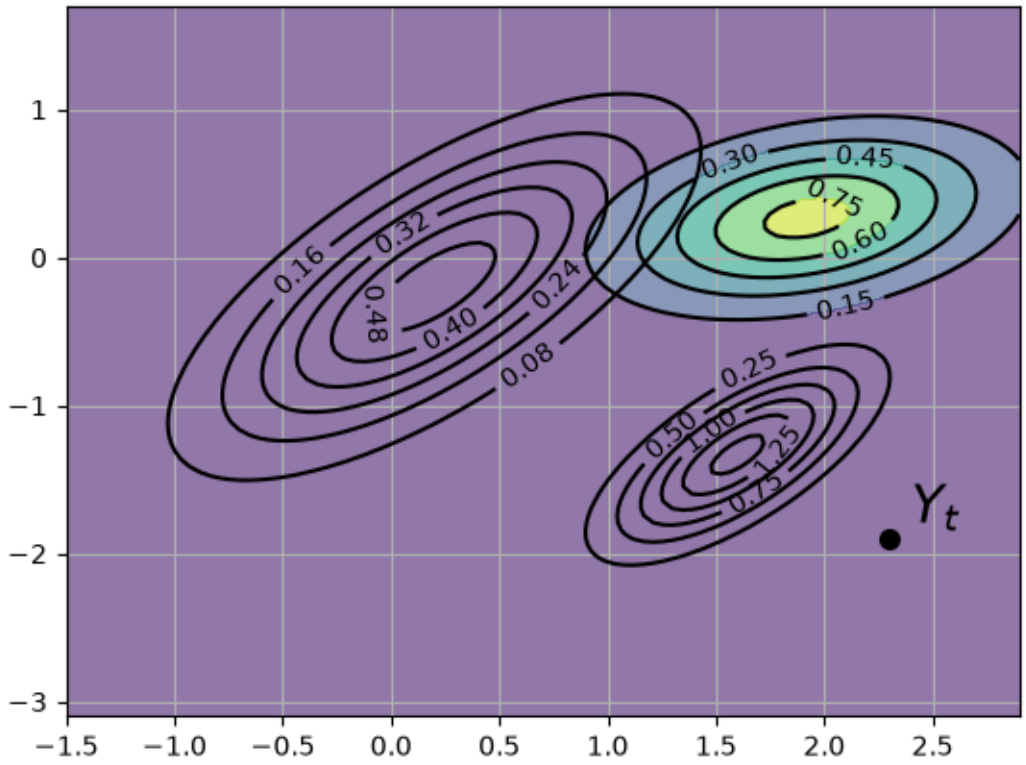
Our updated prediction is the density $N(\mu_{\text{new}}, \Sigma_{\text{new}})$ where

$$\begin{aligned}\mu_{\text{new}} &:= A\mu + K_\Sigma (y - G\mu) \\ \Sigma_{\text{new}} &:= A\Sigma A^\top - K_\Sigma G\Sigma A^\top + Q\end{aligned}$$

- The density $p_{\text{new}}(x) = N(\mu_{\text{new}}, \Sigma_{\text{new}})$ is called the **predictive distribution**

The predictive distribution is the new density shown in the following figure, where the update has used parameters.

$$A = \begin{pmatrix} 1.2 & 0.0 \\ 0.0 & -0.2 \end{pmatrix}, \qquad Q = 0.3\Sigma$$



```
fig, ax = plt.subplots()
ax.grid()

# Density 1
Z = gen_gaussian_plot_vals(μ, Σ)
cs1 = ax.contour(X, Y, Z, 6, colors="black")
ax.clabel(cs1, inline=1, fontsize=10)

# Density 2
M = Σ @ G.T @ linalg.inv(G @ Σ @ G.T + R)
μ_F = μ + M @ (y - G @ μ)
Σ_F = Σ - M @ G @ Σ
Z_F = gen_gaussian_plot_vals(μ_F, Σ_F)
cs2 = ax.contour(X, Y, Z_F, 6, colors="black")
ax.clabel(cs2, inline=1, fontsize=10)

# Density 3
new_μ = A @ μ_F
new_Σ = A @ Σ_F @ A.T + Q
new_Z = gen_gaussian_plot_vals(new_μ, new_Σ)
cs3 = ax.contour(X, Y, new_Z, 6, colors="black")
ax.clabel(cs3, inline=1, fontsize=10)
ax.contourf(X, Y, new_Z, 6, alpha=0.6, cmap="viridis")
y_1, y_2 = y[0].item(), y[1].item()
ax.scatter(y_1, y_2, marker="o", s=50, color="black", zorder=3)
ax.text(y_1 + 0.1, y_2 + 0.1, "$Y_t$", fontsize=20, color="black")

plt.show()
```

49.2.3 The recursive procedure

Let's look back at what we've done.

We started the current period with a prior density $p_t(x)$ for the hidden state X_t.

We then observed the signal Y_t and updated the prior density to the filtering density $p_t(x \mid Y_t)$.

Finally, we used the law of motion (49.6) for $\{X_t\}$ to update to the predictive density $p_{t+1}(x)$ for X_{t+1}.

If we now step into the next period, we are ready to go round again, taking $p_{t+1}(x)$ as the current prior density and reading in the new observation Y_{t+1}.

Using this time-indexed notation, the full recursive procedure is:

1. Start the current period with prior density $p_t(x) = N(\mu_t, \Sigma_t)$ for X_t.
2. Observe current signal $Y_t = y_t$.
3. Compute the filtering density $p_t(x \mid y_t) = N(\mu_t^F, \Sigma_t^F)$ from $p_t(x)$ and y_t, applying Bayes rule and the conditional distribution (49.3).
4. Compute the predictive density $p_{t+1}(x) = N(\mu_{t+1}, \Sigma_{t+1})$ for X_{t+1} from the filtering density and (49.6).
5. Increment t by one and go to step 1.

Repeating (49.7), the dynamics for μ_t and Σ_t are as follows

$$\mu_{t+1} = A\mu_t + K_{\Sigma_t}(y_t - G\mu_t)$$
$$\Sigma_{t+1} = A\Sigma_t A^\top - K_{\Sigma_t} G \Sigma_t A^\top + Q$$

These are the standard dynamic equations for the Kalman filter (see, for example, [Ljungqvist and Sargent, 2018], page 58).

Note

Here μ_t is the filter's prediction of the hidden state X_t.

In much of the Kalman filter literature it is written $\hat{x}_t$, emphasizing that it is an estimate of X_t.

49.3 Convergence

The matrix Σ_t is a measure of the uncertainty of our prediction μ_t of X_t.

Apart from special cases, this uncertainty will never be fully resolved, regardless of how much time elapses.

One reason is that our prediction μ_t is made based on information available at $t-1$, not t.

Even if we knew the precise realized value $X_{t-1} = x_{t-1}$ (which we don't), the transition equation (49.6) implies that $X_t = Ax_{t-1} + W_t$.

Since the shock W_t is not observable at $t-1$, any time $t-1$ prediction of X_t will incur some error (unless W_t is degenerate).

However, it is certainly possible that Σ_t converges to a constant matrix as $t \to \infty$.

To study this topic, let's expand the second equation in (49.7):

$$\Sigma_{t+1} = A\Sigma_t A^\top - A\Sigma_t G^\top (G\Sigma_t G^\top + R)^{-1} G\Sigma_t A^\top + Q \tag{49.7}$$

This is a nonlinear difference equation in Σ_t.

A fixed point of (49.7) is a constant matrix Σ such that

$$\Sigma = A\Sigma A^\top - A\Sigma G^\top (G\Sigma G^\top + R)^{-1} G\Sigma A^\top + Q \tag{49.8}$$

Equation (49.7) is known as a discrete-time Riccati difference equation.

Equation (49.8) is known as a discrete-time algebraic Riccati equation.

Conditions under which a fixed point exists and the sequence $\{\Sigma_t\}$ converges to it are discussed in [Anderson *et al.*, 1996] and [Anderson and Moore, 2005], chapter 4.

A sufficient (but not necessary) condition is that all the eigenvalues λ_i of A satisfy $|\lambda_i| < 1$.

See, for example, [Anderson and Moore, 2005], p. 77.

(This strong condition assures that the unconditional distribution of X_t converges as $t \to \infty$.)

In this case, for any symmetric nonnegative definite initial choice of Σ_0, the sequence $\{\Sigma_t\}$ in (49.7) converges to a nonnegative symmetric matrix Σ that solves (49.8).

49.4 Implementation

The class `Kalman` from the QuantEcon.py package implements the Kalman filter

- Instance data consists of:
  - the moments (μ_t, Σ_t) of the current prior, stored as the attributes `x_hat` and `Sigma` (the mean μ_t is named `x_hat` because it is also written $\hat{x}_t$ in much of the literature).
  - An instance of the LinearStateSpace class from QuantEcon.py.

The latter represents a linear state space model of the form

$$X_{t+1} = AX_t + Cw_{t+1}$$
$$Y_t = GX_t + Hv_t$$

where X_t and Y_t denote random variables, and the shocks w_t and v_t are IID standard normals.

To connect this with the notation of this lecture we set

$$Q := CC^\top \quad \text{and} \quad R := HH^\top$$

- The class `Kalman` from the QuantEcon.py package has a number of methods, some that we will wait to use until we study more advanced applications in subsequent lectures.
- Methods pertinent for this lecture are:
  - `prior_to_filtered`, which updates (μ_t, Σ_t) to (μ_t^F, Σ_t^F)
  - `filtered_to_forecast`, which updates the filtering distribution to the predictive distribution – which becomes the new prior $(\mu_{t+1}, \Sigma_{t+1})$
  - `update`, which combines the last two methods
  - a `stationary_values`, which computes the solution to (49.8) and the corresponding (stationary) Kalman gain

You can view the program on GitHub.

49.5 Exercises

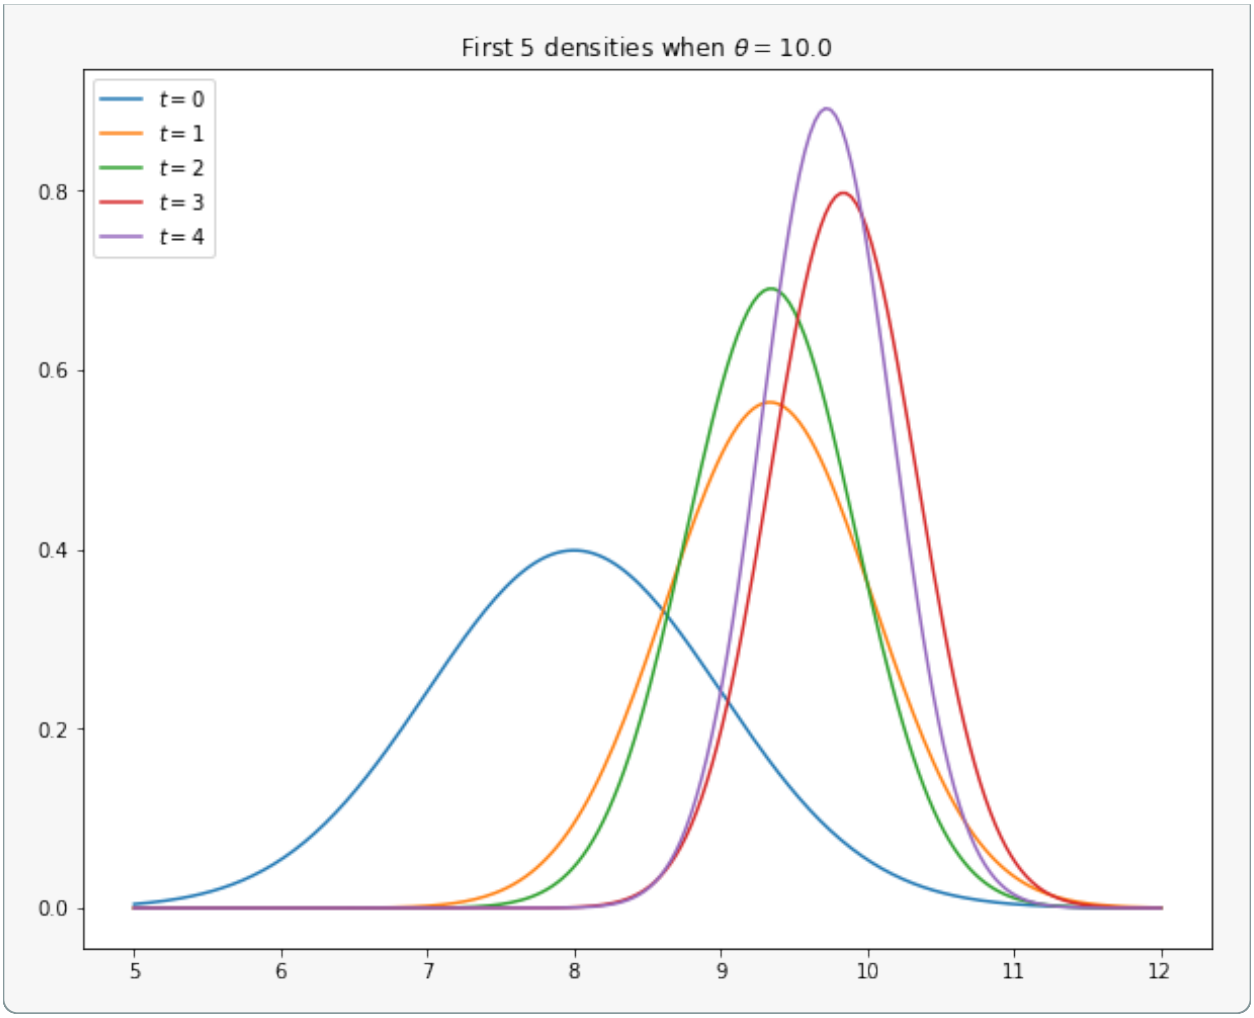
Exercise 49.5.1

Consider the following simple application of the Kalman filter, loosely based on [Ljungqvist and Sargent, 2018], section 2.9.2.

Suppose that

- all variables are scalars
- the hidden state $\{X_t\}$ is in fact constant, equal to some $\theta \in \mathbb{R}$ unknown to the modeler

State dynamics are therefore given by (49.6) with $A = 1$, $Q = 0$ and $X_0 = \theta$.



The measurement equation is $Y_t = \theta + v_t$ where v_t is $N(0, 1)$ and IID.

The task of this exercise is to simulate the model and, using the code from `kalman.py`, plot the first five predictive densities $p_t(x) = N(\mu_t, \Sigma_t)$ for X_t.

As shown in [Ljungqvist and Sargent, 2018], sections 2.9.1–2.9.2, these distributions asymptotically put all mass on the unknown value θ.

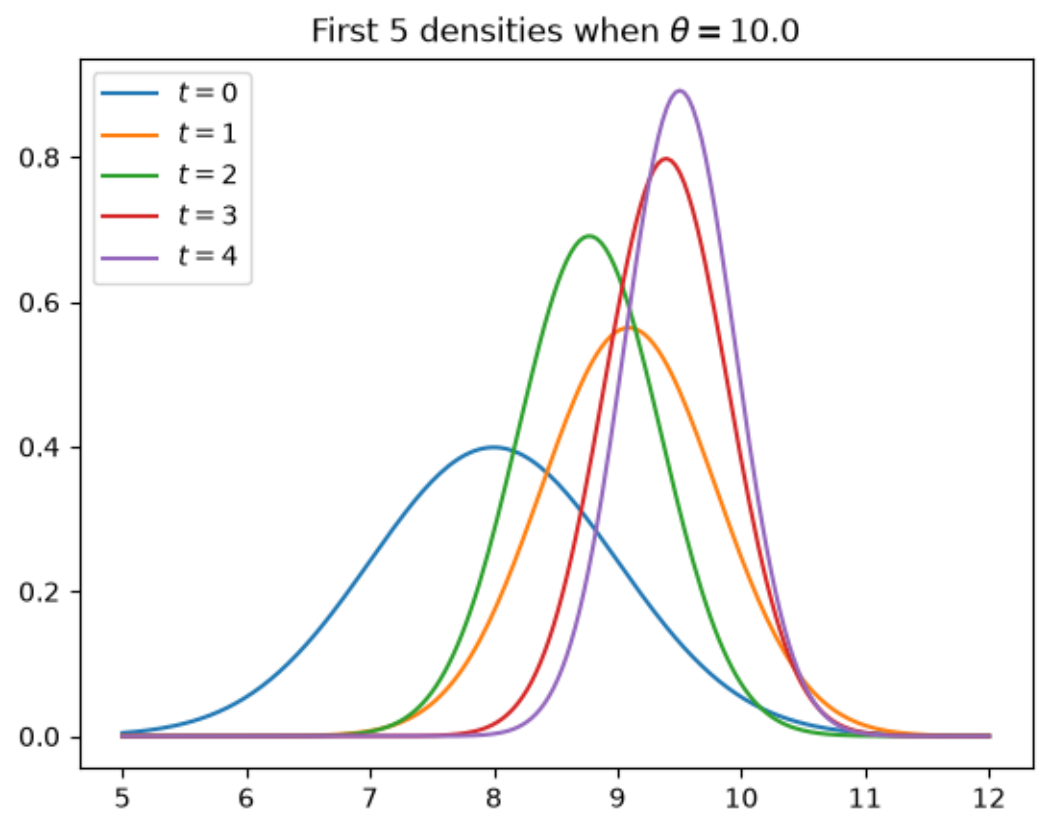
In the simulation, take $\theta = 10$, $\mu_0 = 8$ and $\Sigma_0 = 1$.

Your figure should – modulo randomness – look something like this

Solution

Here is one solution:

```
# Parameters
θ = 10  # Constant value of state X_t
A, C, G, H = 1, 0, 1, 1
ss = LinearStateSpace(A, C, G, H, mu_0=θ)



# Set prior, initialize kalman filter
μ_0, Σ_0 = 8, 1
kalman = Kalman(ss, μ_0, Σ_0)

# Draw observations of y from state space model
N = 5
x, y = ss.simulate(N)
y = y.flatten()

# Set up plot
fig, ax = plt.subplots()
xgrid = np.linspace(θ - 5, θ + 2, 200)
```

```
for i in range(N):
    # Record the current predicted mean and variance
    m, v = kalman.x_hat.item(), kalman.Sigma.item()
    # Plot, update filter
    ax.plot(xgrid, norm.pdf(xgrid, loc=m, scale=np.sqrt(v)), label=f'$t={i}$')
    kalman.update(y[i])

ax.set_title(f'First {N} densities when $\\theta = {θ:.1f}$')
ax.legend(loc='upper left')
plt.show()
```

Exercise 49.5.2

The preceding figure gives some support to the idea that probability mass converges to θ.

To get a better idea, choose a small $\epsilon > 0$ and calculate the error

$$z_t := 1 - \int_{\theta-\epsilon}^{\theta+\epsilon} p_t(x)dx$$

for $t = 0, 1, 2, \ldots, T$.

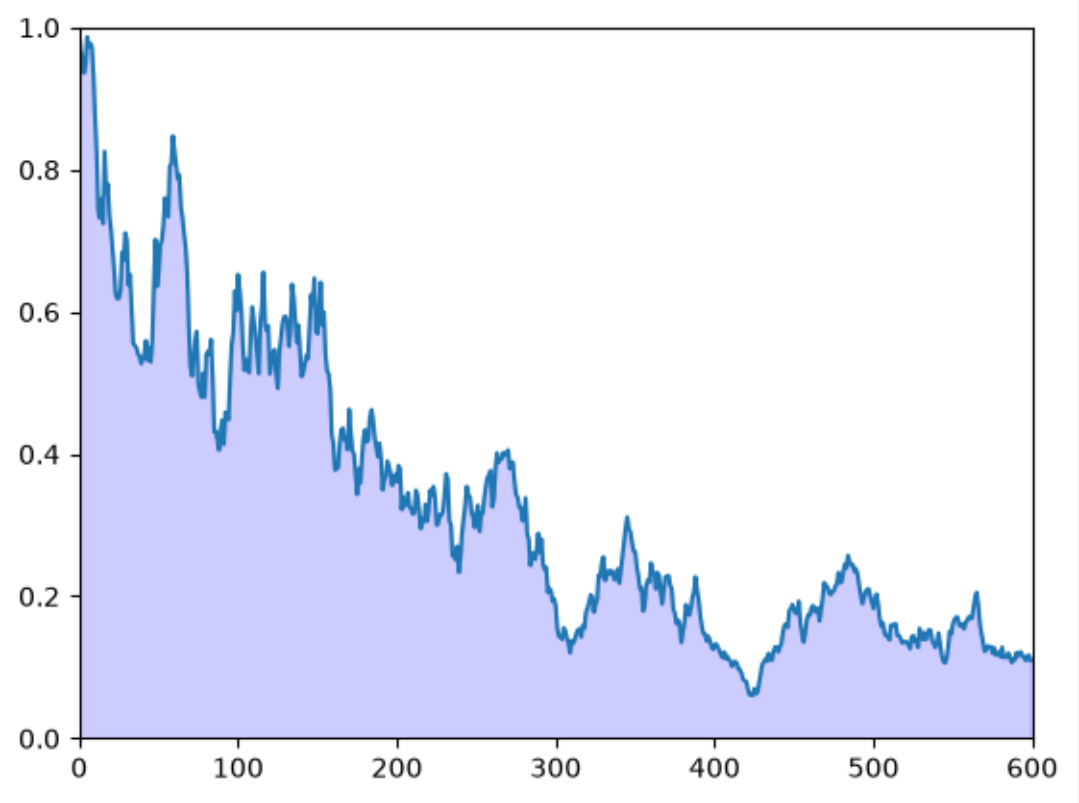
Plot z_t against t, setting $\epsilon = 0.1$ and $T = 600$.

Solution

Here is one solution:

```
ϵ = 0.1
θ = 10  # Constant value of state X_t
A, C, G, H = 1, 0, 1, 1
ss = LinearStateSpace(A, C, G, H, mu_0=θ)

μ_0, Σ_0 = 8, 1
kalman = Kalman(ss, μ_0, Σ_0)



T = 600
z = np.empty(T)
x, y = ss.simulate(T)
y = y.flatten()

for t in range(T):
    # Record the current predicted mean and variance and plot their densities
    m, v = kalman.x_hat.item(), kalman.Sigma.item()

    f = lambda x: norm.pdf(x, loc=m, scale=np.sqrt(v))
    integral, error = quad(f, θ - ϵ, θ + ϵ)
    z[t] = 1 - integral

    kalman.update(y[t])

fig, ax = plt.subplots()
ax.set_ylim(0, 1)
ax.set_xlim(0, T)
ax.plot(range(T), z)
ax.fill_between(range(T), np.zeros(T), z, color="blue", alpha=0.2)
plt.show()
```

Exercise 49.5.3

As discussed *above*, if the shock sequence $\{W_t\}$ is not degenerate, then it is not in general possible to predict X_t without error at time $t-1$ (and this would be the case even if we could observe X_{t-1}).

Let's now compare the prediction μ_t made by the Kalman filter against a competitor who **is** allowed to observe X_{t-1}.

This competitor will use the conditional expectation $\mathbb{E}[X_t \mid X_{t-1}]$, which in this case is AX_{t-1}.

The conditional expectation is known to be the optimal prediction method in terms of minimizing mean squared error.

(More precisely, the minimizer of $\mathbb{E}\,\|X_t - g(X_{t-1})\|^2$ with respect to g is $g^*(X_{t-1}) := \mathbb{E}[X_t \mid X_{t-1}]$)

Thus we are comparing the Kalman filter against a competitor who has more information (in the sense of being able to observe the latent state) and behaves optimally in terms of minimizing squared error.

Our horse race will be assessed in terms of realized squared error.

In particular, your task is to generate a graph plotting simulated realizations of both $\|X_t - AX_{t-1}\|^2$ and $\|X_t - \mu_t\|^2$ against t for $t = 1, \ldots, 49$.

In the code below, `x[:, t]` is the realized value of X_t along the simulated path.

For the parameters, set $G = I$, $R = 0.5I$ and $Q = 0.3I$, where I is the 2×2 identity.

Set

$$A = \begin{pmatrix} 0.5 & 0.4 \\ 0.6 & 0.3 \end{pmatrix}$$

To initialize the prior density, set

$$\Sigma_0 = \begin{pmatrix} 0.9 & 0.3 \\ 0.3 & 0.9 \end{pmatrix}$$

and $\mu_0 = (8, 8)$.

Finally, set the realized initial state to $x_0 = (0, 0)$.

Solution

Here is one solution:

```
# Define A, C, G, H
G = np.identity(2)
H = np.sqrt(0.5) * np.identity(2)

A = [[0.5, 0.4],
     [0.6, 0.3]]
C = np.sqrt(0.3) * np.identity(2)

# Set up state space mode, initial value x_0 set to zero
ss = LinearStateSpace(A, C, G, H, mu_0 = np.zeros(2))

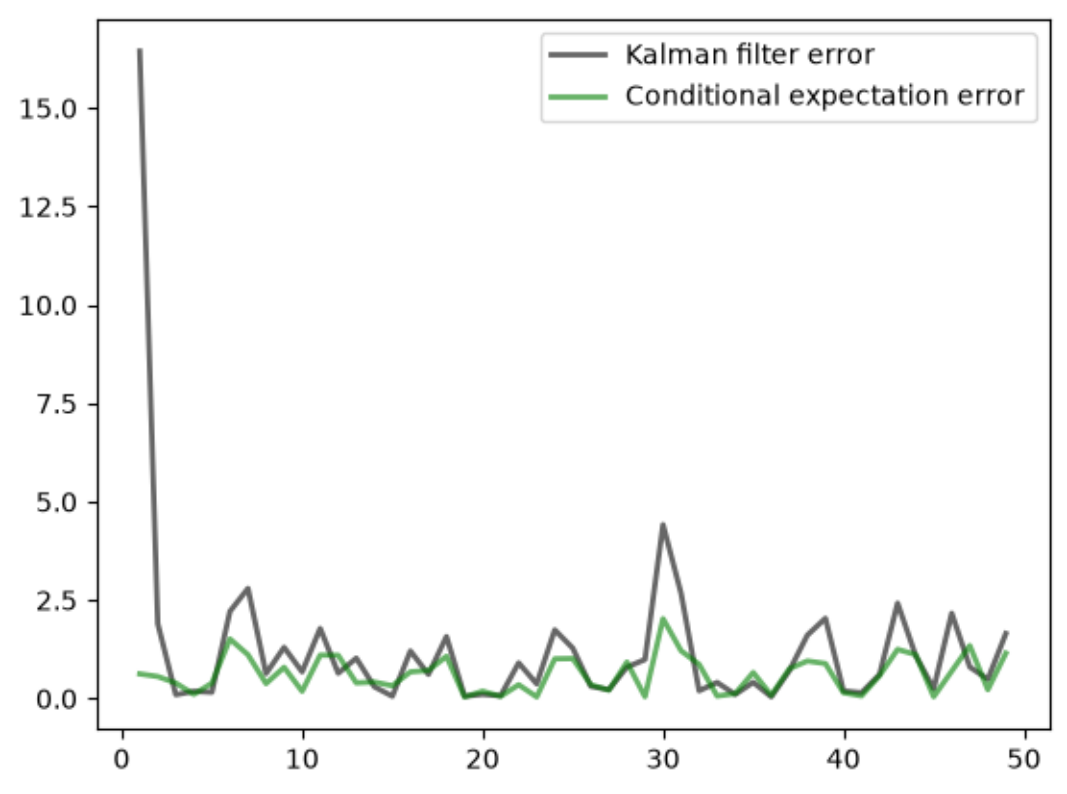
# Define the prior density
Σ = [[0.9, 0.3],
     [0.3, 0.9]]
Σ = np.array(Σ)
μ = np.array([8, 8])

# Initialize the Kalman filter
kn = Kalman(ss, μ, Σ)

# Print eigenvalues of A
print("Eigenvalues of A:")
print(eigvals(A))

# Print stationary Σ
S, K = kn.stationary_values()
print("Stationary prediction error variance:")
print(S)

# Generate the plot
T = 50
x, y = ss.simulate(T)



e1 = np.empty(T-1)
e2 = np.empty(T-1)

for t in range(1, T):
    kn.update(y[:, t-1])
    diff1 = x[:, t] - kn.x_hat.flatten()
    diff2 = x[:, t] - A @ x[:, t-1]
    e1[t-1] = diff1 @ diff1
    e2[t-1] = diff2 @ diff2

fig, ax = plt.subplots()
```

```
ax.plot(range(1, T), e1, 'k-', lw=2, alpha=0.6,
        label='Kalman filter error')
ax.plot(range(1, T), e2, 'g-', lw=2, alpha=0.6,
        label='Conditional expectation error')
ax.legend()
plt.show()
```

```
Eigenvalues of A:
[ 0.9+0.j -0.1+0.j]
Stationary prediction error variance:
[[0.40329108 0.1050718 ]
 [0.1050718  0.41061709]]
```

Observe how, after an initial learning period, the Kalman filter performs quite well, even relative to the competitor who predicts optimally with knowledge of the latent state.

Exercise 49.5.4

Try varying the coefficient 0.3 in $Q = 0.3I$ up and down.

Observe how the diagonal values in the stationary solution Σ (see (49.8)) increase and decrease in line with this coefficient.

The interpretation is that more randomness in the law of motion for X_t causes more (permanent) uncertainty in prediction.

ANOTHER LOOK AT THE KALMAN FILTER

Contents

- *Another Look at the Kalman Filter*
  - *A worker's output*
  - *A firm's wage-setting policy*
  - *A state-space representation*
  - *An innovations representation*
  - *Some computational experiments*
  - *Future extensions*

In *A First Look at the Kalman Filter*, we used a Kalman filter to estimate locations of a rocket.

In this lecture, we'll use the Kalman filter to infer a worker's human capital and the effort that the worker devotes to accumulating human capital, neither of which the firm observes directly.

This lecture is an application of the filtering and forecasting recursion introduced in *A First Look at the Kalman Filter*.

The firm learns about those things only by observing a history of the output that the worker generates for the firm, and from understanding how that output depends on the worker's human capital and how human capital evolves as a function of the worker's effort.

We'll posit a rule that expresses how much the firm pays the worker each period as a function of the firm's information each period.

The lecture *The Kalman Filter and Vector Autoregressions* uses the same recursion to construct innovations, likelihoods, and vector autoregressions.

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

To conduct simulations, we bring in these imports, as in *A First Look at the Kalman Filter*.

```
import matplotlib.pyplot as plt
import numpy as np
from quantecon import Kalman, LinearStateSpace
from typing import NamedTuple
from scipy.stats import multivariate_normal
import matplotlib as mpl
```

(continues on next page)

(continued from previous page)

```
mpl.rcParams['text.usetex'] = True
mpl.rcParams['text.latex.preamble'] = r'\usepackage{amsmath,amsfonts}'
```

50.1 A worker's output

A representative worker is permanently employed at a firm.

A worker's output is described by the following dynamic process:

$$
\begin{aligned}
h_{t+1} &= \alpha h_t + \beta u_t + c\epsilon_{t+1}, \quad \epsilon_{t+1} \sim N(0,1) \\
u_{t+1} &= u_t \\
y_t &= g h_t + v_t, \quad v_t \sim N(0,R)
\end{aligned} \tag{50.1}
$$

Here

- h_t is the logarithm of human capital at time t
- u_t is the logarithm of the worker's effort at accumulating human capital at t
- y_t is the logarithm of the worker's output at time t
- ϵ_{t+1} is an IID standard normal shock to human capital
- $h_0 \sim N(\hat{h}_0, \sigma^2_{h,0})$
- $u_0 \sim N(\hat{u}_0, \sigma^2_{u,0})$

Parameters of the model are $\alpha, \beta, c, R, g, \hat{h}_0, \hat{u}_0, \sigma_{h,0}, \sigma_{u,0}$ where $\sigma_{h,0}$ and $\sigma_{u,0}$ are standard deviations of the firm's initial beliefs about h_0 and u_0.

We assume that h_0, u_0, $\{\epsilon_t\}$, and $\{v_t\}$ are mutually independent.

At time 0, a firm has hired the worker.

The worker is permanently attached to the firm and so works for the same firm at all dates $t = 0, 1, 2, ...$

At the beginning of time 0, the firm observes neither the worker's innate initial human capital h_0 nor its hard-wired permanent effort level u_0.

The firm believes that u_0 for a particular worker is drawn from a Gaussian probability distribution, and so is described by $u_0 \sim N(\hat{u}_0, \sigma^2_{u,0})$.

The h_t part of a worker's "type" moves over time, while the equation $u_{t+1} = u_t$ implies $u_t = u_0$ for all t.

Thus, from the firm's point of view, effort is a fixed, unobserved component of the worker's type that must be inferred from output observations.

At the beginning of time $t \geq 1$, before setting the wage w_t, the firm has observed the history $y^{t-1} = [y_{t-1}, y_{t-2}, \ldots, y_0]$.

The firm does not observe the worker's "type" (h_0, u_0).

After production in period t, the firm observes the worker's output y_t, which it then uses to update its beliefs going into period $t+1$.

50.2 A firm's wage-setting policy

At time $t \geq 1$, before observing current output y_t, the firm sets the worker's log wage using the past output history y^{t-1}:

$$w_t = g\mathbb{E}[h_t | y^{t-1}], \quad t \geq 1$$

and at time 0 pays the worker a log wage equal to the unconditional mean of y_0:

$$w_0 = g\hat{h}_0$$

In using this payment rule, the firm is taking into account that the worker's log output today is partly due to the random component v_t that comes entirely from luck, and that is assumed to be independent of h_t and u_t.

50.3 A state-space representation

Write system *(50.1.1)* in the state-space form

$$\begin{bmatrix} h_{t+1} \\ u_{t+1} \end{bmatrix} = \begin{bmatrix} \alpha & \beta \\ 0 & 1 \end{bmatrix} \begin{bmatrix} h_t \\ u_t \end{bmatrix} + \begin{bmatrix} c \\ 0 \end{bmatrix} \epsilon_{t+1}$$
$$y_t = \begin{bmatrix} g & 0 \end{bmatrix} \begin{bmatrix} h_t \\ u_t \end{bmatrix} + v_t$$

which is equivalent with

$$\begin{aligned} x_{t+1} &= Ax_t + C\epsilon_{t+1} \\ y_t &= Gx_t + v_t \\ x_0 &\sim N(\hat{x}_0, \Sigma_0) \end{aligned} \tag{50.2}$$

where

$$x_t = \begin{bmatrix} h_t \\ u_t \end{bmatrix}, \quad \hat{x}_0 = \begin{bmatrix} \hat{h}_0 \\ \hat{u}_0 \end{bmatrix}, \quad \Sigma_0 = \begin{bmatrix} \sigma_{h,0}^2 & 0 \\ 0 & \sigma_{u,0}^2 \end{bmatrix}$$

To compute the firm's wage setting policy, we first create a `NamedTuple` to store the parameters of the model

```
class WorkerModel(NamedTuple):
    A: np.ndarray
    C: np.ndarray
    G: np.ndarray
    R: float
    xhat_0: np.ndarray
    Σ_0: np.ndarray

def create_worker(α=.8, β=.2, c=.2,
                  R=.5, g=1.0, hhat_0=4, uhat_0=4,
                  σ_h=2, σ_u=2):

    A = np.array([[α, β],
                  [0, 1]])
    C = np.array([[c],
                  [0]])
    G = np.array([g, 0])
```

(continues on next page)

(continued from previous page)

```
    # Define initial state and covariance matrix
    xhat_0 = np.array([[hhat_0],
                       [uhat_0]])

    # σ_h and σ_u are standard deviations, so Σ_0 holds their squares
    Σ_0 = np.array([[σ_h**2, 0],
                    [0, σ_u**2]])

    return WorkerModel(A=A, C=C, G=G, R=R, xhat_0=xhat_0, Σ_0=Σ_0)
```

Please note how the `WorkerModel` NamedTuple creates all of the objects required to compute an associated state-space representation (50.2).

This is handy, because in order to simulate a history $\{y_t, h_t\}$ for a worker, we'll want to form state space system for him/her by using the `LinearStateSpace` class.

```
# Define A, C, G, R, xhat_0, Σ_0
worker = create_worker()
A, C, G, R = worker.A, worker.C, worker.G, worker.R
xhat_0, Σ_0 = worker.xhat_0, worker.Σ_0

# Create a LinearStateSpace object
ss = LinearStateSpace(A, C, G, np.sqrt(R),
        mu_0=xhat_0, Sigma_0=np.zeros((2,2)))

T = 100
x, y = ss.simulate(T)
y = y.flatten()

h_0, u_0 = x[0, 0], x[1, 0]
```

We set `Sigma_0=np.zeros((2,2))` so that the simulation fixes a particular worker's initial state (h_0, u_0), while the firm still enters period 0 with the non-degenerate prior beliefs $\hat{x}_0$ and Σ_0 that drive its Kalman filter.

Next, to compute the firm's policy for setting the log wage based on the information it has about the worker, we use the Kalman filter described in this QuantEcon lecture *A First Look at the Kalman Filter*.

In particular, we want to compute all of the objects in an "innovation representation".

50.4 An innovations representation

We have all the objects in hand required to form an innovations representation for the output process $\{y_t\}_{t=0}^{T-1}$ for a worker.

Let's code that up now.

$$\begin{aligned} \hat{x}_{t+1} &= A\hat{x}_t + K_t a_t \\ y_t &= G\hat{x}_t + a_t \end{aligned}$$

where $\hat{x}_t = \mathbb{E}[x_t | y^{t-1}]$ is the firm's forecast of the state formed before y_t is observed, and K_t is the Kalman gain matrix at time t.

Here $a_t = y_t - G\hat{x}_t$ is the **innovation** at time t, the firm's one-step-ahead error in forecasting output y_t from the history y^{t-1}.

Because $\hat{x}_t$ is conditioned on y^{t-1} rather than y^t, the gain K_t folds together the filtering update that uses the current observation y_t and the one-step-ahead prediction that advances the state to $t+1$.

Writing $\Sigma_t = \mathbb{E}[(x_t - \hat{x}_t)(x_t - \hat{x}_t)' | y^{t-1}]$ for the conditional covariance of the state, the gain is

$$K_t = A\Sigma_t G'(G\Sigma_t G' + R)^{-1} = AL_t,$$

where $L_t = \Sigma_t G'(G\Sigma_t G' + R)^{-1}$ is the filtering gain that updates the firm's beliefs about x_t once y_t is observed.

We accomplish this in the following code that uses the `Kalman` class.

```
kalman = Kalman(ss, xhat_0, Σ_0)
Σ_t = np.zeros((*Σ_0.shape, T))
y_hat_t = np.zeros(T)
x_hat_t = np.zeros((2, T))

for t in range(T):
    # Record the firm's belief about x_t given y^{t-1}, before seeing y_t
    x_hat, Σ = kalman.x_hat, kalman.Sigma
    Σ_t[:, :, t] = Σ
    x_hat_t[:, t] = x_hat.reshape(-1)
    y_hat_t[t] = (worker.G @ x_hat).item()

    # Then incorporate the observation y_t and advance the filter to t+1
    kalman.update(y[t])

u_hat_t = x_hat_t[1, :]
```

For this fixed worker initial state, we plot $\mathbb{E}[y_t | y^{t-1}] = G\hat{x}_t$ where $\hat{x}_t = \mathbb{E}[x_t | y^{t-1}]$.

We also plot $\mathbb{E}[u_0 | y^{t-1}]$, which is the firm's inference about a worker's hard-wired "work ethic" u_0, conditioned on information y^{t-1} that it has about him or her coming into period t.

We can watch how the firm updates its inference $\mathbb{E}[u_0 | y^{t-1}]$ about the worker's work ethic as more output observations arrive.

```
fig, ax = plt.subplots(1, 2)

ax[0].plot(y_hat_t, label=r'$\mathbb{E}[y_t| y^{t-1}]$')
ax[0].set_xlabel('time')
ax[0].set_ylabel(r'$\mathbb{E}[y_t| y^{t-1}]$')
ax[0].set_title(r'$\mathbb{E}[y_t| y^{t-1}]$ over time')
ax[0].legend()

ax[1].plot(u_hat_t, label=r'$\mathbb{E}[u_0|y^{t-1}]$')
ax[1].axhline(y=u_0, color='grey',
              linestyle='dashed', label=fr'$u_0={u_0:.2f}$')
ax[1].set_xlabel('time')
ax[1].set_ylabel(r'$\mathbb{E}[u_0|y^{t-1}]$')
ax[1].set_title('Inferred work ethic over time')
ax[1].legend()

fig.tight_layout()
plt.show()
```

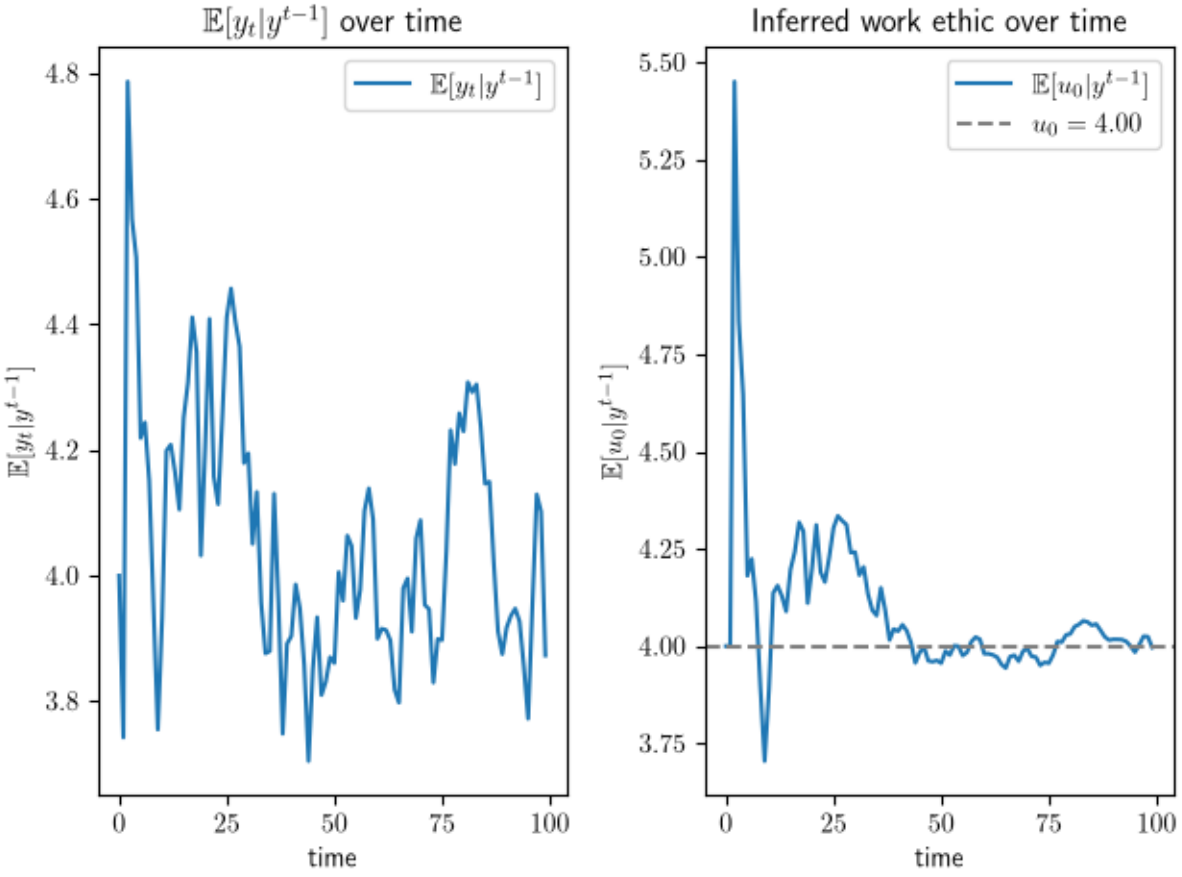

Fig. 50.1: Firm's output forecast and inferred work ethic over time

50.5 Some computational experiments

Let's look at Σ_0 and Σ_{T-1} in order to see how much the firm learns about the hidden state during the horizon we have set.

```
print(Σ_t[:, :, 0])
```

```
[[4. 0.]
 [0. 4.]]
```

```
print(Σ_t[:, :, -1])
```

```
[[0.09403859 0.00997018]
 [0.00997018 0.01592704]]
```

Evidently, the conditional variances become smaller over time.

It is enlightening to portray how the firm's conditional beliefs evolve by plotting contours of the conditional bivariate normal density of x_t given y^{t-1} at various t's.

```
# Create a grid of points for contour plotting
h_range = np.linspace(x_hat_t[0, :].min()-0.5*Σ_t[0, 0, 1],
                      x_hat_t[0, :].max()+0.5*Σ_t[0, 0, 1], 100)
u_range = np.linspace(x_hat_t[1, :].min()-0.5*Σ_t[1, 1, 1],
                      x_hat_t[1, :].max()+0.5*Σ_t[1, 1, 1], 100)
h, u = np.meshgrid(h_range, u_range)

# Create a figure with subplots for each time step
fig, axs = plt.subplots(1, 3, figsize=(12, 7))

# Iterate through each time step
for i, t in enumerate(np.linspace(0, T-1, 3, dtype=int)):
    # Create a multivariate normal distribution with x_hat and Σ at time step t
    μ = x_hat_t[:, t]
    cov = Σ_t[:, :, t]
    mvn = multivariate_normal(mean=μ, cov=cov)

    # Evaluate the multivariate normal PDF on the grid
    pdf_values = mvn.pdf(np.dstack((h, u)))

    # Create a contour plot for the PDF
    con = axs[i].contour(h, u, pdf_values, cmap='viridis')
    axs[i].clabel(con, inline=1, fontsize=10)
    axs[i].set_title(f'time step {t}')
    axs[i].set_xlabel(r'$h_{{{}}}$'.format(str(t)))
    axs[i].set_ylabel(r'$u_{{{}}}$'.format(str(t)))

    cov_latex = (
        r'$\Sigma_{{{}}}= \begin{{bmatrix}} {:.2f} & {:.2f} \\ '
        r'{:.2f} & {:.2f} \end{{bmatrix}}$'
    ).format(t, cov[0, 0], cov[0, 1], cov[1, 0], cov[1, 1])
    axs[i].text(0.33, -0.15, cov_latex, transform=axs[i].transAxes)

plt.tight_layout()
plt.show()
```

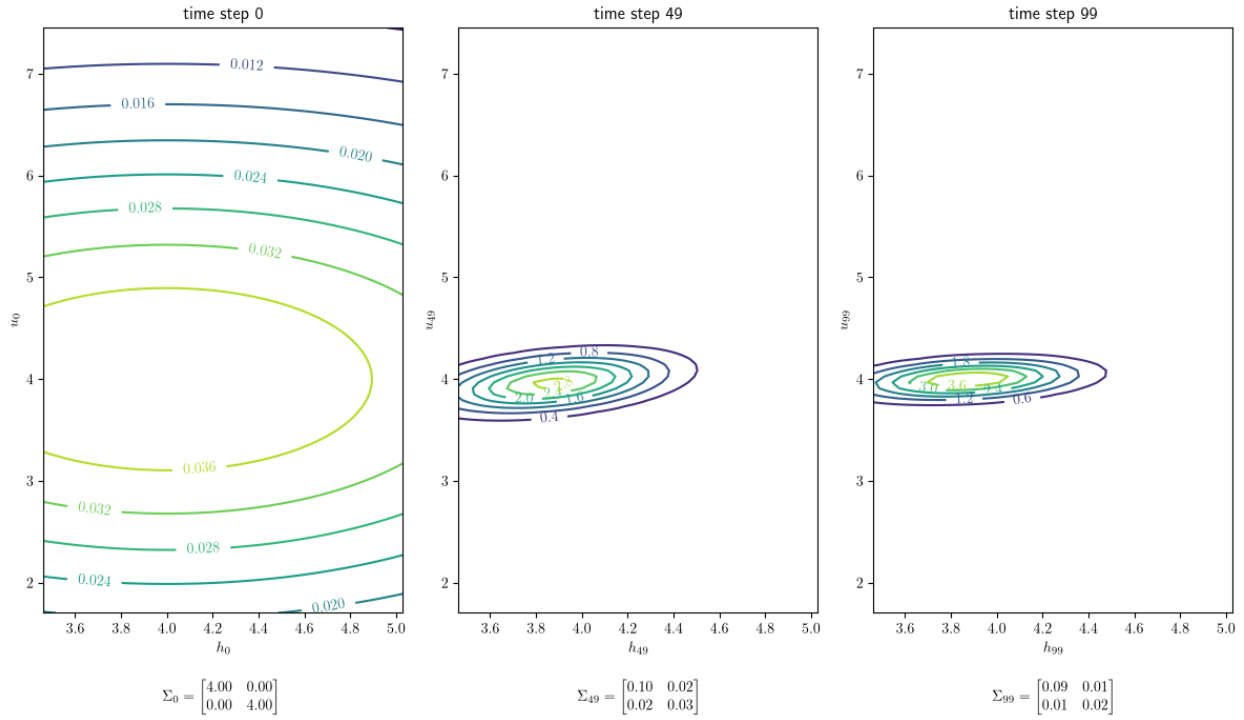

Fig. 50.2: Density contours for the firm's belief about x_t at three dates

Note how the accumulation of evidence y^{t-1} affects the shape of the density contours as sample size t grows.

Now let's use our code to set the hidden state x_0 to a particular vector in order to watch how a firm learns starting from some x_0 we are interested in.

For example, let's say $h_0 = 0$ and $u_0 = 4$.

Here is one way to do this.

```
# For example, we might want h_0 = 0 and u_0 = 4
μ_0 = np.array([[0.0],
                [4.0]])

# Create a LinearStateSpace object with Sigma_0 as a matrix of zeros
ss_example = LinearStateSpace(A, C, G, np.sqrt(R), mu_0=μ_0,
                              # This line forces exact h_0=0 and u_0=4
                              Sigma_0=np.zeros((2, 2))
                             )

T = 100
x, y = ss_example.simulate(T)
y = y.flatten()

# Now h_0=0 and u_0=4
h_0, u_0 = x[0, 0], x[1, 0]
print('h_0 =', h_0)
print('u_0 =', u_0)
```

```
h_0 = 0.0
u_0 = 4.0
```

Another way to accomplish the same goal is to use the following code.

```
# If we want to set the initial
# h_0 = hhat_0 = 0.0 and u_0 = uhat_0 = 4.0:
worker_example = create_worker(hhat_0=0.0, uhat_0=4.0)

# The firm's prior stays at the original xhat_0 and Σ_0
ss_example = LinearStateSpace(A, C, G, np.sqrt(R),
                              # This line takes h_0=hhat_0 and u_0=uhat_0
                              mu_0=worker_example.xhat_0,
                              # This line forces exact h_0=hhat_0 and u_0=uhat_0
                              Sigma_0=np.zeros((2, 2))
                             )

T = 100
x, y = ss_example.simulate(T)
y = y.flatten()

# Now h_0 and u_0 will be exactly hhat_0 and uhat_0
h_0, u_0 = x[0, 0], x[1, 0]
print('h_0 =', h_0)
print('u_0 =', u_0)
```

```
h_0 = 0.0
u_0 = 4.0
```

For this worker, let's generate a plot like the one above.

```
# The firm filters output from ss_example using its prior beliefs
# xhat_0 and Σ_0
kalman = Kalman(ss_example, xhat_0, Σ_0)
Σ_t = []
y_hat_t = np.zeros(T)
u_hat_t = np.zeros(T)

# Then we iteratively update the Kalman filter class using
# observation y based on the linear state model above:
for t in range(T):
    # Record the firm's belief about x_t given y^{t-1}, before seeing y_t
    x_hat, Σ = kalman.x_hat, kalman.Sigma
    Σ_t.append(Σ)
    y_hat_t[t] = (G @ x_hat).item()
    u_hat_t[t] = x_hat[1].item()

    # Then incorporate the observation y_t and advance the filter to t+1
    kalman.update(y[t])

# Generate plots for y_hat_t and u_hat_t
fig, ax = plt.subplots(1, 2)

ax[0].plot(y_hat_t, label=r'$\mathbb{E}[y_t| y^{t-1}]$')
ax[0].set_xlabel('time')
ax[0].set_ylabel(r'$\mathbb{E}[y_t| y^{t-1}]$')
```

(continues on next page)

(continued from previous page)

```
ax[0].set_title(r'$\mathbb{E}[y_t| y^{t-1}]$ over time')
ax[0].legend()

ax[1].plot(u_hat_t, label=r'$\mathbb{E}[u_0|y^{t-1}]$')
ax[1].axhline(y=u_0, color='grey',
              linestyle='dashed', label=fr'$u_0={u_0:.2f}$')
ax[1].set_xlabel('time')
ax[1].set_ylabel(r'$\mathbb{E}[u_0|y^{t-1}]$')
ax[1].set_title('Inferred work ethic over time')
ax[1].legend()

fig.tight_layout()
plt.show()
```

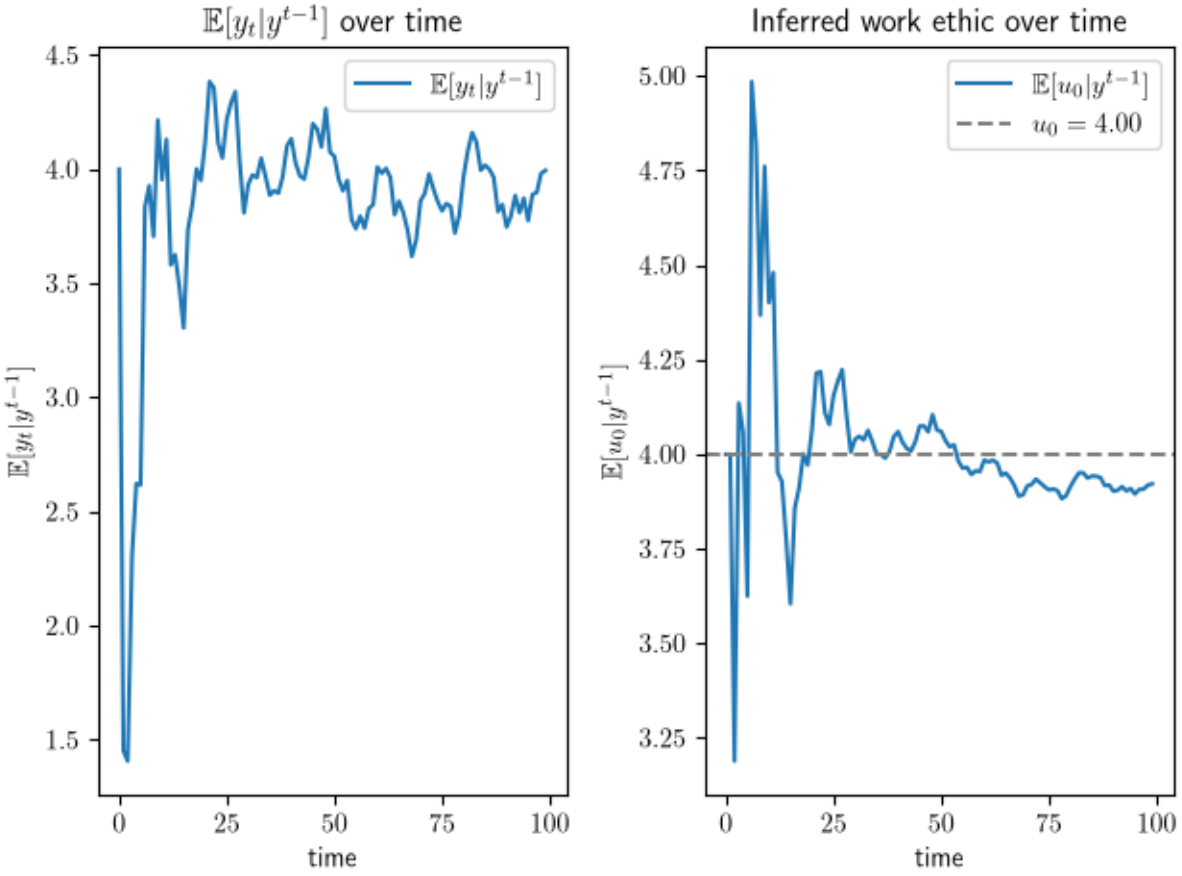

Fig. 50.3: Output forecast and inferred work ethic for the worker with $u_0 = 4$

More generally, we can change some or all of the parameters defining a worker in our `create_worker` factory function.

Here is an example.

```
# We can set these parameters when creating a worker, just like classes!
hard_working_worker = create_worker(α=.4, β=.8,
                        hhat_0=7.0, uhat_0=100, σ_h=2.5, σ_u=3.2)
```

(continues on next page)

(continued from previous page)

```
print(hard_working_worker)
```

```
WorkerModel(A=array([[0.4, 0.8],
       [0. , 1. ]]), C=array([[0.2],
       [0. ]]), G=array([1., 0.]), R=0.5, xhat_0=array([[  7.],
       [100.]]), Σ_0=array([[ 6.25,  0.  ],
       [ 0.  , 10.24]]))
```

We can also simulate the system for $T = 100$ periods for different workers.

When effort feeds into output through human capital, so that $g \neq 0$ and $\beta \neq 0$, the firm's uncertainty about u_0 falls over time and the inferred work ethic converges toward the true u_0.

If $\beta = 0$, effort never affects h_t, and if $g = 0$, output carries no information about h_t, so in either case the firm cannot learn u_0 from output alone.

This shows that, under these observability conditions, the filter gradually teaches the firm about the worker's effort.

For three workers, we first plot the gap between the firm's inferred work ethic and the true u_0 over time.

```
num_workers = 3
T = 100
fig, ax = plt.subplots(figsize=(7, 7))

for i in range(num_workers):
    worker = create_worker(uhat_0=4+2*i)
    simulate_workers(worker, T, ax, name=fr'$\hat u_0 = {4+2*i}$',
                     random_state=2 + i)
ax.set_ylim(ymin=-2, ymax=2)
ax.legend()
plt.show()
```

In this simulation the firm's inferred work ethic moves toward the true u_0.

Under the correctly specified observable linear-Gaussian model, the posterior mean of u_0 is consistent, so this gap shrinks as the output history grows.

By setting `diff=False`, we instead plot the level of each worker's inferred work ethic $\mathbb{E}[u_0|y^{t-1}]$, shown together with a dashed line marking the true u_0.

```
fig, ax = plt.subplots(figsize=(7, 7))

uhat_0s = [2, -2, 1]
αs = [0.2, 0.3, 0.5]
βs = [0.2, 0.9, 0.3]

for i, (uhat_0, α, β) in enumerate(zip(uhat_0s, αs, βs)):
    worker = create_worker(uhat_0=uhat_0, α=α, β=β)
    simulate_workers(worker, T, ax, diff=False,
                     name=r'$u_{{{}, 0}}$'.format(i),
                     random_state=3 + i)

ax.legend(bbox_to_anchor=(1, 0.5))
plt.show()
```

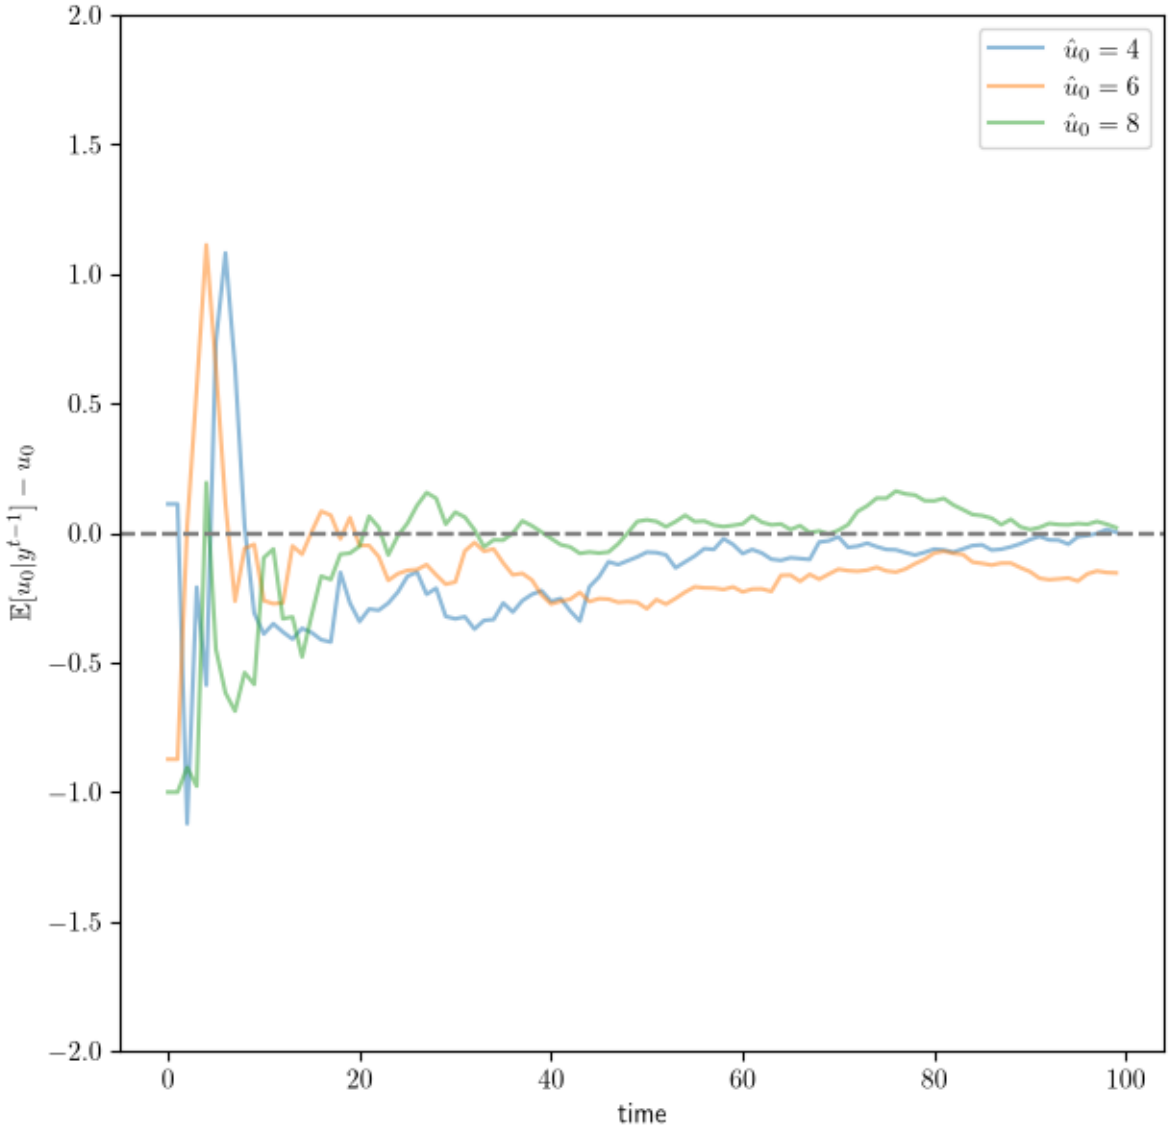

Fig. 50.4: Difference between inferred and true work ethic over time

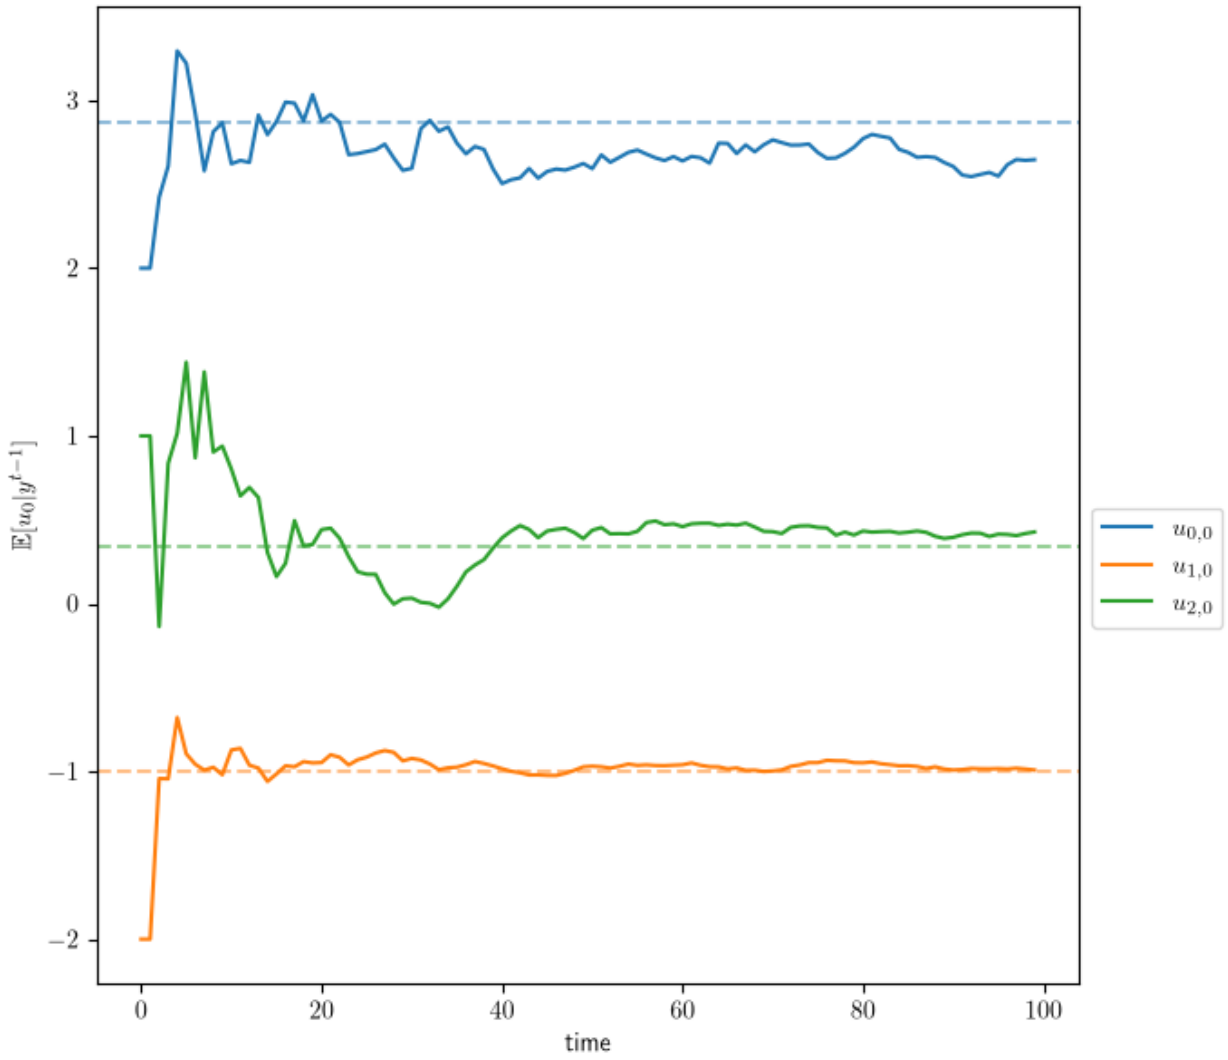

Fig. 50.5: Inferred work ethic over time for three workers

These three workers differ in α and β as well as in $\hat{u}_0$, and the speed of learning differs sharply across them.

The worker with the largest β, here $u_{1,0}$ with $\beta = 0.9$, settles onto its dashed true value almost immediately, while the worker with the smallest β, here $u_{0,0}$ with $\beta = 0.2$, converges slower.

The reason is that effort affects output only through human capital, so in these stable examples with $|\alpha| < 1$ its steady-state effect on output is governed by $g\beta/(1-\alpha)$, and a small β leaves the firm with too little signal to pin down u_0 over this horizon.

The speed of learning also reflects the measurement noise R, the shock scale c, and the firm's prior variances.

We can also give every worker the same true initial state, here $h_0 = 2$ and $u_0 = 1$, by passing a fixed `μ_sim_0` and a zero `Σ_sim_0` to `simulate_workers`.

```
fig, ax = plt.subplots(figsize=(7, 7))

μ_sim_0 = np.array([[2.0],
                    [1.0]])
Σ_sim_0 = np.zeros((2,2))

uhat_0s = [2, -2, 1]
αs = [0.2, 0.3, 0.5]
βs = [0.2, 0.9, 0.3]

for i, (uhat_0, α, β) in enumerate(zip(uhat_0s, αs, βs)):
    worker = create_worker(uhat_0=uhat_0, α=α, β=β)
    simulate_workers(worker, T, ax, μ_sim_0=μ_sim_0, Σ_sim_0=Σ_sim_0,
                     diff=False, name=r'$u_{{{}, 0}}$'.format(i))

# This controls the boundary of plots
ax.set_ylim(ymin=-3, ymax=3)
ax.legend(bbox_to_anchor=(1, 0.5))
plt.show()
```

Even though the firm begins from different prior means $\hat{u}_0$, all three workers share the true work ethic $u_0 = 1$, and the inferred paths converge to that common dashed line at speeds that again reflect each worker's β.

Finally, we track a single worker type under two different true effort levels, comparing a hard-working worker with $u_0 = 100$ against a normal worker with $u_0 = 30$.

```
T = 50
fig, ax = plt.subplots(figsize=(7, 7))

μ_sim_0_1 = np.array([[1],
                      [100]])
μ_sim_0_2 = np.array([[1],
                      [30]])
Σ_sim_0 = np.zeros((2, 2))

worker = create_worker(uhat_0=1, α=0.5, β=0.3)
simulate_workers(worker, T, ax, μ_sim_0=μ_sim_0_1, Σ_sim_0=Σ_sim_0,
                 diff=False, name=r'Hard-working worker')
simulate_workers(worker, T, ax, μ_sim_0=μ_sim_0_2, Σ_sim_0=Σ_sim_0,
                 diff=False, name=r'Normal worker')
ax.legend(bbox_to_anchor=(1, 0.5))
plt.show()
```

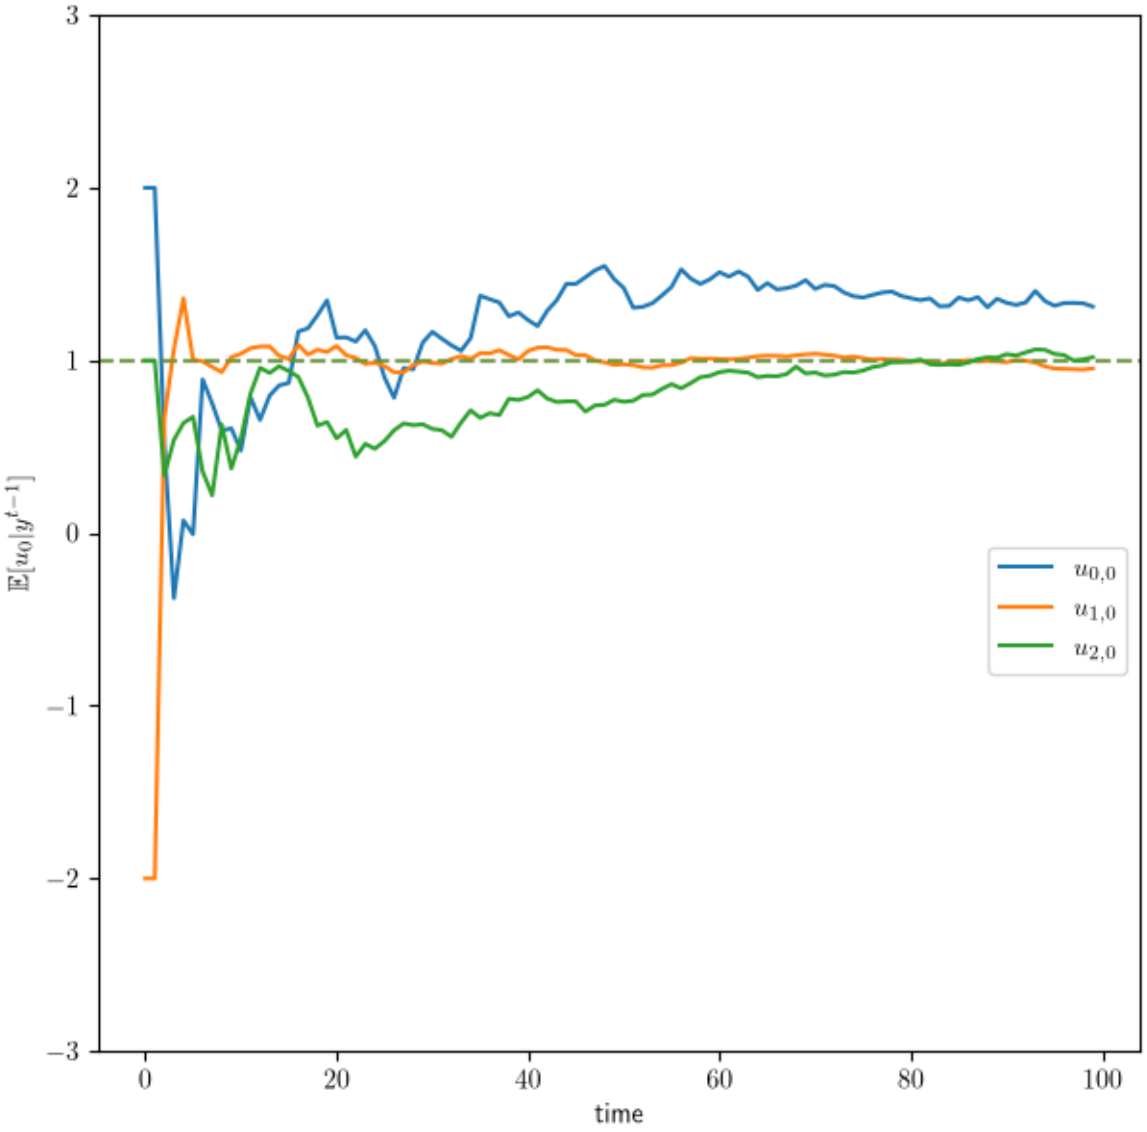

Fig. 50.6: Inferred work ethic when every worker starts at $h_0 = 2$ and $u_0 = 1$

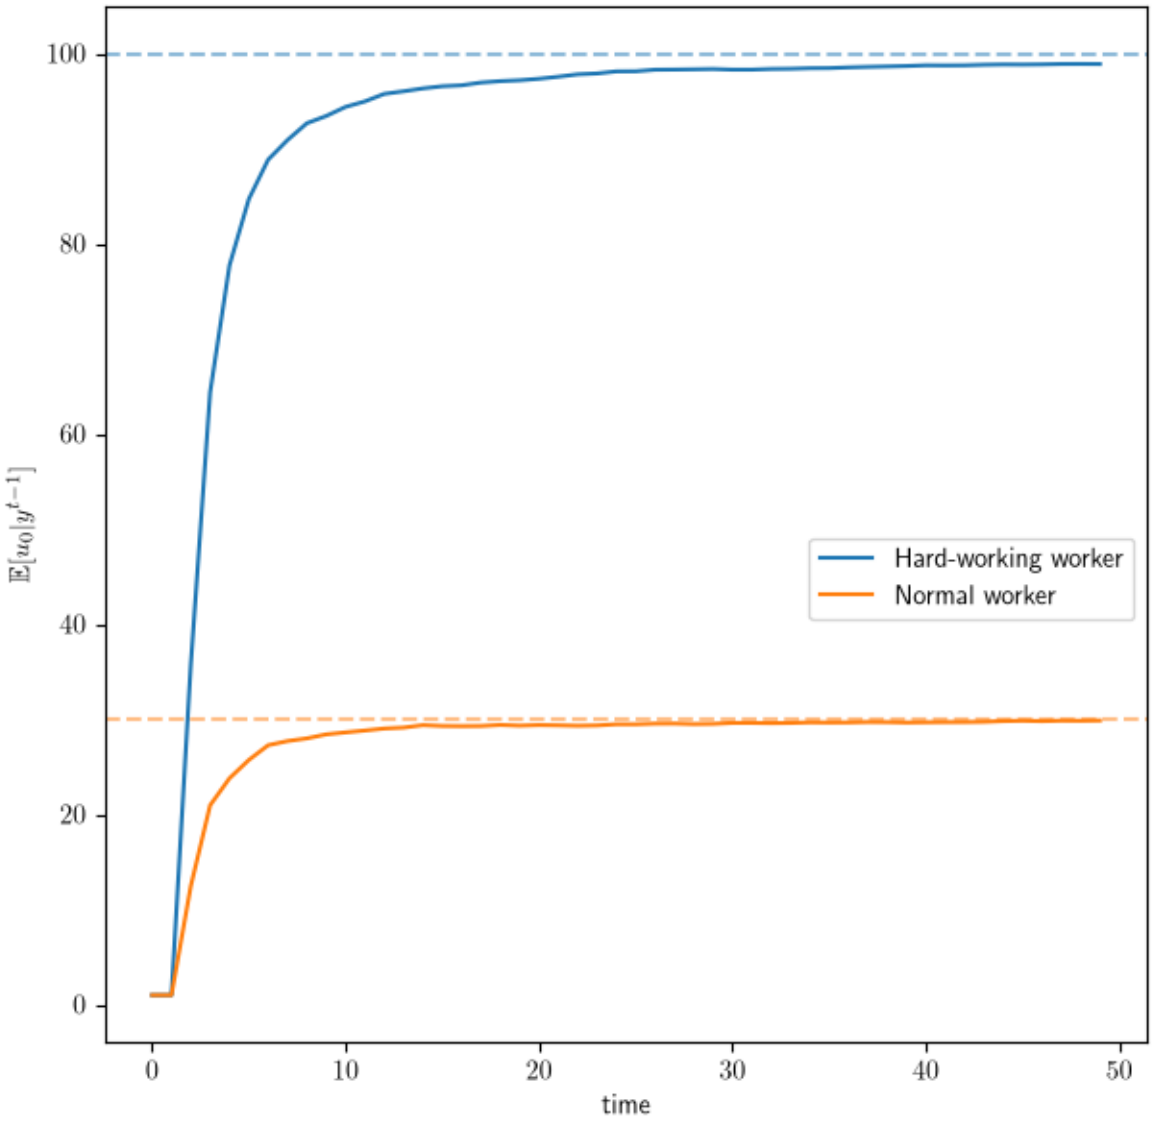

Fig. 50.7: A hard-working worker and a less hard-working worker

Both inferred paths start from the firm's common prior $\widehat{u}_0 = 1$ and climb toward their different true values, showing that the filter corrects the gap between prior and truth as evidence accumulates.

50.6 Future extensions

We can do lots of enlightening experiments by creating new types of workers and letting the firm learn about their hidden (to the firm) states by observing just their output histories.

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

51.1 Overview

This lecture derives the **Kalman filter** for a linear Gaussian state space system and then uses it to construct **vector autoregressions (VARs)**.

It builds on *A First Look at the Kalman Filter*, where the filter is introduced through filtering and forecasting distributions.

It complements *Another Look at the Kalman Filter*, where the same recursion is used in a worker-firm learning problem.

This lecture shifts attention from filtering a hidden state to representing and estimating the observable process generated by that hidden state.

Our approach rests on repeated applications of the **population linear least squares** projection formula, the insight that computing a conditional expectation of a jointly normal random vector is the same as running a population OLS regression.

The lecture covers:

- deriving the Kalman filter recursions from first principles
- the **matrix Riccati difference equation** governing conditional covariance matrices
- the **innovations representation** and the **Gram-Schmidt** whitening property
- the structure of a **hidden Markov model**
- the **likelihood function** for a state space system and its role in maximum likelihood and Bayesian estimation
- how the time-invariant Kalman filter generates a **vector autoregression**
- why the Kalman filter is an essential tool for *interpreting VARs* estimated from economic data

A sequel, *Vector Autoregressions for Subsets of Variables*, applies this machinery to a question that arises constantly in practice: what happens to a VAR when an econometrician observes only some of the variables that appear in it.

51.2 The state space system

The Kalman filter applies to the **state space system** for $t \geq 0$:

$$\begin{aligned} x_{t+1} &= Ax_t + Cw_{t+1} \\ y_t &= Gx_t + v_t \end{aligned} \tag{51.1}$$

where

- x_t is an $n \times 1$ **state vector** (hidden, unobserved)
- y_t is an $m \times 1$ vector of **signals** on the hidden state (observed)
- w_{t+1} is a $p \times 1$ IID sequence of normal random variables with mean 0 and identity covariance matrix
- v_t is an IID sequence of normal random variables with mean zero and covariance matrix R
- w_t and v_s are orthogonal at all pairs of dates

The coefficient matrices have the following dimensions: A is $n \times n$, C is $n \times p$, G is $m \times n$, and R is $m \times m$.

The initial state satisfies

$$x_0 \sim N(\hat{x}_0, \Sigma_0) \tag{51.2}$$

We observe $y_t, \ldots, y_0$ but *not* $x_t, \ldots, x_0$ at time t, and we know all first and second moments implied by (51.1) and (51.2).

51.3 The Kalman filter

51.3.1 Starting distribution

Working forward in time starting at $t = 0$, before observing y_0, the specification (51.1)-(51.2) implies that the marginal distribution of y_0 is

$$y_0 \sim N(G\hat{x}_0,\ G\Sigma_0 G^\top + R) \tag{51.3}$$

For $t \geq 0$ let $y^t = [y_t, y_{t-1}, \ldots, y_0]$.

We want a convenient recursive representation of the conditional distribution of y_t given history y^{t-1}.

The Kalman filter attains this by constructing recursive formulas for $\hat{x}_t$ and Σ_t such that the distribution of y_t conditional on y^{t-1} generalizes (51.3) to

$$y_t \sim N(G\hat{x}_t,\ G\Sigma_t G^\top + R) \tag{51.4}$$

for $t \geq 1$, where the distribution of x_t conditional on y^{t-1} is $N(\hat{x}_t, \Sigma_t)$.

The objects $\hat{x}_t$ and Σ_t characterize the **population regression**

$$\hat{x}_t = \mathbb{E}[x_t \mid y_{t-1}, \dots, y_0]$$

and the **conditional covariance matrix**

$$\Sigma_t = \mathbb{E}[(x_t - \hat{x}_t)(x_t - \hat{x}_t)^\top \mid y_{t-1}, \dots, y_0]$$

51.3.2 Derivation

At each date, our approach is to *regress what we do not know on what we know*.

Note

Because our assumptions imply that $\{x_t, y_t\}_{t=0}^{\infty}$ is a jointly normal stochastic process, linear least squares regressions equal conditional mathematical expectations.

Each step below is an application of Bayes' law.

Under the weaker assumption that all means and covariances exist without joint normality, the same calculations yield "wide-sense conditional expectations" that coincide with true conditional expectations only when those conditional expectations are linear.

We arrive at $t = 0$ knowing $\hat{x}_0$ and Σ_0.

The information about x_0 in y_0 that is new relative to $(\hat{x}_0, \Sigma_0)$ is the **innovation**

$$a_0 \equiv y_0 - G\hat{x}_0$$

Let L_0 be the population regression coefficient of the hidden-state error $x_0 - \hat{x}_0$ on the signal surprise $y_0 - G\hat{x}_0$.

The conditional mean $\mathbb{E}[x_0 \mid y_0] = \hat{x}_0 + L_0(y_0 - G\hat{x}_0)$ satisfies the population regression formula

$$x_0 - \hat{x}_0 = L_0(y_0 - G\hat{x}_0) + \eta \tag{51.5}$$

where η is the least squares residual.

Orthogonality of η to $(y_0 - G\hat{x}_0)$ pins down L_0 via the normal equations

$$\mathbb{E}(x_0 - \hat{x}_0)(y_0 - G\hat{x}_0)^\top = L_0\, \mathbb{E}(y_0 - G\hat{x}_0)(y_0 - G\hat{x}_0)^\top$$

Evaluating the moment matrices and solving for L_0 gives

$$L_0 = \Sigma_0 G^\top (G\Sigma_0 G^\top + R)^{-1} \tag{51.6}$$

Thus L_0 updates the estimate of x_0, while $K_0 = AL_0$ updates the forecast of x_1.

To forecast x_1, note that

$$x_1 = A\hat{x}_0 + A(x_0 - \hat{x}_0) + Cw_1 \tag{51.7}$$

Applying (51.5) gives $\mathbb{E}[x_1 \mid y_0] = A\hat{x}_0 + AL_0(y_0 - G\hat{x}_0)$, which we write as

$$\hat{x}_1 = A\hat{x}_0 + K_0(y_0 - G\hat{x}_0) \tag{51.8}$$

where the **Kalman gain** at time 0 is

$$K_0 = A\Sigma_0 G^\top (G\Sigma_0 G^\top + R)^{-1} \tag{51.9}$$

Subtracting (51.8) from (51.7) yields

$$x_1 - \hat{x}_1 = A(x_0 - \hat{x}_0) + Cw_1 - K_0(y_0 - G\hat{x}_0) \tag{51.10}$$

Using (51.10) and $y_0 = Gx_0 + v_0$ to evaluate $\Sigma_1 \equiv \mathbb{E}[(x_1 - \hat{x}_1)(x_1 - \hat{x}_1)^\top \mid y_0]$ gives

$$\Sigma_1 = (A - K_0 G)\Sigma_0 (A - K_0 G)^\top + CC^\top + K_0 R K_0^\top \tag{51.11}$$

Thus $f(x_1 \mid y_0) \sim N(\hat{x}_1, \Sigma_1)$.

Collecting the time-0 equations:

$$\begin{aligned} a_0 &= y_0 - G\hat{x}_0 \\ K_0 &= A\Sigma_0 G^\top (G\Sigma_0 G^\top + R)^{-1} \\ \hat{x}_1 &= A\hat{x}_0 + K_0 a_0 \\ \Sigma_1 &= CC^\top + K_0 R K_0^\top + (A - K_0 G)\Sigma_0 (A - K_0 G)^\top \end{aligned} \tag{51.12}$$

System (51.12) maps a mean-covariance pair $(\hat{x}_0, \Sigma_0)$ into a new pair $(\hat{x}_1, \Sigma_1)$, with auxiliary outputs (a_0, K_0).

Recognizing that "we are in the same situation at the start of period 1 as at the start of period 0" activates a recursion, the **Kalman filter**.

51.3.3 The Kalman filter recursions

Iterating system (51.12) yields the Kalman filter for $t \geq 0$:

$$\begin{aligned} a_t &= y_t - G\hat{x}_t \\ K_t &= A\Sigma_t G^\top (G\Sigma_t G^\top + R)^{-1} \\ \hat{x}_{t+1} &= A\hat{x}_t + K_t a_t \\ \Sigma_{t+1} &= CC^\top + K_t R K_t^\top + (A - K_t G)\Sigma_t (A - K_t G)^\top \end{aligned} \tag{51.13}$$

Here K_t is the **Kalman gain** at time t.

51.3.4 The matrix Riccati equation

Substituting the expression for K_t from the second line of (51.13) into the fourth line gives an equivalent update formula:

$$\Sigma_{t+1} = A\Sigma_t A^\top + CC^\top - A\Sigma_t G^\top (G\Sigma_t G^\top + R)^{-1} G\Sigma_t A^\top \tag{51.14}$$

Equation (51.14) is the **matrix Riccati difference equation**.

It governs the sequence of conditional covariance matrices $\{\Sigma_t\}_{t=0}^{\infty}$ without reference to the observations $\{y_t\}$.

51.4 The Gram-Schmidt process

The random vector

$$a_t = y_t - \mathbb{E}[y_t \mid y_{t-1}, \dots, y_0]$$

is the **innovation** of y_t with respect to y^{t-1}, the part of y_t that cannot be predicted from past observations.

Note that $\mathbb{E} a_t a_t^\top = G \Sigma_t G^\top + R$, the matrix whose inverse appears in the Kalman gain formula (51.13).

A direct calculation using $a_t = G(x_t - \hat{x}_t) + v_t$ shows that $\mathbb{E} a_t a_{t-1}^\top = 0$ and, more generally, $\mathbb{E}[a_t \mid a_{t-1}, \dots, a_0] = 0$.

Note

An alternative argument from first principles: let $H(y^t)$ denote the closed linear span of y^t.

Since $a_{t+1} = y_{t+1} - \mathbb{E}[y_{t+1} \mid y^t]$ is a least-squares error, $a_{t+1} \perp H(y^t)$, and in particular $a_{t+1} \perp a_t$.

Thus $\{a_t\}$ is a white-noise process of innovations to $\{y_t\}$.

Sometimes (51.13) is called a **whitening filter**: it takes the signal process $\{y_t\}$ as input and produces the white-noise innovation process $\{a_t\}$ as output.

With $H(a^t)$ defined analogously, $H(a^t) = H(y^t)$, and $[a_t, \dots, a_0]$ is an orthogonal basis for that common space.

Rather than computing $\mathbb{E}[x_t \mid y_{t-1}, \dots, y_0]$ via one large regression, the Kalman filter performs a sequence of small regressions on successive orthogonal components of the basis $[a_{t-1}, \dots, a_0]$, an instance of the **Gram-Schmidt procedure**.

51.5 Hidden Markov model

System (51.1)-(51.2) is an example of a **hidden Markov model**.

The observed process $\{y_t\}_{t=0}^\infty$ is *not* Markov, but the hidden process $\{x_t\}_{t=0}^\infty$ *is* Markov.

So is the process of means and covariances $\{(\hat{x}_t, \Sigma_t)\}$, which are sufficient statistics for the distribution of x_t conditional on $[y_{t-1}, \dots, y_0]$.

51.6 Estimation

51.6.1 The innovations representation

The **innovations representation** emerging from the Kalman filter is

$$\begin{aligned} \hat{x}_{t+1} &= A\hat{x}_t + K_t a_t \\ y_t &= G\hat{x}_t + a_t \end{aligned} \tag{51.15}$$

where $\hat{x}_t = \mathbb{E}[x_t \mid y^{t-1}]$ for $t \geq 1$ and $\mathbb{E}[a_t a_t^\top \mid y^{t-1}] = G\Sigma_t G^\top + R \equiv \Omega_t$.

For $t \geq 1$, $\mathbb{E}[y_t \mid y^{t-1}] = G\hat{x}_t$ and the conditional distribution of y_t given y^{t-1} is $N(G\hat{x}_t, \Omega_t)$.

The objects $(G\hat{x}_t, \Omega_t)$ emerging from the Kalman filter recursions therefore completely characterize this conditional distribution.

51.6.2 The likelihood function

We can factor the likelihood of a sample $(y_T, y_{T-1}, \ldots, y_0)$ as

$$f(y_T, \ldots, y_0) = f(y_T \mid y^{T-1})\, f(y_{T-1} \mid y^{T-2}) \cdots f(y_1 \mid y_0)\, f(y_0) \tag{51.16}$$

The log conditional density of the $m \times 1$ vector y_t is

$$\log f(y_t \mid y^{t-1}) = -\frac{m}{2}\log(2\pi) - \frac{1}{2}\log\det(\Omega_t) - \frac{1}{2}\, a_t^\top \Omega_t^{-1} a_t \tag{51.17}$$

Using (51.17) and (51.13) together, we can evaluate the likelihood (51.16) recursively for any parameter vector θ that underlies the matrices A, G, C, R.

Such calculations are at the heart of efficient strategies for computing **maximum likelihood estimators** of free parameters.

51.6.3 Bayesian inference

The likelihood function is also central to **Bayesian inference**.

Where θ is the parameter vector, y_0^T the data, and $\tilde{p}(\theta)$ a prior density over θ before seeing y_0^T, Bayes' law gives the **posterior**

$$\tilde{p}(\theta \mid y_0^T) = \frac{f(y_0^T \mid \theta)\, \tilde{p}(\theta)}{\int f(y_0^T \mid \theta)\, \tilde{p}(\theta)\, d\theta}$$

The denominator is the marginal joint density $f(y_0^T)$.

51.7 Vector autoregressions and the Kalman filter

51.7.1 Convergence to a steady state

Under conditions discussed by Anderson *et al.* [1996], iterations on the Riccati equation (51.14) converge to a **time-invariant** matrix Σ from any positive semi-definite starting value Σ_0.

A time-invariant fixed point $\Sigma_t = \Sigma$ of (51.14) is the covariance matrix of x_t around

$$\mathbb{E}[x_t \mid \{y_s\}_{s \le t-1}]$$

where the conditioning extends over the **semi-infinite** past $s \le t-1$.

51.7.2 A time-invariant VAR

If the fixed point Σ exists and we initialize the filter at $\Sigma_0 = \Sigma$, the innovations representation (51.15) becomes time-invariant:

$$\begin{aligned} \hat{x}_{t+1} &= A\hat{x}_t + Ka_t \\ y_t &= G\hat{x}_t + a_t \end{aligned} \tag{51.18}$$

where $\mathbb{E} a_t a_t^\top = G\Sigma G^\top + R$ and the **steady-state Kalman gain** is $K = A\Sigma G^\top (G\Sigma G^\top + R)^{-1}$.

From (51.18) we obtain $\hat{x}_{t+1} = (A - KG)\hat{x}_t + Ky_t$.

If the eigenvalues of $A - KG$ are bounded in modulus strictly below unity, we can solve this equation forward to get

$$\hat{x}_{t+1} = \sum_{j=0}^{\infty} (A - KG)^j K \, y_{t-j} \tag{51.19}$$

Substituting (51.19) into the observation equation of (51.18) gives the **vector autoregression**

$$y_t = G \sum_{j=0}^{\infty} (A - KG)^j K \, y_{t-j-1} + a_t \tag{51.20}$$

where by construction

$$\mathbb{E}\left[a_t \, y_{t-j-1}^\top\right] = 0 \quad \forall \, j \geq 0 \tag{51.21}$$

The orthogonality conditions (51.21) identify (51.20) as a vector autoregression.

Letting L denote the lag operator, so that $Lx_t = x_{t-1}$, the **moving average representation** deduced from (51.18) is

$$y_t = \left[I + G(I - AL)^{-1} KL\right] a_t = \left[I + G \sum_{j=0}^{\infty} A^j K L^{j+1}\right] a_t$$

51.7.3 Interpreting VARs

Equilibria of economic models (or their linear or log-linear approximations) typically take the form of state space system (51.1).

This hidden Markov model disturbs the state x_t by the $p \times 1$ shock vector w_{t+1} and perturbs the $m \times 1$ vector of observables y_t by the $m \times 1$ measurement error v_t.

An economic theory typically makes w_{t+1} and v_t directly interpretable as shocks to preferences, technologies, endowments, or information sets.

The state space system (51.1) represents $\{y_t\}$ in terms of these **interpretable shocks**.

However, in the typical situation these shocks *cannot* be recovered directly from the y_t's, even when A, G, C, R are known.

The innovations representation (51.18) represents the *same* stochastic process $\{y_t\}$ in terms of the $m \times 1$ vector a_t of innovations that would be recovered by running an infinite-order population vector autoregression.

Its role in mapping the original representation (51.1) to the VAR (51.20) makes the Kalman filter an indispensable tool for *interpreting vector autoregressions*.

51.8 Spectral factorization identity

Because the original state space system (51.1) and the innovations representation (51.18) describe the *same* stochastic process $\{y_t\}$, they imply two distinct formulas for the **spectral density matrix** of $\{y_t\}$.

Equating those formulas yields the *spectral factorization identity*.

51.8.1 Two representations of the spectral density

Consider first the original state space system.

Writing the first line of (51.1) as $x_t = (zI - A)^{-1} C w_{t+1}$ (using the z-transform convention $z^{-1} x_t = x_{t-1}$), the covariance generating function of $\{x_t\}$ is

$$S_x(z) = (zI - A)^{-1} C C^\top (z^{-1} I - A^\top)^{-1}.$$

Since v_t is orthogonal to x_t, the spectral density of $\{y_t\}$ is

$$S_y(z) = G(zI - A)^{-1} C C^\top (z^{-1} I - A^\top)^{-1} G^\top + R. \tag{51.22}$$

Now consider the innovations representation.

The time-invariant innovations representation (51.18) gives $y_t = [G(zI - A)^{-1} K + I]\, a_t$.

Since a_t is white noise with covariance matrix $G \Sigma G^\top + R$, the spectral density is also

$$S_y(z) = \big[G(zI - A)^{-1} K + I\big](G \Sigma G^\top + R)\big[K^\top (z^{-1} I - A^\top)^{-1} G^\top + I\big]. \tag{51.23}$$

51.8.2 The spectral factorization identity

Equating (51.22) and (51.23) gives the **spectral factorization identity**:

$$G(zI - A)^{-1} C C^\top (z^{-1} I - A^\top)^{-1} G^\top + R = \big[G(zI - A)^{-1} K + I\big](G \Sigma G^\top + R)\big[K^\top (z^{-1} I - A^\top)^{-1} G^\top + I\big]. \tag{51.24}$$

The left side expresses $S_y(z)$ in terms of the **structural shocks** (w_{t+1}, v_t) and the matrices (A, C, G, R).

The right side expresses the same object as a spectral factor built from the innovations a_t and the steady-state Kalman gain K.

51.8.3 Wold and autoregressive representations

Starting from the innovations representation (51.18), we can obtain both a Wold moving average representation and an autoregressive representation.

For the Wold representation, iterate the state equation in (51.18) to express the current observation in terms of current and past innovations.

With L denoting the lag operator, (51.18) implies

$$y_t = \big[I + G(I - AL)^{-1} K L\big]\, a_t \tag{51.25}$$

This is the Wold moving-average representation of $\{y_t\}$ in terms of its one-step forecast errors.

For the autoregressive representation, invert the moving-average operator in (51.25) and solve for a_t in terms of current and past observations.

Using the identity

$$\big[I + G(I - AL)^{-1} K L\big]^{-1} = I - G\,[I - (A - KG)L]^{-1}\, KL$$

gives

$$y_t = G\big[I - (A - KG)L\big]^{-1} K\, y_{t-1} + a_t = \sum_{j=1}^{\infty} G(A - KG)^{j-1} K\, y_{t-j} + a_t, \tag{51.26}$$

which is the vector autoregression already stated in (51.20).

The key analytical fact is that, under mild stability conditions, the zeros of $\det[G(zI - A)^{-1}K + I]$ all lie *inside* the unit circle.

This ensures that the moving-average operator in (51.25) has a causal one-sided inverse.

Hence a_t lies in the closed linear span of current and past observations y^t, so a_t is the population forecast error in the VAR.

51.9 Python implementation

We now illustrate the theory using the `quantecon` library, which provides `LinearStateSpace` and `Kalman` classes that implement everything derived above.

We use the following imports:

```
import numpy as np
import matplotlib.pyplot as plt
import quantecon as qe
```

51.9.1 A scalar hidden AR(1) model

Consider a scalar hidden AR(1) state observed with measurement noise:

$$x_{t+1} = \rho\, x_t + \sigma_w\, w_{t+1}$$
$$y_t = x_t + \sigma_v\, v_t$$

with $w_t, v_t \sim N(0,1)$ IID.

Here ρ is the persistence parameter, while σ_w and σ_v are shock standard deviations.

The `LinearStateSpace` class parameterizes measurement noise by a matrix H such that $R = HH^\top$.

```
# Model parameters
ρ = 0.9
σ_w = 0.5
σ_v = 1.0

# State-space matrices
A = np.array([[ρ]])
C = np.array([[σ_w]])
G = np.array([[1.0]])
R = np.array([[σ_v**2]])

# Build a LinearStateSpace and a Kalman filter object
H = np.array([[σ_v]])   # measurement noise factor: R = H @ H.T
lss = qe.LinearStateSpace(
  A, C, G, H, mu_0=np.zeros(1), Sigma_0=np.eye(1) * 10.0)
kf = qe.Kalman(lss)
kf.set_state(np.zeros(1), np.eye(1) * 10.0)  # diffuse prior
```

We first simulate a sample path of the true hidden state and noisy observations.

```
T = 200
x_path, y_path = lss.simulate(ts_length=T, random_state=42)

# Shapes: x_path is (n, T), y_path is (m, T)
x_true = x_path[0, :]
y_obs = y_path[0, :]
```

We then run the Kalman filter manually, step by step.

The `Kalman.update` method performs a *complete* cycle, moving the prior to the filtering distribution and then on to next period's prior.

So $(\hat{x}_t, \Sigma_t)$ as defined in (51.13) are the values held by the object *before* `update` is called, and we record them there.

```
x_hats = np.zeros(T)
Sigmas = np.zeros(T)
innovations = np.zeros(T)

for t in range(T):
    x_hats[t] = kf.x_hat.item()       # x_hat_t = E[x_t | y^{t-1}]
    Sigmas[t] = kf.Sigma.item()       # Sigma_t
    innovations[t] = y_obs[t] - (G @ kf.x_hat).item()
    kf.update(y_obs[t:t+1])           # one full filter cycle
```

Getting this ordering right matters.

Recording `kf.x_hat` *after* the call would store the one-step-ahead forecast $\hat{x}_{t+1}$, and differencing it from y_t would produce a series that is not the innovation and does not have variance $G\Sigma G^\top + R$.

```
fig, axes = plt.subplots(3, 1, figsize=(10, 8), sharex=True)

t_range = np.arange(T)

axes[0].plot(t_range, x_true, lw=2,
        label='true state $x_t$')
axes[0].plot(t_range, x_hats, lw=2,
        linestyle='--', label=r'$\hat{x}_t$ (Kalman)')
axes[0].plot(t_range, y_obs, alpha=0.35, lw=2, label='observation $y_t$')
axes[0].set_title('state and observation')
axes[0].legend(fontsize=9)

axes[1].plot(t_range, Sigmas, color='C1', lw=2,
             label=r'conditional variance $\Sigma_t$')
axes[1].axhline(kf.Sigma_infinity[0, 0], ls='--', color='k',
                label=r'steady-state $\Sigma_\infty$')
axes[1].set_title('conditional variance')
axes[1].legend(fontsize=9)

axes[2].plot(t_range, innovations, color='C2', lw=2, alpha=0.7,
             label=r'innovation $a_t = y_t - G\hat{x}_t$')
axes[2].set_title('innovation')
axes[2].set_xlabel('time $t$')
axes[2].legend(fontsize=9)
fig.tight_layout()
plt.show()
```

After a short adjustment, the Kalman estimate follows the hidden state much more closely than the raw noisy observations.

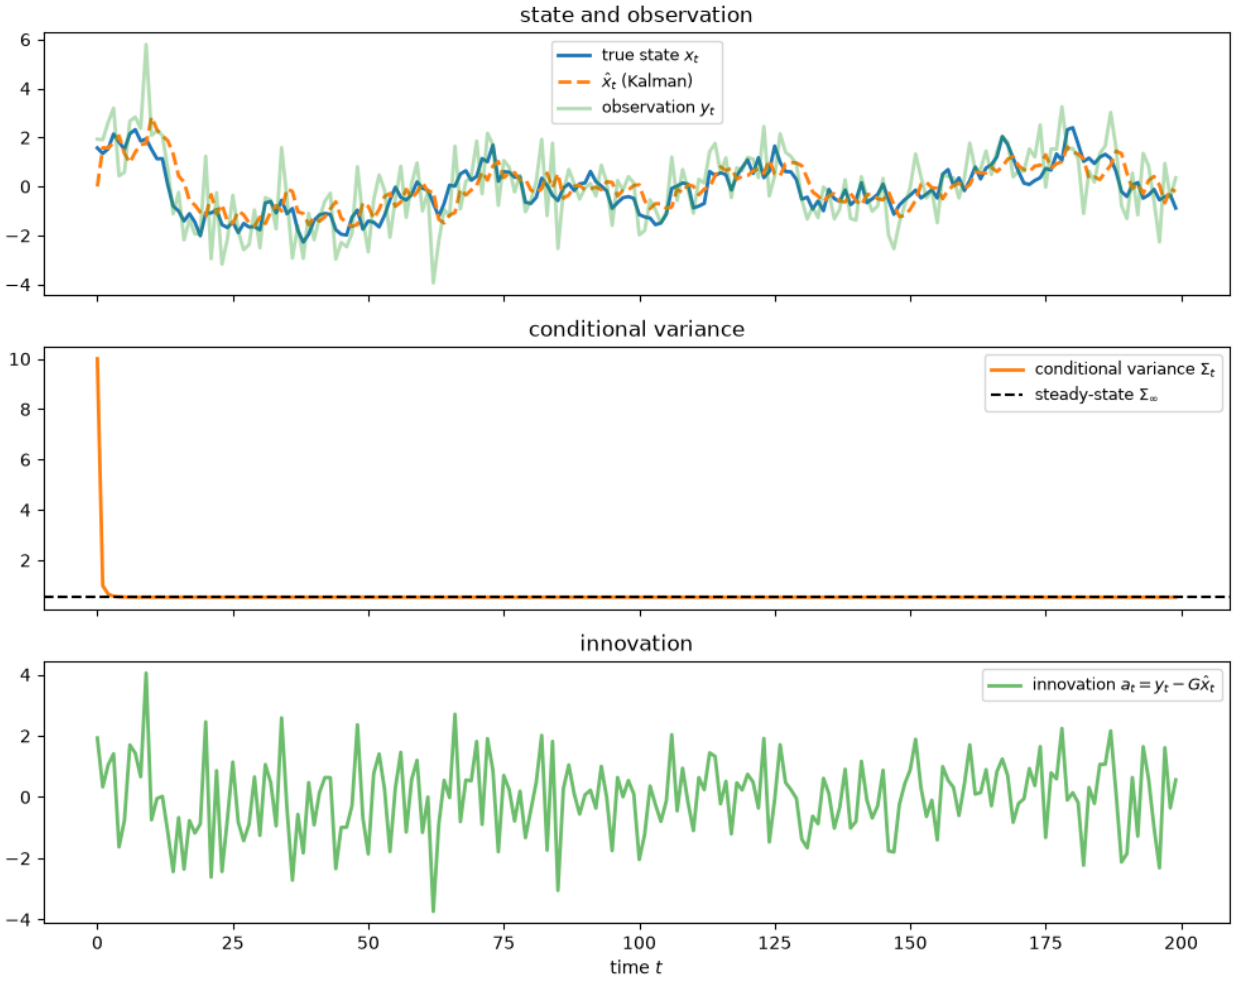

Fig. 51.1: Scalar Kalman filtering

The conditional variance drops quickly from the diffuse prior and then settles onto its steady-state value.

The innovation series fluctuates around zero, as a one-step forecast error should.

Its sample standard deviation should be close to $\sqrt{G\Sigma_\infty G^\top + R}$.

```
print(f"sample sd of innovations   = {innovations.std():.4f}")
print(f"steady-state sd            = "
      f"{np.sqrt(kf.Sigma_infinity[0, 0] + R[0, 0]):.4f}")
print(f"first-order autocorrelation = "
      f"{np.corrcoef(innovations[1:], innovations[:-1])[0, 1]:.4f}")
```

```
sample sd of innovations   = 1.2297
steady-state sd            = 1.2373
first-order autocorrelation = -0.0455
```

The autocorrelation is near zero, confirming that the filter has whitened the observed series.

51.9.2 Convergence of the Riccati equation

The `Kalman` class computes the steady-state covariance Σ_∞ by solving the discrete algebraic Riccati equation directly.

```
Sigma_inf, K_inf = kf.stationary_values()

print(f"Steady-state covariance  Σ_inf = {Sigma_inf[0, 0]:.6f}")
print(f"Kalman filter converged to Σ_t = {Sigmas[-1]:.6f}")
print(f"Steady-state Kalman gain K  = {K_inf[0, 0]:.6f}")

A_minus_KG = A - K_inf @ G
eigval = np.linalg.eigvals(A_minus_KG)[0]
print(f"\nEigenvalue of (A - KG)      = {eigval:.6f}")
print(f"Stable VAR: {np.abs(eigval) < 1}")
```

```
Steady-state covariance  Σ_inf = 0.530899
Kalman filter converged to Σ_t = 0.530899
Steady-state Kalman gain K  = 0.312110

Eigenvalue of (A - KG)      = 0.587890
Stable VAR: True
```

51.9.3 The VAR representation

Using (51.20), the coefficients in the infinite-order VAR representation are $G(A-KG)^j K$ for $j = 0, 1, 2, \ldots$

We retrieve them via `stationary_coefficients`:

```
J = 30
var_coeffs = kf.stationary_coefficients(J, coeff_type='var')

# Lag j+1 coefficient matrices
lags = np.arange(1, J + 1)
coeff_values = np.array([var_coeffs[j][0, 0] for j in range(J)])

fig, ax = plt.subplots()
ax.stem(lags, coeff_values, basefmt=' ')
```

(continues on next page)

(continued from previous page)

```
ax.set_xlabel('lag $j$')
ax.set_ylabel(r'VAR coefficient $G(A{-}KG)^{j-1}K$')
fig.tight_layout()
plt.show()
```

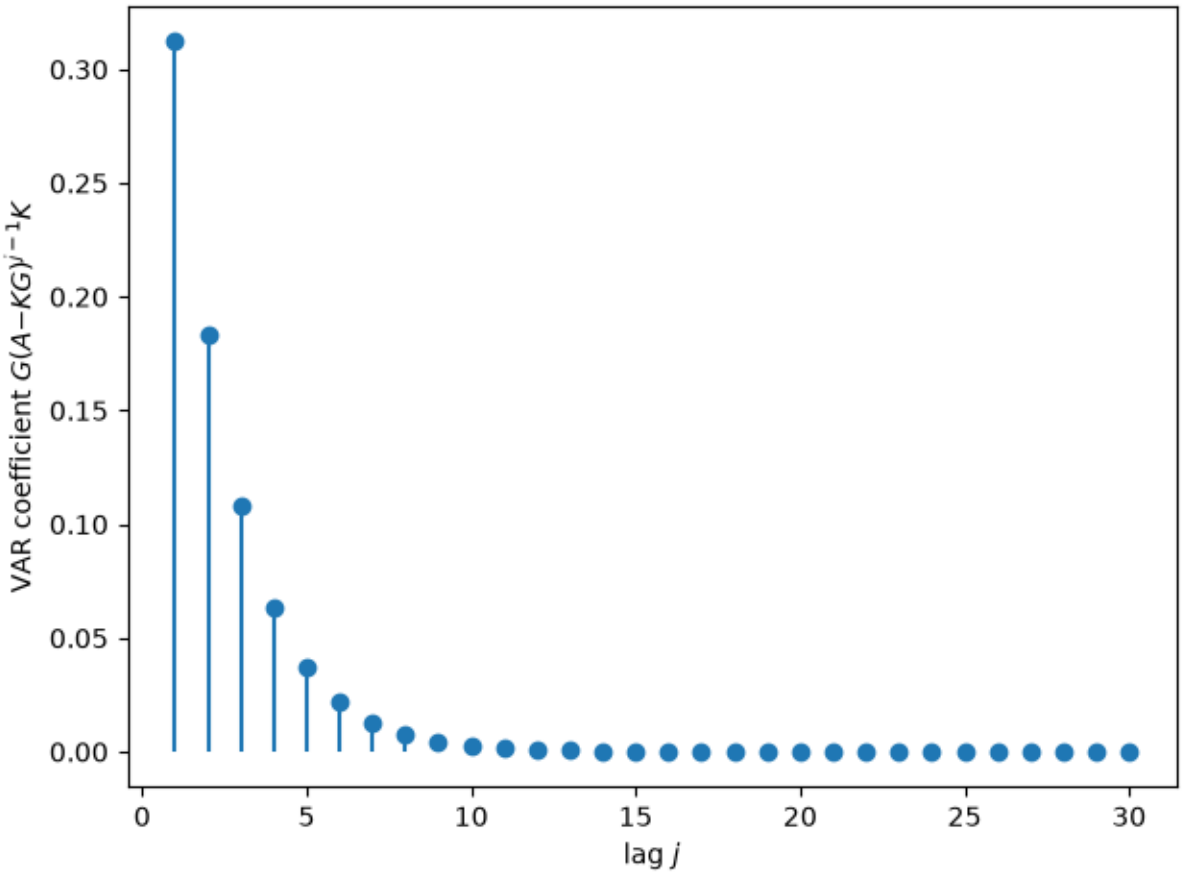

Fig. 51.2: VAR coefficients from the innovations representation

Most of the autoregressive weight is concentrated in the first few lags.

The later coefficients are nearly zero, so a short finite-lag VAR captures most of the infinite-order representation in this example.

51.9.4 Likelihood evaluation

We use (51.17) to evaluate the log-likelihood of the simulated sample.

```
def log_likelihood(A, C, G, R, y_data, x_hat_0, Sigma_0):
    """Evaluate the log-likelihood using the Kalman filter recursions."""
    H_ = np.linalg.cholesky(R)    # R = H_ @ H_.T
    lss_ = qe.LinearStateSpace(A, C, G, H_, mu_0=x_hat_0, Sigma_0=Sigma_0)
    kf_ = qe.Kalman(lss_)
    kf_.set_state(x_hat_0, Sigma_0)

    T_, m_ = y_data.shape
    loglik = 0.0

    for t in range(T_):
        x_h = kf_.x_hat
        Sig = kf_.Sigma
        Omega = G @ Sig @ G.T + R        # innovation covariance
        a_t = y_data[t] - (G @ x_h).flatten()

        sign, logdet = np.linalg.slogdet(Omega)
        loglik += -0.5 * (m_ * np.log(2 * np.pi) + logdet
                          + float(a_t @ np.linalg.solve(Omega, a_t)))
        kf_.update(y_data[t])

    return loglik

y_data_col = y_obs.reshape(-1, 1)
ll = log_likelihood(A, C, G, R,
                    y_data_col,
                    np.zeros(1), np.eye(1) * 10.0)
print(f"Log-likelihood of sample: {ll:.4f}")
```

```
Log-likelihood of sample: -325.2335
```

51.10 Where this leads

The Kalman filter maps a state space system into the VAR that a population regression of y_t on its own past would recover.

That map is most interesting when the state x_t contains variables that the econometrician does *not* see.

The sequel *Vector Autoregressions for Subsets of Variables* takes the leading case of this: Y_t follows a finite-order VAR, and the econometrician observes only a subvector $y_t = S_y Y_t$.

There we build general code that, given the VAR for Y_t and the selector matrix S_y, returns the VAR and moving average representations for y_t and expresses the innovations in the small system as a distributed lag of the innovations in the large one.

51.11 Summary

The Kalman filter recursively updates beliefs about a hidden state by combining a prior forecast with the new information contained in the current observation.

The Riccati equation tracks how the filter's conditional covariance evolves, and its steady state makes the filter time invariant.

At that steady state, the innovations representation writes the observable process in terms of one-step forecast errors that are white noise by construction.

Solving the innovations representation backward gives an infinite-order VAR, while solving it forward gives the Wold moving-average representation.

Which variables an econometrician observes determines the Kalman gain and therefore the VAR and Wold representations, even when the underlying state dynamics are held fixed.

Vector Autoregressions for Subsets of Variables pursues that observation systematically.

51.12 Exercises

Exercise 51.12.1

Consider the scalar AR(1) state space system used above with $\rho = 0.9$, $\sigma_w = 0.5$, $\sigma_v = 1.0$.

Derive an algebraic expression for the **steady-state** conditional variance Σ_∞ by solving the scalar Riccati equation (51.14) at its fixed point $\Sigma_{t+1} = \Sigma_t = \Sigma$.

Show that Σ satisfies a quadratic equation, find its positive root, and verify numerically that your formula matches `kf.Sigma_infinity`.

Solution

Here is one solution:

Setting $\Sigma_{t+1} = \Sigma_t = \Sigma$ in the scalar version of (51.14) with $A = \rho$, $CC^\top = \sigma_w^2$, $GG^\top = 1$, $R = \sigma_v^2$:

$$\Sigma = \rho^2 \Sigma + \sigma_w^2 - \frac{\rho^2 \Sigma^2}{\Sigma + \sigma_v^2}$$

Multiplying through by $\Sigma + \sigma_v^2$ and rearranging:

$$\Sigma^2 + \left[\sigma_v^2(1-\rho^2) - \sigma_w^2\right]\Sigma - \sigma_v^2 \sigma_w^2 = 0$$

Taking the positive root of this quadratic:

$$\Sigma_\infty = \frac{\sigma_w^2 - \sigma_v^2(1-\rho^2) + \sqrt{\left[\sigma_v^2(1-\rho^2) - \sigma_w^2\right]^2 + 4\sigma_v^2\sigma_w^2}}{2}$$

```
ρ_, σ_w_, σ_v_ = 0.9, 0.5, 1.0

b = σ_v_**2 * (1 - ρ_**2) - σ_w_**2
discriminant = b**2 + 4 * σ_v_**2 * σ_w_**2
Sigma_formula = (-b + np.sqrt(discriminant)) / 2

A_ = np.array([[ρ_]])
C_ = np.array([[σ_w_]])
G_ = np.array([[1.0]])
R_ = np.array([[σ_v_**2]])
H_ = np.array([[σ_v_]])   # R_ = H_ @ H_.T
lss_ = qe.LinearStateSpace(A_, C_, G_, H_, mu_0=np.zeros(1), Sigma_0=np.eye(1))
kf_ = qe.Kalman(lss_)

print(f"Analytical Σ_inf   = {Sigma_formula:.8f}")
print(f"Numerical  Σ_inf   = {kf_.Sigma_infinity[0, 0]:.8f}")
```

```
Analytical Σ_inf   = 0.53089919
Numerical  Σ_inf   = 0.53089919
```

Exercise 51.12.2

This exercise considers a two-dimensional state with a one-dimensional observation:

$$A = \begin{pmatrix} 0.9 & 0.1 \\ 0 & 0.8 \end{pmatrix}, \quad C = \begin{pmatrix} 0.4 \\ 0.1 \end{pmatrix}, \quad G = \begin{pmatrix} 1 & 0 \end{pmatrix}, \quad R = [0.5]$$

1. Simulate $T = 500$ observations from this system starting from a diffuse prior.
2. Run the Kalman filter and plot both components of $\hat{x}_t$ against the true hidden state path.
3. Compute and report the steady-state covariance Σ_∞ and Kalman gain K_∞.
4. Check that the eigenvalues of $A - K_\infty G$ lie strictly inside the unit circle, confirming that the VAR representation (51.20) is stable.

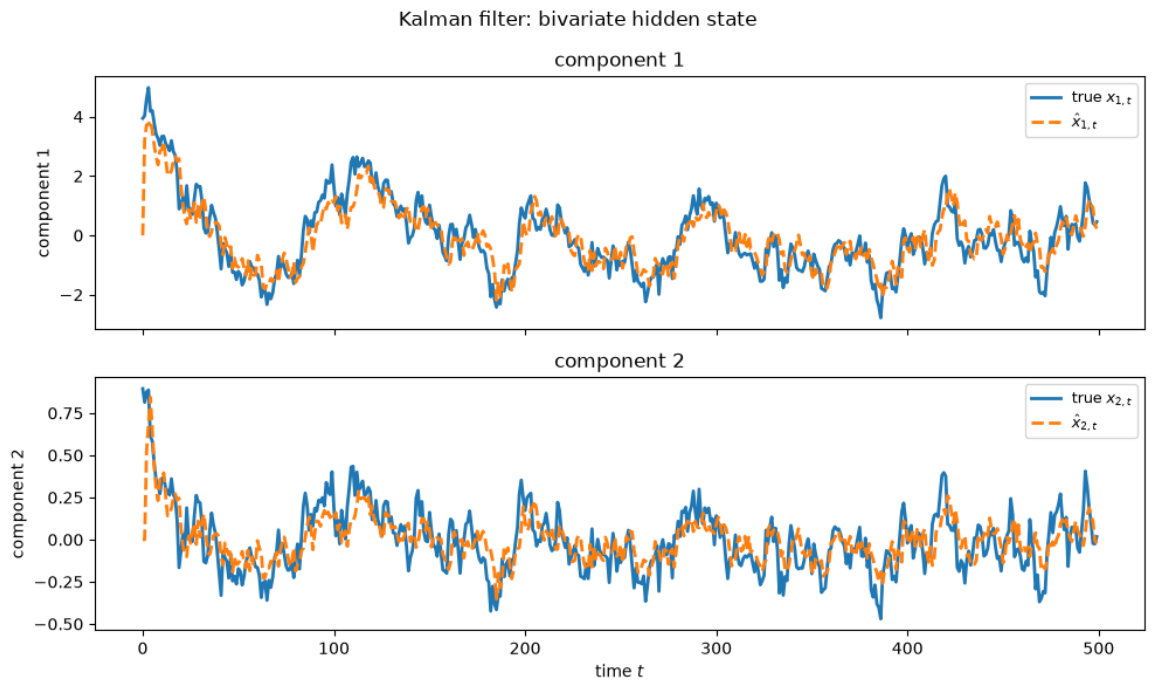
Solution

Here is one solution:

```
A2 = np.array([[0.9, 0.1],
               [0.0, 0.8]])
C2 = np.array([[0.4],
               [0.1]])
G2 = np.array([[1.0, 0.0]])
R2 = np.array([[0.5]])
H2 = np.array([[np.sqrt(0.5)]])   # R2 = H2 @ H2.T

lss2 = qe.LinearStateSpace(A2, C2, G2, H2,
                           mu_0=np.zeros(2),
                           Sigma_0=np.eye(2) * 5.0)
kf2 = qe.Kalman(lss2)
kf2.set_state(np.zeros(2), np.eye(2) * 5.0)

T2 = 500
```



```
x2_path, y2_path = lss2.simulate(ts_length=T2, random_state=0)

x_hats2 = np.zeros((T2, 2))
for t in range(T2):
    x_hats2[t] = kf2.x_hat.ravel()      # record x_hat_t before updating
    kf2.update(y2_path[:, t])

fig, axes = plt.subplots(2, 1, figsize=(10, 6), sharex=True)
for i, ax in enumerate(axes):
    ax.plot(x2_path[i, :], lw=2, label=f'true $x_{{{i+1},t}}$')
    ax.plot(x_hats2[:, i], lw=2, ls='--', label=rf'$\hat{{x}}_{{{i+1},t}}$')
    ax.set_title(f'component {i+1}')
    ax.legend(fontsize=9)
    ax.set_ylabel(f'component {i+1}')
axes[1].set_xlabel('time $t$')
fig.suptitle('Kalman filter: bivariate hidden state')
fig.tight_layout()
plt.show()

# Steady-state values
Sigma2_inf, K2_inf = kf2.stationary_values()
print("Steady-state covariance Σ_inf:")
print(np.round(Sigma2_inf, 5))
print("\nSteady-state Kalman gain K_inf:")
print(np.round(K2_inf, 5))

# Eigenvalues of A - K_inf G
AKG2 = A2 - K2_inf @ G2
eigvals2 = np.linalg.eigvals(AKG2)
print(f"\nEigenvalues of A - K_inf G: {np.round(eigvals2, 5)}")
print(f"Stable VAR: {np.all(np.abs(eigvals2) < 1)}")
```

```
Steady-state covariance Σ_inf:
[[0.32854 0.07219]
 [0.07219 0.0166 ]]

Steady-state Kalman gain K_inf:
[[0.36559]
 [0.06971]]

Eigenvalues of A - K_inf G: [0.56394 0.77047]
Stable VAR: True
```

After the diffuse-prior transient, both Kalman estimates move closely with their corresponding hidden state paths.

The second component is not observed directly, so its tracking comes from the state dynamics and its connection to the observed signal.

The printed eigenvalues then check the separate stability condition for the VAR representation.

Exercise 51.12.3

This exercise studies likelihood and parameter estimation using the scalar model from the main text with true parameters $(\rho, \sigma_w, \sigma_v) = (0.9, 0.5, 1.0)$:

1. Simulate $T = 300$ observations.
2. Write a function that evaluates the **log-likelihood** as a function of $\rho \in (0, 1)$, holding $\sigma_w = 0.5$ and $\sigma_v = 1.0$ fixed, and plot the log-likelihood against ρ for a grid of values.
3. Locate the maximum numerically and check that it is close to the true value $\rho = 0.9$.

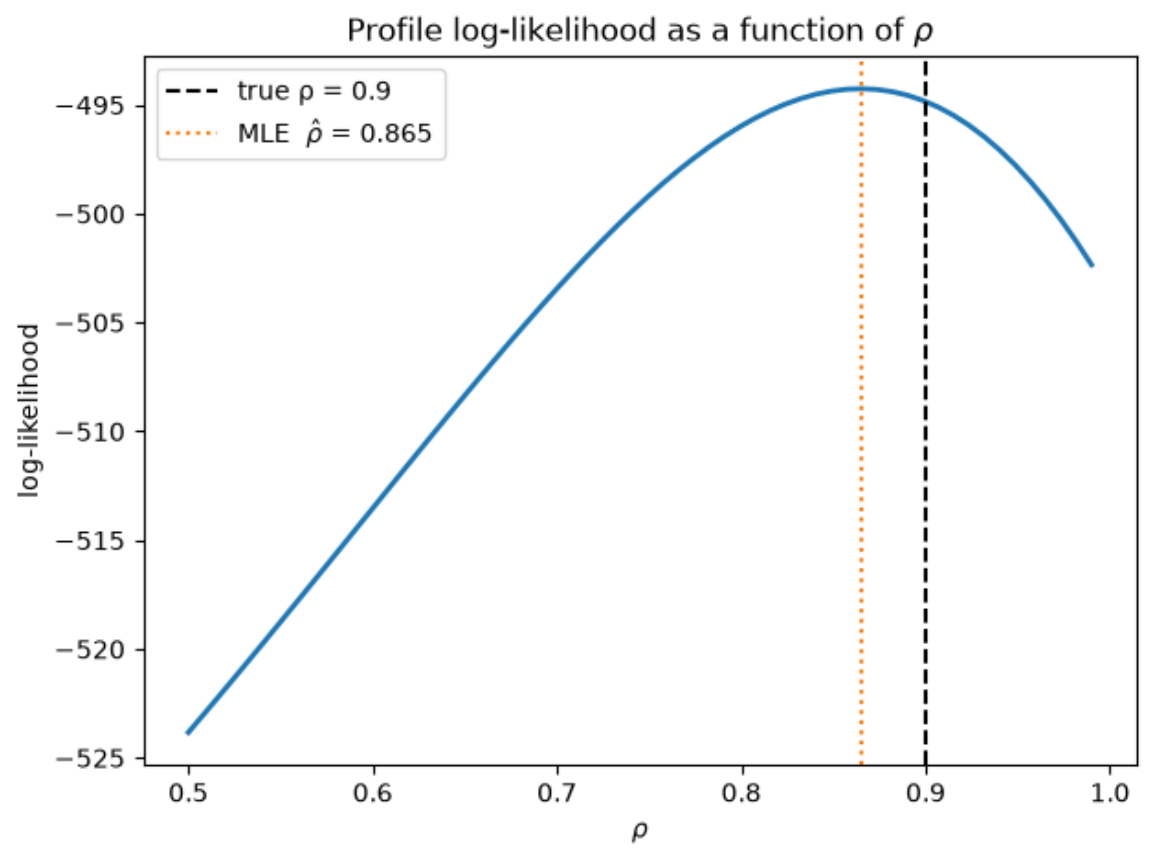
Solution

Here is one solution:

```
# True parameters
ρ_true, sw_true, sv_true = 0.9, 0.5, 1.0

A_t = np.array([[ρ_true]])
C_t = np.array([[sw_true]])
G_t = np.array([[1.0]])
R_t = np.array([[sv_true**2]])
H_t = np.array([[sv_true]])   # R_t = H_t @ H_t.T

lss_t = qe.LinearStateSpace(A_t, C_t, G_t, H_t,
                            mu_0=np.zeros(1), Sigma_0=np.eye(1))
_, y_sim = lss_t.simulate(ts_length=300, random_state=7)
y_sim = y_sim.T          # shape (300, 1)



def ll_rho(ρ_val):
    A_ = np.array([[ρ_val]])
    C_ = np.array([[sw_true]])
    G_ = np.array([[1.0]])
    R_ = np.array([[sv_true**2]])
    return log_likelihood(A_, C_, G_, R_, y_sim,
                          np.zeros(1), np.eye(1) * 10.0)
```

```
ρ_grid = np.linspace(0.5, 0.99, 60)
ll_vals = np.array([ll_rho(r) for r in ρ_grid])

ρ_mle = ρ_grid[np.argmax(ll_vals)]

fig, ax = plt.subplots()
ax.plot(ρ_grid, ll_vals, lw=2)
ax.axvline(ρ_true, color='k',   ls='--', label=f'true ρ = {ρ_true}')
ax.axvline(ρ_mle, color='C1', ls=':', label=f'MLE  $\\hat{{\\rho}}$ = {ρ_mle:.3f}')
ax.set_xlabel(r'$\rho$')
ax.set_ylabel('log-likelihood')
ax.set_title('Profile log-likelihood as a function of $\\rho$')
ax.legend()
fig.tight_layout()
plt.show()

print(f"True ρ = {ρ_true},  MLE ρ_hat = {ρ_mle:.4f}")
```

```
True ρ = 0.9,  MLE ρ_hat = 0.8654
```

The likelihood curve is single-peaked and reaches its maximum close to the true value $\rho = 0.9$.

The small gap between the grid maximizer and the true value comes from finite-sample randomness and the use of a discrete grid.

  - *Exercises*

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

52.1 Overview

An economic model delivers a vector autoregression for a list of variables Y_t.

An econometrician often observes only *some* of them.

This lecture answers three questions about that situation.

Given an mth order VAR for an $n \times 1$ vector Y_t and a selector matrix S_y that extracts an $n_y \times 1$ subvector $y_t = S_y Y_t$:

1. What vector autoregression does y_t obey?
2. What is its moving average representation?
3. How are the innovations in the small system related to the innovations in the large one?

The answers all come from the *Kalman filter*.

The state is the history of Y_t that a finite-order VAR requires, and the observation is the subvector y_t.

Because y_t is a subvector of the state and not a noisy signal about it, this is a state space system with *no* measurement error.

The main results are

- y_t obeys an **infinite-order** VAR whose coefficients we compute exactly,
- the innovation a_t of the small system is a **one-sided distributed lag** of the innovations ε_t of the large system,
- that distributed lag has a wide coefficient matrix at every lag, so ε_t *cannot* be recovered from the history of y_t,
- the forecast error variance of the small system exceeds that of the large one by a quantity we compute.

Two special cases where the small VAR stays finite-order are identified and verified.

This lecture generalizes the worked example that used to close *The Kalman Filter and Vector Autoregressions*.

Let's start with imports.

```
import matplotlib.pyplot as plt
import numpy as np
import quantecon as qe

plt.rcParams['figure.figsize'] = (10, 5)
np.set_printoptions(precision=4, suppress=True)
```

52.2 The large system

Let Y_t be $n \times 1$ and suppose it obeys the mth order vector autoregression

$$Y_{t+1} = A_1 Y_t + A_2 Y_{t-1} + \cdots + A_m Y_{t-m+1} + \varepsilon_{t+1}, \qquad \mathbb{E}\,\varepsilon_t \varepsilon_t^\top = V, \tag{52.1}$$

where $\{\varepsilon_t\}$ is a serially uncorrelated sequence with $\mathbb{E}[\varepsilon_{t+1} \mid Y_t, Y_{t-1}, ...] = 0$.

Stack m lags into the $nm \times 1$ state vector

$$X_t = \begin{pmatrix} Y_t \\ Y_{t-1} \\ \vdots \\ Y_{t-m+1} \end{pmatrix}.$$

Then (52.1) becomes the first-order **companion form**

$$X_{t+1} = A X_t + C \varepsilon_{t+1}, \qquad A = \begin{pmatrix} A_1 & A_2 & \cdots & A_{m-1} & A_m \\ I & 0 & \cdots & 0 & 0 \\ 0 & I & \cdots & 0 & 0 \\ \vdots & & \ddots & & \vdots \\ 0 & 0 & \cdots & I & 0 \end{pmatrix}, \qquad C = \begin{pmatrix} I_n \\ 0 \\ \vdots \\ 0 \end{pmatrix}. \tag{52.2}$$

We write A without a subscript for the companion matrix and $A_1, \ldots, A_m$ with subscripts for the VAR coefficient matrices.

Let $J = \begin{pmatrix} I_n & 0 & \cdots & 0 \end{pmatrix}$ be the $n \times nm$ matrix that reads Y_t off the state, so that $Y_t = J X_t$ and $C = J^\top$.

We assume all eigenvalues of A are strictly inside the unit circle, so $\{Y_t\}$ is covariance stationary.

52.3 The small system

The econometrician observes

$$y_t = S_y Y_t = G X_t, \qquad G = S_y J, \tag{52.3}$$

where S_y is $n_y \times n$ with $n_y < n$.

Usually S_y picks out n_y coordinates of Y_t, but nothing below requires that, so linear combinations are allowed too.

Equations (52.2) and (52.3) are a state space system of the form studied in *The Kalman Filter and Vector Autoregressions*, with shock loading C, observation matrix G, and measurement error covariance

$$R = 0.$$

The observation is *exact*, but it is a strict subvector of the state, so the econometrician still faces a filtering problem.

Let Σ solve the steady-state Riccati equation

$$\Sigma = A\Sigma A^\top + CVC^\top - A\Sigma G^\top \left(G\Sigma G^\top\right)^{-1} G\Sigma A^\top \tag{52.4}$$

with associated Kalman gain

$$K = A\Sigma G^\top \left(G\Sigma G^\top\right)^{-1}. \tag{52.5}$$

Here Σ is the covariance matrix of $X_t - \mathbb{E}[X_t \mid y^{t-1}]$.

Note

Because X_t contains lags of Y_t whose S_y components the econometrician has already seen exactly, Σ is singular.

That is harmless.

What the Kalman gain (52.5) requires is that the *innovation* covariance $G\Sigma G^\top$ be nonsingular, which holds whenever no linear combination of y_t is perfectly predictable from y^{t-1}.

The innovation in the small system is

$$a_t = y_t - \mathbb{E}[y_t \mid y^{t-1}] = G(X_t - \hat{X}_t), \qquad \Omega \equiv \mathbb{E}\, a_t a_t^\top = G\Sigma G^\top. \tag{52.6}$$

52.4 Four representations

52.4.1 The Wold representation

The steady-state innovations representation derived in *The Kalman Filter and Vector Autoregressions* is

$$\hat{X}_{t+1} = A\hat{X}_t + K a_t, \qquad y_t = G\hat{X}_t + a_t. \tag{52.7}$$

Solving (52.7) forward gives the moving average representation of y_t in terms of its own innovations,

$$y_t = \sum_{h=0}^{\infty} \Psi_h \, a_{t-h}, \qquad \Psi_0 = I_{n_y}, \qquad \Psi_h = GA^{h-1}K \quad (h \geq 1). \tag{52.8}$$

52.4.2 The vector autoregression

Solving (52.7) backward instead gives

$$y_t = \sum_{j=1}^{\infty} B_j \, y_{t-j} + a_t, \qquad B_j = G(A - KG)^{j-1} K. \tag{52.9}$$

This is an infinite-order VAR, convergent because the eigenvalues of $A - KG$ lie inside the unit circle.

52.4.3 Innovations of the small system in terms of the large one

This is the question that motivates the lecture.

Let $e_t = X_t - \hat{X}_t$ be the filtering error.

Subtracting the Kalman recursion $\hat{X}_{t+1} = A\hat{X}_t + Ka_t$ from the state equation (52.2) and using $a_t = Ge_t$ gives

$$e_{t+1} = (A - KG)e_t + C\varepsilon_{t+1}. \tag{52.10}$$

Solving (52.10) backward and premultiplying by G yields the answer.

Proposition 52.4.1

The innovations of the small system are the one-sided distributed lag

$$a_t = \sum_{j=0}^{\infty} \Gamma_j \, \varepsilon_{t-j}, \qquad \Gamma_j = G(A - KG)^j C, \tag{52.11}$$

of the innovations of the large system, with leading coefficient

$$\Gamma_0 = GC = S_y J J^\top = S_y.$$

Since each Γ_j is $n_y \times n$ with $n_y < n$, the map from $\{\varepsilon_t\}$ to $\{a_t\}$ has no inverse.

Knowing the entire history of y_t is not enough to recover ε_t.

52.4.4 The structural moving average

For comparison, iterating (52.2) gives y_t directly in terms of the large system's innovations,

$$y_t = \sum_{j=0}^{\infty} \Phi_j \, \varepsilon_{t-j}, \qquad \Phi_j = GA^j C. \tag{52.12}$$

52.4.5 A forecast error that contains past shocks

Separating the $j = 0$ term in (52.11) and using $\Gamma_0 = S_y$ gives

$$a_t = \underbrace{S_y \varepsilon_t}_{\text{full-information forecast error}} + \underbrace{\sum_{j=1}^{\infty} \Gamma_j \, \varepsilon_{t-j}}_{\text{shocks realized before } t}. \tag{52.13}$$

The first term is what it appears to be.

Because $\mathbb{E}[\varepsilon_t \mid Y^{t-1}] = 0$, we have $y_t - \mathbb{E}[y_t \mid Y^{t-1}] = S_y \varepsilon_t$, so $S_y \varepsilon_t$ is the error made in forecasting y_t by someone who observes the *entire* history of Y.

The second term deserves a pause, because at first sight it looks impossible.

By construction a_t is a forecast error, orthogonal to everything known at $t-1$.

Yet (52.13) says that a_t loads on $\varepsilon_{t-1}, \varepsilon_{t-2}, \ldots$, shocks that had already been realized by then.

The two facts are consistent, and both are true:

$$\mathbb{E}\, a_t\, \varepsilon_{t-j}^\top = \Gamma_j V \neq 0 \quad (j \geq 1), \qquad \text{while} \qquad \mathbb{E}\, a_t\, y_{t-k}^\top = 0 \quad (k \geq 1). \tag{52.14}$$

The resolution is that past shocks are known to the *large* system's econometrician, not to the small one.

The small econometrician's information set is $H(y^{t-1})$, the closed linear span of $y_{t-1}, y_{t-2}, \ldots$, and ε_{t-j} does not lie in it.

Let P_{t-1} denote projection onto $H(y^{t-1})$.

Applying P_{t-1} to (52.13), using $P_{t-1} a_t = 0$ and $P_{t-1}\varepsilon_t = 0$, delivers the identity

$$\sum_{j=1}^{\infty} \Gamma_j\, P_{t-1}\varepsilon_{t-j} = 0. \tag{52.15}$$

So the distributed lag in (52.13) loads only on the parts of past shocks that the small econometrician has *not yet* learned,

$$a_t = S_y \varepsilon_t + \sum_{j=1}^{\infty} \Gamma_j (\varepsilon_{t-j} - P_{t-1}\varepsilon_{t-j}). \tag{52.16}$$

A shock that happened three quarters ago can still be news today, if the only series you watch has not finished revealing it.

That is the whole content of the filtering problem, and it is why Ω exceeds $S_y V S_y^\top$.

52.4.6 What the coefficients Γ_j are

Substituting the moving average (52.12) into the autoregression (52.9) and matching the coefficient on ε_{t-k} gives a second formula for the same objects,

$$\Gamma_k = \Phi_k - \sum_{j=1}^{k} B_j\, \Phi_{k-j}. \tag{52.17}$$

So Γ_k measures the failure of the small system's own autoregression to reproduce the large system's k-lag response.

The case $k = 1$ is worth writing out.

Since $\Phi_0 = S_y$ and $\Phi_1 = GAC = S_y A_1$,

$$\Gamma_1 = S_y A_1 - B_1 S_y. \tag{52.18}$$

Suppose S_y selects coordinates, and partition $Y_t = (y_t^\top, \tilde{y}_t^\top)^\top$ as before.

Then $B_1 S_y$ has zeros in the columns belonging to the dropped variables, so (52.18) reads

$$\Gamma_1 = \begin{pmatrix} A_1^{yy} - B_1 & A_1^{y\tilde{y}} \end{pmatrix}. \tag{52.19}$$

The loading of a_t on last period's *omitted* shocks is exactly $A_1^{y\tilde{y}}$, the block through which the omitted variables enter the retained equations.

Equation (52.19) also previews *Proposition 52.5.2*: block exogeneity sets $A_1^{y\tilde{y}} = 0$, which forces $B_1 = A_1^{yy}$ and hence $\Gamma_1 = 0$.

52.4.7 A factorization identity

Representations (52.8), (52.11), and (52.12) describe the same process, so with $\Psi(z) = \sum_h \Psi_h z^h$ and similarly for Γ and Φ,

$$\Phi(z) = \Psi(z)\,\Gamma(z). \tag{52.20}$$

Equation (52.20) says the structural moving average operator factors into the Wold operator of the small system times the innovation map.

It is a sharp numerical check on everything above, and we use it as one.

Matching variances at each lag also gives

$$\Omega = \sum_{j=0}^{\infty} \Gamma_j V \Gamma_j^\top = S_y V S_y^\top + \sum_{j=1}^{\infty} \Gamma_j V \Gamma_j^\top. \tag{52.21}$$

Every term in the second sum is positive semidefinite, so

$$\Omega \succeq S_y V S_y^\top.$$

The small system's one-step forecast error variance is never smaller than the corresponding block of the large system's, and (52.21) says exactly how much is lost.

52.5 Two cases where nothing is lost

Proposition 52.5.1

If $S_y = I_n$, then $\Gamma_0 = I_n$ and $\Gamma_j = 0$ for $j \geq 1$, so $a_t = \varepsilon_t$, and (52.9) collapses to the original mth order VAR (52.1).

Nothing is hidden, so the Wold innovations *are* the structural innovations.

The second case is more interesting.

Partition $Y_t = (y_t^\top, \tilde{y}_t^\top)^\top$ and correspondingly

$$A_k = \begin{pmatrix} A_k^{yy} & A_k^{y\tilde{y}} \\ A_k^{\tilde{y}y} & A_k^{\tilde{y}\tilde{y}} \end{pmatrix}, \qquad k = 1, \dots, m.$$

Proposition 52.5.2

Suppose y_t is **block exogenous**, meaning $A_k^{y\tilde{y}} = 0$ for all k, so that no lag of the omitted variables appears in the equations for y.

Then $\Gamma_j = 0$ for $j \geq 1$, $a_t = S_y \varepsilon_t$, $\Omega = S_y V S_y^\top$, and y_t obeys the finite mth order VAR

$$y_t = \sum_{k=1}^{m} A_k^{yy}\, y_{t-k} + a_t.$$

Proof. Block exogeneity makes the y rows of (52.1) read $y_{t+1} = \sum_k A_k^{yy} y_{t+1-k} + S_y \varepsilon_{t+1}$.

The right side involves only lags of y, and $S_y \varepsilon_{t+1}$ is orthogonal to the whole history Y^t and hence to y^t.

So this *is* the projection of y_{t+1} on y^t, which identifies it as the Wold representation.

Note what *Proposition 52.5.2* does *not* require: V need not be block diagonal.

Contemporaneous correlation between ε^y and $\varepsilon^{\tilde{y}}$ is fine.

What matters for whether an omitted variable damages a VAR is Granger causality, not contemporaneous correlation.

52.6 Code

The class below packages everything.

```
class VARSubsystem:
    """
    A VAR for Y and the implied representations for a subvector y = S_y Y.

        Y[t+1] = A_1 Y[t] + ... + A_m Y[t-m+1] + eps[t+1],  E eps eps' = V
        y[t]   = S_y Y[t]

    Parameters
    ----------
    A_list : list of (n, n) arrays, the VAR coefficient matrices A_1, ..., A_m
    V      : (n, n) array, covariance matrix of eps
    S_y    : (n_y, n) selector matrix
    """

52.7 Example 1: a bivariate VAR(2)

Two observable series r_t and z_t obey the VAR(2)

$$\begin{pmatrix} r_{t+1} \\ z_{t+1} \end{pmatrix} = A_1 \begin{pmatrix} r_t \\ z_t \end{pmatrix} + A_2 \begin{pmatrix} r_{t-1} \\ z_{t-1} \end{pmatrix} + \varepsilon_{t+1},$$

with

$$A_1 = \begin{pmatrix} 0.80 & 0.75 \\ 0 & 0.75 \end{pmatrix}, \qquad A_2 = \begin{pmatrix} 0.05 & -0.72 \\ 0 & 0.20 \end{pmatrix}, \qquad V = I_2.$$

Note that z is block exogenous: its equation contains no lags of r.

But r is *not*, since z enters the r equation with both lags.

So dropping z should matter, while dropping r should not.

```
A1 = np.array([[0.80,  0.75],
               [0.00,  0.75]])
A2 = np.array([[0.05, -0.72],
               [0.00,  0.20]])
V2 = np.eye(2)

S_both = np.eye(2)                    # observe (r, z)
S_r    = np.array([[1.0, 0.0]])       # observe r only
S_z    = np.array([[0.0, 1.0]])       # observe z only

mod_both = VARSubsystem([A1, A2], V2, S_both)
mod_r    = VARSubsystem([A1, A2], V2, S_r)
mod_z    = VARSubsystem([A1, A2], V2, S_z)

Psi_both, Gam_both, _ = report(mod_both, label='observe r and z')
print()
Psi_r, Gam_r, _ = report(mod_r, label='observe r only')
print()
Psi_z, Gam_z, _ = report(mod_z, label='observe z only')
```

```
--- observe r and z (n = 2, m = 2, n_y = 2)

  det Omega / det S_y V S_y'    1.0000
```

Every identity holds to machine precision.

The three cases differ exactly as the propositions predict.

Observing both variables gives $\Gamma_j = 0$ for $j \geq 1$, so $a_t = \varepsilon_t$, as *Proposition 52.5.1* requires.

Observing only z, which is block exogenous, also gives $\Gamma_j = 0$ for $j \geq 1$, so $a_t = \varepsilon_{z,t}$, as *Proposition 52.5.2* requires.

Observing only r is different.

Here $\Gamma_j \neq 0$ for $j \geq 1$, and the ratio of forecast error variances reports how much the r-only econometrician loses.

```
print('observe r only:')
print(f'  Omega           = {mod_r.innovation_cov()[0, 0]:.4f}')
print(f'  S_y V S_y\'      = {(S_r @ V2 @ S_r.T)[0, 0]:.4f}')
print('\n  Gamma[j] for j = 0, ..., 5 (rows: response of a to eps_r, eps_z)')
print(Gam_r[:6, 0, :])
```

```
observe r only:
  Omega           = 1.5786
  S_y V S_y'      = 1.0000

  Gamma[j] for j = 0, ..., 5 (rows: response of a to eps_r, eps_z)
[[ 1.      0.    ]
 [ 0.0769  0.75  ]
 [-0.0097 -0.0998]
 [ 0.0017  0.0125]
 [ 0.0002 -0.0023]
 [ 0.0004 -0.0003]]
```

The forecast error variance is over 50 percent larger than V_{11}.

The extra variance is entirely attributable to past ε_z shocks that the econometrician sees only through their effect on r.

52.7.1 The VAR for the subsystem

```
B_r = mod_r.var_coefficients(12)

fig, ax = plt.subplots()
ax.stem(np.arange(1, 13), B_r[:, 0, 0], basefmt=' ')
ax.axhline(0, color='k', lw=0.6)
ax.set_xlabel('lag $j$')
ax.set_ylabel('$B_j$')
ax.set_title(r'Population VAR coefficients for $r_t$ when only $r$ is observed')
fig.tight_layout()
plt.show()
```

(continues on next page)

(continued from previous page)

```
print('B_1, ..., B_6:', np.round(B_r[:6, 0, 0], 5))
print('\nfor comparison, A_1[0,0] and A_2[0,0]:', A1[0, 0], A2[0, 0])
```

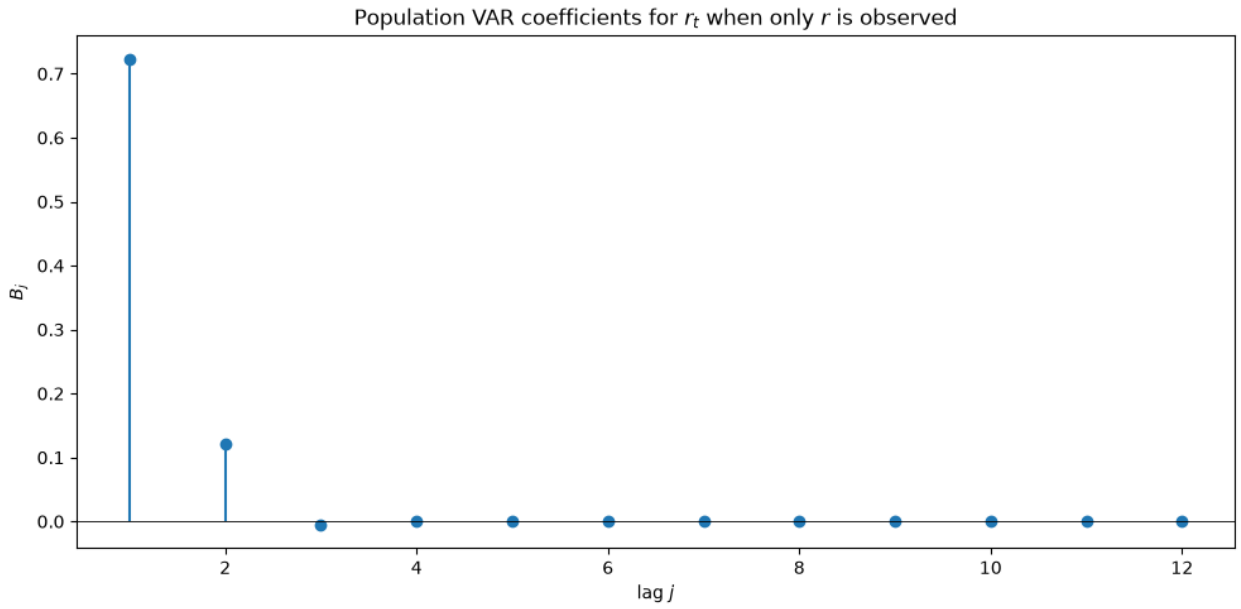

Fig. 52.1: VAR coefficients for the subsystem

```
B_1, ..., B_6: [ 0.7231  0.1212 -0.0056  0.0007 -0.0001 -0.    ]

for comparison, A_1[0,0] and A_2[0,0]: 0.8 0.05
```

The infinite-order VAR for r alone is dominated by two lags, but neither coefficient equals the corresponding coefficient in the bivariate system.

Dropping z does not simply delete the z columns of the VAR; it changes what is left.

52.7.2 Wold impulse responses

```
H = 25
h = np.arange(H + 1)
Psi_both = mod_both.wold(H)

fig, axes = plt.subplots(2, 2, figsize=(10, 6), sharex=True)
names, shocks = [r'$r_t$', r'$z_t$'], [r'$a_{r,t}$', r'$a_{z,t}$']
for i in range(2):
    for j in range(2):
        axes[i, j].plot(h, Psi_both[:, i, j], lw=2)
        axes[i, j].axhline(0, color='k', lw=0.6, ls='--')
        axes[i, j].set_title(f'{names[i]} to {shocks[j]}', fontsize=10)
        if i == 1:
            axes[i, j].set_xlabel('horizon $h$')
fig.suptitle('Wold responses, both variables observed')
fig.tight_layout()
plt.show()
```

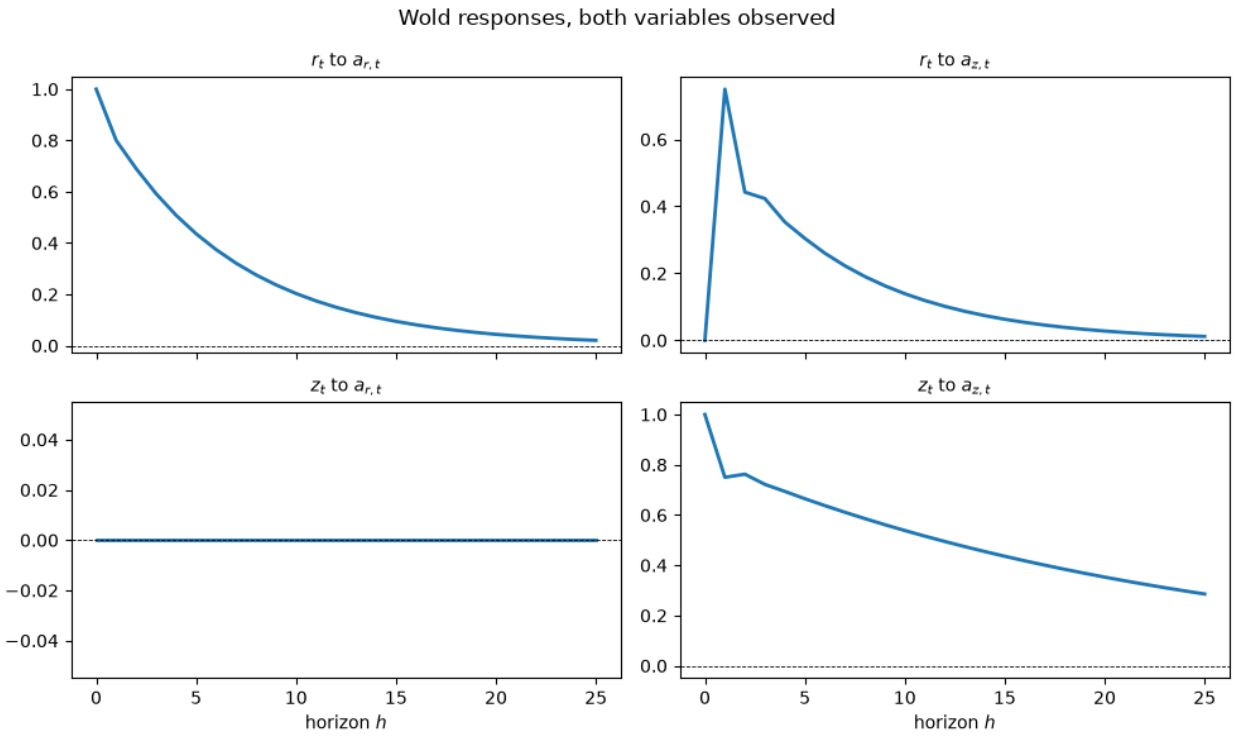

Fig. 52.2: Wold responses when both variables are observed

Because $a_t = \varepsilon_t$ here, these Wold responses coincide with the structural responses of the bivariate VAR.

```
Psi_r = mod_r.wold(H)
Phi_r = mod_r.structural_ma(H)

fig, ax = plt.subplots()
ax.plot(h, Psi_r[:, 0, 0], lw=2, label=r'$\Psi_h$: $r_t$ to its own innovation $a_t$')
ax.plot(h, Phi_r[:, 0, 0], lw=2, ls='--',
        label=r'$\Phi_h$: $r_t$ to $\varepsilon_{r,t}$')
ax.plot(h, Phi_r[:, 0, 1], lw=2, ls=':',
        label=r'$\Phi_h$: $r_t$ to $\varepsilon_{z,t}$')
ax.axhline(0, color='k', lw=0.6)
ax.set_xlabel('horizon $h$')
ax.set_ylabel('response')
ax.set_title(r'Wold versus structural responses of $r_t$')
ax.legend()
fig.tight_layout()
plt.show()
```

The Wold response to a_t is not the response to either structural shock.

It is a blend, and (52.20) says exactly how the blending works.

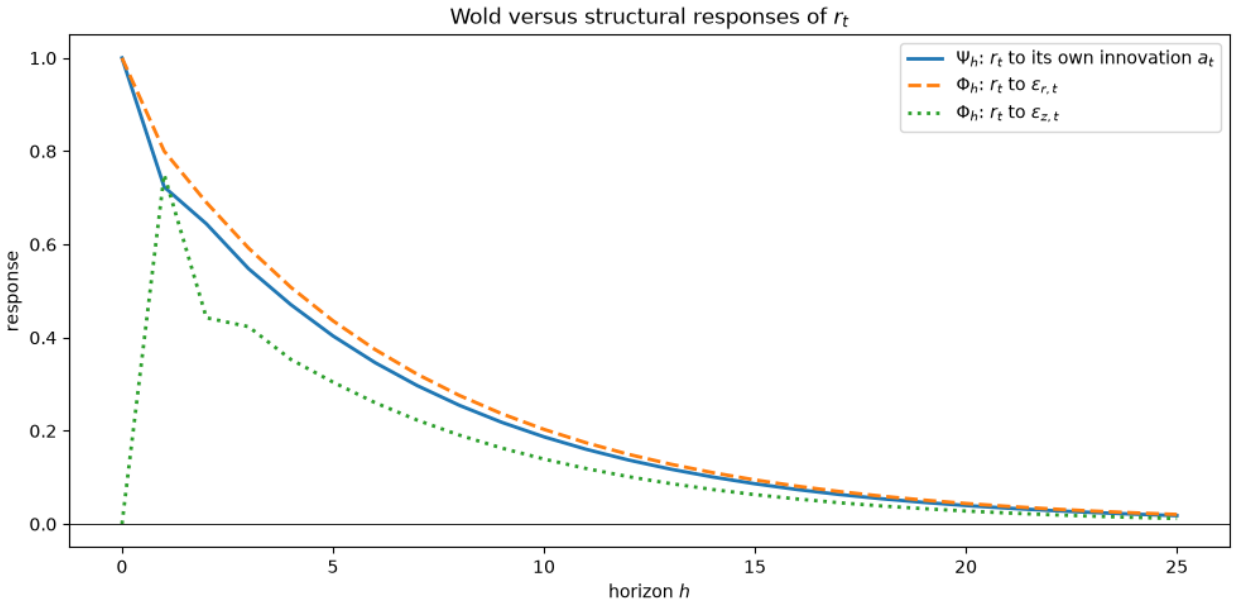

Fig. 52.3: Wold response when only r is observed

52.7.3 Checking the innovation map by simulation

Proposition *Proposition 52.4.1* is a statement about population objects.

We check it on a long simulated sample by comparing the innovations that the Kalman filter extracts from the observed r series with the distributed lag $\sum_j \Gamma_j \varepsilon_{t-j}$ built from the shocks that generated it.

```
T = 100_000
Y_sim, eps_sim = mod_r.simulate(T, seed=1)
y_sim = Y_sim @ S_r.T

a_filtered = mod_r.filter_innovations(y_sim)

J_lag = 400          # the distributed lag is infinite, so truncate generously
Gam_long = mod_r.innovation_map(J_lag)
a_theory = np.zeros_like(a_filtered)
for j in range(J_lag + 1):
    a_theory[j:] += eps_sim[:T - j] @ Gam_long[j].T

burn = J_lag + 1
print(f'correlation of the two series   '
      f'{np.corrcoef(a_filtered[burn:, 0], a_theory[burn:, 0])[0, 1]:.8f}')
print(f'max absolute difference         '
      f'{np.abs(a_filtered[burn:] - a_theory[burn:]).max():.2e}')
print(f'sample variance of a            {a_filtered[burn:, 0].var():.4f}')
print(f'population Omega                {mod_r.innovation_cov()[0, 0]:.4f}')
print(f'sample corr(a_t, a_(t-1))       '
      f'{np.corrcoef(a_filtered[burn + 1:, 0], a_filtered[burn:-1, 0])[0, 1]:.4f}')
```

```
correlation of the two series   1.00000000
max absolute difference         6.45e-10
sample variance of a            1.5706
population Omega                1.5786
```

(continues on next page)

(continued from previous page)

```
sample corr(a_t, a_(t-1))       -0.0048
```

The two constructions of a_t agree to the accuracy of the truncated distributed lag, the sample variance of a_t matches Ω, and a_t is serially uncorrelated.

52.7.4 The two orthogonality facts

Now we check (52.14) directly, by running two regressions on the simulated data.

The first regresses a_t on current and lagged *structural* shocks, which the small econometrician cannot see.

The second regresses a_t on lagged *observations*, which are all that the small econometrician can see.

```
P_lags = 4
Z_eps = np.column_stack([eps_sim[P_lags - l:T - l] for l in range(P_lags + 1)])
target = a_filtered[P_lags:, 0]
b_eps = np.linalg.lstsq(Z_eps, target, rcond=None)[0].reshape(P_lags + 1, 2)
fit = Z_eps @ b_eps.ravel()
r2_eps = 1 - ((target - fit) ** 2).sum() / target.var() / len(target)

print('OLS of a_t on eps_t, ..., eps_{t-4}:')
print(b_eps)
print('population Gamma_0, ..., Gamma_4:')
print(Gam_long[:P_lags + 1, 0, :])
print(f'max discrepancy {np.abs(b_eps - Gam_long[:P_lags + 1, 0, :]).max():.2e}')
print(f'R^2 = {r2_eps:.6f}')
```

```
OLS of a_t on eps_t, ..., eps_{t-4}:
[[ 1.     -0.    ]
 [ 0.0769  0.75  ]
 [-0.0097 -0.0998]
 [ 0.0017  0.0125]
 [ 0.0002 -0.0023]]
population Gamma_0, ..., Gamma_4:
[[ 1.      0.    ]
 [ 0.0769  0.75  ]
 [-0.0097 -0.0998]
 [ 0.0017  0.0125]
 [ 0.0002 -0.0023]]
max discrepancy 1.64e-05
R^2 = 0.999996
```

```
Q_lags = 8
Z_y = np.column_stack([y_sim[Q_lags - l - 1:T - l - 1, 0] for l in range(Q_lags)])
tgt = a_filtered[Q_lags:, 0]
b_y = np.linalg.lstsq(Z_y, tgt, rcond=None)[0]
resid = tgt - Z_y @ b_y
r2_y = 1 - (resid ** 2).sum() / tgt.var() / len(tgt)

print('OLS of a_t on y_{t-1}, ..., y_{t-8}:')
print(np.round(b_y, 5))
print(f'R^2 = {r2_y:.6f}')
```

```
OLS of a_t on y_{t-1}, ..., y_{t-8}:
[-0.0046  0.0044 -0.0015  0.001   0.0018 -0.0063  0.0055 -0.0024]
R^2 = 0.000056
```

The first regression recovers the Γ_j and fits almost perfectly, the small shortfall coming only from truncating the distributed lag at four lags.

So a_t really is built out of shocks stretching back before t.

The second explains essentially nothing, confirming that a_t is nonetheless orthogonal to the small econometrician's information set.

We can see why by asking how much of each past shock the small econometrician has managed to learn.

```
print('R^2 from projecting a structural shock on y_{t-1}, ..., y_{t-8}')
for lag in [0, 1, 2, 3]:
    r2s = []
    for k in range(2):
        shock = eps_sim[Q_lags - lag:T - lag, k]
        c = np.linalg.lstsq(Z_y, shock, rcond=None)[0]
        e = shock - Z_y @ c
        r2s.append(1 - (e ** 2).sum() / shock.var() / len(shock))
    print(f'   eps_(t-{lag}):   eps_r {r2s[0]:6.4f}    eps_z {r2s[1]:6.4f}')
```

```
R^2 from projecting a structural shock on y_{t-1}, ..., y_{t-8}
   eps_(t-0):   eps_r 0.0000    eps_z 0.0001
   eps_(t-1):   eps_r 0.6314    eps_z 0.0001
   eps_(t-2):   eps_r 0.6351    eps_z 0.3561
   eps_(t-3):   eps_r 0.6352    eps_z 0.3624
```

The current shock ε_t is entirely unpredictable from y^{t-1}, as it must be.

Shocks from two or more periods back are substantially learned.

The interesting row is ε_{t-1}: its r component is largely known, while its z component is *completely* unknown, because z_{t-1} reaches r only with a one-period lag and so has not yet shown up anywhere in y^{t-1}.

That is why (52.19) gives a_t a loading on $\varepsilon_{z,t-1}$ equal to the full structural coefficient $A_1^{y\tilde{y}} = 0.75$, while its loading on $\varepsilon_{r,t-1}$ is only the much smaller residual $A_1^{yy} - B_1$.

```
B1 = mod_r.var_coefficients(1)[0]
print(f'Gamma_1                   = {Gam_long[1, 0, :]}')
print(f'[A1[0,0] - B_1,  A1[0,1]] = '
      f'[{A1[0, 0] - B1[0, 0]:.4f}, {A1[0, 1]:.4f}]')

Phi_r = mod_r.structural_ma(6)
B_r6 = mod_r.var_coefficients(6)
recursion = np.array([Phi_r[k] - sum(B_r6[j - 1] @ Phi_r[k - j]
                                     for j in range(1, k + 1))
                      for k in range(7)])
print(f'\nmax |Gamma_k - (Phi_k - sum_j B_j Phi_(k-j))| = '
      f'{np.abs(recursion - Gam_long[:7]).max():.2e}')
```

```
Gamma_1                   = [0.0769 0.75  ]
[A1[0,0] - B_1,  A1[0,1]] = [0.0769, 0.7500]

max |Gamma_k - (Phi_k - sum_j B_j Phi_(k-j))| = 1.25e-16
```

52.8 Example 2: an omitted interest rate

Now a trivariate VAR(1) in output growth g_t, inflation π_t, and an interest rate i_t, from which the econometrician drops i_t.

We contrast two coefficient matrices that differ *only* in whether the interest rate feeds back onto g and π.

$$A_1^{\text{exog}} = \begin{pmatrix} 0.60 & 0.10 & 0.00 \\ 0.15 & 0.55 & 0.00 \\ 0.30 & 0.40 & 0.70 \end{pmatrix}, \qquad A_1^{\text{fb}} = \begin{pmatrix} 0.60 & 0.10 & -0.35 \\ 0.15 & 0.55 & 0.25 \\ 0.30 & 0.40 & 0.70 \end{pmatrix}.$$

The shock covariance matrix V is the same in both, and it is *not* diagonal, so the interest rate innovation is contemporaneously correlated with the other two.

```
V3 = np.array([[0.36, 0.05, 0.02],
               [0.05, 0.25, 0.06],
               [0.02, 0.06, 0.16]])
S_gpi = np.array([[1.0, 0.0, 0.0],
                  [0.0, 1.0, 0.0]])

A_exog = np.array([[0.60, 0.10, 0.00],
                   [0.15, 0.55, 0.00],
                   [0.30, 0.40, 0.70]])
A_fb = np.array([[0.60, 0.10, -0.35],
                 [0.15, 0.55,  0.25],
                 [0.30, 0.40,  0.70]])

mod_exog = VARSubsystem([A_exog], V3, S_gpi)
mod_fb = VARSubsystem([A_fb], V3, S_gpi)

_, Gam_exog, _ = report(mod_exog, label='i is block exogenous')
print()
_, Gam_fb, _ = report(mod_fb, label='i feeds back')
```

```
--- i is block exogenous (n = 3, m = 1, n_y = 2)
  max |eig| of companion A      0.700000
  max |eig| of A - KG           0.700000
  Riccati residual              5.55e-17
  |Gamma[0] - S_y|              0.00e+00
  |Phi - Psi * Gamma|           2.78e-17
  |Omega - sum Gamma V Gamma'|  0.00e+00
  max |Gamma[j]|, j >= 1        1.110e-16
  det Omega / det S_y V S_y'    1.0000

--- i feeds back (n = 3, m = 1, n_y = 2)
  max |eig| of companion A      0.792688
  max |eig| of A - KG           0.558938
  Riccati residual              1.11e-16
  |Gamma[0] - S_y|              0.00e+00
  |Phi - Psi * Gamma|           1.11e-16
  |Omega - sum Gamma V Gamma'|  1.11e-16
  max |Gamma[j]|, j >= 1        3.500e-01
  det Omega / det S_y V S_y'    1.1614
```

The block exogenous case behaves exactly as *Proposition 52.5.2* says it must, despite the correlated shocks.

The feedback case does not.

```
print('block exogenous: B_1 versus the (g, pi) block of A_1')
print(mod_exog.var_coefficients(3)[0])
print(A_exog[:2, :2])
print(f'  max |B_j| for j >= 2: {np.abs(mod_exog.var_coefficients(12)[1:]).max():.2e}
 ↪')

print('\nfeedback: B_1 versus the (g, pi) block of A_1')
print(mod_fb.var_coefficients(3)[0])
print(A_fb[:2, :2])
print(f'  max |B_j| for j >= 2: {np.abs(mod_fb.var_coefficients(12)[1:]).max():.4f}')
```

```
block exogenous: B_1 versus the (g, pi) block of A_1
[[0.6  0.1 ]
 [0.15 0.55]]
[[0.6  0.1 ]
 [0.15 0.55]]
  max |B_j| for j >= 2: 6.66e-17

feedback: B_1 versus the (g, pi) block of A_1
[[ 0.643  -0.0373]
 [ 0.1193  0.648 ]]
[[0.6  0.1 ]
 [0.15 0.55]]
  max |B_j| for j >= 2: 0.1455
```

With block exogeneity the subsystem VAR is *exactly* the corresponding block of the large VAR, and it stops at one lag.

With feedback the one-lag coefficients are distorted and higher-order terms appear.

The effect on the coefficient of lagged inflation in the output growth equation is worth noticing: a positive number in the large system becomes a negative one in the subsystem.

```
J_max = 10
labels = [r'$\varepsilon_g$', r'$\varepsilon_\pi$', r'$\varepsilon_i$']
fig, axes = plt.subplots(2, 2, figsize=(11, 6), sharex=True)
for col, (Gam, ttl) in enumerate([(Gam_exog, 'block exogenous'),
                                  (Gam_fb, 'feedback')]):
    for row, obs in enumerate([r'$a_g$', r'$a_\pi$']):
        ax = axes[row, col]
        for k in range(3):
            ax.plot(np.arange(J_max + 1), Gam[:J_max + 1, row, k],
                    marker='o', ms=3, lw=1.5, label=labels[k])
        ax.axhline(0, color='k', lw=0.6)
        ax.set_title(f'{obs}, {ttl}', fontsize=10)
        if row == 1:
            ax.set_xlabel('lag $j$')
        if row == 0 and col == 0:
            ax.legend(fontsize=8)
axes[0, 0].set_ylabel(r'$\Gamma_j$')
axes[1, 0].set_ylabel(r'$\Gamma_j$')
fig.suptitle(r'Coefficients $\Gamma_j$ in $a_t = \sum_j \Gamma_j \varepsilon_{t-j}$')
fig.tight_layout()
plt.show()
```

In the left column only the $j = 0$ coefficients are nonzero, and they equal the rows of S_y.

In the right column the omitted interest rate shock ε_i leaks into the observed innovations at every lag.

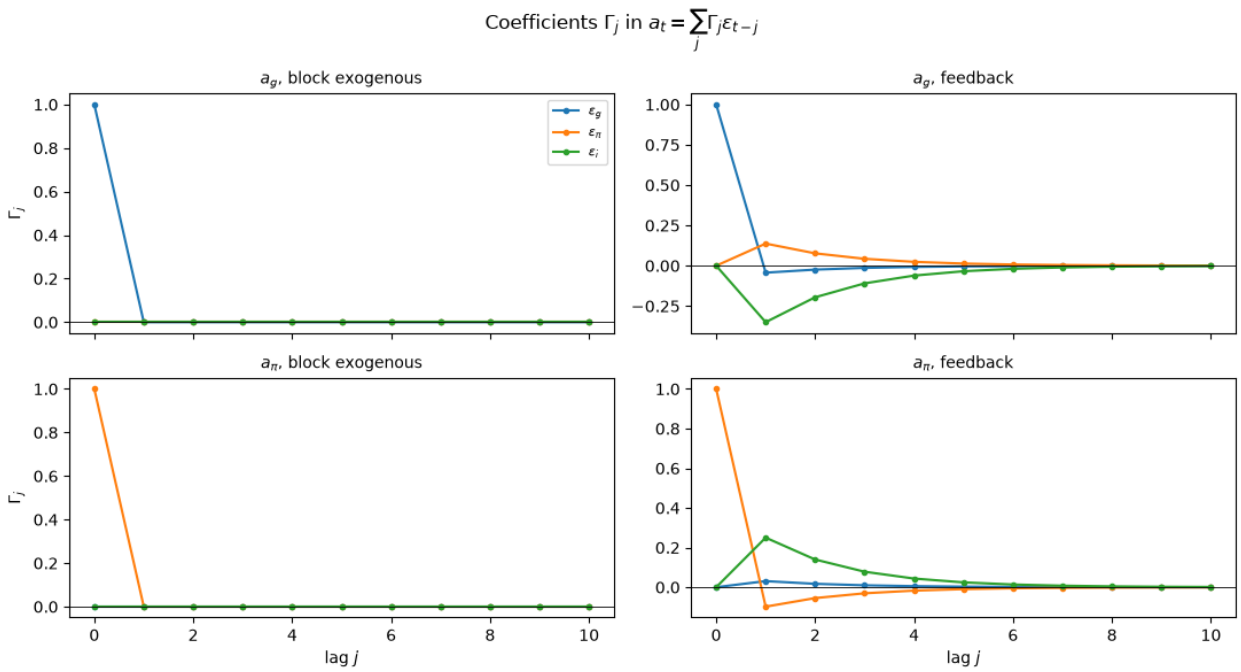

Fig. 52.4: Innovation map coefficients with and without feedback

52.9 Summary

A finite-order VAR for Y_t implies, for any subvector $y_t = S_y Y_t$, an infinite-order VAR whose coefficients $B_j = G(A - KG)^{j-1}K$ come from the steady-state Kalman filter for the companion system.

The innovations of the small system are a one-sided distributed lag $a_t = \sum_j \Gamma_j \varepsilon_{t-j}$ of the innovations of the large system, with $\Gamma_j = G(A - KG)^j C$ and $\Gamma_0 = S_y$.

Because Γ_j is wide, that map cannot be inverted, which is a precise statement of the informational deficiency of a subsystem VAR.

The price is measured by $\Omega - S_y V S_y^\top = \sum_{j \geq 1} \Gamma_j V \Gamma_j^\top$.

The price is zero when everything is observed, and also when the retained block is block exogenous, in which case the subsystem VAR is exactly the corresponding block of the original one.

52.10 Exercises

Exercise 52.10.1

Take the trivariate system of Example 2 and put the feedback of the interest rate onto (g, π) under your control by writing

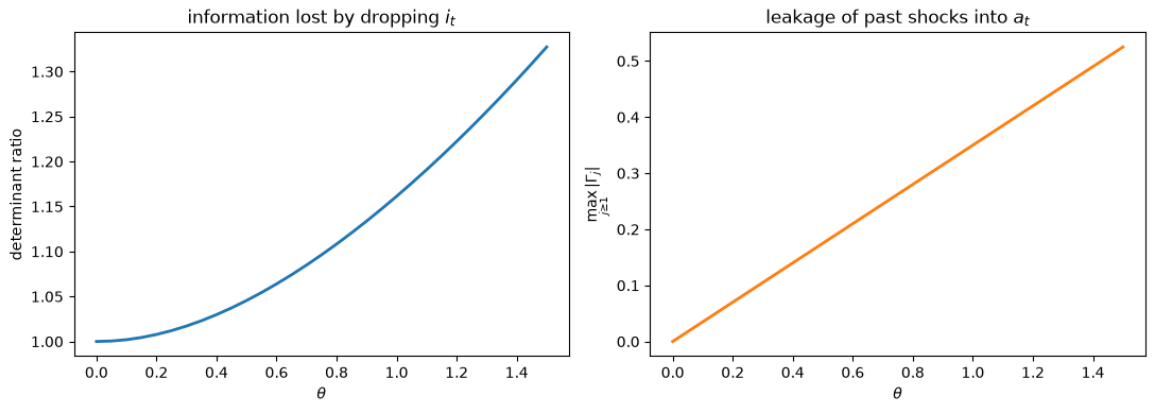
$$A_1(\theta) = A_1^{\text{exog}} + \theta \begin{pmatrix} 0 & 0 & -0.35 \\ 0 & 0 & 0.25 \\ 0 & 0 & 0 \end{pmatrix}.$$

For θ on a grid from 0 to 1.5, plot

1. $\det \Omega / \det(S_y V S_y^\top)$, the information lost by dropping i_t,
2. $\max_{j \geq 1} |\Gamma_j|$, the size of the leakage of past shocks into the observed innovations.

Explain the shape you find at $\theta = 0$.

Solution



Here is one solution:

```
E = np.zeros((3, 3))
E[0, 2], E[1, 2] = -0.35, 0.25

thetas = np.linspace(0, 1.5, 31)
det_ratio, leak = [], []
for th in thetas:
    mod = VARSubsystem([A_exog + th * E], V3, S_gpi)
    Om = mod.innovation_cov()
    det_ratio.append(np.linalg.det(Om)
                     / np.linalg.det(S_gpi @ V3 @ S_gpi.T))
    leak.append(np.abs(mod.innovation_map(40)[1:]).max())

fig, axes = plt.subplots(1, 2, figsize=(11, 4))
axes[0].plot(thetas, det_ratio, lw=2)
axes[0].set(xlabel=r'$\theta$', ylabel='determinant ratio',
            title='information lost by dropping $i_t$')
axes[1].plot(thetas, leak, lw=2, color='C1')
axes[1].set(xlabel=r'$\theta$', ylabel=r'$\max_{j \geq 1} |\Gamma_j|$',
            title='leakage of past shocks into $a_t$')
for ax in axes:
    ax.axhline(ax.get_ylim()[0], color='k', lw=0.6)
fig.tight_layout()
plt.show()

print(f'at theta = 0:   ratio = {det_ratio[0]:.6f}, leakage = {leak[0]:.2e}')
print(f'at theta = 1:   ratio = {det_ratio[20]:.4f}, leakage = {leak[20]:.4f}')
```

```
at theta = 0:   ratio = 1.000000, leakage = 1.11e-16
at theta = 1:   ratio = 1.1614, leakage = 0.3500
```

Both curves start at their minima, exactly zero leakage and a determinant ratio of exactly one.

That is *Proposition 52.5.2*: at $\theta = 0$ the interest rate does not Granger cause (g, π), so dropping it costs nothing even

though its innovation is contemporaneously correlated with the others.

Both measures rise as the feedback strengthens.

Exercise 52.10.2

Return to the bivariate system, but replace A_1 and A_2 by the single matrix

$$A_1 = \begin{pmatrix} 0.5 & 0.6 \\ 0 & \rho_z \end{pmatrix}, \qquad V = I_2,$$

so that ρ_z controls the persistence of the omitted variable z.

Observing r only, report for $\rho_z \in \{0.2, 0.5, 0.75, 0.9, 0.95, 0.99\}$

1. the forecast error variance Ω,
2. the number of lags needed before $\sum_{j>p} |B_j| < 10^{-3}$.

What does a persistent omitted variable do to the VAR that an econometrician should fit?

Solution

Here is one solution:

```
print(' rho_z    Omega    lags needed')
for rho_z in [0.2, 0.5, 0.75, 0.9, 0.95, 0.99]:
    mod = VARSubsystem([np.array([[0.5, 0.6], [0.0, rho_z]])],
                       np.eye(2), np.array([[1.0, 0.0]]))
    B = mod.var_coefficients(400)
    tails = [np.abs(B[p:]).sum() for p in range(400)]
    p_need = next(p for p in range(400) if tails[p] < 1e-3)
    print(f' {rho_z:5.2f}   {mod.innovation_cov()[0, 0]:6.4f}      {p_need:3d}')
```

```
rho_z    Omega    lags needed
 0.20   1.3708        3
 0.50   1.4359        5
 0.75   1.5625        5
 0.90   1.6910        7
 0.95   1.7454        8
 0.99   1.7937        8
```

Both columns rise with ρ_z.

A persistent omitted variable both inflates the forecast error variance and lengthens the autoregression, because the econometrician must reach further back to extract the same information about z from the history of r.

An empirical VAR with too few lags will therefore be worst exactly where the missing variable is most persistent.

Exercise 52.10.3

The coefficients B_j are population objects.

Simulate $T = 200{,}000$ observations of the bivariate system of Example 1, retain only r_t, and fit finite-order autoregressions of orders $p = 1, 2, 4, 8$ by ordinary least squares.

Compare the estimates with $B_1, \ldots, B_p$ and the residual variance with Ω.

Which order is too short, and what does fitting too short a lag length do to the first coefficient?

Solution

Here is one solution:

```
Y_big, _ = mod_r.simulate(200_000, seed=3)
r_series = Y_big[:, 0]
B_pop = mod_r.var_coefficients(8)[:, 0, 0]

for p in [1, 2, 4, 8]:
    X = np.column_stack([r_series[p - 1 - l:len(r_series) - 1 - l]
                         for l in range(p)])
    zz = r_series[p:]
    b_hat = np.linalg.lstsq(X, zz, rcond=None)[0]
    resid = zz - X @ b_hat
    print(f'p = {p}')
    print(f'   OLS        {np.round(b_hat, 4)}')
    print(f'   population {np.round(B_pop[:p], 4)}')
    print(f'   residual variance {resid.var():.4f}   Omega {mod_r.innovation_
↪cov()[0, 0]:.4f}')
```

```
p = 1
   OLS        [0.8179]
   population [0.7231]
   residual variance 1.6037   Omega 1.5786
p = 2
   OLS        [0.7201 0.1196]
   population [0.7231 0.1212]
   residual variance 1.5807   Omega 1.5786
p = 4
   OLS        [ 0.7207  0.1238 -0.0036 -0.0025]
   population [ 0.7231  0.1212 -0.0056  0.0007]
   residual variance 1.5807   Omega 1.5786
p = 8
   OLS        [ 0.7207  0.1238 -0.0035 -0.0022 -0.0019 -0.0011  0.003   0.0003]
   population [ 0.7231  0.1212 -0.0056  0.0007 -0.0001 -0.     -0.     -0.    ]
   residual variance 1.5806   Omega 1.5786
```

An AR(1) is too short.

Its single coefficient is pulled well above B_1, because it has to stand in for the omitted second lag, and its residual variance exceeds Ω.

From $p = 2$ onward the estimates track the population coefficients and the residual variance settles on Ω, which matches the finding above that B_j is negligible beyond the second lag in this example.

CHAPTER

FIFTYTHREE

ORGANIZATION CAPITAL

53.1 Overview

This lecture describes a theory of **organization capital** proposed by Prescott and Visscher [1980].

Prescott and Visscher define organization capital as information that a firm accumulates about its employees, teams, and production processes.

This information is an *asset* to the firm because it affects the production possibility set and is produced jointly with output.

Costs of adjusting the stock of organization capital constrain the firm's growth rate, providing an explanation for

1. why firm growth rates are independent of firm size (Gibrat's Law)
2. why adjustment costs for rapid growth arise endogenously rather than being assumed

The paper offers three examples of organization capital:

- *Personnel information*: knowledge about the match between workers and tasks
- *Team information*: knowledge about how well groups of workers mesh
- *Firm-specific human capital*: skills of employees enhanced by on-the-job training

In each case, the investment possibilities lead firms to grow at a common rate, yielding constant returns to scale together with increasing costs of rapid size adjustment.

Note

The theory is related to ideas of Coase [1937] and Williamson [1975] about the nature of the firm.

Prescott and Visscher stress the firm's role as a storehouse of information and argue that incentives within the firm are created for efficient accumulation and use of that information.

Let's start with some imports:

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.stats import norm
from scipy.optimize import brentq
```

53.2 The basic idea

The firm is a storehouse of information.

Within the firm, incentives are created for the efficient accumulation and use of that information.

Prescott and Visscher exploit this concept to explain certain facts about firm growth and size distribution.

The key insight: the process by which information is accumulated naturally leads to

1. *constant returns to scale*, and
2. *increasing costs to rapid firm size adjustment*

Constant returns to scale explain the absence of an observed unique optimum firm size (see Stigler [1958]).

Without costs of adjustment, the pattern of investment by firms in the face of a change in market demand would exhibit discontinuities we do not observe.

Further, without a cost penalty to rapid growth, the first firm to discover a previously untapped market would preempt competition by usurping all profitable investments as they appear, thus implying monopoly more prevalent than it is.

53.3 Personnel information as organization capital

The first example of organization capital is information about the match between workers and tasks.

53.3.1 Setup

Workers have different sets of skills and talents.

A variable θ measures the aptitude of a worker for a particular kind of work.

- Workers with high θ have comparative advantage in tasks requiring repeated attention to detail
- Workers with low θ have comparative advantage in work requiring broadly defined duties

The population distribution of θ is normal with mean zero and precision (inverse of variance) π:

$$\theta \sim N(0, 1/\pi)$$

When a worker is hired from the labor pool, neither the worker nor the employer knows θ.

Both know only the population distribution.

53.3.2 Three tasks

If q units of output are produced, assume:

- $\varphi_1 q$ workers are assigned to *task 1* (screening)
- φq workers are assigned to *task 2*
- the remaining workers are assigned to *task 3*

where $\varphi_1 + 2\varphi = 1$.

> **Note**
>
> The fixed coefficients technology requires a constant ratio between the number of personnel in jobs 2 and 3 and the number assigned to job 1.

For task 1, the screening task, per unit cost of production is *invariant* to the θ-values of the individuals assigned.

However, the larger a worker's θ, the larger is his product in task 2 relative to his product in task 3.

Consequently:

- a worker with a highly positive θ is much better suited for task 2
- a worker with a highly negative θ is much better suited for task 3

53.3.3 Bayesian learning

Performance in tasks 2 or 3 cannot be observed at the individual level.

But information about a worker's θ-value can be obtained from observing performance in task 1, the screening task.

The expert supervising the apprentice determines a value of z each period:

$$z_{it} = \theta_i + \epsilon_{it} \tag{53.1}$$

where $\epsilon_{it} \sim N(0, 1)$ are independently distributed over both workers i and periods t.

After n observations on a worker in the screening job, the *posterior distribution* of θ is normal with

posterior mean:

$$m = \frac{1}{\pi + n} \sum_{k=1}^{n} z_k \tag{53.2}$$

posterior precision:

$$h = \pi + n \tag{53.3}$$

Knowledge of an individual is thus completely characterized by the pair (m, h).

```
def bayesian_update(z_observations, prior_precision):
    """
    Compute posterior mean and precision after observing signals.
    """
    n = len(z_observations)
    h = prior_precision + n
    m = np.sum(z_observations) / h
    return m, h
```

Let's visualize how the posterior evolves as we observe a worker whose true $\theta = 0.8$:

```
rng = np.random.default_rng(0)

θ_true = 0.8
π = 1.0

T = 20
```

(continues on next page)

(continued from previous page)

```
ε = rng.standard_normal(T)
z_signals = θ_true + ε

posterior_means = []
posterior_stds = []

for n in range(1, T + 1):
    m, h = bayesian_update(z_signals[:n], π)
    posterior_means.append(m)
    posterior_stds.append(1 / np.sqrt(h))

fig, axes = plt.subplots(1, 2, figsize=(12, 5))

ax = axes[0]
ax.plot(range(1, T + 1), posterior_means, '-o', markersize=4, lw=2,
        label='Posterior mean $m$')
ax.axhline(θ_true, color='r', linestyle='--',
           label=fr'True $\theta = {θ_true}$')
ax.set_xlabel('number of observations $n$')
ax.set_ylabel('posterior mean $m$')
ax.legend()

ax = axes[1]
ax.plot(range(1, T + 1), posterior_stds, '-o', markersize=4, lw=2,
        label=r'Posterior std $1/\sqrt{h}$')
ax.set_xlabel('number of observations $n$')
ax.set_ylabel('posterior standard deviation')
ax.legend()

plt.tight_layout()
plt.show()
```

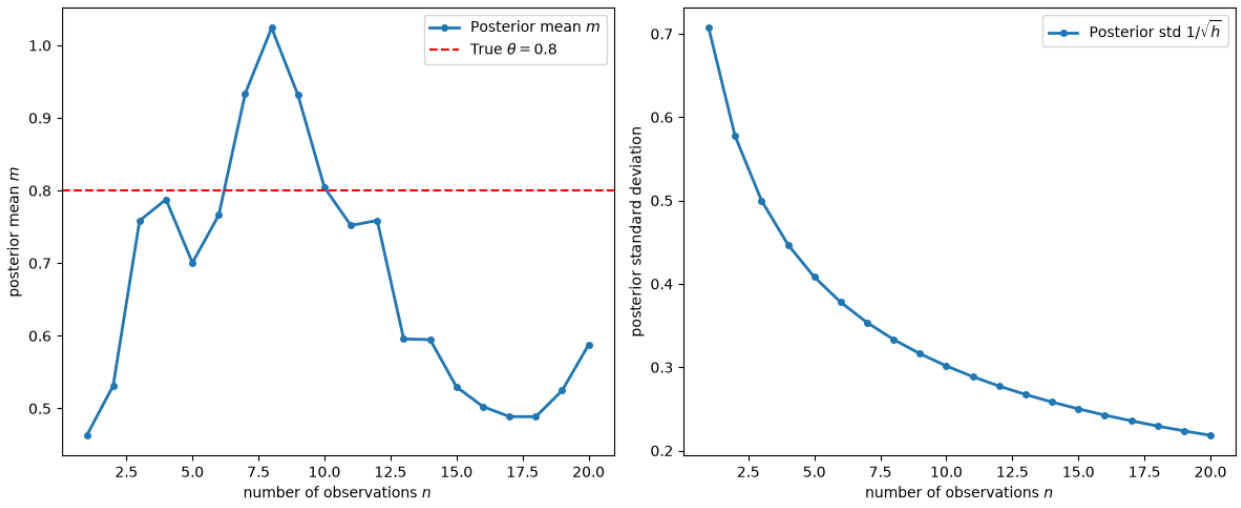


Fig. 53.1: Posterior mean convergence and uncertainty

As the number of screening observations n increases, the posterior mean converges to the true θ, and the posterior uncertainty shrinks at rate $1/\sqrt{n}$.

53.3.4 Per unit costs of production

Under the nonsequential assignment rule, employees with the greatest seniority are assigned to jobs 2 and 3, while newer employees remain in the screening task.

Workers with $m > 0$ are assigned to task 2, and those with $m \leq 0$ to task 3.

Per unit costs of production, assuming this assignment after n screening periods, are:

$$c(n) = c_1 + c_2 + c_3 - E\{\theta \mid m > 0\} + E\{\theta \mid m \leq 0\} \tag{53.4}$$

Because m is normally distributed, evaluation of the conditional expectation in (53.4) yields per unit costs as a function of n:

$$c(n) = c - 0.7978 \frac{n}{\pi(\pi + n)} \tag{53.5}$$

where $c = c_1 + c_2 + c_3$ and $0.7978 = 2 \int_0^\infty \frac{t}{\sqrt{2\pi}} e^{-t^2/2} dt$.

Note

The constant $0.7978 \approx \sqrt{2/\pi}$ is the mean of the standard half-normal distribution.

It arises from computing $E[\theta \mid m > 0] - E[\theta \mid m \leq 0]$ for a normal distribution.

The function $c(n)$ decreases at a *decreasing rate* in n.

More screening observations reduce costs but with diminishing returns.

```
def cost_per_unit(n_vals, π, c_bar=1.0):
    """
    Per unit cost as a function of screening periods n.
    """
    n_vals = np.asarray(n_vals, dtype=float)
    return c_bar - 0.7978 * n_vals / (π * (π + n_vals))

fig, ax = plt.subplots(figsize=(10, 6))

n_vals = np.linspace(0.1, 50, 200)

for π in [0.5, 1.0, 2.0, 5.0]:
    costs = cost_per_unit(n_vals, π)
    ax.plot(n_vals, costs, lw=2, label=fr'$\pi = {π}$')

ax.set_xlabel('screening periods $n$')
ax.set_ylabel('per unit cost $c(n)$')
ax.legend()
ax.set_xlim(0, 50)
plt.tight_layout()
plt.show()
```

The figure shows that:

- costs decrease with more screening time n
- the decrease is at a declining rate (diminishing returns to screening)

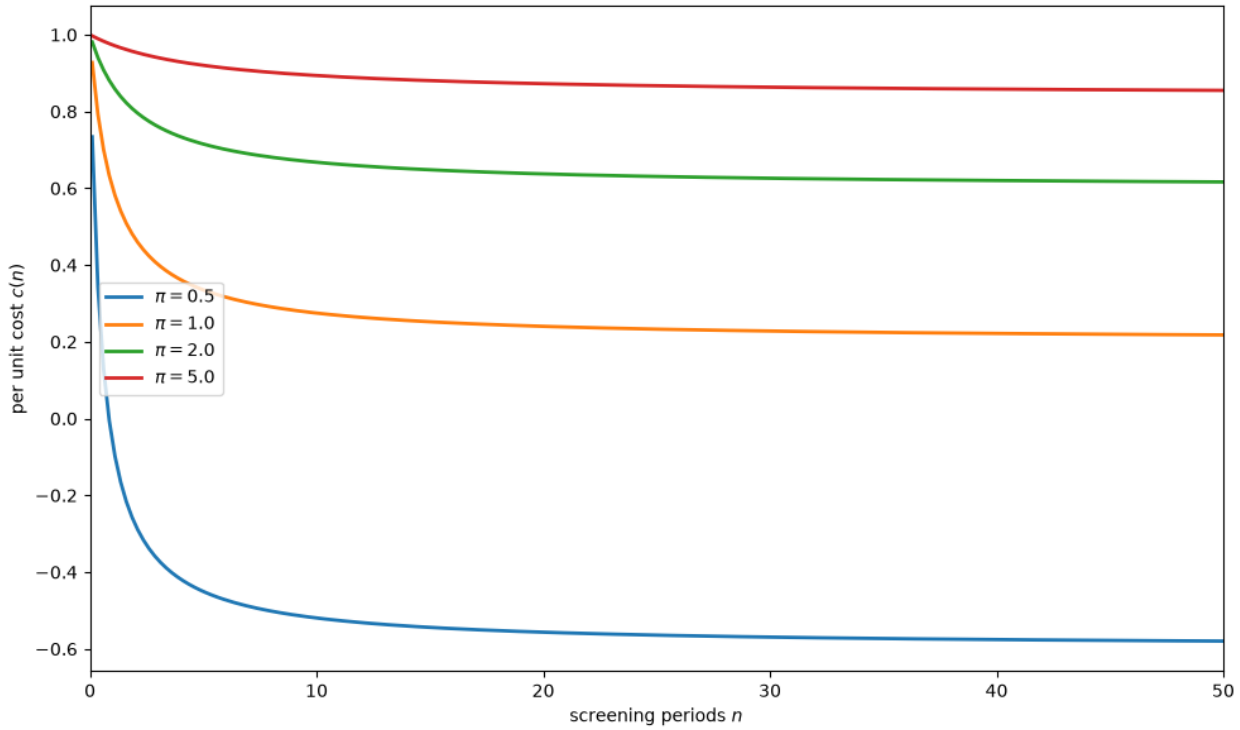

Fig. 53.2: Per unit costs by screening time

- for smaller prior precision π (more initial uncertainty about worker types), the gains from screening are larger

This diminishing-returns structure is the source of the *increasing costs of rapid adjustment*.

53.3.5 Growth rate and screening time

The greater the growth rate, the smaller must be n — the time spent in the screening task before assignment to job 2 or 3.

If γ is the growth rate of output and ρ is the quit rate, and y_i is the current number of vintage i employees, then

$$(1+\gamma)y_{i+1} = (1-\rho)y_i$$

Letting $\xi = (1-\rho)/(1+\gamma)$, from the above $y_i = \xi^i y_0$.

For the fixed coefficients technology, the fraction of present personnel with vintage greater than n must equal $2\varphi/(\varphi_1 + 2\varphi)$, which gives:

$$\xi^{n+1} = \frac{2\varphi}{\varphi_1 + 2\varphi} \tag{53.6}$$

Solving for n as a function of γ:

$$n(\gamma) = \frac{\log(2\varphi) - \log(\varphi_1 + 2\varphi)}{\log(1-\rho) - \log(1+\gamma)} - 1 \quad \text{for } \gamma > -\rho \tag{53.7}$$

```
def screening_time(γ, ρ, φ1, φ):
    """
```

(continues on next page)

(continued from previous page)

```
    Screening time n as a function of growth rate γ.
    """
    γ = np.asarray(γ, dtype=float)
    numerator = np.log(2 * ψ) - np.log(ψ1 + 2 * ψ)
    denominator = np.log(1 - ρ) - np.log(1 + γ)
    return numerator / denominator - 1

ρ = 0.1
ψ1 = 0.5
ψ = 0.25

γ_vals = np.linspace(-0.05, 0.30, 200)

valid = γ_vals > -ρ
γ_valid = γ_vals[valid]
n_vals = screening_time(γ_valid, ρ, ψ1, ψ)
mask = n_vals > 0
γ_plot = γ_valid[mask]
n_plot = n_vals[mask]

fig, ax = plt.subplots(figsize=(10, 6))
ax.plot(γ_plot, n_plot, lw=2)
ax.set_xlabel(r'growth rate $\gamma$')
ax.set_ylabel(r'screening periods $n(\gamma)$')
ax.set_xlim(γ_plot[0], γ_plot[-1])
plt.tight_layout()
plt.show()
```

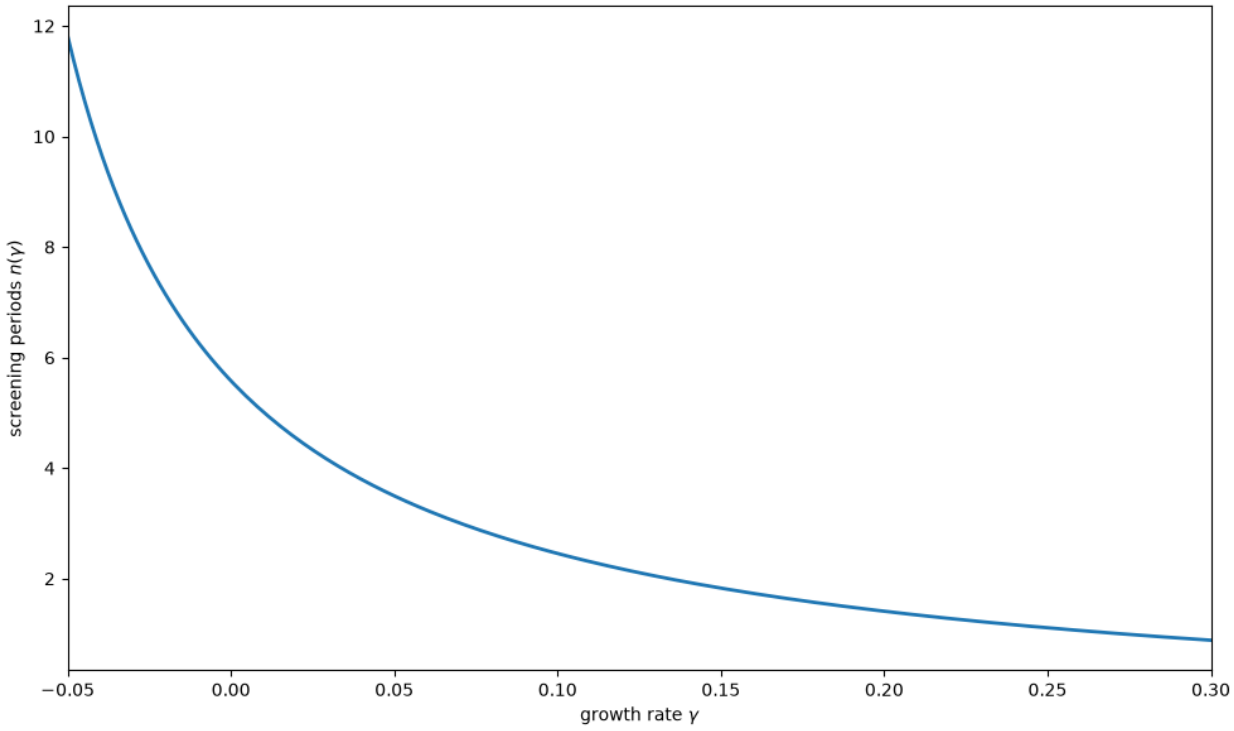

Fig. 53.3: Screening time vs. growth rate

The figure shows the key trade-off: *faster growth forces shorter screening periods*.

When growth is rapid, new workers must be promoted from the screening task to productive tasks more quickly, so less information is gathered about each worker before assignment.

53.3.6 Combined effect: growth rate and per unit costs

Composing the functions $c(n)$ and $n(\gamma)$ reveals how per unit costs depend on the growth rate:

```
fig, ax = plt.subplots(figsize=(10, 6))

π = 1.0
c_bar = 1.0

n_of_γ = screening_time(γ_plot, ρ, ψ1, ψ)
costs_of_γ = cost_per_unit(n_of_γ, π, c_bar)

ax.plot(γ_plot, costs_of_γ, lw=2)
ax.set_xlabel(r'growth rate $\gamma$')
ax.set_ylabel(r'per unit cost $c(n(\gamma))$')
ax.set_xlim(γ_plot[0], γ_plot[-1])
plt.tight_layout()
plt.show()
```

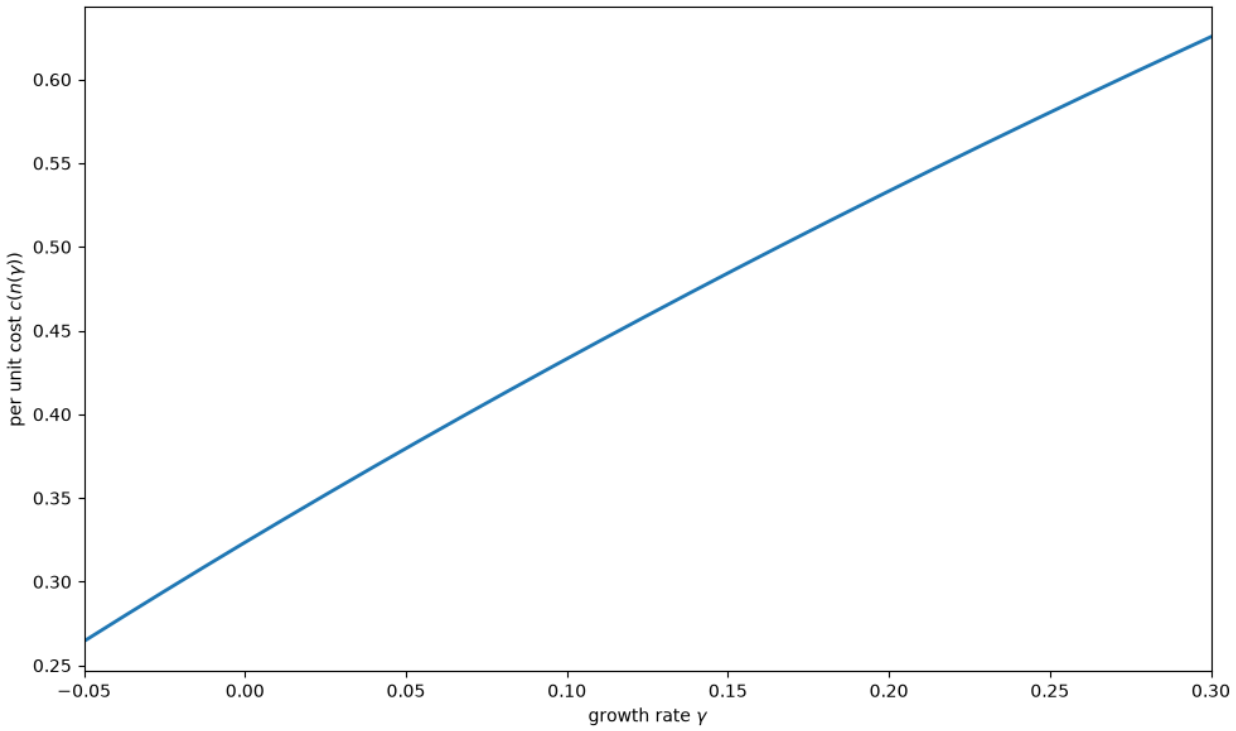

Fig. 53.4: Per unit costs vs. growth rate

This establishes the key result: *increasing costs of rapid adjustment arise endogenously* from the trade-off between screening and growth.

The faster the firm grows, the less time it has to screen workers, the poorer the match between workers and tasks, and the higher the per unit production costs.

53.4 Industry equilibrium

Firm growth rates are independent of firm size in this model because the mathematical structure of the technology constraint is the same as that considered in Lucas Jr [1967], except that the stock of organization capital is a vector rather than a scalar.

The technology set facing price-taking firms is a **convex cone**: there are constant returns to scale.

Constant returns and internal adjustment costs, along with some costs of transferring capital between firms, yield an optimum rate of firm growth *independent of the firm's size* — this is Gibrat's Law.

The bounded, downward-sloping, inverse industry demand function is

$$P_t = p(Q_t, u_t)$$

where Q_t is the sum of output over all firms and u_t is a demand shock subject to a stationary Markov process.

Prescott and Visscher show that a competitive equilibrium exists using the framework of Lucas and Prescott [1971].

The discounted consumer surplus to be maximized is

$$\sum_{t=0}^{\infty} \beta^t \left\{ \int_0^{Q_t} p(y, u_t) dy - Bw - Q_t \sum_i (A_{i2t} + A_{i3t}) c(i) / \sum_i (A_{i2t} + A_{i3t}) \right\} \tag{53.8}$$

where A_{i2t}, A_{i3t}, and B are obtained by summing a_{i2t}, a_{i3t}, and b, respectively, over all firms in the industry.

53.4.1 Key property: growth rates independent of size

If two firms have organization capital vectors $\underline{k}$ that are proportional at a point in time, they will be proportional in all future periods.

That is, *growth rates are independent of firm size*.

```
def simulate_firm_growth(T, γ, ρ, q0, seed=42):
    """
    Simulate firm output growth with stochastic shocks.
    """
    rng = np.random.default_rng(seed)
    output = np.zeros(T)
    output[0] = q0
    for t in range(1, T):
        shock = rng.normal(0, 0.02)
        output[t] = output[t-1] * (1 + γ + shock)
    return output

T = 50
γ_eq = 0.05
ρ = 0.1
```

(continues on next page)

(continued from previous page)

```
fig, axes = plt.subplots(1, 2, figsize=(14, 5))

ax = axes[0]
for q0, label in [(10, 'Small firm'), (50, 'Medium firm'),
                  (200, 'Large firm')]:
    output = simulate_firm_growth(T, y_eq, ρ, q0,
                                  seed=int(q0))
    ax.plot(range(T), output, lw=2, label=f'{label} ($q_0={q0}$)')
ax.set_xlabel('period')
ax.set_ylabel('output $q_t$')
ax.legend()

ax = axes[1]
for q0, label in [(10, 'Small firm'), (50, 'Medium firm'),
                  (200, 'Large firm')]:
    output = simulate_firm_growth(T, y_eq, ρ, q0,
                                  seed=int(q0))
    ax.plot(range(T), np.log(output), lw=2,
            label=f'{label} ($q_0={q0}$)')
ax.set_xlabel('period')
ax.set_ylabel(r'$\log(q_t)$')
ax.legend()

plt.tight_layout()
plt.show()
```

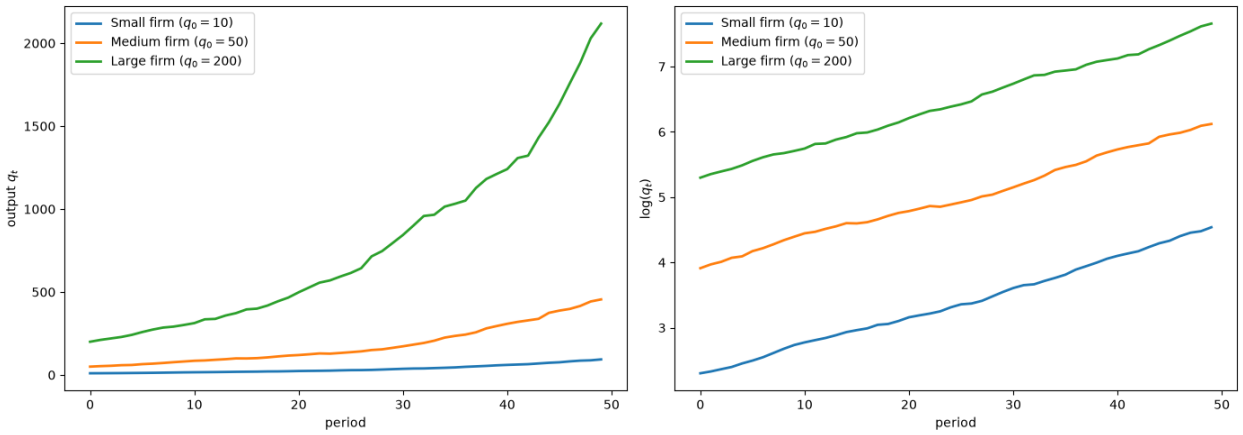

Fig. 53.5: Firm output levels and growth rates

The right panel shows that all firms grow at the same rate regardless of initial size — the log output paths are parallel.

This is **Gibrat's Law**: growth rates are independent of firm size.

53.5 Bayesian screening simulation

Let's simulate the full screening and assignment process for a single firm.

We draw workers from the population, observe their signals in the screening task, and then assign them to the appropriate productive task based on the posterior mean.

```
def simulate_screening(n_workers, n_screen, π, seed=123):
    """
    Simulate screening and assignment of workers.
    """
    rng = np.random.default_rng(seed)

    θ = rng.normal(0, 1/np.sqrt(π), n_workers)
    signals = (θ[:, None]
               + rng.normal(0, 1, (n_workers, n_screen)))
    posterior_means = signals.sum(axis=1) / (π + n_screen)

    assignment = np.where(posterior_means > 0, 2, 3)
    correct_assignment = np.where(θ > 0, 2, 3)
    misassignment_rate = np.mean(assignment != correct_assignment)

    return {
        'theta': θ,
        'posterior_means': posterior_means,
        'assignment': assignment,
        'correct_assignment': correct_assignment,
        'misassignment_rate': misassignment_rate
    }

π = 1.0
n_workers = 5000
screening_periods = [1, 3, 5, 10, 20, 50]

fig, axes = plt.subplots(2, 3, figsize=(15, 10))
axes = axes.flatten()

misassignment_rates = []

for idx, n_screen in enumerate(screening_periods):
    results = simulate_screening(n_workers, n_screen, π)
    misassignment_rates.append(results['misassignment_rate'])

    ax = axes[idx]
    θ = results['theta']
    m = results['posterior_means']

    correct = results['assignment'] == results['correct_assignment']
    ax.scatter(θ[correct], m[correct], alpha=0.1, s=5,
               color='blue', label='Correct')
    ax.scatter(θ[~correct], m[~correct], alpha=0.3, s=5,
               color='red', label='Misassigned')
    ax.axhline(0, color='k', linewidth=0.5)
    ax.axvline(0, color='k', linewidth=0.5)
    mis = results['misassignment_rate']
    ax.set_xlabel(r'true $\theta$')
```

(continues on next page)

(continued from previous page)

```
    ax.set_ylabel('posterior mean $m$')
    if idx == 0:
        ax.legend(markerscale=5, loc='upper left')

plt.tight_layout()
plt.show()
```

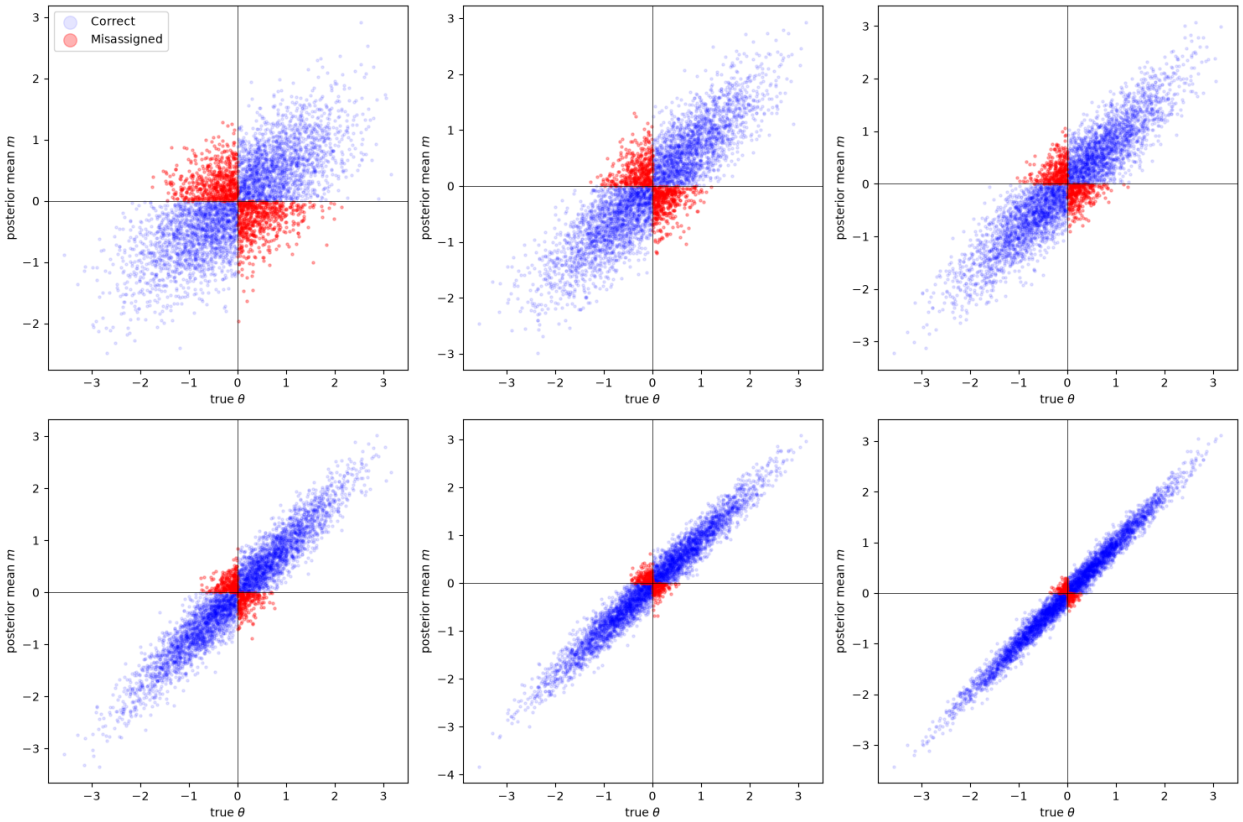

Fig. 53.6: Screening and worker assignment accuracy

Red dots are workers who are *misassigned* — placed in the wrong productive task because the posterior mean had the wrong sign relative to their true θ.

As n increases:

- The posterior mean m becomes more strongly correlated with θ
- Misassignment rates fall

```
fig, ax = plt.subplots(figsize=(10, 6))

n_range = np.arange(1, 51)
mis_rates = []
for n_screen in n_range:
    results = simulate_screening(n_workers, n_screen, π)
    mis_rates.append(results['misassignment_rate'])
```

(continues on next page)

(continued from previous page)

```
ax.plot(n_range, mis_rates, '-o', markersize=3, lw=2)
ax.set_xlabel('screening periods $n$')
ax.set_ylabel('misassignment rate')
plt.tight_layout()
plt.show()
```

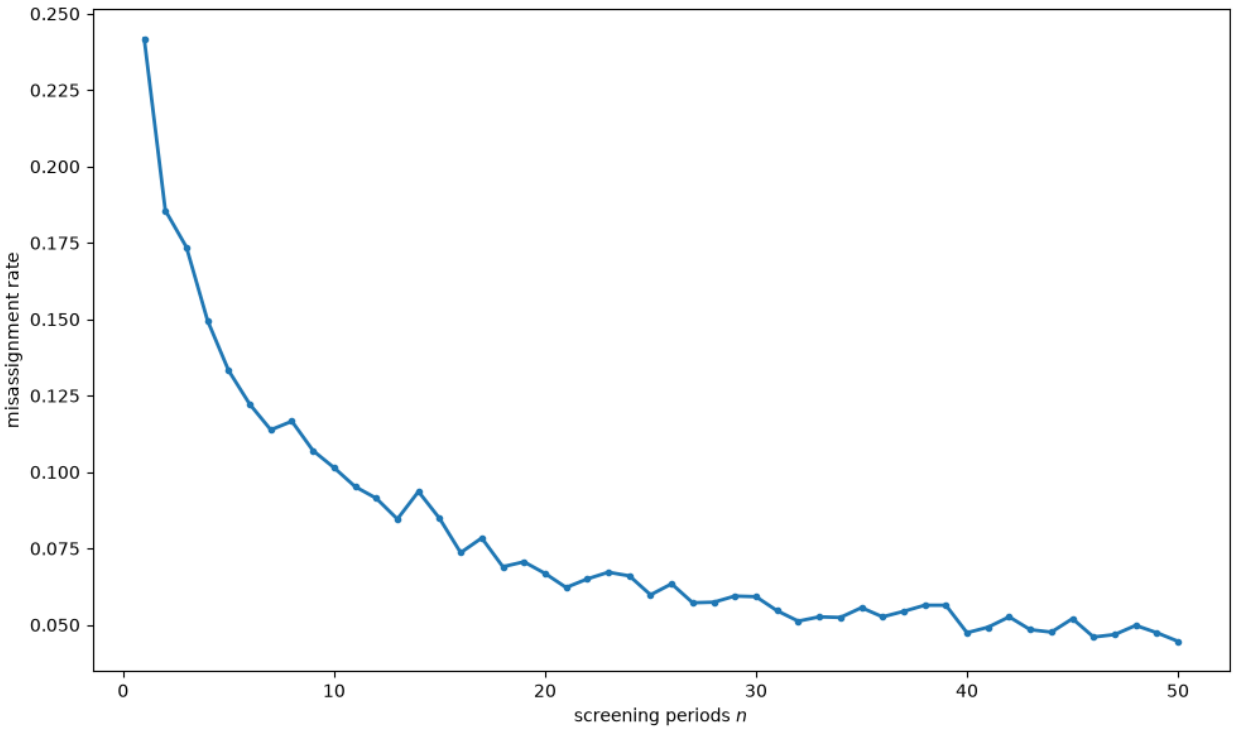

Fig. 53.7: Misassignment rate by screening time

This confirms the theoretical prediction: the cost savings from better assignment exhibit *diminishing returns* in the screening time n.

53.6 Team information

Personnel information need not be valuable only because it facilitates the matching of workers to tasks.

Another equally valuable use of personnel information is in the *matching of workers to workers*.

What is important to performance in many activities within the firm is not just the aptitude of an individual assigned to a task, but also how well the characteristics of the individual mesh with those of others performing related duties.

53.6.1 Structure

Suppose workers are grouped into teams, and team i assigned to a screening task has an observed productivity indicator

$$z_{it} = \theta_i + \epsilon_{it}$$

where:

- θ_i is a deterministic component directly related to how well team workers are paired
- $\epsilon_{it} \sim N(0,1)$ are i.i.d. stochastic components

The θ from all possible teams are approximately independently and normally distributed $N(\mu, 1/\pi)$.

After n observations on team i, the posterior distribution on θ_i is normal with

$$m = \mu + \frac{1}{\pi + n}\sum_{k=1}^{n}(z_k - \mu)$$

and precision $h = \pi + n$.

If dissolution of a team also dissolves the accrued information, the team information model has the *same mathematical structure* as the personnel information model.

```
def simulate_team_screening(n_teams, n_screen, π, μ=0.5,
                            seed=456):
    """
    Simulate team screening with Bayesian updating.
    """
    rng = np.random.default_rng(seed)

    θ = rng.normal(μ, 1/np.sqrt(π), n_teams)
    signals = (θ[:, None]
               + rng.normal(0, 1, (n_teams, n_screen)))
    z_bar = signals.mean(axis=1)
    post_means = μ + n_screen * (z_bar - μ) / (π + n_screen)
    post_prec = π + n_screen

    return {
        'theta': θ,
        'posterior_means': post_means,
        'posterior_precision': post_prec
    }

fig, axes = plt.subplots(1, 3, figsize=(15, 5))

for idx, n_screen in enumerate([1, 5, 20]):
    results = simulate_team_screening(500, n_screen, π=1.0, μ=0.5)

    ax = axes[idx]
    ax.scatter(results['theta'], results['posterior_means'],
               alpha=0.4, s=10)
    lims = [-1.5, 2.5]
    ax.plot(lims, lims, 'r--', alpha=0.5, lw=2, label='45° line')
    ax.set_xlabel(r'true team quality $\theta$')
    ax.set_ylabel('posterior mean $m$')
    ax.set_xlim(lims)
    ax.set_ylim(lims)
```

(continues on next page)

(continued from previous page)

```
    ax.legend()
    ax.set_aspect('equal')

plt.tight_layout()
plt.show()
```

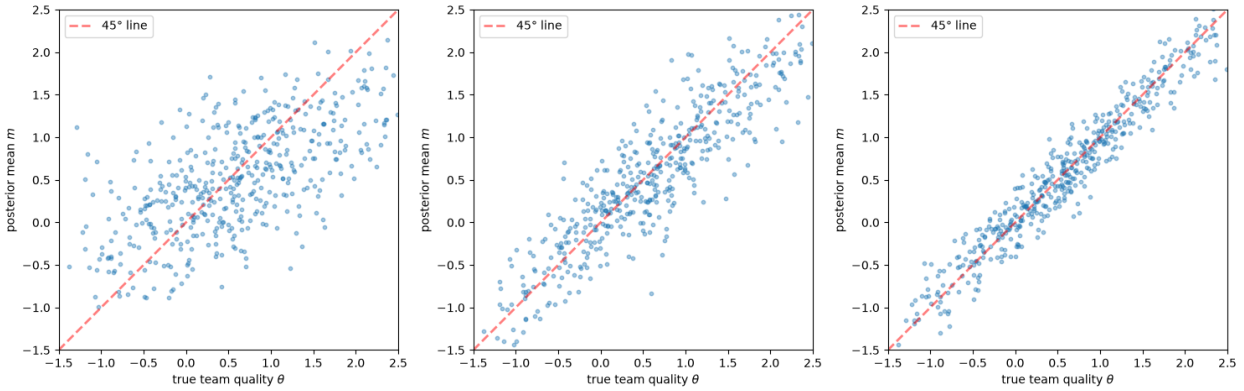

Fig. 53.8: Team quality estimates by screening periods

As with individual screening, more observations improve the precision of team quality estimates.

Rapid growth forces fewer observations before team assignments must be finalized, leading to higher costs.

53.7 Firm-specific human capital

The third example: organization capital consists of the **human capital** of the firm's employees.

The capacity of the organization to function effectively as a production unit is determined largely by the level and meshing of the skills of the employees.

Note

The case for the human capital of employees being part of the capital stock of the firm is well established (see Becker [1975]).

Productivity in the future depends on levels of human capital in the future, but to acquire human capital for the future, a sacrifice in real resources is required in the present.

The key features are:

- Output and skill enhancement are **joint products** resulting from the combination of labor inputs possessing different skill levels
- Experienced and inexperienced workers are combined in one of several available technical processes to generate the firm's product, and in the process, the overall competence of the work force is improved
- The transformation frontier between current output and future human capital is *concave* and linearly homogeneous

This gives the technology set the structure of a closed convex cone with a vertex at the origin — sufficient for optimal proportional growth by firms.

53.7.1 Concave transformation frontier

```
def transformation_frontier(q, α=0.7):
    """
    Concave transformation frontier between output and human capital.
    """
    q = np.asarray(q, dtype=float)
    return (1 - q**α)**(1/α)

fig, ax = plt.subplots(figsize=(8, 8))

q_vals = np.linspace(0, 1, 200)

for α in [0.5, 0.7, 1.0, 1.5]:
    hk = transformation_frontier(q_vals, α)
    ax.plot(q_vals, hk,
            label=fr'$\alpha = {α}$', lw=2)

ax.set_xlabel('current output $q$ (fraction of capacity)')
ax.set_ylabel('future human capital increment $\\Delta h$')
ax.legend()
ax.set_xlim(0, 1.05)
ax.set_ylim(0, 1.05)
ax.set_aspect('equal')
plt.tight_layout()
plt.show()
```

The concavity of the transformation frontier means that moving from an extremely unbalanced bundle of production and learning activity to a more balanced bundle entails little sacrifice.

But a workday consisting primarily of learning also has diminishing returns, creating the cost of rapid adjustment.

53.8 Costs of transferring organization capital

If there were no cost to transferring organization capital from one firm to another, the model would not place constraints on the firm's growth rate.

Firms could then merge, divest, or pirate each other's personnel without a cost penalty and thus produce a pattern of growth not restricted by the model.

Organization capital is *not* costlessly moved, however:

1. *Moving is disruptive*: relocating from one locale to another is disruptive to both employee and family
2. *Information is firm-specific*: the information set that makes a person productive in one organization may not make that person as productive in another, even if both firms produce identical output
    - Facility with a computer system at one firm
    - Knowing whom to ask when problems arise
    - Rapport with buyers or sellers

These are types of organization capital in one firm that *cannot be transferred costlessly* to another.

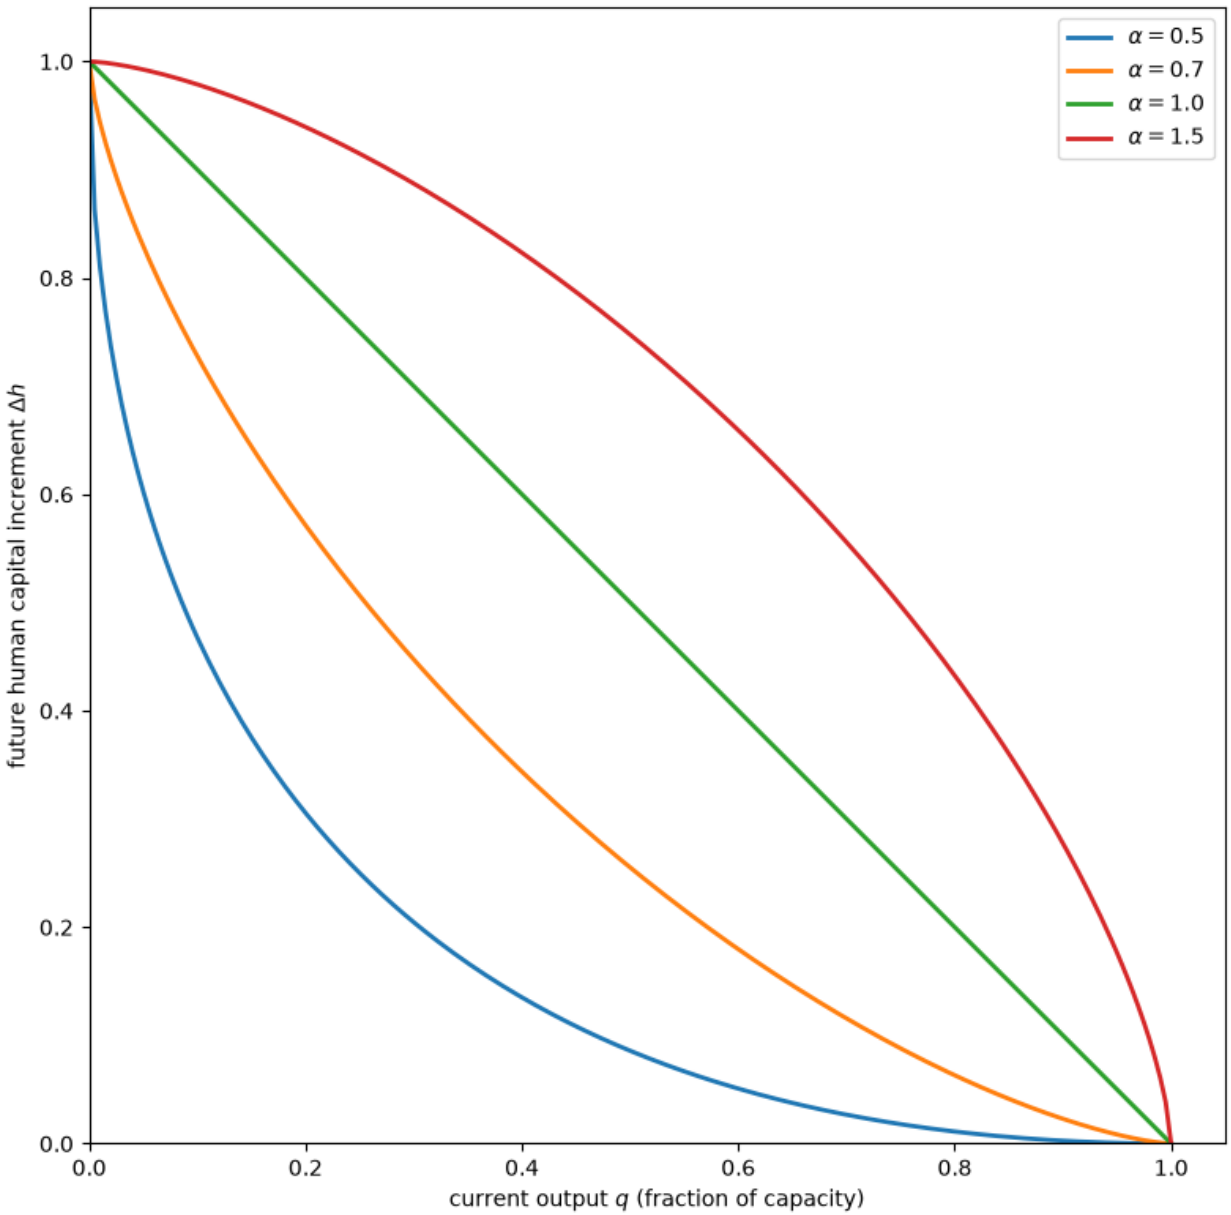

Fig. 53.9: Concave transformation frontier

53.9 Summary and implications

The Prescott-Visscher model provides a unified framework in which:

- The firm exists as an entity because it is an efficient structure for accumulating, storing, and using information
- *Constant returns to scale* arise because once the best combinations of worker types are discovered, nothing prevents the firm from replicating those combinations with proportional gains in product
- *Increasing adjustment costs* arise endogenously from the trade-off between current production and investment in organization capital
- *Gibrat's Law* — growth rates independent of firm size — is a natural implication
- Large firms should have growth rates that display *less variance* than small firms because large firms are essentially portfolios of smaller production units

```
def simulate_growth_rate_distribution(n_firms, n_subunits, γ,
                                      σ, T=100, seed=789):
    """
    Simulate growth rate distributions for firms of different sizes.
    """
    rng = np.random.default_rng(seed)

The figure shows that although all firms have the *same mean growth rate* (Gibrat's Law), large firms display *less variance* in realized growth rates because they are effectively portfolios of independent subunits.

This is consistent with the empirical findings of Mansfield [1962] and Hymer and Pashigian [1962].

The essence of the Prescott-Visscher theory is that the nature of the firm is tied to *organization capital*.

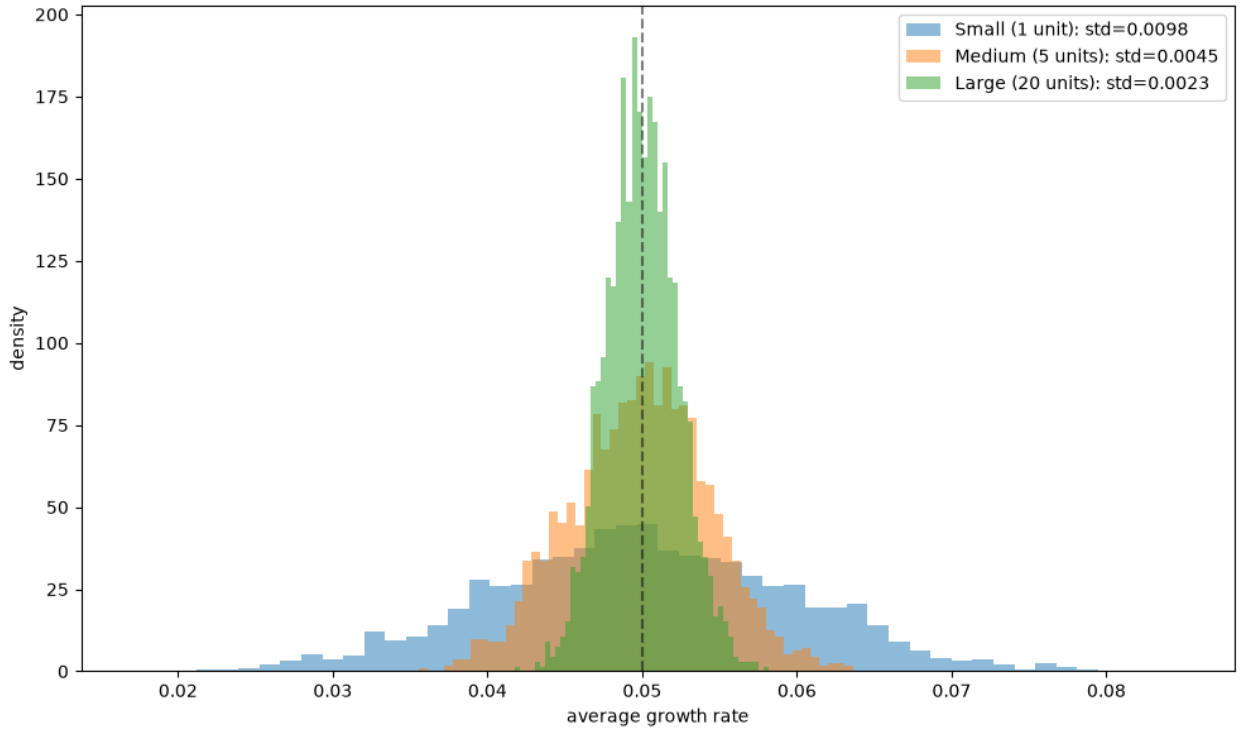

Fig. 53.10: Growth rate distributions by firm size

What distinguishes the firm from other relationships is that it is a structure within which agents have the incentive to acquire and reveal information in a manner that is less costly than in possible alternative institutions.

54.1 Overview

"Rational expectations econometrics" aims to interpret economic time series in terms of objects that are meaningful to economists, namely, parameters describing preferences, technologies, information sets, endowments, and equilibrium concepts.

When fully worked out, rational expectations models typically deliver a well-defined mapping from these economically interpretable parameters to the moments of the time series determined by the model.

If accurate observations on these time series are available, one can use that mapping to implement parameter estimation methods based either on the likelihood function or on the method of moments.

Note

This is why econometric estimation is often called an "inverse" problem, while simulating a model for given parameter values is called a "direct" problem. The direct problem refers to the mapping we have just described, while the inverse problem involves somehow applying an "inverse" of that mapping to a data set that is treated as if it were one draw from the joint probability distribution described by the mapping.

However, if only error-ridden data exist for the variables of interest, then more steps are needed to extract parameter estimates.

In effect, we require a model of the data reporting agency, one that is workable enough that we can determine the mapping induced jointly by the dynamic economic model and the measurement process to the probability law for the measured data.

The model chosen for the data collection agency is an aspect of an econometric specification that can make big differences in inferences about the economic structure.

Sargent [1989] describes two alternative models of data generation in a *permanent income* economy in which the investment accelerator, the mechanism studied in these two quantecon lectures – *Samuelson Multiplier-Accelerator* and *The Acceleration Principle and the Nature of Business Cycles* – shapes business cycle fluctuations.

- In Model 1, the data collecting agency simply reports the error-ridden data that it collects.
- In Model 2, the data collection agency first collects error-ridden data that satisfy a classical errors-in-variables model, then filters the data, and reports the filtered objects.

Although the two models have the same "deep parameters," they produce quite different sets of restrictions on the data.

In this lecture we follow Sargent [1989] and study how these alternative measurement schemes affect empirical implications.

We start with imports and helper functions to be used throughout this lecture to generate LaTeX output

```
import numpy as np
import pandas as pd
import matplotlib.pyplot as plt
from scipy import linalg
from IPython.display import Latex

np.set_printoptions(precision=3, suppress=True)

def df_to_latex_matrix(df, label=''):
    """Convert DataFrame to LaTeX matrix."""
    lines = [r'\begin{bmatrix}']

    for idx, row in df.iterrows():
        row_str = ' & '.join(
          [f'{v:.4f}' if isinstance(v, (int, float))
            else str(v) for v in row]) + r' \\'
        lines.append(row_str)

    lines.append(r'\end{bmatrix}')

    if label:
        return '$' + label + ' = ' + '\n'.join(lines) + '$'
    else:
        return '$' + '\n'.join(lines) + '$'

def df_to_latex_array(df):
    """Convert DataFrame to LaTeX array."""
    n_rows, n_cols = df.shape

    # Build column format (centered columns)
    col_format = 'c' * (n_cols + 1)  # +1 for index

    # Start array
    lines = [r'\begin{array}{' + col_format + '}']
```

(continues on next page)

(continued from previous page)

```
    # Header row
    header = ' & '.join([''] + [str(c) for c in df.columns]) + r' \\'
    lines.append(header)
    lines.append(r'\hline')

    # Data rows
    for idx, row in df.iterrows():
        row_str = str(idx) + ' & ' + ' & '.join(
          [f'{v:.3f}' if isinstance(v, (int, float)) else str(v)
          for v in row]) + r' \\'
        lines.append(row_str)

    lines.append(r'\end{array}')

    return '$' + '\n'.join(lines) + '$'
```

54.2 The economic model

The data are generated by a linear-quadratic version of a stochastic optimal growth model that is an instance of models described in this quantecon lecture: *The Permanent Income Model*.

A social planner chooses a stochastic process for $\{c_t, k_{t+1}\}_{t=0}^{\infty}$ that maximizes

$$E \sum_{t=0}^{\infty} \beta^t \left(u_0 + u_1 c_t - \frac{u_2}{2} c_t^2 \right) \tag{54.1}$$

subject to the restrictions imposed by the technology

$$c_t + k_{t+1} = f k_t + \theta_t, \qquad \beta f^2 > 1. \tag{54.2}$$

Here c_t is consumption, k_t is the capital stock, f is the gross rate of return on capital, and θ_t is an endowment or technology shock following

$$a(L)\, \theta_t = \varepsilon_t, \tag{54.3}$$

where L is the backward shift (or 'lag') operator, ε_t is a scalar white noise, and $a(z) = 1 - a_1 z - a_2 z^2 - \cdots - a_r z^r$ has all its zeroes outside the unit circle.

54.2.1 Optimal decision rule

The optimal decision rule for c_t is

$$c_t = \frac{-\alpha}{f-1} + \left(1 - \frac{1}{\beta f^2}\right) \left[\frac{L - f^{-1} a(f^{-1})^{-1} a(L)}{L - f^{-1}}\, \theta_t + f k_t \right], \qquad k_{t+1} = f k_t + \theta_t - c_t, \tag{54.4}$$

where $\alpha = u_1 [1 - (\beta f)^{-1}] / u_2$.

Equations (54.3) and (54.4) exhibit the cross-equation restrictions characteristic of rational expectations models: the parameters $a_1, \ldots, a_r$ of the shock process also appear in the decision rule for consumption.

54.2.2 Net income and the accelerator

Define net output or national income as

$$y_{nt} = (f-1)k_t + \theta_t. \tag{54.5}$$

Note that (54.2) and (54.5) imply $(k_{t+1} - k_t) + c_t = y_{nt}$.

To obtain both a version of Friedman [1956]'s geometric distributed lag consumption function and a distributed lag accelerator, we impose two assumptions:

1. $a(L) = 1$, so that θ_t is white noise.
2. $\beta f = 1$, so the rate of return on capital equals the rate of time preference.

Assumption 1 is crucial for the strict form of the accelerator.

Relaxing it to allow serially correlated θ_t preserves an accelerator in a broad sense but loses the sharp geometric-lag form of (54.8).

Adding a second shock breaks the one-index structure entirely and can generate nontrivial Granger causality even without measurement error.

Assumption 2 is less important, affecting only various constants.

Under both assumptions, $\alpha = 0$ and (54.4) simplifies to

$$c_t = (1 - f^{-1})\,\theta_t + (f-1)\,k_t, \tag{54.6}$$

so that the capital stock obeys $k_{t+1} = k_t + f^{-1}\theta_t$.

When (54.6), (54.5), and (54.2) are combined, the optimal plan satisfies

$$c_t = \left(\frac{1-\beta}{1-\beta L}\right) y_{nt}, \tag{54.7}$$

$$k_{t+1} - k_t = f^{-1}\left(\frac{1-L}{1-\beta L}\right) y_{nt}, \tag{54.8}$$

$$y_{nt} = \theta_t + (1-\beta)(\theta_{t-1} + \theta_{t-2} + \cdots). \tag{54.9}$$

Equation (54.7) is Friedman's consumption model: consumption is a geometric distributed lag of income, with the decay coefficient β equal to the discount factor.

Equation (54.8) is the distributed lag accelerator: investment is a geometric distributed lag of the first difference of income.

This is the same mechanism that Chow [1968] documented empirically (see *The Acceleration Principle and the Nature of Business Cycles*).

Equation (54.9) states that the first difference of net income, $y_{nt} - y_{n,t-1} = \theta_t - \beta\theta_{t-1}$, is a first-order moving average process with innovation equal to the innovation of the endowment shock θ_t.

As Muth [1960] showed, such a process is optimally forecast via a geometric distributed lag or "adaptive expectations" scheme.

Consumption itself is a martingale: (54.6) and $k_t - k_{t-1} = f^{-1}\theta_{t-1}$ imply $c_t - c_{t-1} = (1-\beta)\theta_t$, the random walk property of consumption emphasized by Hall [1978].

So consumption, the capital stock, and net income all have unit roots, while investment $k_{t+1} - k_t = f^{-1}\theta_t$ is serially uncorrelated.

54.2.3 The accelerator puzzle

When all variables are measured accurately and are driven by the single shock θ_t, the spectral density matrix of the covariance-stationary vector $(c_t - c_{t-1},\ k_{t+1} - k_t,\ y_{nt} - y_{n,t-1})$ has rank one at all frequencies.

Each variable is an invertible one-sided distributed lag of the same white noise, so no variable Granger-causes any other.

Empirically, however, measures of output Granger-cause investment but not vice versa.

Sargent [1989] shows that measurement error can resolve this puzzle.

To illustrate, suppose first that output y_{nt} is measured perfectly while consumption and capital are each polluted by serially correlated measurement errors v_{ct} and v_{kt} orthogonal to θ_t.

Let $\bar{c}_t$ and $\bar{k}_{t+1} - \bar{k}_t$ denote the measured series. Then

$$\bar{c}_t = \left(\frac{1-\beta}{1-\beta L}\right) y_{nt} + v_{ct}, \tag{54.10}$$

$$\bar{k}_{t+1} - \bar{k}_t = \beta \left(\frac{1-L}{1-\beta L}\right) y_{nt} + (v_{k,t+1} - v_{kt}), \tag{54.11}$$

where y_{nt} is given by (54.9).

In this case income Granger-causes consumption and investment but is not Granger-caused by them.

When each measured series is corrupted by measurement error, every measured variable will in general Granger-cause every other.

The strength of this Granger causality, as measured by decompositions of j-step-ahead prediction error variances, depends on the relative variances of the measurement errors.

In this case, each observed series mixes the common signal θ_t with idiosyncratic measurement noise.

A series whose measurement error is small **relative to the variation in the true series** tracks θ_t more closely, so its innovations contain more information about future values of the other series.

Accordingly, in a forecast-error-variance decomposition, shocks to better-measured series account for a larger share of other variables' j-step-ahead prediction errors.

In a one-common-index model like this one (θ_t is the common index), better-measured variables extend more Granger causality to less well measured series than vice versa.

This asymmetry drives the numerical results we observe soon.

54.2.4 State-space formulation

Let's map the economic model and the measurement process into a linear state-space framework.

Set $f = 1.05$ and $\theta_t \sim \mathcal{N}(0, 1)$.

Define the state and observation vectors

$$x_t = \begin{bmatrix} k_t \\ \theta_t \end{bmatrix}, \qquad z_t = \begin{bmatrix} y_{nt} \\ c_t \\ \Delta k_t \end{bmatrix},$$

where $\Delta k_t \equiv k_{t+1} - k_t$ denotes investment at time t.

The error-free data are described by the state-space system

$$\begin{aligned} x_{t+1} &= Ax_t + w_t, \\ z_t &= Cx_t, \end{aligned} \tag{54.12}$$

where $w_t = \begin{bmatrix} 0 \\ \theta_{t+1} \end{bmatrix}$ has covariance $Ew_t w_t^\top = Q$ and the matrices are

$$A = \begin{bmatrix} 1 & f^{-1} \\ 0 & 0 \end{bmatrix}, \qquad C = \begin{bmatrix} f-1 & 1 \\ f-1 & 1-f^{-1} \\ 0 & f^{-1} \end{bmatrix}, \qquad Q = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}.$$

Here we date the shock w_t that arrives between t and $t+1$ by t; this matches the timing convention for the measurement errors below.

Q is singular because there is only one source of randomness θ_t; the capital stock k_t evolves deterministically given θ_t.

Notice that the rows of C satisfy $C_c + C_{\Delta k} = C_y$, which is the national income identity $c_t + \Delta k_t = y_{nt}$.

```
# Baseline structural matrices for the true economy
f = 1.05
β = 1 / f

A = np.array([
    [1.0, 1.0 / f],
    [0.0, 0.0]
])

C = np.array([
    [f - 1.0, 1.0],
    [f - 1.0, 1.0 - 1.0 / f],
    [0.0, 1.0 / f]
])

Q = np.array([
    [0.0, 0.0],
    [0.0, 1.0]
])
```

54.2.5 True impulse responses

Before introducing measurement error, we compute the impulse response of the error-free variables to a unit shock $\theta_0 = 1$.

This benchmark clarifies what changes when we later switch from error-free variables to variables reported by the statistical agency.

The response shows the investment accelerator clearly: the full impact on net income y_n occurs at lag 0, while consumption adjusts by only $1 - f^{-1} \approx 0.048$ and investment absorbs the remainder.

From lag 1 onward the economy is in its new steady state, with permanently higher capital, income, and consumption

```
def table2_irf(A, C, n_lags=6):
    x = np.array([0.0, 1.0])  # k_0 = 0, theta_0 = 1
    rows = []
    for j in range(n_lags):
        y_n, c, d_k = C @ x
        rows.append([y_n, c, d_k])
        x = A @ x
    return pd.DataFrame(rows, columns=[r'y_n', r'c', r'\Delta k'],
                        index=pd.Index(range(n_lags), name='lag'))

table2 = table2_irf(A, C, n_lags=6)
display(Latex(df_to_latex_array(table2)))
```

	y_n	c	Δk
0	1.000	0.048	0.952
1	0.048	0.048	0.000
2	0.048	0.048	0.000
3	0.048	0.048	0.000
4	0.048	0.048	0.000
5	0.048	0.048	0.000

54.3 Measurement errors

Let's add the measurement layer that generates reported data.

The econometrician does not observe z_t directly but instead sees $\bar{z}_t = z_t + v_t$, where v_t is a vector of measurement errors.

Measurement errors follow an AR(1) process

$$v_{t+1} = Dv_t + \eta_t, \tag{54.13}$$

where η_t is a vector white noise with $E\eta_t\eta_t^\top = \Sigma_\eta$ and $Ew_t v_s^\top = 0$ for all t, s.

The parameters are

$$D = \text{diag}(\rho_y, \rho_c, \rho_{\Delta k}) = \text{diag}(0.6, 0.7, 0.3), \qquad \Sigma_\eta = \text{diag}(\sigma_\eta^2), \quad \sigma_\eta = (0.05, 0.035, 0.65),$$

so the unconditional covariance of v_t is

$$R = \text{diag}\left(\frac{\sigma_{\eta,i}^2}{1-\rho_i^2}\right).$$

The innovation standard deviations σ_η are smallest for consumption (0.035), next for income (0.05), and largest for investment (0.65).

What matters for Granger-causality asymmetries, however, is the size of each measurement error **relative to the signal** in the corresponding true series.

The innovations to the true series are θ_t for income (standard deviation 1), $(1-\beta)\theta_t$ for consumption (standard deviation 0.048), and $\beta\theta_t$ for investment (standard deviation 0.95).

Relative to these, income is very well measured (a ratio of about 0.05), while consumption and investment are both poorly measured (ratios of about 0.7).

```
ρ = np.array([0.6, 0.7, 0.3])
D = np.diag(ρ)

# Innovation std. devs of η_t
σ_η = np.array([0.05, 0.035, 0.65])
Σ_η = np.diag(σ_η**2)

# Unconditional covariance of measurement errors v_t
R = np.diag((σ_η / np.sqrt(1.0 - ρ**2))**2)

print(f"f = {f},  β = 1/f = {β:.6f}")
print()
display(Latex(df_to_latex_matrix(pd.DataFrame(A), 'A')))
display(Latex(df_to_latex_matrix(pd.DataFrame(C), 'C')))
display(Latex(df_to_latex_matrix(pd.DataFrame(D), 'D')))
```

```
f = 1.05,  β = 1/f = 0.952381
```

$$A = \begin{bmatrix} 1.0000 & 0.9524 \\ 0.0000 & 0.0000 \end{bmatrix}$$

$$C = \begin{bmatrix} 0.0500 & 1.0000 \\ 0.0500 & 0.0476 \\ 0.0000 & 0.9524 \end{bmatrix}$$

$$D = \begin{bmatrix} 0.6000 & 0.0000 & 0.0000 \\ 0.0000 & 0.7000 & 0.0000 \\ 0.0000 & 0.0000 & 0.3000 \end{bmatrix}$$

We will analyze the two reporting schemes separately, but first we need a solver for the steady-state Kalman gain and error covariances.

The function below iterates on the Riccati equation until convergence, returning the Kalman gain K, the state covariance S, and the innovation covariance V

```
def steady_state_kalman(A, C_obs, Q, R, W=None, tol=1e-13, max_iter=200_000):
    """
    Solve steady-state Kalman equations for
        x_{t+1} = A x_t + w_t
        y_t     = C_obs x_t + v_t
    with cov(w)=Q, cov(v)=R, cov(w,v)=W.
    """
    n = A.shape[0]
    m = C_obs.shape[0]
    if W is None:
        W = np.zeros((n, m))

    S = Q.copy()
    for _ in range(max_iter):
        V = C_obs @ S @ C_obs.T + R
        K = (A @ S @ C_obs.T + W) @ np.linalg.inv(V)
        S_new = Q + A @ S @ A.T - K @ V @ K.T

        if np.max(np.abs(S_new - S)) < tol:
            S = S_new
            break
        S = S_new

    V = C_obs @ S @ C_obs.T + R
    K = (A @ S @ C_obs.T + W) @ np.linalg.inv(V)
    return K, S, V
```

With structural matrices and tools we need in place, we now follow Sargent [1989]'s two reporting schemes in sequence.

54.4 A classical model of measurements initially collected by an agency

A data collecting agency observes a noise-corrupted version of z_t, namely

$$\bar{z}_t = Cx_t + v_t. \tag{54.14}$$

We refer to this as *Model 1*: the agency collects noisy data and reports them without filtering.

To represent the second moments of the $\bar{z}_t$ process, it is convenient to obtain its population vector autoregression.

The error vector in the vector autoregression is the innovation to $\bar{z}_t$ and can be taken to be the white noise in a Wold moving average representation, which can be obtained by "inverting" the autoregressive representation.

The population vector autoregression, and how it depends on the parameters of the state-space system and the measurement error process, carries insights about how to interpret estimated vector autoregressions for $\bar{z}_t$.

Constructing the vector autoregression is also useful as an intermediate step in computing the likelihood of a sample of $\bar{z}_t$'s as a function of the free parameters $\{A, C, D, Q, \Sigma_\eta\}$.

The particular method that will be used to construct the vector autoregressive representation also proves useful as an intermediate step in constructing a model of an optimal reporting agency.

We use recursive (Kalman filtering) methods to obtain the vector autoregression for $\bar{z}_t$.

54.4.1 Quasi-differencing

Because the measurement errors v_t are serially correlated, the standard Kalman filter with white-noise measurement error cannot be applied directly to $\bar{z}_t = Cx_t + v_t$.

An alternative is to augment the state vector with the measurement-error AR components (see Appendix B of Sargent [1989]).

Here we take the quasi-differencing route described in Sargent [1989], which reduces the system to one with serially uncorrelated observation noise.

Define

$$\tilde{z}_t = \bar{z}_{t+1} - D\bar{z}_t, \qquad \bar{\nu}_t = Cw_t + \eta_t, \qquad \bar{C} = CA - DC. \tag{54.15}$$

Then the state-space system (54.12), the measurement error process (54.13), and the observation equation (54.14) imply the state-space system

$$\begin{aligned} x_{t+1} &= Ax_t + w_t, \\ \tilde{z}_t &= \bar{C}\, x_t + \bar{\nu}_t, \end{aligned} \tag{54.16}$$

where $(w_t, \bar{\nu}_t)$ is a white noise process with

$$E \begin{bmatrix} w_t \\ \bar{\nu}_t \end{bmatrix} \begin{bmatrix} w_t \\ \bar{\nu}_t \end{bmatrix}^\top = \begin{bmatrix} Q & W_1 \\ W_1^\top & R_1 \end{bmatrix}, \qquad R_1 = CQC^\top + \Sigma_\eta, \quad W_1 = QC^\top. \tag{54.17}$$

Notice that R_1 involves the covariance matrix Σ_η of the **innovations** η_t to the measurement errors, not the unconditional covariance matrix R of the measurement errors themselves: quasi-differencing removes the serially correlated part of v_t.

System (54.16) with covariances (54.17) is characterized by the five matrices $[A, \bar{C}, Q, R_1, W_1]$.

54.4.2 Innovations representation

Associated with (54.16) and (54.17) is the **innovations representation** for $\tilde{z}_t$,

$$\begin{aligned} \hat{x}_{t+1} &= A\hat{x}_t + K_1 u_t, \\ \tilde{z}_t &= \bar{C}\hat{x}_t + u_t, \end{aligned} \tag{54.18}$$

where

$$\begin{aligned} \hat{x}_t &= E[x_t \mid \tilde{z}_{t-1}, \tilde{z}_{t-2}, \ldots, \hat{x}_0] = E[x_t \mid \bar{z}_t, \bar{z}_{t-1}, \ldots], \\ u_t &= \tilde{z}_t - E[\tilde{z}_t \mid \tilde{z}_{t-1}, \tilde{z}_{t-2}, \ldots] = \bar{z}_{t+1} - E[\bar{z}_{t+1} \mid \bar{z}_t, \bar{z}_{t-1}, \ldots], \end{aligned} \tag{54.19}$$

$[K_1, S_1]$ are computed from the steady-state Kalman filter applied to $[A, \bar{C}, Q, R_1, W_1]$, and

$$S_1 = E[(x_t - \hat{x}_t)(x_t - \hat{x}_t)^\top]. \tag{54.20}$$

From (54.19), u_t is the innovation process for the $\bar{z}_t$ process.

54.4.3 Wold representation

System (54.18) and definition (54.15) can be used to obtain a Wold vector moving average representation for the $\bar{z}_t$ process:

$$\bar{z}_{t+1} = (I - DL)^{-1}[\bar{C}(I - AL)^{-1}K_1 L + I]u_t, \tag{54.21}$$

where L is the lag operator.

From (54.16) and (54.18) the innovation covariance is

$$V_1 = E\, u_t u_t^\top = \bar{C}\, S_1\, \bar{C}^\top + R_1. \tag{54.22}$$

Below we compute K_1, S_1, and V_1 numerically

```
C_bar = C @ A - D @ C
R1 = C @ Q @ C.T + Σ_η
W1 = Q @ C.T

K1, S1, V1 = steady_state_kalman(A, C_bar, Q, R1, W1)
```

54.4.4 Computing coefficients in a Wold moving average representation

To compute the moving average coefficients in (54.21) numerically, define the augmented state

$$r_t = \begin{bmatrix} \hat{x}_{t-1} \\ \bar{z}_{t-1} \end{bmatrix},$$

with dynamics

$$r_{t+1} = F_1 r_t + G_1 u_{t-1}, \qquad \bar{z}_t = H_1 r_t + u_{t-1},$$

where

$$F_1 = \begin{bmatrix} A & 0 \\ \bar{C} & D \end{bmatrix}, \quad G_1 = \begin{bmatrix} K_1 \\ I \end{bmatrix}, \quad H_1 = [\bar{C} \;\; D].$$

(Recall that u_{t-1} is the innovation to $\bar{z}_t$.)

The moving average coefficients are then $\psi_0 = I$ and $\psi_j = H_1 F_1^{j-1} G_1$ for $j \geq 1$.

```
F1 = np.block([
    [A, np.zeros((2, 3))],
    [C_bar, D]
])
G1 = np.vstack([K1, np.eye(3)])
H1 = np.hstack([C_bar, D])

def measured_wold_coeffs(F, G, H, n_terms=25):
    psi = [np.eye(3)]
    Fpow = np.eye(F.shape[0])
    for _ in range(1, n_terms):
        psi.append(H @ Fpow @ G)
        Fpow = Fpow @ F
    return psi

def fev_contributions(psi, V, n_horizons=20):
    """
    Returns contrib[var, shock, h-1] = contribution at horizon h.
    """
    P = linalg.cholesky(V, lower=True)
    out = np.zeros((3, 3, n_horizons))
    for h in range(1, n_horizons + 1):
        acc = np.zeros((3, 3))
        for j in range(h):
            T = psi[j] @ P
            acc += T**2
        out[:, :, h - 1] = acc
    return out

psi1 = measured_wold_coeffs(F1, G1, H1, n_terms=40)
resp1 = np.array(
      [psi1[j] @ linalg.cholesky(V1, lower=True) for j in range(14)])
decomp1 = fev_contributions(psi1, V1, n_horizons=20)
```

54.4.5 Gaussian likelihood

The Gaussian log-likelihood function for a sample $\{\bar{z}_t,\ t = 0, \ldots, T\}$, conditioned on an initial state estimate $\hat{x}_0$, can be represented as

$$\mathcal{L}^* = -\tfrac{3}{2} T \ln 2\pi - \tfrac{1}{2} T \ln |V_1| - \tfrac{1}{2} \sum_{t=0}^{T-1} u_t^\top V_1^{-1} u_t, \tag{54.23}$$

where u_t is a function of $\{\bar{z}_t\}$ defined by (54.24) below and the 3 in the first term is the number of measured series.

To use (54.18) to compute $\{u_t\}$, it is useful to represent it as

$$\begin{aligned} \hat{x}_{t+1} &= (A - K_1 \bar{C})\, \hat{x}_t + K_1 \tilde{z}_t, \\ u_t &= -\bar{C}\, \hat{x}_t + \tilde{z}_t, \end{aligned} \tag{54.24}$$

where $\tilde{z}_t = \bar{z}_{t+1} - D\bar{z}_t$ is the quasi-differenced observation.

Given $\hat{x}_0$, equation (54.24) can be used recursively to compute a $\{u_t\}$ process.

Equations (54.23) and (54.24) give the likelihood function of a sample of error-corrupted data $\{\bar{z}_t\}$.

54.4.6 Forecast-error-variance decomposition

To measure the relative importance of each innovation, we decompose the j-step-ahead forecast-error variance of each measured variable.

Write $\bar{z}_{t+j} - E_t \bar{z}_{t+j} = \sum_{i=0}^{j-1} \psi_i u_{t+j-i}$, where, to lighten notation, here u_{t+j-i} denotes the innovation to $\bar{z}_{t+j-i}$.

Let P be the lower-triangular Cholesky factor of V_1 so that the orthogonalized innovations are $e_t = P^{-1} u_t$.

Then the contribution of orthogonalized innovation k to the j-step-ahead variance of variable m is $\sum_{i=0}^{j-1} (\psi_i P)_{mk}^2$.

We order the variables as y_n, c, Δk.

With this ordering, the first orthogonalized innovation is the innovation in y_n, the second is the part of the innovation in c that is orthogonal to the innovation in y_n, and the third is the part of the innovation in Δk that is orthogonal to the first two.

The table below shows the cumulative contribution of each orthogonalized innovation to the forecast-error variance of y_n, c, and Δk at horizons 1 through 20.

Each panel fixes one orthogonalized innovation and reports its cumulative contribution to each variable's forecast-error variance.

Rows are forecast horizons and columns are forecasted variables.

```
horizons = np.arange(1, 21)
labels = [r'y_n', r'c', r'\Delta k']

def fev_table(decomp, shock_idx, horizons):
    return pd.DataFrame(
        np.round(decomp[:, shock_idx, :].T, 4),
        columns=labels,
        index=pd.Index(horizons, name='j')
    )
```

```
shock_titles = [r'\text{A. Innovation in } y_n',
                r'\text{B. Innovation in } c',
                r'\text{C. Innovation in } \Delta k']

parts = []
for i, title in enumerate(shock_titles):
    arr = df_to_latex_array(fev_table(decomp1, i, horizons)).strip('$')
    parts.append(
      r'\begin{array}{c} ' + title + r' \\ ' + arr + r' \end{array}')

display(Latex('$' + r' \quad '.join(parts) + '$'))
```

18	0.000	0.000	0.467
19	0.000	0.000	0.467
20	0.000	0.000	0.467

The income innovation accounts for substantial proportions of forecast-error variance in all three variables, while the consumption and investment innovations contribute mainly to their own variances.

This is a **Granger causality** pattern: income appears to Granger-cause consumption and investment, but not vice versa.

This matches the paper's message that, in a one-common-index model, the relatively best measured series has the strongest predictive content.

Because income is ordered first, the decomposition attributes to the income innovation all of the variance that it shares with the other innovations.

Below we confirm the Granger-causality pattern with a calculation that does not depend on an ordering.

Let's look at the covariance matrix of the innovations

```
print('Covariance matrix of innovations:')
df_v1 = pd.DataFrame(np.round(V1, 4), index=labels, columns=labels)
display(Latex(df_to_latex_matrix(df_v1)))
```

```
Covariance matrix of innovations:
```

$$\begin{bmatrix} 1.0037 & 0.0476 & 0.9530 \\ 0.0476 & 0.0035 & 0.0453 \\ 0.9530 & 0.0453 & 1.3298 \end{bmatrix}$$

The covariance matrix of the innovations is not diagonal, but the eigenvalues are well separated as shown below

```
print('Eigenvalues of covariance matrix:')
print(np.sort(np.linalg.eigvalsh(V1))[::-1].round(4))
```

```
Eigenvalues of covariance matrix:
[2.136 0.2   0.001]
```

The first eigenvalue is much larger than the others, consistent with the presence of a dominant common shock θ_t

54.4.7 Granger causality without an ordering

The population vector autoregression for $\bar{z}_t$ gives a direct view of Granger causality.

Iterating on (54.24) gives

$$\tilde{z}_t = \sum_{j=1}^{\infty} \bar{C}(A - K_1\bar{C})^{j-1} K_1 \tilde{z}_{t-j} + u_t.$$

Let $B_j = \bar{C}(A - K_1\bar{C})^{j-1}K_1$.

Substituting $\tilde{z}_t = \bar{z}_{t+1} - D\bar{z}_t$ and collecting terms gives the vector autoregression

$$\bar{z}_{t+1} = \sum_{j=1}^{\infty} \Pi_j \bar{z}_{t+1-j} + u_t, \qquad \Pi_1 = D + B_1, \quad \Pi_j = B_j - B_{j-1}D \ \ (j \geq 2).$$

Variable i fails to Granger-cause variable m if and only if the (m, i) entries of all the Π_j are zero.

Here are the first two coefficient matrices; rows are equations and columns are lagged variables.

```
M_filter = A - K1 @ C_bar
print("eigenvalues of A - K1 C_bar:", np.linalg.eigvals(M_filter).round(4))

B_coef = [C_bar @ np.linalg.matrix_power(M_filter, j) @ K1 for j in range(3)]
Π = [D + B_coef[0]] + [B_coef[j] - B_coef[j-1] @ D for j in range(1, 3)]

eq_labels = [r'\text{eq. } ' + lab for lab in labels]
for j in range(2):
    df = pd.DataFrame(Π[j], index=eq_labels, columns=labels)
    display(Latex(r'$\Pi_' + str(j + 1) + ' = '
                  + df_to_latex_array(df).strip('$') + '$'))
```

```
eigenvalues of A - K1 C_bar: [0.932 0.594]
```

$$\Pi_1 = \begin{array}{l|ccc} & y_n & c & \Delta k \\ \hline \text{eq. } y_n & 0.056 & -0.048 & -0.004 \\ \text{eq. } c & 0.013 & 0.720 & 0.000 \\ \text{eq. } \Delta k & -0.281 & -0.037 & 0.298 \end{array}$$

$$\Pi_2 = \begin{array}{l|ccc} & y_n & c & \Delta k \\ \hline \text{eq. } y_n & 0.047 & 0.035 & -0.001 \\ \text{eq. } c & 0.012 & 0.006 & 0.000 \\ \text{eq. } \Delta k & 0.016 & 0.013 & -0.000 \end{array}$$

The eigenvalues of $A - K_1\bar{C}$ are inside the unit circle, so the vector autoregression converges.

In the investment equation, the coefficient on lagged income is large (about -0.28).

In the income equation, the coefficient on lagged investment is tiny (about -0.004).

Lagged income helps to predict investment, but lagged investment barely helps to predict income, which is the Granger-causality pattern that Sargent [1989] set out to explain.

Exercise 54.8.2 computes an ordering-free measure of the strength of Granger causality due to Geweke [1982].

54.4.8 Wold impulse responses

Impulse responses in the Wold representation are reported using orthogonalized innovations (Cholesky factorization of V_1 with ordering y_n, c, Δk).

Under this method, lag-0 responses reflect both contemporaneous covariance and the Cholesky ordering.

We first define a helper function to format the response coefficients as a LaTeX array

```
lags = np.arange(14)

def wold_response_table(resp, shock_idx, lags):
    return pd.DataFrame(
        np.round(resp[:, :, shock_idx], 4),
        columns=labels,
        index=pd.Index(lags, name='j')
    )
```

Now we report the impulse responses to each orthogonalized innovation in a single table with three panels

```
wold_titles = [r'\text{A. Response to } y_n \text{ innovation}',
               r'\text{B. Response to } c \text{ innovation}',
               r'\text{C. Response to } \Delta k \text{ innovation}']

parts = []
for i, title in enumerate(wold_titles):
    arr = df_to_latex_array(wold_response_table(resp1, i, lags)).strip('$')
    parts.append(
      r'\begin{array}{c} ' + title + r' \\ ' + arr + r' \end{array}')

display(Latex('$' + r' \quad '.join(parts) + '$'))
```

A. Response to y_n innovation

	y_n	c	Δk
0	1.002	0.048	0.951
1	0.050	0.048	0.000
2	0.049	0.048	0.000
3	0.048	0.048	0.000
4	0.048	0.048	0.000
5	0.048	0.048	0.000
6	0.048	0.048	0.000
7	0.048	0.048	0.000
8	0.048	0.048	0.000
9	0.048	0.048	0.000
10	0.048	0.048	0.000
11	0.048	0.048	0.000
12	0.048	0.048	0.000
13	0.048	0.048	0.000

B. Response to c innovation

	y_n	c	Δk
0	0.000	0.035	0.003
1	−0.002	0.025	−0.000
2	−0.000	0.019	−0.000
3	0.001	0.014	−0.000
4	0.002	0.010	−0.000
5	0.002	0.008	−0.000
6	0.002	0.006	−0.000
7	0.002	0.005	−0.000
8	0.002	0.004	−0.000
9	0.002	0.004	−0.000
10	0.002	0.003	−0.000
11	0.002	0.003	−0.000
12	0.002	0.003	−0.000
13	0.002	0.003	−0.000

C. Response to Δk innovation

	y_n	c	Δk
0	0.000	0.000	0.652
1	−0.003	0.000	0.194
2	−0.002	0.000	0.058
3	−0.001	0.000	0.018
4	−0.001	0.000	0.005
5	−0.000	0.000	0.002
6	−0.000	0.000	0.001
7	−0.000	0.000	0.000
8	0.000	0.000	0.000
9	0.000	0.000	0.000
10	0.000	0.000	0.000
11	0.000	0.000	0.000
12	0.000	0.000	0.000
13	0.000	0.000	0.000

At impact, the first orthogonalized innovation loads on all three measured variables.

At subsequent lags the income innovation generates persistent responses in all three variables because, being the best-measured series, its innovation is dominated by the true permanent shock θ_t.

The consumption and investment innovations produce responses that decay at rates close to the autoregressive coefficients of their respective measurement errors ($\rho_c = 0.7$, $\rho_{\Delta k} = 0.3$), with little spillover to other variables.

54.5 A model of optimal estimates reported by an agency

Suppose that instead of reporting the error-corrupted data $\bar{z}_t$, the data collecting agency reports linear least-squares projections of the true data on a history of the error-corrupted data.

This model provides a possible way of interpreting two features of the data-reporting process.

- *seasonal adjustment*: if the components of v_t have strong seasonals, the optimal filter will assume a shape that can be interpreted partly in terms of a seasonal adjustment filter, one that is one-sided in current and past $\bar{z}_t$'s.
- *data revisions*: if z_t contains current and lagged values of some variable of interest, then the model simultaneously determines "preliminary," "revised," and "final" estimates as successive conditional expectations based on progressively longer histories of error-ridden observations.

To make this operational, we impute to the reporting agency a model of the joint process generating the true data and the measurement errors.

We assume that the reporting agency has "rational expectations": it knows the economic and measurement structure leading to (54.16)–(54.17).

To prepare its estimates, the reporting agency itself computes the Kalman filter to obtain the innovations representation (54.18).

Rather than reporting the error-corrupted data $\bar{z}_t$, the agency reports $\hat{z}_t = G\hat{x}_t$, where G is a "selection matrix," possibly equal to C, for the data reported by the agency.

The reported data are $\hat{z}_t = G\hat{x}_t = E[Gx_t \mid \bar{z}_t, \bar{z}_{t-1}, \ldots, \hat{x}_0]$.

The state-space representation for the reported data is then

$$\begin{aligned} \hat{x}_{t+1} &= A\hat{x}_t + K_1 u_t, \\ \hat{z}_t &= G\hat{x}_t, \end{aligned} \tag{54.25}$$

where the first line of (54.25) is from the innovations representation (54.18).

Note that u_t is the innovation to $\bar{z}_{t+1}$ and is *not* the innovation to $\hat{z}_t$.

To obtain a Wold representation for $\hat{z}_t$ and the likelihood function for a sample of $\hat{z}_t$ requires that we obtain an innovations representation for (54.25).

54.5.1 Innovations representation for filtered data

To add a little generality to (54.25) we amend it to the system

$$\begin{aligned} \hat{x}_{t+1} &= A\hat{x}_t + K_1 u_t, \\ \hat{z}_t &= G\hat{x}_t + \zeta_t, \end{aligned} \tag{54.26}$$

where ζ_t is a type 2 white-noise measurement error process ("typos") with presumably very small covariance matrix R_2.

The covariance matrix of the joint noise is

$$E \begin{bmatrix} K_1 u_t \\ \zeta_t \end{bmatrix} \begin{bmatrix} K_1 u_t \\ \zeta_t \end{bmatrix}^\top = \begin{bmatrix} Q_2 & 0 \\ 0 & R_2 \end{bmatrix}, \tag{54.27}$$

where $Q_2 = K_1 V_1 K_1^\top$.

If R_2 is singular, it is necessary to adjust the Kalman filtering formulas by using transformations that induce a "reduced order observer."

In practice, we approximate a zero R_2 matrix with the matrix ϵI for a small $\epsilon > 0$ to keep the Kalman filter numerically well-conditioned.

For system (54.26) and (54.27), an innovations representation is

$$\begin{aligned} \breve{x}_{t+1} &= A\breve{x}_t + K_2 a_t, \\ \hat{z}_t &= G\breve{x}_t + a_t, \end{aligned} \tag{54.28}$$

where

$$\begin{aligned} a_t &= \hat{z}_t - E[\hat{z}_t \mid \hat{z}_{t-1}, \hat{z}_{t-2}, ...], \\ \breve{x}_t &= E[\hat{x}_t \mid \hat{z}_{t-1}, \hat{z}_{t-2}, \dots, \breve{x}_0], \\ S_2 &= E[(\hat{x}_t - \breve{x}_t)(\hat{x}_t - \breve{x}_t)^\top], \\ [K_2, S_2] &= \text{kalmanfilter}(A, G, Q_2, R_2, 0). \end{aligned} \tag{54.29}$$

Thus $\{a_t\}$ is the innovation process for the reported data $\hat{z}_t$, with innovation covariance

$$V_2 = E\, a_t a_t^\top = G\, S_2\, G^\top + R_2. \tag{54.30}$$

54.5.2 Wold representation

A Wold moving average representation for $\hat{z}_t$ is found from (54.28) to be

$$\hat{z}_t = [G(I - AL)^{-1} K_2 L + I] a_t, \tag{54.31}$$

with coefficients $\psi_0 = I$ and $\psi_j = GA^{j-1}K_2$ for $j \geq 1$.

Note that this is simpler than the Model 1 Wold representation (54.21) because there is no quasi-differencing to undo.

54.5.3 Gaussian likelihood

When a method analogous to Model 1 is used, a Gaussian log-likelihood for $\hat{z}_t$ can be computed by first computing an $\{a_t\}$ sequence from observations on $\hat{z}_t$ by using

$$\begin{aligned} \breve{x}_{t+1} &= (A - K_2 G)\, \breve{x}_t + K_2 \hat{z}_t, \\ a_t &= -G\, \breve{x}_t + \hat{z}_t. \end{aligned} \tag{54.32}$$

The likelihood function for a sample of T observations $\{\hat{z}_t\}$ is then

$$\mathcal{L}^{**} = -\tfrac{3}{2} T \ln 2\pi - \tfrac{1}{2} T \ln |V_2| - \tfrac{1}{2} \sum_{t=0}^{T-1} a_t^\top V_2^{-1} a_t. \tag{54.33}$$

Note that relative to computing the likelihood function (54.23) for the error-corrupted data, computing the likelihood function for the optimally filtered data requires more calculations.

Both likelihood functions require that the Kalman filter (54.19) be computed, while the likelihood function for the filtered data requires that the Kalman filter (54.29) also be computed.

In effect, in order to interpret and use the filtered data reported by the agency, it is necessary to retrace the steps that the agency used to synthesize those data.

The Kalman filter (54.19) is supposed to be formed by the agency.

The agency need not use Kalman filter (54.29) because it does not need the Wold representation for the filtered data.

In our parameterization $G = C$.

Because the rows of C satisfy the national income identity, the reported data satisfy $\hat{c}_t + \Delta\hat{k}_t = \hat{y}_{nt}$ exactly.

So when $R_2 = 0$, the innovation covariance matrix V_2 is singular, and the likelihood (54.33) of all three reported series is degenerate; Exercise 54.8.3 explores this "stochastic singularity."

```
Q2 = K1 @ V1 @ K1.T
ε = 1e-6

K2, S2, V2 = steady_state_kalman(A, C, Q2, ε * np.eye(3))

def filtered_wold_coeffs(A, C, K, n_terms=25):
    psi = [np.eye(3)]
    Apow = np.eye(2)
    for _ in range(1, n_terms):
        psi.append(C @ Apow @ K)
        Apow = Apow @ A
    return psi

psi2 = filtered_wold_coeffs(A, C, K2, n_terms=40)
resp2 = np.array(
  [psi2[j] @ linalg.cholesky(V2, lower=True) for j in range(14)])
decomp2 = fev_contributions(psi2, V2, n_horizons=20)
```

54.5.4 Forecast-error-variance decomposition

Because the filtered data are nearly noiseless, the innovation covariance V_2 is close to singular with one dominant eigenvalue.

This means the filtered economy is driven by essentially one shock, just like the true economy

```
parts = []
for i, title in enumerate(shock_titles):
    arr = df_to_latex_array(fev_table(decomp2, i, horizons)).strip('$')
    parts.append(
      r'\begin{array}{c} ' + title + r' \\ ' + arr + r' \end{array}')

display(Latex('$' + r' \quad '.join(parts) + '$'))
```

19	0.000	0.000	0.000
20	0.000	0.000	0.000

In Model 2, the first innovation accounts for virtually all forecast-error variance, just as in the true economy where the single structural shock θ_t drives everything.

The second and third innovations contribute negligibly.

This confirms that filtering strips away the measurement noise that created the appearance of multiple independent sources of variation in Model 1.

The covariance matrix and eigenvalues of the Model 2 innovations are

```
print('Covariance matrix of innovations:')
df_v2 = pd.DataFrame(np.round(V2, 4), index=labels, columns=labels)
display(Latex(df_to_latex_matrix(df_v2)))
```

```
Covariance matrix of innovations:
```

$$\begin{bmatrix} 0.9965 & 0.0475 & 0.9490 \\ 0.0475 & 0.0023 & 0.0452 \\ 0.9490 & 0.0452 & 0.9038 \end{bmatrix}$$

```
print('Eigenvalues of covariance matrix:')
print(np.array2string(np.sort(np.linalg.eigvalsh(V2))[::-1],
                      formatter={'float': '{:.2e}'.format}))
```

```
Eigenvalues of covariance matrix:
[1.90e+00 8.54e-06 1.00e-06]
```

One eigenvalue is large.

A second eigenvalue is positive but tiny: it reflects revisions to the agency's estimate of the capital stock, which enter the reported data only through the small coefficient $f - 1$.

The third eigenvalue equals ϵ and would be exactly zero if $R_2 = 0$, because of the national income identity.

As Sargent [1989] emphasizes, the two models of measurement produce quite different inferences about the economy's dynamics despite sharing identical underlying parameters.

54.5.5 Wold impulse responses

We again use orthogonalized Wold representation impulse responses with a Cholesky decomposition of V_2 ordered as y_n, c, Δk.

```
parts = []
for i, title in enumerate(wold_titles):
    arr = df_to_latex_array(
      wold_response_table(resp2, i, lags)).strip('$')
    parts.append(
      r'\begin{array}{c} ' + title + r' \\ ' + arr + r' \end{array}')

display(Latex('$' + r' \quad '.join(parts) + '$'))
```

The income innovation in Model 2 produces responses that closely approximate the true impulse response function from the structural shock θ_t.

Readers can compare the left table with the table in the *True impulse responses* section above.

The numbers are essentially the same.

The consumption and investment innovations produce responses that are orders of magnitude smaller, confirming that the filtered data are driven by essentially one shock.

Unlike Model 1, the filtered data from Model 2 *cannot* reproduce the apparent Granger causality pattern that the accelerator literature has documented empirically.

Hence, at the population level, the two measurement models imply different empirical stories even though they share the same structural economy.

- In Model 1 (raw data), measurement noise creates multiple innovations and an apparent Granger-causality pattern.
- In Model 2 (filtered data), innovations collapse back to essentially one dominant shock, mirroring the true one-index economy.

Let's verify these implications in a finite sample simulation.

54.6 Simulation

The tables above characterize population moments of the two models.

Let's simulate 80 periods of true, measured, and filtered data to compare population implications with finite-sample behavior.

First, we define a function to simulate the true economy, generate measured data with AR(1) measurement errors, and apply the Model 1 Kalman filter to produce filtered estimates

```
def simulate_series(seed=7909, T=80, k0=10.0):
    """
    Simulate true, measured, and filtered series.
    """
    rng = np.random.default_rng(seed)

    # True state/observables
    θ = rng.normal(0.0, 1.0, size=T)
    k = np.empty(T + 1)
    k[0] = k0

    y = np.empty(T)
    c = np.empty(T)
    dk = np.empty(T)

    for t in range(T):
        x_t = np.array([k[t], θ[t]])
        y[t], c[t], dk[t] = C @ x_t
        k[t + 1] = k[t] + (1.0 / f) * θ[t]

    # Measured data with AR(1) errors
    v_prev = np.zeros(3)
    v = np.empty((T, 3))
    for t in range(T):
        η_t = rng.multivariate_normal(np.zeros(3), Σ_η)
        v_prev = D @ v_prev + η_t
        v[t] = v_prev

    z_meas = np.column_stack([y, c, dk]) + v

    # Filtered data via Model 1 transformed filter
    xhat_prev = np.array([k0, 0.0])
    z_prev = C @ xhat_prev    # model-implied value of the unobserved z̄_{-1}
    z_filt = np.empty((T, 3))
    k_filt = np.empty(T)

    for t in range(T):
        z_bar_t = z_meas[t] - D @ z_prev
        u_t = z_bar_t - C_bar @ xhat_prev
        xhat_t = A @ xhat_prev + K1 @ u_t

        z_filt[t] = C @ xhat_t
        k_filt[t] = xhat_t[0]
```

(continues on next page)

(continued from previous page)

```
        xhat_prev = xhat_t
        z_prev = z_meas[t]

    out = {
        "y_true": y, "c_true": c, "dk_true": dk, "k_true": k[:-1],
        "y_meas": z_meas[:, 0], "c_meas": z_meas[:, 1],
        "dk_meas": z_meas[:, 2],
        "y_filt": z_filt[:, 0], "c_filt": z_filt[:, 1],
        "dk_filt": z_filt[:, 2], "k_filt": k_filt
    }
    return out

sim = simulate_series(seed=7909, T=80, k0=10.0)
```

We use the following helper function to plot the true series against either the measured or filtered series

```
def plot_true_vs_other(t, true_series, other_series,
                                    other_label, ylabel=""):
    fig, ax = plt.subplots(figsize=(8, 4))
    ax.plot(t, true_series, lw=2, label="true")
    ax.plot(t, other_series, lw=2, ls="--", label=other_label)
    ax.set_xlabel("time")
    ax.set_ylabel(ylabel)
    ax.legend()
    plt.tight_layout()
    plt.show()

t = np.arange(1, 81)
```

Let's first compare the true series with the measured series to see how measurement errors distort the data

```
plot_true_vs_other(t, sim["c_true"], sim["c_meas"],
                                    "measured", ylabel="consumption")
```

```
plot_true_vs_other(t, sim["dk_true"], sim["dk_meas"],
                                    "measured", ylabel="investment")
```

```
plot_true_vs_other(t, sim["y_true"], sim["y_meas"],
                                    "measured", ylabel="income")
```

Investment is distorted the most because its measurement error has the largest innovation variance ($\sigma_\eta = 0.65$), while income is distorted the least ($\sigma_\eta = 0.05$).

For the filtered series, we expect the Kalman filter to recover the true series more closely by stripping away measurement noise

```
plot_true_vs_other(t, sim["c_true"], sim["c_filt"],
                                    "filtered", ylabel="consumption")
```

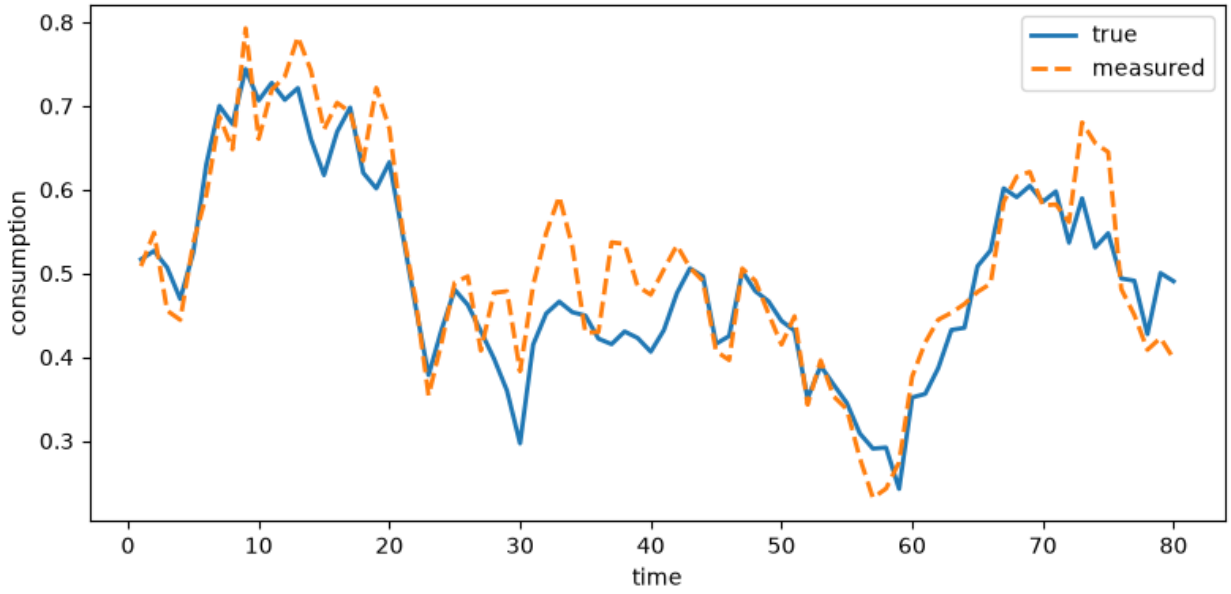

Fig. 54.1: True and measured consumption

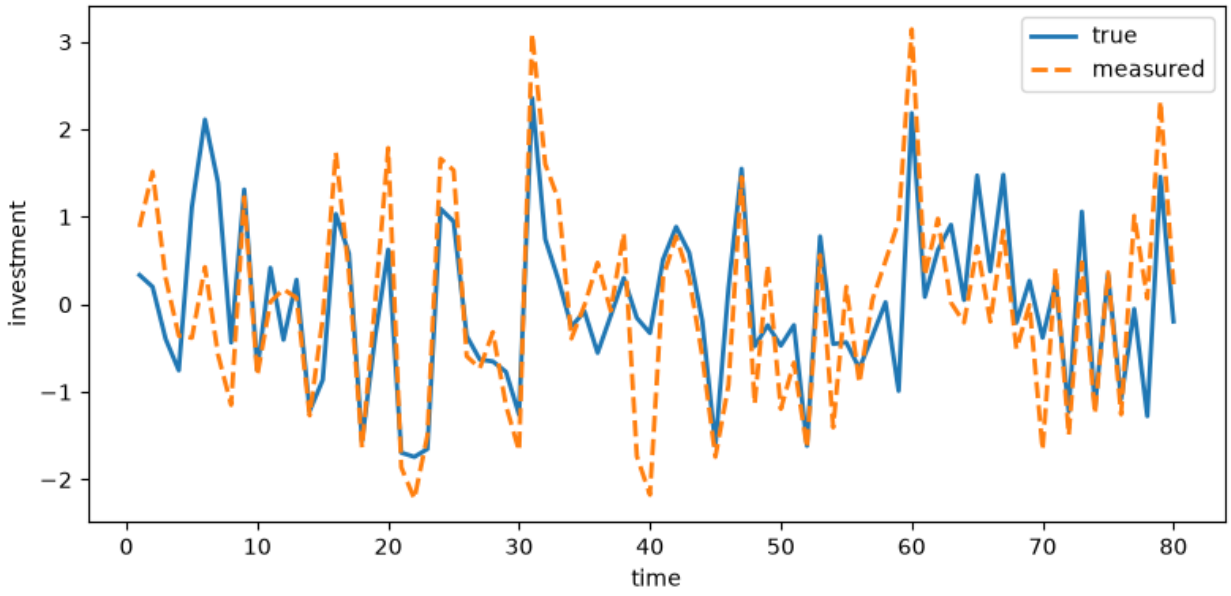

Fig. 54.2: True and measured investment

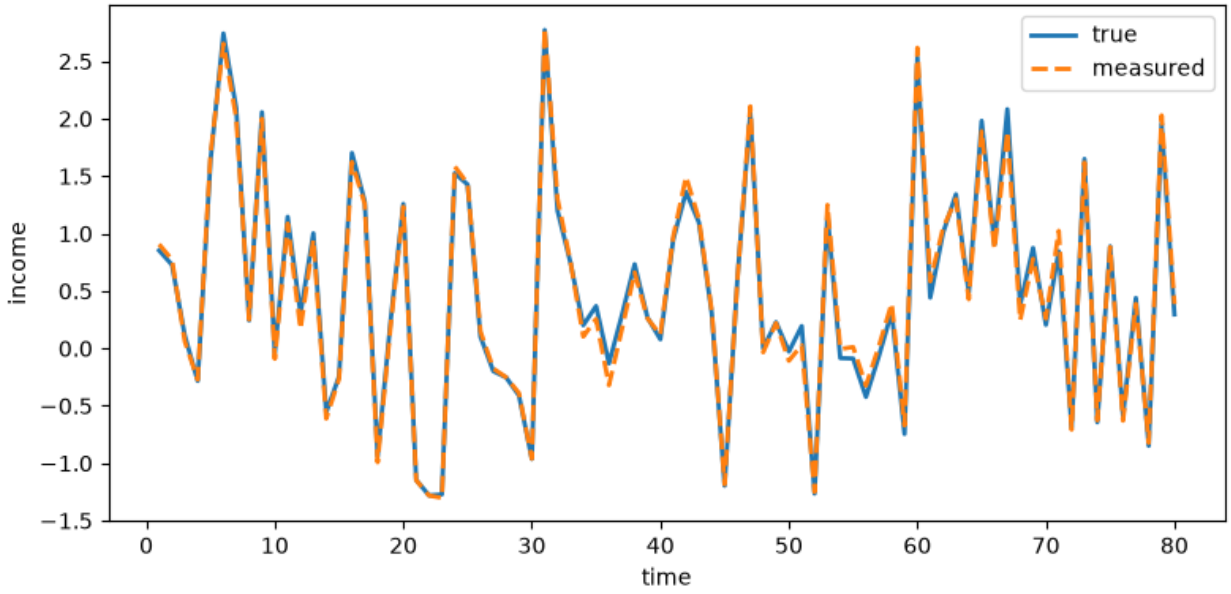

Fig. 54.3: True and measured income

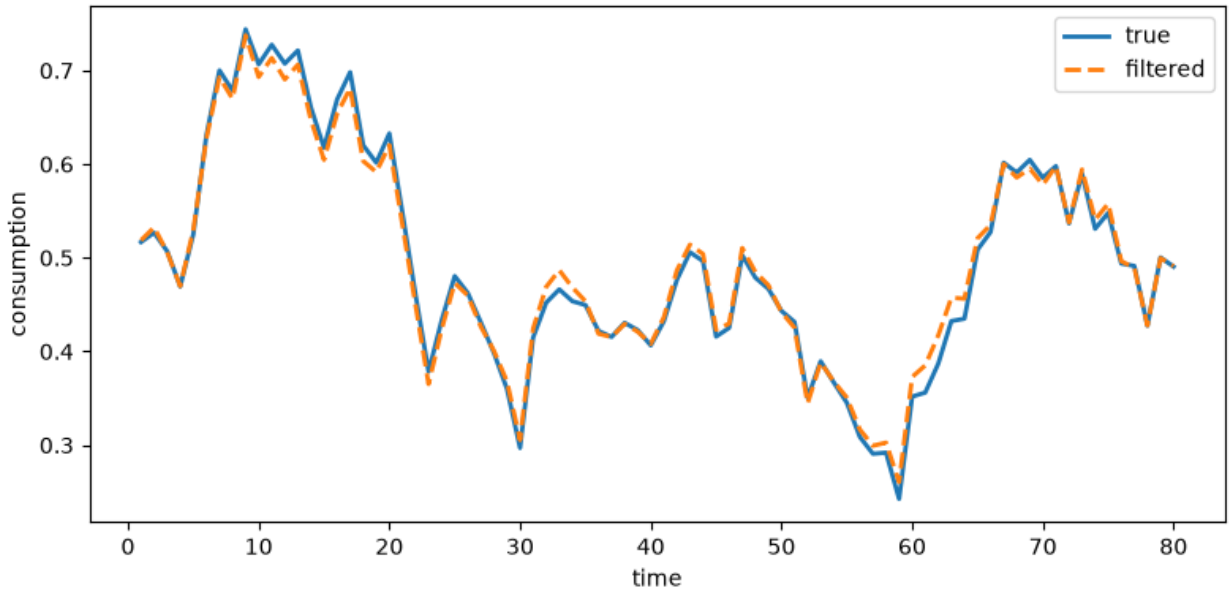

Fig. 54.4: True and filtered consumption

```
plot_true_vs_other(t, sim["dk_true"], sim["dk_filt"],
                                    "filtered", ylabel="investment")
```

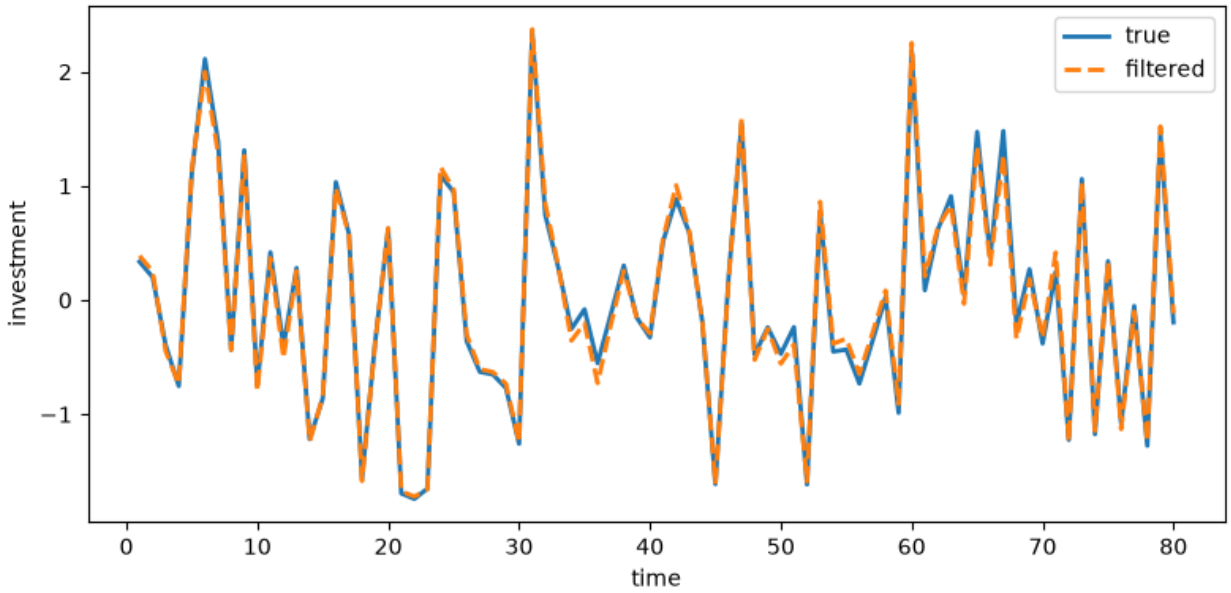

Fig. 54.5: True and filtered investment

```
plot_true_vs_other(t, sim["y_true"], sim["y_filt"],
                                    "filtered", ylabel="income")
```

```
plot_true_vs_other(t, sim["k_true"], sim["k_filt"],
                                    "filtered", ylabel="capital stock")
```

Indeed, Kalman-filtered estimates from Model 1 remove much of the measurement noise and track the truth closely.

The improvement is largest for investment, the series whose measurement error is largest; income was already well measured.

In the true model the national income identity $c_t + \Delta k_t = y_{n,t}$ holds exactly.

Independent measurement errors break this accounting identity in the measured data.

Because the filtered series are all of the form $C\hat{x}_t$, and the rows of C satisfy the identity, the filtered data satisfy it exactly.

The following figure confirms this by showing the residual $c_t + \Delta k_t - y_{n,t}$ for both measured and filtered data

```
fig, (ax1, ax2) = plt.subplots(1, 2, figsize=(14, 4))

ax1.plot(t, sim["c_meas"] + sim["dk_meas"] - sim["y_meas"], lw=2)
ax1.axhline(0, color='black', lw=0.8, ls='--', alpha=0.5)
ax1.set_xlabel("time")
ax1.set_ylabel("measured residual")
```

(continues on next page)

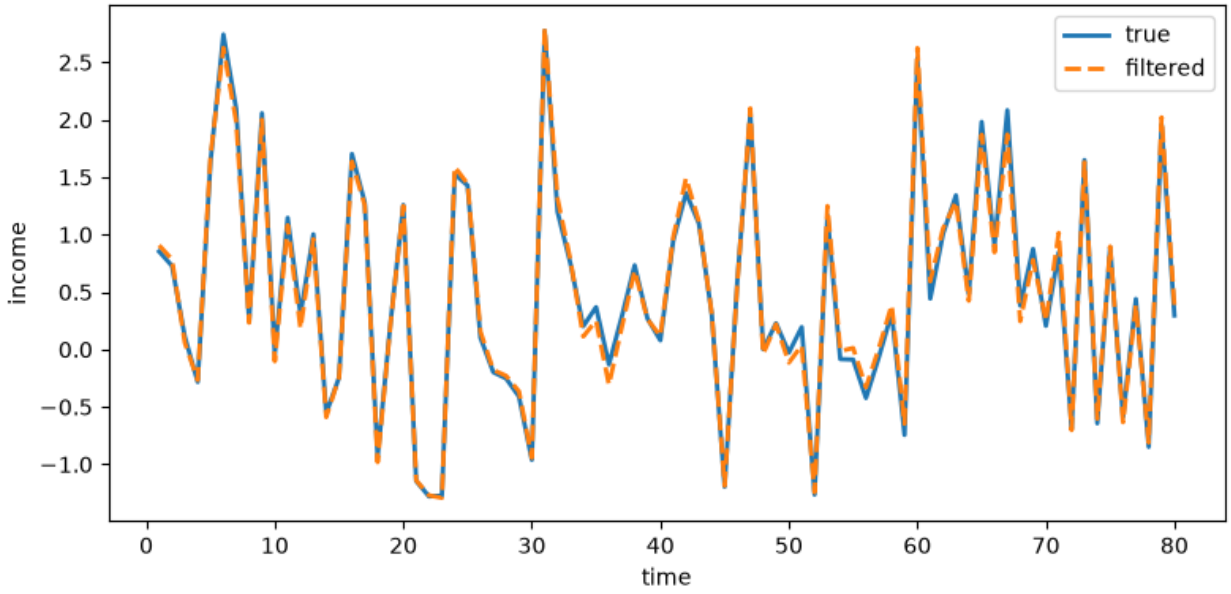

Fig. 54.6: True and filtered income

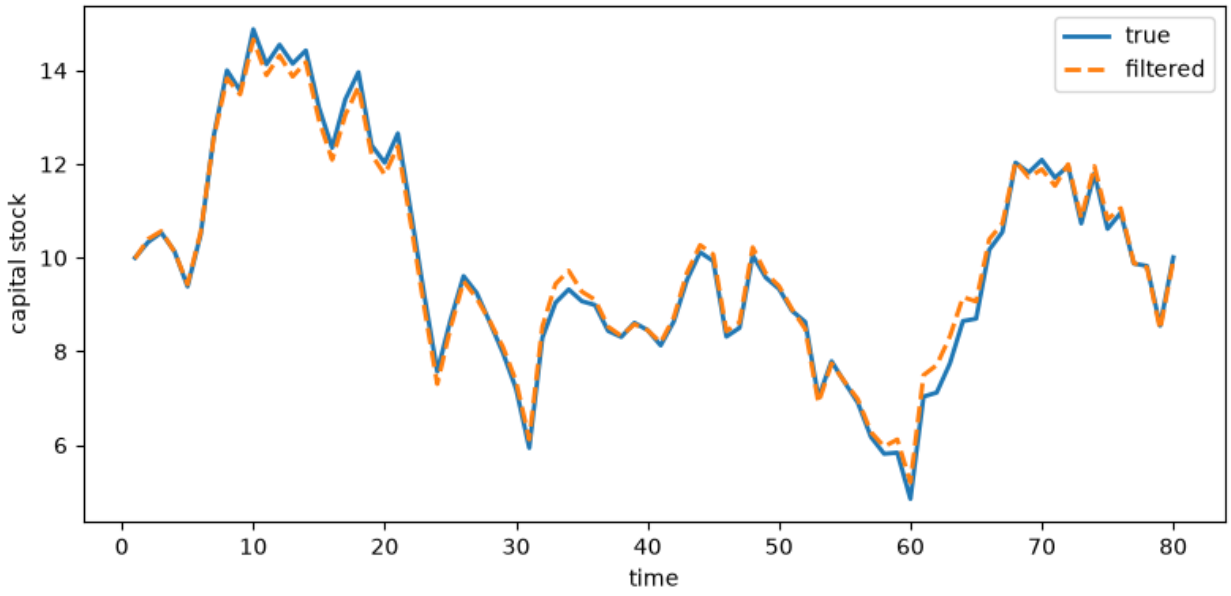

Fig. 54.7: True and filtered capital stock

(continued from previous page)

```
ax2.plot(t, sim["c_filt"] + sim["dk_filt"] - sim["y_filt"], lw=2)
ax2.axhline(0, color='black', lw=0.8, ls='--', alpha=0.5)
ax2.set_xlabel("time")
ax2.set_ylabel("filtered residual")

plt.tight_layout()
plt.show()
```

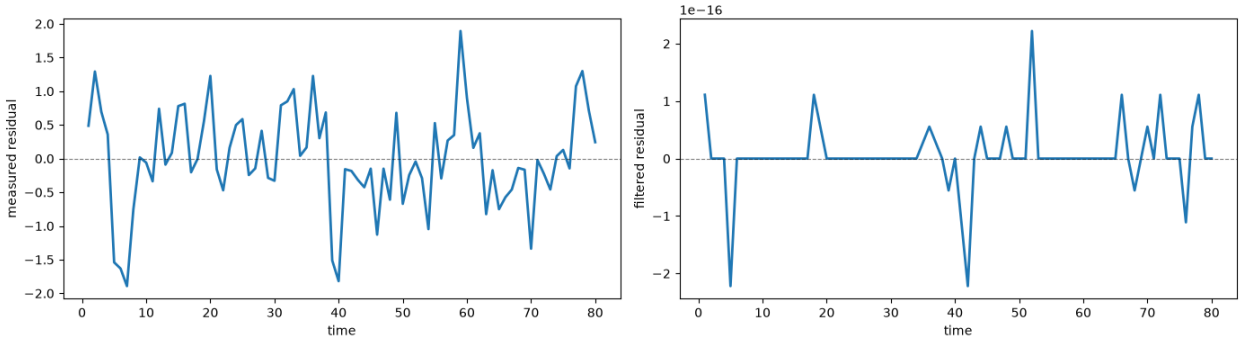

Fig. 54.8: National income identity residual

As we have predicted, the residual for the measured data is large and volatile, while the residual for the filtered data is zero up to rounding error.

54.7 Summary

Sargent [1989] shows how measurement error alters an econometrician's view of a permanent income economy driven by the investment accelerator.

The Wold representations and variance decompositions of Model 1 (raw measurements) and Model 2 (filtered measurements) differ substantially, even though the underlying economy is the same.

Measurement error can reshape inferences about which shocks drive which variables.

Model 1 reproduces the **Granger causality** pattern documented in the empirical accelerator literature: income appears to Granger-cause consumption and investment, a result Sargent [1989] attributes to measurement error and signal extraction in raw reported data.

What matters for this pattern is how large each series' measurement error is relative to the variation in the true series.

Model 2, working with filtered data, attributes nearly all variance to the single structural shock θ_t and *cannot* reproduce the Granger causality pattern.

The *Kalman filter* effectively strips measurement noise from the data, so the filtered series track the truth closely.

Raw measurement error breaks the national income accounting identity, while the filtered data satisfy it exactly, which makes the three reported series stochastically singular.

54.8 Exercises

Exercise 54.8.1

Under the assumptions $a(L) = 1$ and $\beta f = 1$, use the decision rule (54.6) and the law of motion $k_{t+1} = k_t + f^{-1}\theta_t$ to show that

1. $c_t - c_{t-1} = (1-\beta)\theta_t$, so that consumption is a martingale
2. $c_t - \beta c_{t-1} = (1-\beta)y_{nt}$, which is Friedman's consumption function (54.7)
3. $y_{nt} - y_{n,t-1} = \theta_t - \beta\theta_{t-1}$, which is equation (54.9)
4. $(k_{t+1} - k_t) - \beta(k_t - k_{t-1}) = \beta(y_{nt} - y_{n,t-1})$, which is the accelerator (54.8)

Then verify all four identities numerically using the true series in `sim`, recovering θ_t from $\theta_t = y_{nt} - (f-1)k_t$.

Solution

From $k_t - k_{t-1} = \beta\theta_{t-1}$ and (54.6),

$$c_t - c_{t-1} = (f-1)\beta\theta_{t-1} + (1-\beta)(\theta_t - \theta_{t-1}) = (1-\beta)\theta_t$$

because $(f-1)\beta = 1-\beta$.

Similarly, $y_{nt} - y_{n,t-1} = (f-1)\beta\theta_{t-1} + \theta_t - \theta_{t-1} = \theta_t - \beta\theta_{t-1}$.

For the second claim, substitute $k_t = k_{t-1} + \beta\theta_{t-1}$ into (54.6) and (54.5):

$$\begin{aligned} c_t - \beta c_{t-1} &= (f-1)(1-\beta)k_{t-1} + (1-\beta)\theta_t + [(f-1)\beta - \beta(1-\beta)]\,\theta_{t-1} \\ (1-\beta)y_{nt} &= (1-\beta)(f-1)k_{t-1} + (1-\beta)\theta_t + (1-\beta)(f-1)\beta\,\theta_{t-1} \end{aligned}$$

and use $(f-1)\beta = 1-\beta$ to see that the two right sides are equal.

Finally, $k_{t+1} - k_t = \beta\theta_t$ implies $(1-\beta L)(k_{t+1} - k_t) = \beta(\theta_t - \beta\theta_{t-1}) = \beta(y_{nt} - y_{n,t-1})$.

```
y, c, dk, k = sim["y_true"], sim["c_true"], sim["dk_true"], sim["k_true"]
θ = y - (f - 1) * k

print("martingale:  ", np.allclose(np.diff(c), (1 - β) * θ[1:]))
print("Friedman:    ", np.allclose(c[1:] - β * c[:-1], (1 - β) * y[1:]))
print("MA(1):       ", np.allclose(np.diff(y), θ[1:] - β * θ[:-1]))
print("accelerator: ", np.allclose(dk[1:] - β * dk[:-1], β * np.diff(y)))
```

```
martingale:   True
Friedman:     True
MA(1):        True
accelerator:  True
```

Exercise 54.8.2

Forecast-error-variance decompositions based on a Cholesky factorization depend on how the variables are ordered.

Geweke [1982] proposed a measure of Granger causality that does not depend on an ordering.

For measured series i and j, let σ_j^2 be the one-step-ahead prediction error variance of $\bar{z}_{j,t+1}$ given its own past only, and let $\sigma_{j|i}^2$ be its prediction error variance given the past of both $\bar{z}_i$ and $\bar{z}_j$.

Then $F_{i\to j} = \log(\sigma_j^2/\sigma_{j|i}^2) \geq 0$, with equality if and only if $\bar{z}_i$ does not Granger-cause $\bar{z}_j$.

Because the measurement errors are mutually independent AR(1) processes, both variances can be computed by applying `steady_state_kalman` to the quasi-differenced system (54.16) using only the rows of $\bar{C}$, R_1, and the columns of W_1 that correspond to the included series.

1. Compute $F_{y\to\Delta k}$, $F_{\Delta k\to y}$, $F_{y\to c}$, and $F_{c\to y}$ for the baseline measurement-error parameters.
2. Recompute them after swapping the measurement-error innovation standard deviations of income and investment, so that $\sigma_\eta = (0.65, 0.035, 0.05)$.
3. Recompute them with $\sigma_\eta = (0.3, 0.3, 0.3)$ and explain why equal measurement error variances do **not** produce symmetric Granger causality.

Solution

Here is one solution.

```
def geweke(σ_η, ρ=np.array([0.6, 0.7, 0.3]), pair=(0, 2)):
    """
    Return (F_{i->j}, F_{j->i}) for the measured series pair = (i, j).
    """
    D = np.diag(ρ)
    Σ = np.diag(np.asarray(σ_η)**2)
    C_bar = C @ A - D @ C
    R1 = C @ Q @ C.T + Σ
    W1 = Q @ C.T

    def pev(idx):
        idx = list(idx)
        return steady_state_kalman(A, C_bar[idx], Q,
                                   R1[np.ix_(idx, idx)], W1[:, idx])[2]

    i, j = pair
    V_i, V_j, V_ij = pev([i])[0, 0], pev([j])[0, 0], pev([i, j])
    return np.log(V_j / V_ij[1, 1]), np.log(V_i / V_ij[0, 0])

cases = {"baseline": (0.05, 0.035, 0.65),
         "swapped y and Δk": (0.65, 0.035, 0.05),
         "equal": (0.3, 0.3, 0.3)}

for name, σ in cases.items():
    F_yk, F_ky = geweke(σ, pair=(0, 2))
    F_yc, F_cy = geweke(σ, pair=(0, 1))
    print(f"{name:18s} y→Δk {F_yk:.4f}  Δk→y {F_ky:.4f}  "
          f"y→c {F_yc:.4f}  c→y {F_cy:.4f}")
```

```
baseline           y→Δk 0.0199  Δk→y 0.0000  y→c 0.0452  c→y 0.0001
swapped y and Δk   y→Δk 0.0000  Δk→y 0.0777  y→c 0.0045  c→y 0.0345
equal              y→Δk 0.0035  Δk→y 0.0171  y→c 0.0305  c→y 0.0009
```

In the baseline, income Granger-causes both investment and consumption, while neither Granger-causes income.

Swapping the measurement errors of income and investment reverses the direction of Granger causality between

them.

With equal measurement error variances, investment Granger-causes income more than income Granger-causes investment, and income strongly Granger-causes consumption.

What matters is not the variance of the measurement error but its size **relative to the signal** in each series.

The innovation to true investment $\beta\theta_t$ has standard deviation 0.95, while the innovation to true consumption $(1-\beta)\theta_t$ has standard deviation only 0.048.

So a measurement error with innovation standard deviation 0.3 obscures investment much less than it swamps consumption.

In the baseline, consumption's measurement error innovation (0.035) is small in absolute terms but not relative to the tiny innovation in true consumption, which is why income Granger-causes consumption.

Exercise 54.8.3

In Model 2, the agency reports $\hat{z}_t = C\hat{x}_t$.

1. Show that the reported data satisfy the national income identity $\hat{c}_t + \Delta\hat{k}_t - \hat{y}_{nt} = 0$ **exactly**, for any estimate $\hat{x}_t$.
2. Explain why this implies that the innovation covariance matrix V_2 of the reported data is singular when $R_2 = 0$.
3. Compute the eigenvalues of V_2 for $R_2 = \epsilon I$ with $\epsilon = 10^{-2}, 10^{-4}, 10^{-6}$ and interpret them.
4. What does this "stochastic singularity" imply for an econometrician who wants to compute the likelihood (54.33) from all three reported series?

Solution

The rows of C satisfy $C_c + C_{\Delta k} - C_y = [(f-1) + 0 - (f-1),\ (1-f^{-1}) + f^{-1} - 1] = [0, 0]$.

So $\hat{c}_t + \Delta\hat{k}_t - \hat{y}_{nt} = (C_c + C_{\Delta k} - C_y)\hat{x}_t = 0$ for every $\hat{x}_t$.

Because the vector $b = [-1, 1, 1]$ satisfies $b\,C\hat{x}_t = 0$ for all t, it also satisfies $b\,a_t = 0$ when $R_2 = 0$, so $bV_2b^\top = 0$ and V_2 is singular.

```
print("C_c + C_Δk - C_y =", C[1] + C[2] - C[0])
print("max |identity residual| in reported data:",
      np.max(np.abs(sim['c_filt'] + sim['dk_filt'] - sim['y_filt'])))

for ε_R in (1e-2, 1e-4, 1e-6):
    _, _, V2_ε = steady_state_kalman(A, C, Q2, ε_R * np.eye(3))
    print(f"ε = {ε_R:.0e}:  eigenvalues of V2 = "
          f"{np.array2string(np.sort(np.linalg.eigvalsh(V2_ε))[::-1], formatter={
↪'float': '{:.2e}'.format})}")
```

```
C_c + C_Δk - C_y = [0. 0.]
max |identity residual| in reported data: 2.220446049250313e-16
ε = 1e-02:  eigenvalues of V2 = [1.91e+00 1.03e-02 1.00e-02]
ε = 1e-04:  eigenvalues of V2 = [1.90e+00 1.27e-04 1.00e-04]
ε = 1e-06:  eigenvalues of V2 = [1.90e+00 8.54e-06 1.00e-06]
```

One eigenvalue of V_2 is large: it reflects news about the permanent shock θ_t.

A second eigenvalue is tiny but positive: it reflects revisions to the agency's estimate of the capital stock, which enter the reported data only through the small coefficient $f - 1$.

The third eigenvalue is approximately ϵ and vanishes as $\epsilon \to 0$ because of the identity.

An econometrician who tries to compute the Gaussian likelihood of all three reported series with $R_2 = 0$ faces a degenerate distribution: $\ln |V_2| = -\infty$.

In practice, one must either drop one of the three series, or add "type 2" reporting errors with $R_2 > 0$ as in (54.26).

In the raw data of Model 1, by contrast, independent measurement errors break the identity, so the three measured series have a nonsingular innovation covariance matrix.

JOB SEARCH I: THE MCCALL SEARCH MODEL

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

> "Questioning a McCall worker is like having a conversation with an out-of-work friend: 'Maybe you are setting your sights too high', or 'Why did you quit your old job before you had a new one lined up?' This is real social science: an attempt to model, to understand, human behavior by visualizing the situation people find themselves in, the options they face and the pros and cons as they themselves see them." – Robert E. Lucas, Jr.

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon jax
```

55.1 Overview

The McCall search model [McCall, 1970] helped transform economists' way of thinking about labor markets.

To clarify notions such as "involuntary" unemployment, McCall modeled the decision problem of an unemployed worker in terms of factors including

- current and likely future wages
- impatience
- unemployment compensation

To solve the decision problem McCall used dynamic programming.

Here we set up McCall's model and use dynamic programming to analyze it.

As we'll see, McCall's model is not only interesting in its own right but also an excellent vehicle for learning dynamic programming.

Let's start with some imports:

```
import matplotlib.pyplot as plt
import numpy as np
import numba
import jax
import jax.numpy as jnp
from typing import NamedTuple
from functools import partial
import quantecon as qe
from quantecon.distributions import BetaBinomial
```

55.2 The McCall Model

An unemployed agent receives in each period a job offer at wage W_t.

In this lecture, we adopt the following simple environment:

- The offer sequence $\{W_t\}_{t \geq 0}$ is IID, with $q(w)$ being the probability of observing wage w in finite set $\mathbb{W}$.
- The agent observes W_t at the start of t.
- The agent knows that $\{W_t\}$ is IID with common distribution q and can use this when computing expectations.

(In later lectures, we will relax these assumptions.)

At time t, our agent has two choices:

1. Accept the offer and work permanently at constant wage W_t.
2. Reject the offer, receive unemployment compensation c, and reconsider next period.

The agent is infinitely lived and aims to maximize the expected discounted sum of earnings

$$\mathbb{E} \sum_{t=0}^{\infty} \beta^t y_t \tag{55.1}$$

The constant β lies in $(0, 1)$ and is called a **discount factor**.

The smaller is β, the more the agent discounts future earnings relative to current earnings.

The variable y_t is income, equal to

- his/her wage W_t when employed
- unemployment compensation c when unemployed

55.2.1 A Trade-Off

The worker faces a trade-off:

- Waiting too long for a good offer is costly, since the future is discounted.
- Accepting too early is costly, since better offers might arrive in the future.

To decide the optimal wait time in the face of this trade-off, we use dynamic programming.

Dynamic programming can be thought of as a two-step procedure that

1. first assigns values to "states" and
2. then deduces optimal actions given those values

We'll go through these steps in turn.

55.2.2 The Value Function

In order to optimally trade-off current and future rewards, we need to think about two things:

1. the current payoffs we get from different choices
2. the different states that those choices will lead to in next period

To weigh these two aspects of the decision problem, we need to assign *values* to states.

To this end, let $v^*(w)$ be the total lifetime value accruing to an unemployed worker who enters the current period unemployed when the wage is $w \in \mathbb{W}$.

(In particular, the agent has wage offer w in hand and can accept or reject it.)

More precisely, $v^*(w)$ denotes the total sum of expected discounted earnings when an agent always behaves in an optimal way. points in time.

Of course $v^*(w)$ is not trivial to calculate because we don't yet know what decisions are optimal and what aren't!

If we don't know what opimal choices are, it feels imposible to calculate $v^*(w)$.

But let's put this aside for now and think of v^* as a function that assigns to each possible wage w the maximal lifetime value $v^*(w)$ that can be obtained with that offer in hand.

A crucial observation is that this function v^* must satisfy

$$v^*(w) = \max \left\{ \frac{w}{1-\beta}, \, c + \beta \sum_{w' \in \mathbb{W}} v^*(w') q(w') \right\} \tag{55.2}$$

for every possible w in $\mathbb{W}$.

This is a version of the **Bellman equation**, which is ubiquitous in economic dynamics and other fields involving planning over time.

The intuition behind it is as follows:

- the first term inside the max operation is the lifetime payoff from accepting current offer, since such a worker works forever at w and values this income stream as

$$\frac{w}{1-\beta} = w + \beta w + \beta^2 w + \cdots$$

- the second term inside the max operation is the continuation value, which is the lifetime payoff from rejecting the current offer and then behaving optimally in all subsequent periods

If we optimize and pick the best of these two options, we obtain maximal lifetime value from today, given current offer w.

But this is precisely $v^*(w)$, which is the left-hand side of (55.2).

Putting this all together, we see that (55.2) is valid for all w.

55.2.3 The Optimal Policy

We still don't know how to compute v^* (although (55.2) gives us hints we'll return to below).

But suppose for now that we do know v^*.

Once we have this function in hand we can easily make optimal choices (i.e., make the right choice between accept and reject given any w).

All we have to do is select the maximal choice on the right-hand side of (55.2).

In other words, we make the best choice between stopping and continuing, given the information provided to us by v^*.

The optimal action is best thought of as a **policy**, which is, in general, a map from states to actions.

Given any w, we can read off the corresponding best choice (accept or reject) by picking the max on the right-hand side of (55.2).

Thus, we have a map from $\mathbb{W}$ to $\{0, 1\}$, with 1 meaning accept and 0 meaning reject.

We can write the policy as follows

$$\sigma(w) := \mathbf{1}\left\{\frac{w}{1-\beta} \geq c + \beta \sum_{w' \in \mathbb{W}} v^*(w')q(w')\right\}$$

Here $\mathbf{1}\{P\} = 1$ if statement P is true and equals 0 otherwise.

We can also write this as

$$\sigma(w) := \mathbf{1}\{w \geq \bar{w}\}$$

where

$$\bar{w} := (1-\beta)\left\{c + \beta \sum_{w'} v^*(w')q(w')\right\} \tag{55.3}$$

Here $\bar{w}$ (called the **reservation wage**) is a constant depending on β, c and the wage distribution.

The agent should accept if and only if the current wage offer exceeds the reservation wage.

In view of (55.3), we can compute this reservation wage if we can compute the value function.

55.3 Computing the Optimal Policy: Take 1

To put the above ideas into action, we need to compute the value function at each $w \in \mathbb{W}$.

To simplify notation, let's set

$$\mathbb{W} := \{w_1, \ldots, w_n\} \quad \text{and} \quad v^*(i) := v^*(w_i)$$

The value function is then represented by the vector $v^* = (v^*(i))_{i=1}^n$.

In view of (55.2), this vector satisfies the nonlinear system of equations

$$v^*(i) = \max\left\{\frac{w(i)}{1-\beta},\, c + \beta \sum_{j=1}^n v^*(j) q(j)\right\} \quad \text{for } i = 1, \ldots, n \tag{55.4}$$

55.3.1 The Algorithm

To compute this vector, we use successive approximations:

Step 1: pick an arbitrary initial guess $v \in \mathbb{R}^n$.

Step 2: compute a new vector $v' \in \mathbb{R}^n$ via

$$v'(i) = \max\left\{\frac{w(i)}{1-\beta},\, c + \beta \sum_{j=1}^n v(j) q(j)\right\} \quad \text{for } i = 1, \ldots, n \tag{55.5}$$

Step 3: calculate a measure of a discrepancy between v and v', such as $\max_i |v(i) - v'(i)|$.

Step 4: if the deviation is larger than some fixed tolerance, set $v = v'$ and go to step 2, else continue.

Step 5: return v.

For a small tolerance, the returned function v is a close approximation to the value function v^*.

The theory below elaborates on this point.

55.3.2 Fixed Point Theory

What's the mathematics behind these ideas?

First, one defines a mapping T from $\mathbb{R}^n$ to itself via

$$(Tv)(i) = \max\left\{\frac{w(i)}{1-\beta},\, c + \beta \sum_{j=1}^n v(j) q(j)\right\} \quad \text{for } i = 1, \ldots, n \tag{55.6}$$

(A new vector Tv is obtained from given vector v by evaluating the r.h.s. at each i.)

The element v_k in the sequence $\{v_k\}$ of successive approximations corresponds to $T^k v$.

- This is T applied k times, starting at the initial guess v

One can show that the conditions of the Banach fixed point theorem are satisfied by T on $\mathbb{R}^n$.

One implication is that T has a unique fixed point in $\mathbb{R}^n$.

- That is, a unique vector $\bar{v}$ such that $T\bar{v} = \bar{v}$.

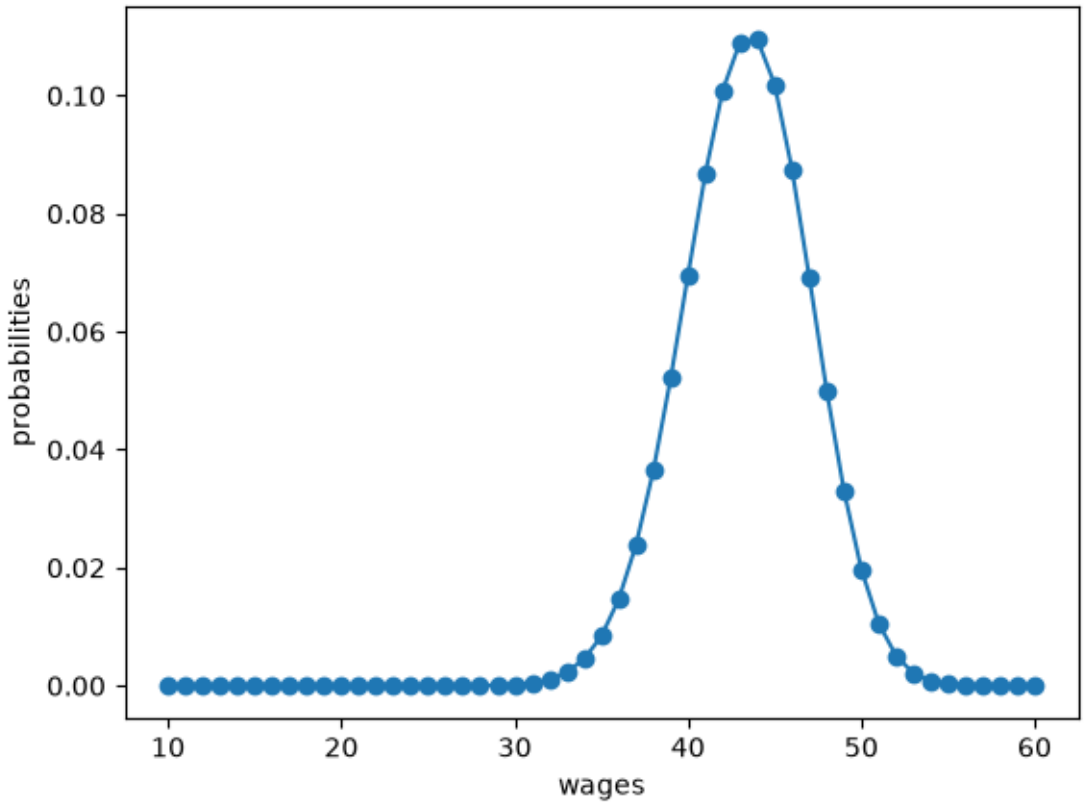
Moreover, it's immediate from the definition of T that this fixed point is v^*.

A second implication of the Banach contraction mapping theorem is that $\{T^k v\}$ converges to the fixed point v^* regardless of v.

55.3.3 Implementation

Our default for q, the wage offer distribution, will be Beta-binomial.

```
n, a, b = 50, 200, 100                          # default parameters
q_default = jnp.array(BetaBinomial(n, a, b).pdf())
```



Our default set of values for wages will be

```
w_min, w_max = 10, 60
w_default = jnp.linspace(w_min, w_max, n+1)
```

Here's a plot of the probabilities of different wage outcomes:

```
fig, ax = plt.subplots()
ax.plot(w_default, q_default, '-o', label='$q(w(i))$')
ax.set_xlabel('wages')
ax.set_ylabel('probabilities')

plt.show()
```

We will use JAX to write our code.

We'll use `NamedTuple` for our model class to maintain immutability, which works well with JAX's functional programming paradigm.

Here's a class that stores the model parameters with default values.

```
class McCallModel(NamedTuple):
    c: float = 25                # unemployment compensation
    β: float = 0.99              # discount factor
    w: jnp.ndarray = w_default   # array of wage values, w[i] = wage at state i
    q: jnp.ndarray = q_default   # array of probabilities
```

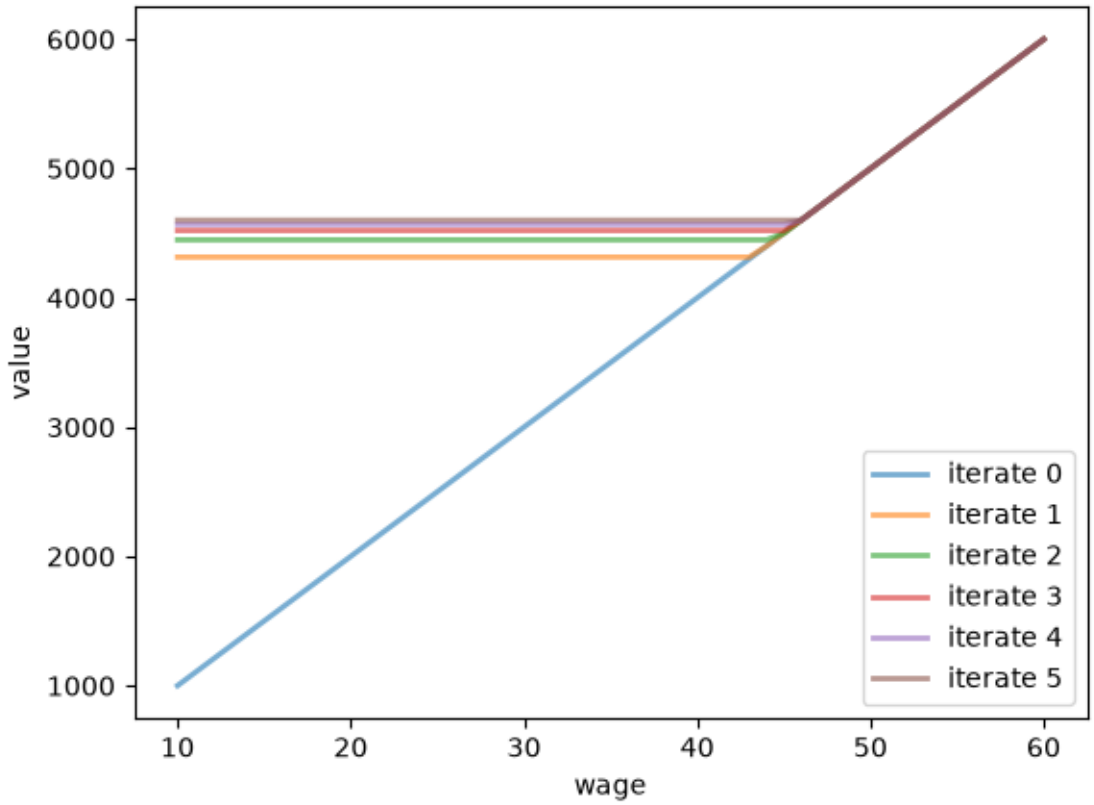
We implement the Bellman operator T from (55.6), which we can write in terms of array operations as

$$Tv = \max \left\{ \frac{w}{1-\beta}, c + \beta \sum_{j=1}^{n} v(j) q(j) \right\} \tag{55.7}$$

(The first term inside the max is an array and the second is just a number – here we mean that the max comparison against this number is done element-by-element for all elements in the array.)

We can code T up as follows.

```
def T(model: McCallModel, v: jnp.ndarray):
    c, β, w, q = model
    accept = w / (1 - β)
    reject = c + β * v @ q
    return jnp.maximum(accept, reject)
```



Based on these defaults, let's try plotting the first few approximate value functions in the sequence $\{T^k v\}$.

We will start from guess v given by $v(i) = w(i)/(1-\beta)$, which is the value of accepting at every given wage.

```
model = McCallModel()
c, β, w, q = model
v = w / (1 - β)    # Initial condition
fig, ax = plt.subplots()

num_plots = 6
for i in range(num_plots):
    ax.plot(w, v, '-', alpha=0.6, lw=2, label=f"iterate {i}")
    v = T(model, v)

ax.legend(loc='lower right')
ax.set_xlabel('wage')
ax.set_ylabel('value')
plt.show()
```

You can see that convergence is occurring: successive iterates are getting closer together.

Here's a more serious iteration effort to compute the limit, which continues until measured deviation between successive iterates is below `tol`.

Once we obtain a good approximation to the limit, we will use it to calculate the reservation wage.

```
def compute_reservation_wage(
        model: McCallModel,    # instance containing default parameters
        v_init: jnp.ndarray,   # initial condition for iteration
        tol: float=1e-6,       # error tolerance
        max_iter: int=500,     # maximum number of iterations for loop
    ):
    "Computes the reservation wage in the McCall job search model."
    c, β, w, q = model
    i = 0
    error = tol + 1
    v = v_init

    while i < max_iter and error > tol:
        v_next = T(model, v)
        error = jnp.max(jnp.abs(v_next - v))
        v = v_next
        i += 1

    w_bar = (1 - β) * (c + β * v @ q)
    return v, w_bar
```

The cell computes the reservation wage at the default parameters

```
model = McCallModel()
c, β, w, q = model
v_init = w / (1 - β)  # initial guess
v, w_bar = compute_reservation_wage(model, v_init)
print(w_bar)
```

```
47.316475
```

55.3.4 Comparative Statics

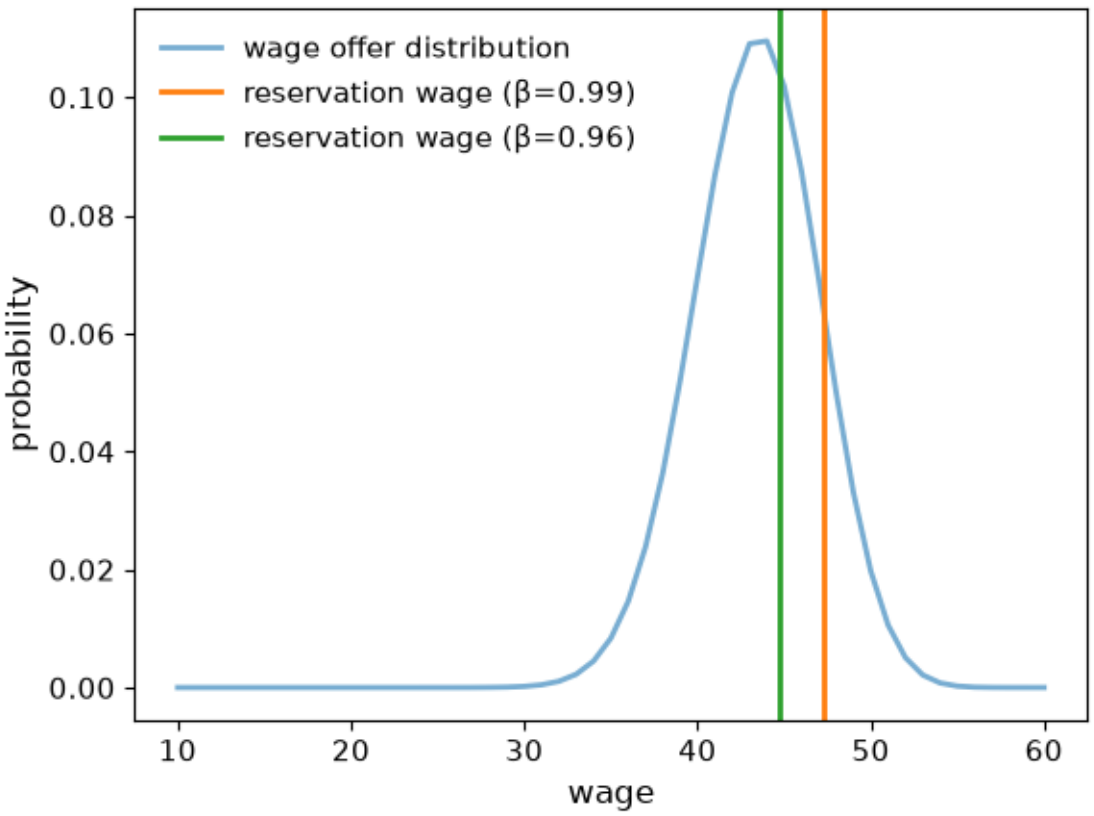
Now that we know how to compute the reservation wage, let's see how it varies with parameters.

Here we compare the reservation wage at two values of β.

The reservation wages will be plotted alongside the wage offer distribution, so that we can get a sense of what fraction of offers will be accepted.

```
fig, ax = plt.subplots()

# Get the default color cycle
prop_cycle = plt.rcParams['axes.prop_cycle']
colors = prop_cycle.by_key()['color']



# Plot the wage offer distribution
ax.plot(w, q, '-', alpha=0.6, lw=2,
        label='wage offer distribution',
        color=colors[0])

# Compute reservation wage with default beta
model_default = McCallModel()
c, β, w, q = model_default
v_init = w / (1 - β)
v_default, res_wage_default = compute_reservation_wage(
    model_default, v_init
)

# Compute reservation wage with lower beta
β_new = 0.96
model_low_beta = McCallModel(β=β_new)
c, β_low, w, q = model_low_beta
v_init_low = w / (1 - β_low)
v_low, res_wage_low = compute_reservation_wage(
    model_low_beta, v_init_low
)

# Plot vertical lines for reservation wages
ax.axvline(x=res_wage_default, color=colors[1], lw=2,
           label=f'reservation wage (β={β})')
ax.axvline(x=res_wage_low, color=colors[2], lw=2,
           label=f'reservation wage (β={β_new})')

ax.set_xlabel('wage', fontsize=12)
ax.set_ylabel('probability', fontsize=12)
ax.tick_params(axis='both', which='major', labelsize=11)
ax.legend(loc='upper left', frameon=False, fontsize=11)
plt.show()
```

We see that the reservation wage is higher when β is higher.

This is not surprising, since higher β is associated with more patience.

Now let's look more systematically at what happens when we change β and c.

As a first step, given that we'll use it many times, let's create a more efficient, jit-complied version of the function that computes the reservation wage:

```
@jax.jit
def compute_res_wage_jitted(
        model: McCallModel,    # instance containing default parameters
        v_init: jnp.ndarray,   # initial condition for iteration
        tol: float=1e-6,       # error tolerance
        max_iter: int=500,     # maximum number of iterations for loop
    ):
    c, β, w, q = model
    i = 0
    error = tol + 1
    initial_state = v_init, i, error

    def cond(loop_state):
        v, i, error = loop_state
        return jnp.logical_and(i < max_iter, error > tol)

    def update(loop_state):
        v, i, error = loop_state
        v_next = T(model, v)
        error = jnp.max(jnp.abs(v_next - v))
        i += 1
```

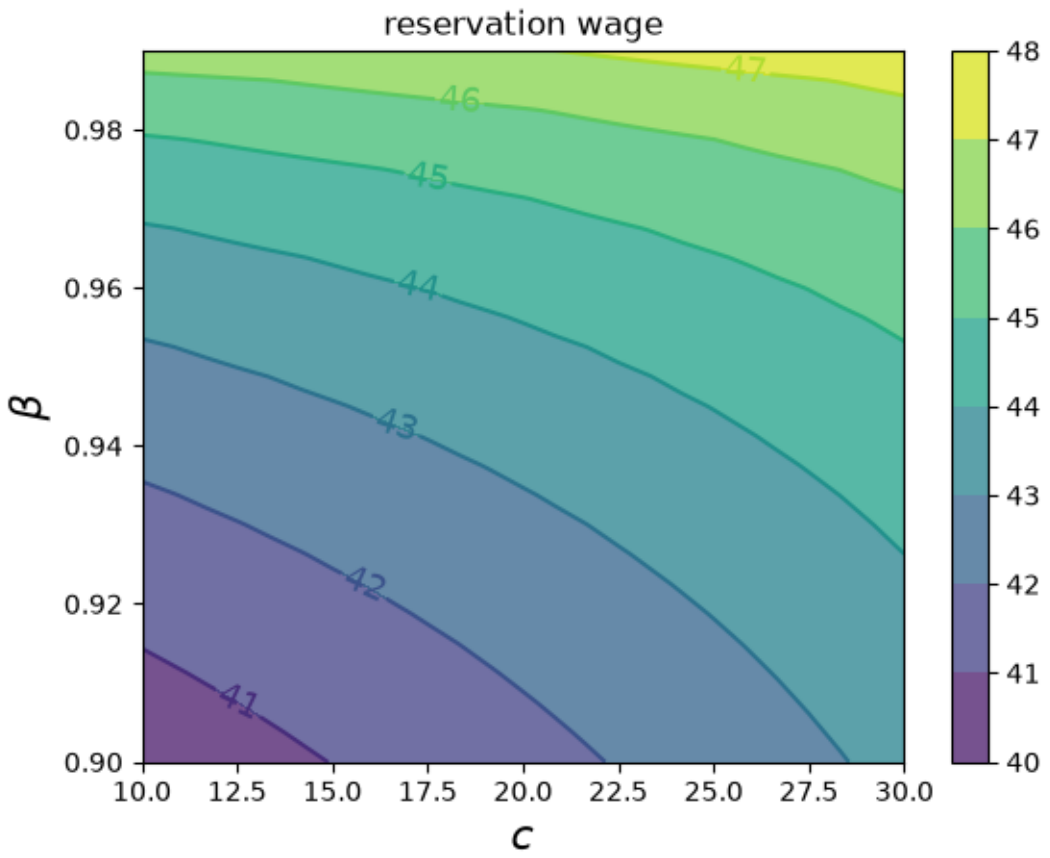
(continues on next page)

(continued from previous page)

```
        new_loop_state = v_next, i, error
        return new_loop_state

    final_state = jax.lax.while_loop(cond, update, initial_state)
    v, i, error = final_state

    w_bar = (1 - β) * (c + β * v @ q)
    return v, w_bar
```



Now we compute the reservation wage at each c, β pair.

```
grid_size = 25
c_vals = jnp.linspace(10.0, 30.0, grid_size)
β_vals = jnp.linspace(0.9, 0.99, grid_size)

res_wage_matrix = np.empty((grid_size, grid_size))
model = McCallModel()
v_init = model.w / (1 - model.β)

for i, c in enumerate(c_vals):
    for j, β in enumerate(β_vals):
        model = McCallModel(c=c, β=β)
        v, w_bar = compute_res_wage_jitted(model, v_init)
        v_init = v
        res_wage_matrix[i, j] = w_bar

fig, ax = plt.subplots()
cs1 = ax.contourf(c_vals, β_vals, res_wage_matrix.T, alpha=0.75)
ctr1 = ax.contour(c_vals, β_vals, res_wage_matrix.T)
plt.clabel(ctr1, inline=1, fontsize=13)
plt.colorbar(cs1, ax=ax)
ax.set_title("reservation wage")
ax.set_xlabel("$c$", fontsize=16)
ax.set_ylabel("$β$", fontsize=16)
ax.ticklabel_format(useOffset=False)
plt.show()
```

As expected, the reservation wage increases with both patience and unemployment compensation.

55.4 Computing an Optimal Policy: Take 2

The approach to dynamic programming just described is standard and broadly applicable.

But for our McCall search model there's also an easier way that circumvents the need to compute the value function.

Let h denote the continuation value:

$$h = c + \beta \sum_{w'} v^*(w') q(w') \tag{55.8}$$

The Bellman equation can now be written as

$$v^*(w') = \max \left\{ \frac{w'}{1-\beta}, \, h \right\} \tag{55.9}$$

Now let's derive a nonlinear equation for h alone.

Starting from (55.9), we multiply both sides by $q(w')$ to get

$$v^*(w') q(w') = \max \left\{ \frac{w'}{1-\beta}, h \right\} q(w')$$

Next, we sum both sides over $w' \in \mathbb{W}$:

$$\sum_{w' \in \mathbb{W}} v^*(w') q(w') = \sum_{w' \in \mathbb{W}} \max \left\{ \frac{w'}{1-\beta}, h \right\} q(w')$$

Now multiply both sides by β:

$$\beta \sum_{w' \in \mathbb{W}} v^*(w') q(w') = \beta \sum_{w' \in \mathbb{W}} \max \left\{ \frac{w'}{1-\beta}, h \right\} q(w')$$

Add c to both sides:

$$c + \beta \sum_{w' \in \mathbb{W}} v^*(w') q(w') = c + \beta \sum_{w' \in \mathbb{W}} \max \left\{ \frac{w'}{1-\beta}, h \right\} q(w')$$

Finally, using the definition of h from (55.8), the left-hand side is just h, giving us

$$h = c + \beta \sum_{w' \in \mathbb{W}} \max \left\{ \frac{w'}{1-\beta}, h \right\} q(w') \tag{55.10}$$

This is a nonlinear equation in the single scalar h that we can solve for h.

As before, we will use successive approximations:

Step 1: pick an initial guess h.

Step 2: compute the update h' via

$$h' = c + \beta \sum_{w' \in \mathbb{W}} \max \left\{ \frac{w'}{1-\beta}, h \right\} q(w') \tag{55.11}$$

Step 3: calculate the deviation $|h - h'|$.

Step 4: if the deviation is larger than some fixed tolerance, set $h = h'$ and go to step 2, else return h.

One can again use the Banach contraction mapping theorem to show that this process always converges.

The big difference here, however, is that we're iterating on a scalar h, rather than an n-vector, $v(i), i = 1, \ldots, n$.

Here's an implementation:

```
def compute_reservation_wage_two(
        model: McCallModel,    # instance containing default parameters
        tol: float=1e-5,       # error tolerance
        max_iter: int=500,     # maximum number of iterations for loop
    ):
    c, β, w, q = model
    h = (w @ q) / (1 - β)  # initial condition
    i = 0
    error = tol + 1
    initial_loop_state = i, h, error

    def cond(loop_state):
        i, h, error = loop_state
        return jnp.logical_and(i < max_iter, error > tol)

    def update(loop_state):
        i, h, error = loop_state
        s = jnp.maximum(w / (1 - β), h)
        h_next = c + β * (s @ q)
        error = jnp.abs(h_next - h)
        i_next = i + 1
        new_loop_state = i_next, h_next, error
        return new_loop_state
```

(continues on next page)

(continued from previous page)

```
    final_state = jax.lax.while_loop(cond, update, initial_loop_state)
    i, h, error = final_state

    # Compute and return the reservation wage
    return (1 - β) * h
```

You can use this code to solve the exercise below.

55.5 Continuous Offer Distribution

The discrete wage offer distribution used above is convenient for theory and computation, but many realistic distributions are continuous (i.e., have a density).

Fortunately, the theory changes little in our simple model when we shift to a continuous offer distribution.

Recall that h in (55.8) denotes the value of not accepting a job in this period but then behaving optimally in all subsequent periods.

To shift to a continuous offer distribution, we can replace (55.8) by

$$h = c + \beta \int v^*(s') q(s') ds'. \tag{55.12}$$

Equation (55.10) becomes

$$h = c + \beta \int \max \left\{ \frac{w(s')}{1-\beta}, h \right\} q(s') ds' \tag{55.13}$$

The aim is to solve this nonlinear equation by iteration, and from it obtain the reservation wage.

55.5.1 Implementation with Lognormal Wages

Let's implement this for the case where

- the state sequence $\{s_t\}$ is IID and standard normal and
- the wage function is $w(s) = \exp(\mu + \sigma s)$.

This gives us a lognormal wage distribution.

We use Monte Carlo integration to evaluate the integral, averaging over a large number of wage draws.

For default parameters, we use `c=25, β=0.99, σ=0.5, μ=2.5`.

```
class McCallModelContinuous(NamedTuple):
    c: float              # unemployment compensation
    β: float              # discount factor
    σ: float              # scale parameter in lognormal distribution
    μ: float              # location parameter in lognormal distribution
    w_draws: jnp.ndarray  # draws of wages for Monte Carlo

def create_mccall_continuous(
        c=25, β=0.99, σ=0.5, μ=2.5, mc_size=1000, seed=1234
    ):
    key = jax.random.key(seed)
```

(continues on next page)

(continued from previous page)

```
    s = jax.random.normal(key, (mc_size,))
    w_draws = jnp.exp(μ + σ * s)
    return McCallModelContinuous(c, β, σ, μ, w_draws)

@jax.jit
def compute_reservation_wage_continuous(model, max_iter=500, tol=1e-5):
    c, β, σ, μ, w_draws = model

    h = jnp.mean(w_draws) / (1 - β)  # initial guess

    def update(state):
        h, i, error = state
        integral = jnp.mean(jnp.maximum(w_draws / (1 - β), h))
        h_next = c + β * integral
        error = jnp.abs(h_next - h)
        return h_next, i + 1, error

    def cond(state):
        h, i, error = state
        return jnp.logical_and(i < max_iter, error > tol)

    initial_state = (h, 0, tol + 1)
    final_state = jax.lax.while_loop(cond, update, initial_state)
    h_final, _, _ = final_state

    # Now compute the reservation wage
    return (1 - β) * h_final
```

Now let's investigate how the reservation wage changes with c and β using a contour plot.

```
grid_size = 25
c_vals = jnp.linspace(10.0, 30.0, grid_size)
β_vals = jnp.linspace(0.9, 0.99, grid_size)

def compute_R_element(c, β):
    model = create_mccall_continuous(c=c, β=β)
    return compute_reservation_wage_continuous(model)

# First, vectorize over β (holding c fixed)
compute_R_over_β = jax.vmap(compute_R_element, in_axes=(None, 0))

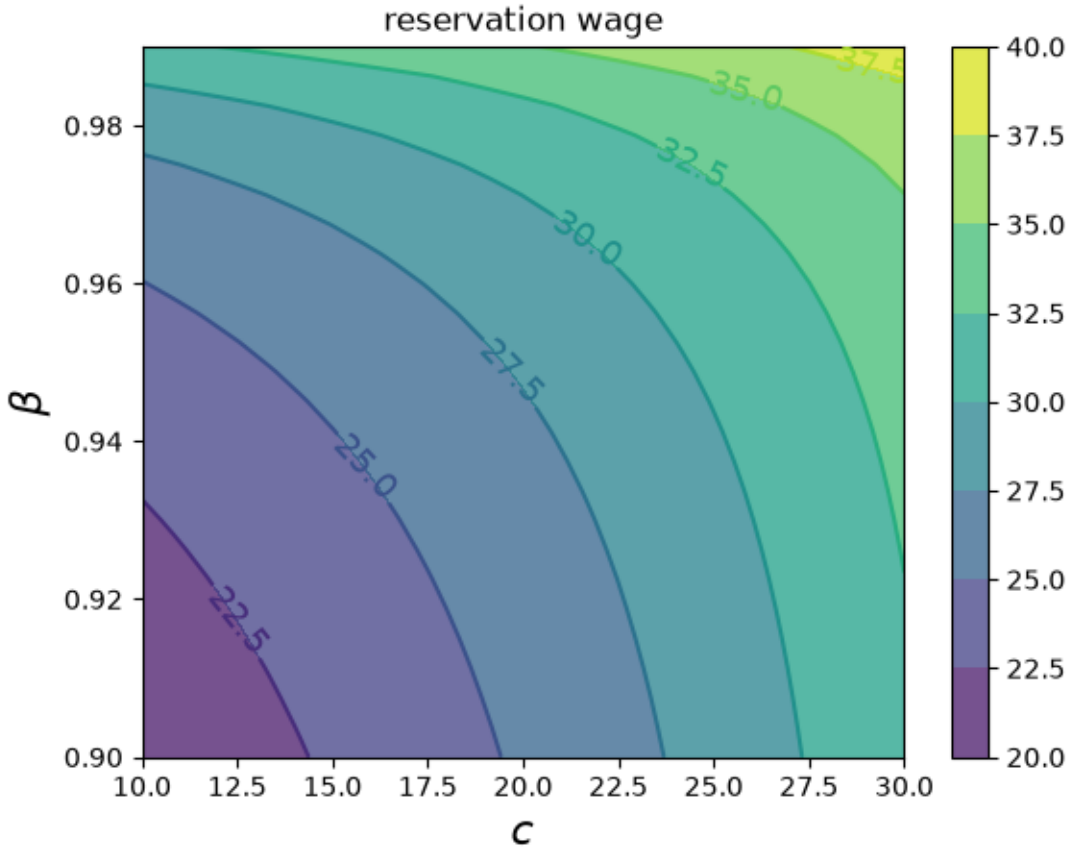
# Next, vectorize over c (applying the above function to each c)
compute_R_vectorized = jax.vmap(compute_R_over_β, in_axes=(0, None))

# Apply to compute the full grid
R = compute_R_vectorized(c_vals, β_vals)
```

```
fig, ax = plt.subplots()

cs1 = ax.contourf(c_vals, β_vals, R.T, alpha=0.75)
ctr1 = ax.contour(c_vals, β_vals, R.T)

plt.clabel(ctr1, inline=1, fontsize=13)
plt.colorbar(cs1, ax=ax)
```



(continues on next page)

(continued from previous page)

```
ax.set_title("reservation wage")
ax.set_xlabel("$c$", fontsize=16)
ax.set_ylabel("$β$", fontsize=16)

ax.ticklabel_format(useOffset=False)

plt.show()
```

As with the discrete case, the reservation wage increases with both patience and unemployment compensation.

55.6 Volatility

An interesting feature of the McCall model is that increased volatility in wage offers tends to increase the reservation wage.

The intuition is that volatility is attractive to the worker because they can enjoy the upside (high wage offers) while rejecting the downside (low wage offers).

Hence, with more volatility, workers are more willing to continue searching rather than accept a given offer, which means the reservation wage rises.

To illustrate this phenomenon, we use a mean-preserving spread of the wage distribution.

In particular, we vary the scale parameter σ in the lognormal wage distribution $w(s) = \exp(\mu + \sigma s)$ while adjusting μ to keep the mean constant.

Recall that for a lognormal distribution with parameters μ and σ, the mean is $\exp(\mu + \sigma^2/2)$.

To keep the mean constant at some value m, we need:

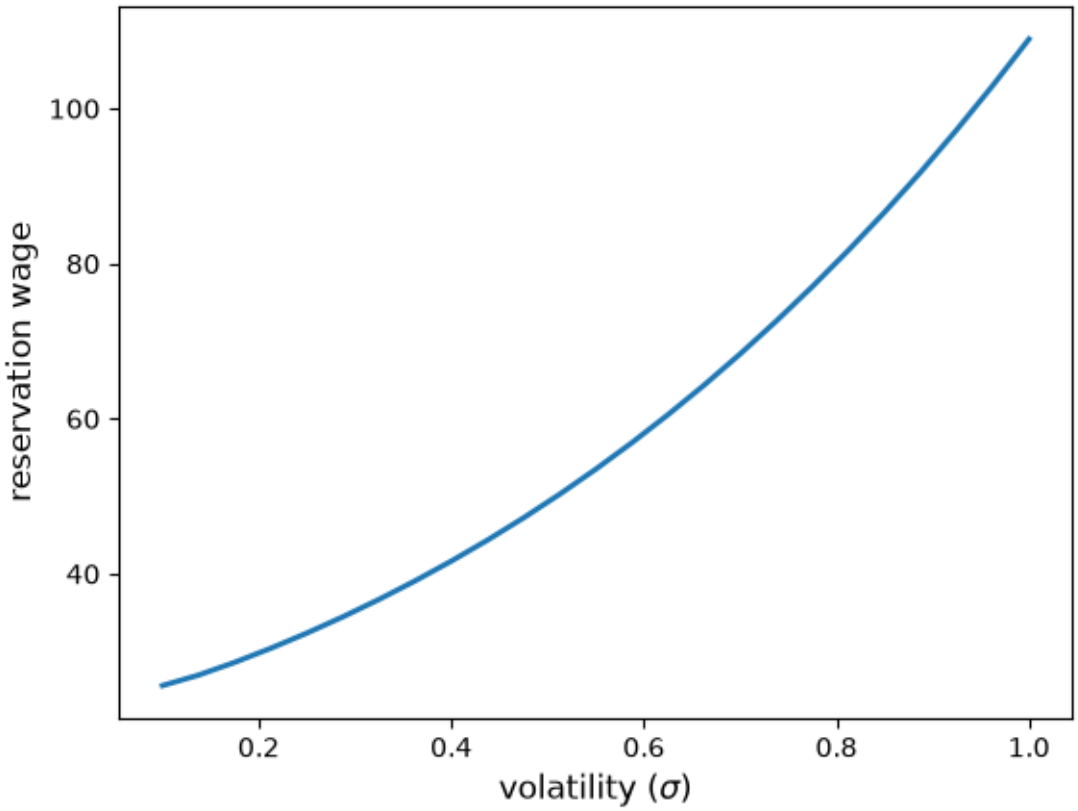
$$\mu = \ln(m) - \frac{\sigma^2}{2}$$

Let's implement this and compute the reservation wage for different values of σ:

```
# Fix the mean wage
mean_wage = 20.0

# Create a range of volatility values
σ_vals = jnp.linspace(0.1, 1.0, 25)

# Given σ, compute μ to maintain constant mean
def compute_μ_for_mean(σ, mean_wage):
    return jnp.log(mean_wage) - (σ**2) / 2



# Compute reservation wage for each volatility level
res_wages_volatility = []

for σ in σ_vals:
    μ = compute_μ_for_mean(σ, mean_wage)
    model = create_mccall_continuous(σ=float(σ), μ=float(μ))
    w_bar = compute_reservation_wage_continuous(model)
    res_wages_volatility.append(w_bar)

res_wages_volatility = jnp.array(res_wages_volatility)
```

Now let's plot the reservation wage as a function of volatility:

```
fig, ax = plt.subplots()
ax.plot(σ_vals, res_wages_volatility, linewidth=2)
ax.set_xlabel(r'volatility ($\sigma$)', fontsize=12)
ax.set_ylabel('reservation wage', fontsize=12)
plt.show()
```

As expected, the reservation wage is increasing in σ.

55.6.1 Lifetime Value and Volatility

We've seen that the reservation wage increases with volatility.

It's also the case that maximal lifetime value increases with volatility.

Higher volatility provides more upside potential, while at the same time workers can protect themselves against downside risk by rejecting low offers.

This option value translates into higher expected lifetime utility.

To demonstrate this, we will:

1. Compute the reservation wage for each volatility level
2. Calculate the expected discounted value of the lifetime income stream associated with that reservation wage, using Monte Carlo.

The simulation works as follows:

1. Compute the present discounted value of one lifetime earnings path, from a given wage path.
2. Average over a large number of such calculations to approximate expected discounted value.

We truncate each path at $T = 100$, which provides sufficient resolution for our purposes.

```
@jax.jit
def simulate_lifetime_value(key, model, w_bar, n_periods=100):
    """
```

(continues on next page)

(continued from previous page)

```
    Simulate one realization of the wage path and compute lifetime value.

    Parameters:
    -----------
    key : jax.random.key
        Random key for JAX
    model : McCallModelContinuous
        The model containing parameters
    w_bar : float
        The reservation wage
    n_periods : int
        Number of periods to simulate

    Returns:
    --------
    lifetime_value : float
        Discounted sum of income over n_periods
    """
    c, β, σ, μ, w_draws = model

    # Draw all wage offers upfront
    key, subkey = jax.random.split(key)
    s_vals = jax.random.normal(subkey, (n_periods,))
    wage_offers = jnp.exp(μ + σ * s_vals)

    # Determine which offers are acceptable
    accept = wage_offers >= w_bar

    # Track employment status: employed from first acceptance onward
    employed = jnp.cumsum(accept) > 0

    # Get the accepted wage (first wage where accept is True)
    first_accept_idx = jnp.argmax(accept)
    accepted_wage = wage_offers[first_accept_idx]

    # Earnings at each period: accepted_wage if employed, c if unemployed
    earnings = jnp.where(employed, accepted_wage, c)

    # Compute discounted sum
    periods = jnp.arange(n_periods)
    discount_factors = β ** periods
    lifetime_value = jnp.sum(discount_factors * earnings)

    return lifetime_value

@jax.jit
def compute_mean_lifetime_value(model, w_bar, num_reps=10000, seed=1234):
    """
    Compute mean lifetime value across many simulations.

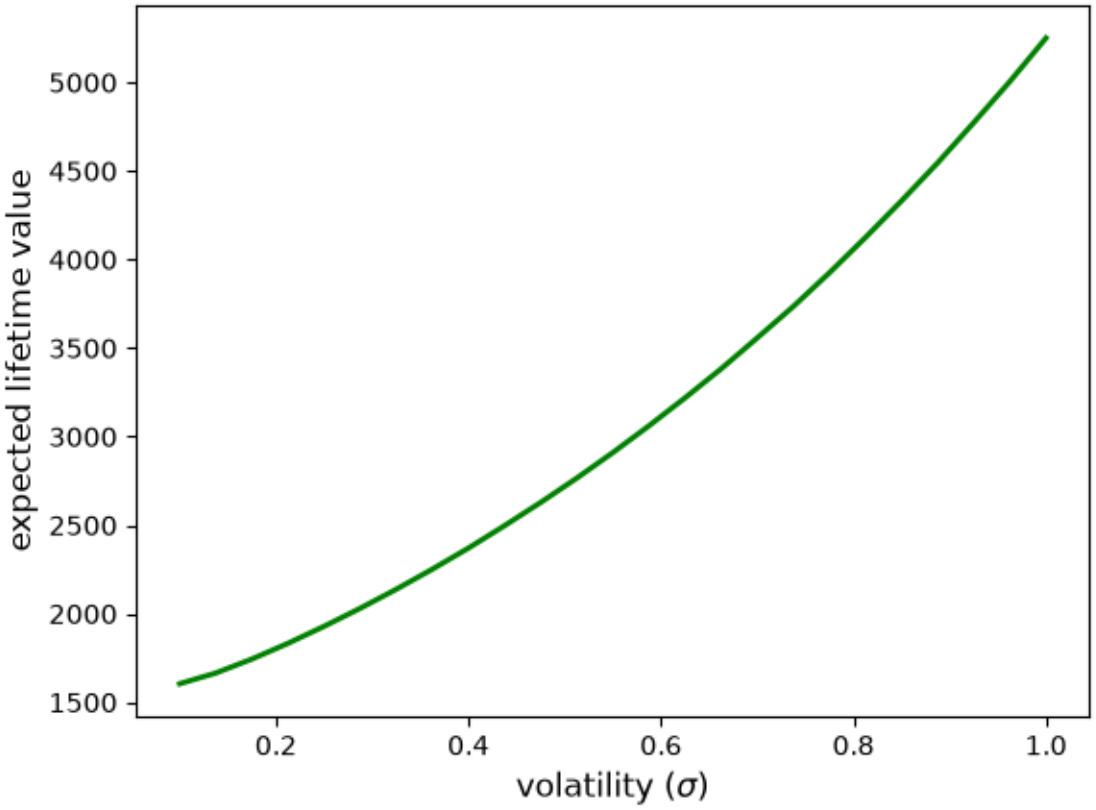
    """
    key = jax.random.key(seed)
    keys = jax.random.split(key, num_reps)

    # Vectorize the simulation across all replications
    simulate_fn = jax.vmap(simulate_lifetime_value, in_axes=(0, None, None))
```

(continues on next page)

(continued from previous page)

```
    lifetime_values = simulate_fn(keys, model, w_bar)
    return jnp.mean(lifetime_values)
```



Now let's compute the expected lifetime value for each volatility level:

```
# Use the same volatility range and mean wage
σ_vals = jnp.linspace(0.1, 1.0, 25)
mean_wage = 20.0

lifetime_vals = []
for σ in σ_vals:
    μ = compute_μ_for_mean(σ, mean_wage)
    model = create_mccall_continuous(σ=σ, μ=μ)
    w_bar = compute_reservation_wage_continuous(model)
    lv = compute_mean_lifetime_value(model, w_bar)
    lifetime_vals.append(lv)
```

Let's visualize the expected lifetime value as a function of volatility:

```
fig, ax = plt.subplots()
ax.plot(σ_vals, lifetime_vals, linewidth=2, color='green')
ax.set_xlabel(r'volatility ($\sigma$)', fontsize=12)
ax.set_ylabel('expected lifetime value', fontsize=12)
plt.show()
```

The plot confirms that despite workers setting higher reservation wages when facing more volatile wage offers (as shown above), they achieve higher expected lifetime values due to the option value of search.

55.7 Exercises

Exercise 55.7.1

Compute the average duration of unemployment when $\beta = 0.99$ and c takes the following values

```
c_vals = np.linspace(10, 40, 4)
```

That is, start the agent off as unemployed, compute their reservation wage given the parameters, and then simulate to see how long it takes to accept.

Repeat a large number of times and take the average.

Plot mean unemployment duration as a function of c in `c_vals`.

Try to explain what you see.

Solution

Here's a solution using the continuous wage offer distribution with JAX.

```
def compute_stopping_time_continuous(w_bar, key, model):
    """
    Compute stopping time by drawing wages from the continuous distribution
    until one exceeds `w_bar`.

    Parameters:
    -----------
    w_bar : float
        The reservation wage
    key : jax.random.key
        Random key for JAX
    model : McCallModelContinuous
        The model containing wage draws

    Returns:
    --------
    t_final : int
        The stopping time (number of periods until acceptance)
    """
    c, β, σ, μ, w_draws = model

    def update(loop_state):
        t, key, accept = loop_state
        key, subkey = jax.random.split(key)
        # Draw a standard normal and transform to wage
        s = jax.random.normal(subkey)
        w = jnp.exp(μ + σ * s)
        accept = w >= w_bar
        t = t + 1
        return t, key, accept

    def cond(loop_state):
        _, _, accept = loop_state
        return jnp.logical_not(accept)

    initial_loop_state = (0, key, False)
```

```
    t_final, _, _ = jax.lax.while_loop(cond, update, initial_loop_state)
    return t_final

def compute_mean_stopping_time_continuous(w_bar, model, num_reps=100000,␣
↪seed=1234):
    """
    Generate a mean stopping time over `num_reps` repetitions.

    Parameters:
    -----------
    w_bar : float
        The reservation wage
    model : McCallModelContinuous
        The model containing parameters
    num_reps : int
        Number of simulation replications
    seed : int
        Random seed

    Returns:
    --------
    mean_time : float
        Average stopping time across all replications
    """
    # Generate a key for each MC replication
    key = jax.random.key(seed)
    keys = jax.random.split(key, num_reps)

    # Vectorize compute_stopping_time_continuous and evaluate across keys

JOB SEARCH II: SEARCH AND SEPARATION

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

Contents

- *Job Search II: Search and Separation*
  - *Overview*
  - *The model*
  - *Solving the model*
  - *Code*
  - *A simplifying transformation*
  - *Implementation*
  - *Impact of parameters*
  - *Exercises*

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon jax myst-nb
```

56.1 Overview

Previously *we looked* at the McCall job search model [McCall, 1970] as a way of understanding unemployment and worker decisions.

One unrealistic feature of that version of the model was that every job is permanent.

In this lecture, we extend the model by introducing job separation.

Once separation enters the picture, the agent comes to view

- the loss of a job as a capital loss, and
- a spell of unemployment as an *investment* in searching for an acceptable job

The other minor addition is that a utility function will be included to make worker preferences slightly more sophisticated.

We'll need the following imports

```
import matplotlib.pyplot as plt
import numpy as np
import jax
import jax.numpy as jnp
from typing import NamedTuple
from quantecon.distributions import BetaBinomial
from myst_nb import glue
```

56.2 The model

The model is similar to the *baseline McCall job search model*.

It concerns the life of an infinitely lived worker and

- the opportunities he or she (let's say he to save one character) has to work at different wages
- exogenous events that destroy his current job
- his decision making process while unemployed

The worker can be in one of two states: employed or unemployed.

He wants to maximize

$$\mathbb{E} \sum_{t=0}^{\infty} \beta^t u(y_t) \tag{56.1}$$

At this stage the only difference from the *baseline model* is that we've added some flexibility to preferences by introducing a utility function u.

It satisfies $u' > 0$ and $u'' < 0$.

Wage offers $\{W_t\}$ are IID with common distribution q.

The set of possible wage values is denoted by $\mathbb{W}$.

56.2.1 Timing and decisions

At the start of each period, the agent can be either

- unemployed or
- employed at some existing wage level w.

If currently employed at wage w, the worker

1. receives utility $u(w)$ from their current wage and
2. is fired with some (small) probability α, becoming unemployed next period.

If currently unemployed, the worker receives random wage offer W_t and either accepts or rejects.

If he accepts, then he begins work immediately at wage W_t.

If he rejects, then he receives unemployment compensation c.

The process then repeats.

Note

We do not allow for job search while employed—this topic is taken up in a *later lecture*.

56.3 Solving the model

We drop time subscripts in what follows and primes denote next period values.

Let

- $v_e(w)$ be maximum lifetime value for a worker who enters the current period employed with wage w
- $v_u(w)$ be maximum lifetime for a worker who who enters the current period unemployed and receives wage offer w.

Here, **maximum lifetime value** means the value of (56.1) when the worker makes optimal decisions at all future points in time.

As we now show, obtaining these functions is key to solving the model.

56.3.1 The Bellman equations

We recall that, in *the original job search model*, the value function (the value of being unemployed with a given wage offer) satisfied a Bellman equation.

Here this function again satisfies a Bellman equation that looks very similar.

$$v_u(w) = \max \left\{ v_e(w),\ u(c) + \beta \sum_{w' \in \mathbb{W}} v_u(w') q(w') \right\} \tag{56.2}$$

The difference is that the value of accepting is $v_e(w)$ rather than $w/(1-\beta)$.

We have to make this change because jobs are not permanent.

Accepting transitions the worker to employment and hence yields reward $v_e(w)$, which we discuss below.

Rejecting leads to unemployment compensation and unemployment tomorrow.

Equation (56.2) expresses the value of being unemployed with offer w in hand as a maximum over the value of two options: accept or reject the current offer.

The function v_e also satisfies a Bellman equation:

$$v_e(w) = u(w) + \beta \left[(1-\alpha) v_e(w) + \alpha \sum_{w' \in \mathbb{W}} v_u(w') q(w') \right] \tag{56.3}$$

Note

This equation differs from a traditional Bellman equation because there is no max.

There is no max because an employed agent has no choices.

Nonetheless, in keeping with most of the literature, we also refer to it as a Bellman equation.

Equation (56.3) expresses the value of being employed at wage w in terms of

- current reward $u(w)$ plus
- discounted expected reward tomorrow, given the α probability of being fired

As we will see, equations (56.3) and (56.2) provide enough information to solve for both v_e and v_u.

Once we have them in hand, we will be able to make optimal choices.

56.3.2 The reservation wage

Let

$$h := u(c) + \beta \sum_{w' \in \mathbb{W}} v_u(w') q(w') \tag{56.4}$$

This is the **continuation value** for an unemployed agent – the value of rejecting the current offer and then making optimal choices.

From (56.2), we see that an unemployed agent accepts current offer w if $v_e(w) \geq h$.

This means precisely that the value of accepting is higher than the value of rejecting.

The function v_e is increasing in w, since an employed agent is never made worse off by a higher current wage.

Hence, we can express the optimal choice as accepting wage offer w if and only if $w \geq \bar{w}$, where the **reservation wage** $\bar{w}$ is the first wage level $w \in \mathbb{W}$ such that

$$v_e(w) \geq h$$

56.4 Code

Let's now implement a solution method based on the two Bellman equations (56.2) and (56.3).

56.4.1 Set up

The default utility function is a CRRA utility function

```
def u(x, γ):
    return (x**(1 - γ) - 1) / (1 - γ)
```

Also, here's a default wage distribution, based around the BetaBinomial distribution:

```
n = 60                                  # n possible outcomes for w
w_default = jnp.linspace(10, 20, n)     # wages between 10 and 20
a, b = 600, 400                         # shape parameters
dist = BetaBinomial(n-1, a, b)          # distribution
q_default = jnp.array(dist.pdf())       # probabilities as a JAX array
```

Here's our model class for the McCall model with separation.

```
class Model(NamedTuple):
    α: float = 0.2              # job separation rate
    β: float = 0.98             # discount factor
    γ: float = 2.0              # utility parameter (CRRA)
    c: float = 6.0              # unemployment compensation
    w: jnp.ndarray = w_default  # wage outcome space
    q: jnp.ndarray = q_default  # probabilities over wage offers
```

56.4.2 Operators

We'll use a similar iterative approach to solving the Bellman equations that we adopted in the *first job search lecture*.

As a first step, to iterate on the Bellman equations, we define two operators, one for each value function.

These operators take the current value functions as inputs and return updated versions.

```
def T_u(model, v_u, v_e):
    """
    Apply the unemployment Bellman update rule and return new guess of v_u.

    """
    α, β, γ, c, w, q = model
    h = u(c, γ) + β * (v_u @ q)
    v_u_new = jnp.maximum(v_e, h)
    return v_u_new
```

```
def T_e(model, v_u, v_e):
    """
    Apply the employment Bellman update rule and return new guess of v_e.

    """
    α, β, γ, c, w, q = model
    v_e_new = u(w, γ) + β * ((1 - α) * v_e + α * (v_u @ q))
    return v_e_new
```

56.4.3 Iteration

Now we write an iteration routine, which updates the pair of arrays v_u, v_e until convergence.

More precisely, we iterate until successive realizations are closer together than some small tolerance level.

```
def solve_full_model(
        model,
        tol: float = 1e-6,
        max_iter: int = 1_000,
    ):
    """
    Solves for both value functions v_u and v_e iteratively.

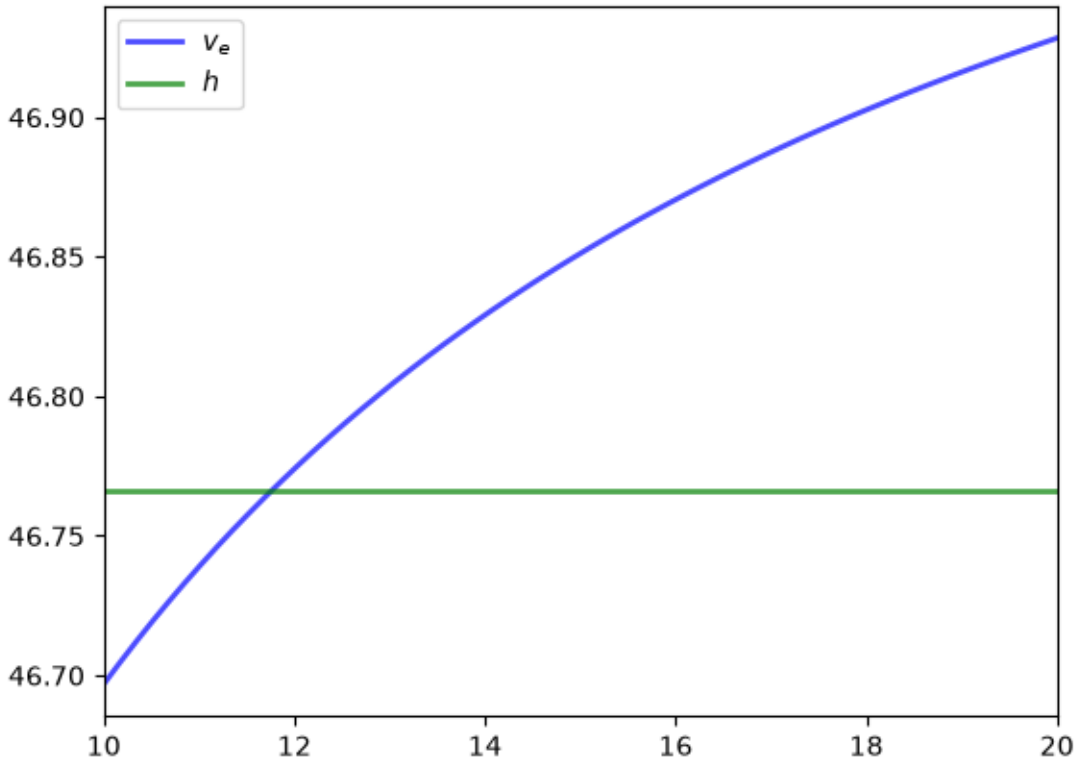
    """
    α, β, γ, c, w, q = model
    i = 0
    error = tol + 1
    v_e = v_u = w / (1 - β)

    while i < max_iter and error > tol:
        v_u_next = T_u(model, v_u, v_e)
        v_e_next = T_e(model, v_u, v_e)
        error_u = jnp.max(jnp.abs(v_u_next - v_u))
        error_e = jnp.max(jnp.abs(v_e_next - v_e))
        error = jnp.max(jnp.array([error_u, error_e]))
        v_u = v_u_next
        v_e = v_e_next
        i += 1

    return v_u, v_e
```

56.4.4 Computing the reservation wage

Now that we can solve for both value functions, let's investigate the reservation wage.



Recall from above that the reservation wage $\bar{w}$ is the first $w \in \mathbb{W}$ satisfying $v_e(w) \geq h$, where h is the continuation value defined in (56.4).

Let's compare v_e and h to see what they look like.

We'll use the default parameterizations found in the code above.

```
model = Model()
α, β, γ, c, w, q = model
v_u, v_e = solve_full_model(model)
h = u(c, γ) + β * (v_u @ q)

fig, ax = plt.subplots()
ax.plot(w, v_e, 'b-', lw=2, alpha=0.7, label='$v_e$')
ax.plot(w, [h] * len(w), 'g-', lw=2, alpha=0.7, label='$h$')
ax.set_xlim(min(w), max(w))
ax.legend()
plt.show()
```

The value v_e is increasing because higher w generates a higher wage flow conditional on staying employed.

The reservation wage is the w where these lines meet.

Let's compute this reservation wage explicitly:

```
def compute_reservation_wage_full(model):
    """
    Computes the reservation wage using the full model solution.
    """
    α, β, γ, c, w, q = model
    v_u, v_e = solve_full_model(model)
    h = u(c, γ) + β * (v_u @ q)
    # Find the first w such that v_e(w) >= h, or +inf if none exist
    accept = v_e >= h
    i = jnp.argmax(accept)  # returns first accept index
    w_bar = jnp.where(jnp.any(accept), w[i], jnp.inf)
    return w_bar

w_bar_full = compute_reservation_wage_full(model)
print(f"Reservation wage (full model): {w_bar_full:.4f}")
```

```
Reservation wage (full model): 11.8644
```

This value seems close to where the two lines meet.

56.5 A simplifying transformation

The approach above works, but iterating over two vector-valued functions is computationally expensive.

With some mathematics and some brain power, we can form a solution method that is far more efficient.

(This process will be analogous to our *second pass* at the plain vanilla McCall model, where we reduced the Bellman equation to an equation in an unknown scalar value, rather than an unknown vector.)

First, we use the continuation value h, as defined in (56.4), to write (56.2) as

$$v_u(w) = \max\{v_e(w),\, h\}$$

Taking the expectation of both sides and then discounting, this becomes

$$\beta \sum_{w'} v_u(w') q(w') = \beta \sum_{w'} \max\{v_e(w'),\, h\}\, q(w')$$

Adding $u(c)$ to both sides and using (56.4) again gives

$$h = u(c) + \beta \sum_{w'} \max\{v_e(w'),\, h\}\, q(w') \tag{56.5}$$

This is a nice scalar equation in the continuation value, which is already useful.

But we can go further, but eliminating v_e from the above equation.

56.5.1 Simplifying to a single equation

As a first step, we rearrange the expression defining h (see (56.4)) to obtain

$$\sum_{w'} v_u(w') q(w') = \frac{h - u(c)}{\beta}$$

Using this, the Bellman equation for v_e, as given in (56.3), can now be rewritten as

$$v_e(w) = u(w) + \beta \left[(1-\alpha) v_e(w) + \alpha \frac{h - u(c)}{\beta} \right] \tag{56.6}$$

Our next step is to solve (56.6) for v_e as a function of h.

Rearranging (56.6) gives

$$v_e(w) = u(w) + \beta(1-\alpha) v_e(w) + \alpha(h - u(c))$$

or

$$v_e(w) - \beta(1-\alpha) v_e(w) = u(w) + \alpha(h - u(c))$$

Solving for $v_e(w)$ gives

$$v_e(w) = \frac{u(w) + \alpha(h - u(c))}{1 - \beta(1-\alpha)} \tag{56.7}$$

Substituting this into (56.5) yields

$$h = u(c) + \beta \sum_{w' \in \mathbb{W}} \max\left\{ \frac{u(w') + \alpha(h - u(c))}{1 - \beta(1-\alpha)},\, h \right\} q(w') \tag{56.8}$$

Finally we have a single scalar equation in h!

If we can solve this for h, we can easily recover v_e using (56.7).

Then we have enough information to compute the reservation wage.

56.5.2 Solving the Bellman equations

To solve (56.8), we use the iteration rule

$$h_{n+1} = u(c) + \beta \sum_{w' \in \mathbb{W}} \max \left\{ \frac{u(w') + \alpha(h_n - u(c))}{1 - \beta(1-\alpha)}, \, h_n \right\} q(w') \tag{56.9}$$

starting from some initial condition h_0.

(It is possible to prove that (56.9) converges via the Banach contraction mapping theorem.)

56.6 Implementation

To implement iteration on h, we provide a function that provides one update, from h_n to h_{n+1}

```
def update_h(model, h):
    " One update of the scalar h. "
    α, β, γ, c, w, q = model
    v_e = compute_v_e(model, h)
    h_new = u(c, γ) + β * (jnp.maximum(v_e, h) @ q)
    return h_new
```

Also, we provide a function to compute v_e from (56.7).

```
def compute_v_e(model, h):
    " Compute v_e from h using the closed-form expression. "
    α, β, γ, c, w, q = model
    return (u(w, γ) + α * (h - u(c, γ))) / (1 - β * (1 - α))
```

This function will be applied once convergence is achieved.

Now we can write our model solver.

```
@jax.jit
def solve_model(model, tol=1e-5, max_iter=2000):
    " Iterates to convergence on the Bellman equations. "

    def cond(loop_state):
        h, i, error = loop_state
        return jnp.logical_and(error > tol, i < max_iter)

    def update(loop_state):
        h, i, error = loop_state
        h_new = update_h(model, h)
        error_new = jnp.abs(h_new - h)
        return h_new, i + 1, error_new

    # Initialize
    h_init = u(model.c, model.γ) / (1 - model.β)
    i_init = 0
    error_init = tol + 1
    init_state = (h_init, i_init, error_init)

    final_state = jax.lax.while_loop(cond, update, init_state)
    h_final, _, _ = final_state
```

(continues on next page)

(continued from previous page)

```
    # Compute v_e from the converged h
    v_e_final = compute_v_e(model, h_final)

    return v_e_final, h_final
```

Finally, here's a function `compute_reservation_wage` that uses all the logic above, taking an instance of `Model` and returning the associated reservation wage.

```
def compute_reservation_wage(model):
    """
    Computes the reservation wage of an instance of the McCall model
    by finding the smallest w such that v_e(w) >= h.

    """
    # Find the first i such that v_e(w_i) >= h and return w[i]
    # If no such w exists, then w_bar is set to np.inf
    v_e, h = solve_model(model)
    accept = v_e >= h
    i = jnp.argmax(accept)    # take first accept index
    w_bar = jnp.where(jnp.any(accept), model.w[i], jnp.inf)
    return w_bar
```

Let's verify that this simplified approach gives the same answer as the full model:

```
w_bar_simplified = compute_reservation_wage(model)
print(f"Reservation wage (simplified): {w_bar_simplified:.4f}")
print(f"Reservation wage (full model): {w_bar_full:.4f}")
print(f"Difference: {abs(w_bar_simplified - w_bar_full):.6f}")
```

```
Reservation wage (simplified): 11.8644
Reservation wage (full model): 11.8644
Difference: 0.000000
```

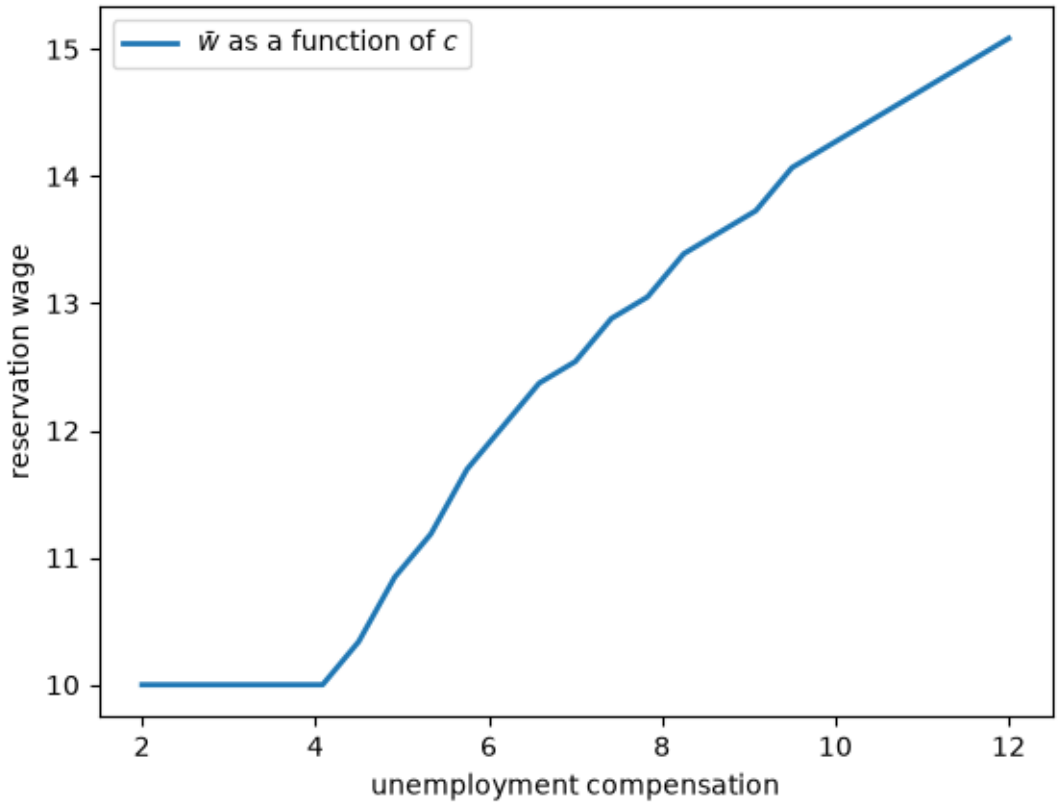
As we can see, both methods produce essentially the same reservation wage.

However, the simplified method is far more efficient.

Next we will investigate how the reservation wage varies with parameters.

56.7 Impact of parameters

In each instance below, we'll show you a figure and then ask you to reproduce it in the exercises.



56.7.1 The reservation wage and unemployment compensation

First, let's look at how $\bar{w}$ varies with unemployment compensation.

In the figure below, we use the default parameters in the `Model` class, apart from c (which takes the values given on the horizontal axis)

As expected, higher unemployment compensation causes the worker to hold out for higher wages.

In effect, the cost of continuing job search is reduced.

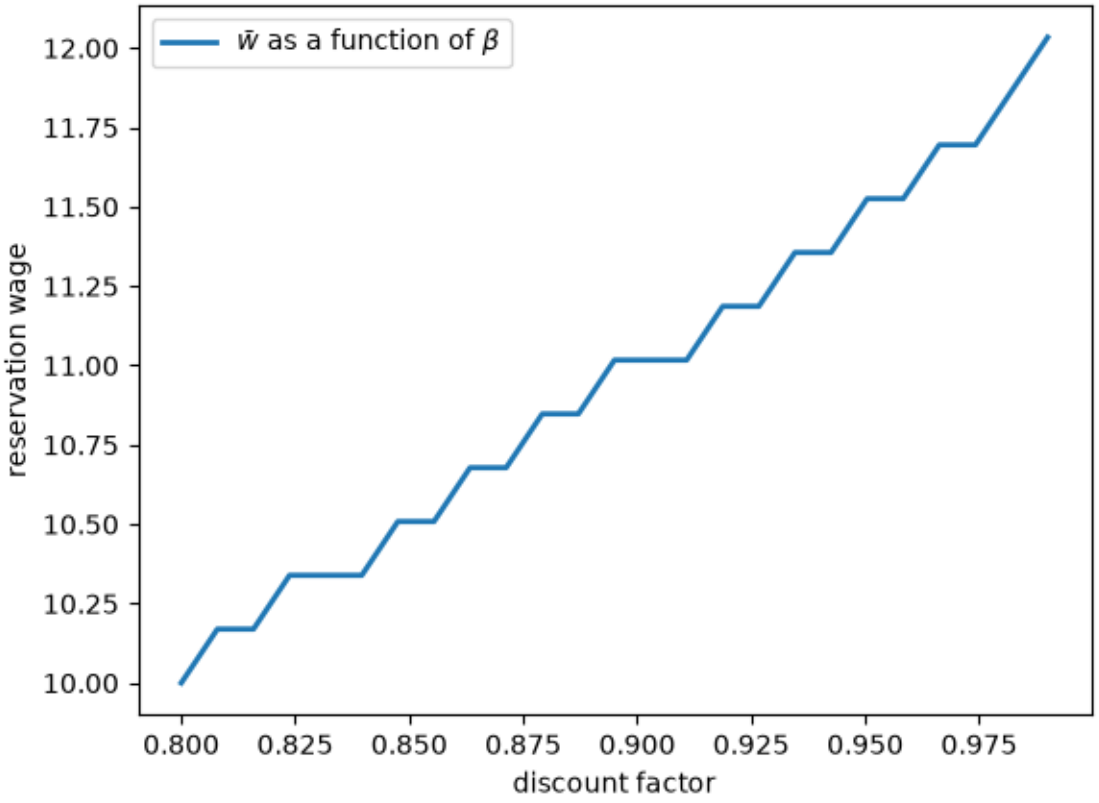
56.7.2 The reservation wage and discounting

Next, let's investigate how $\bar{w}$ varies with the discount factor.

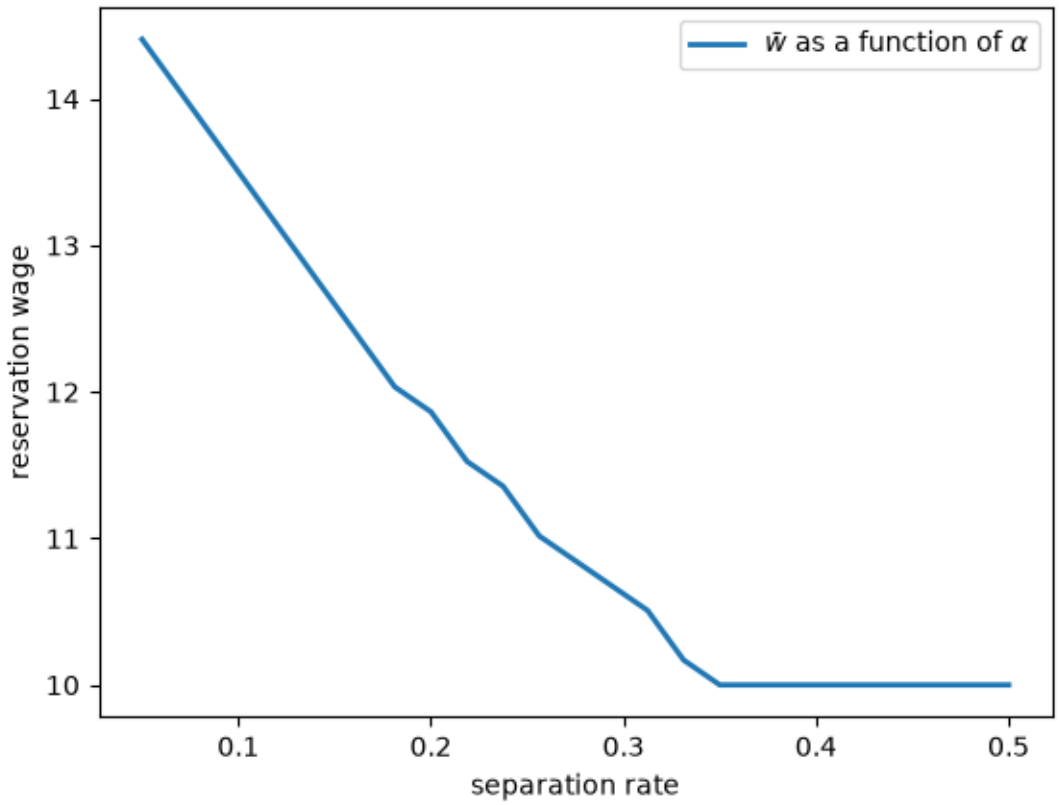
The next figure plots the reservation wage associated with different values of β

Again, the results are intuitive: More patient workers will hold out for higher wages.

56.7.3 The reservation wage and job destruction



Finally, let's look at how $\bar{w}$ varies with the job separation rate α.



Higher α translates to a greater chance that a worker will face termination in each period once employed.

Once more, the results are in line with our intuition.

If the separation rate is high, then the benefit of holding out for a higher wage falls.

Hence the reservation wage is lower.

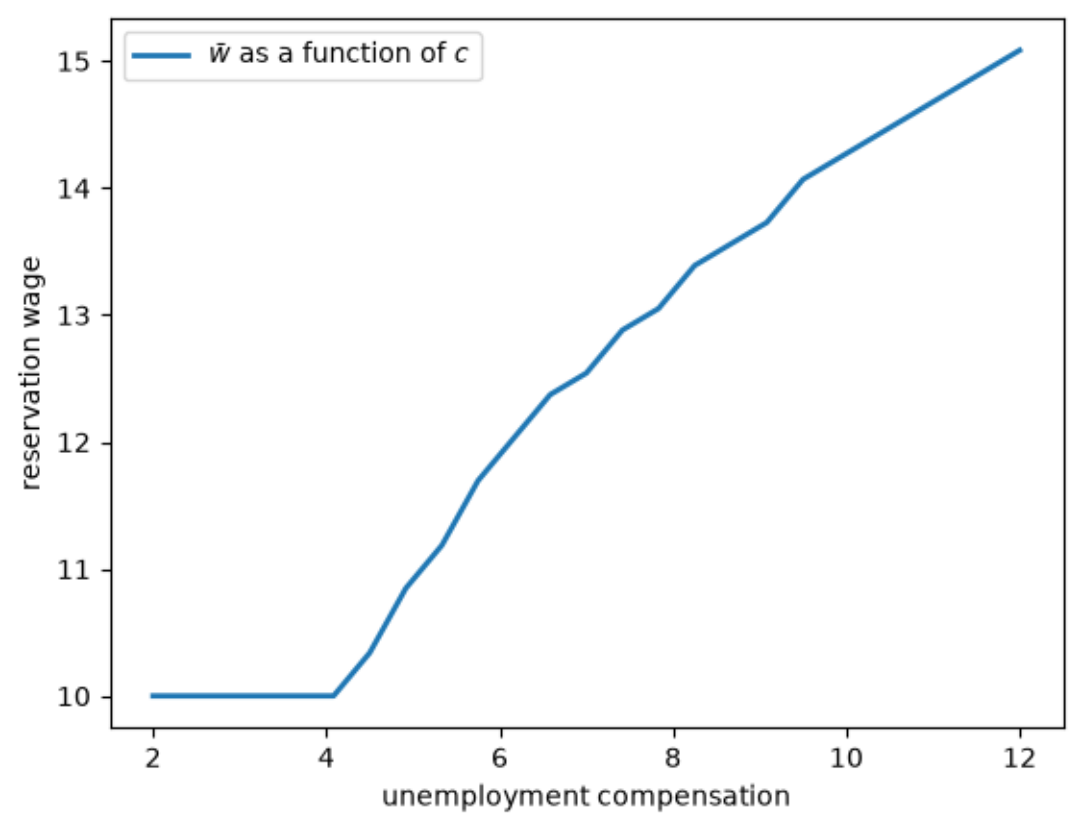
56.8 Exercises

Exercise 56.8.1

Reproduce all the reservation wage figures shown above.

Regarding the values on the horizontal axis, use

```
grid_size = 25
c_vals = jnp.linspace(2, 12, grid_size)          # unemployment compensation
β_vals = jnp.linspace(0.8, 0.99, grid_size)      # discount factors
α_vals = jnp.linspace(0.05, 0.5, grid_size)      # separation rate
```



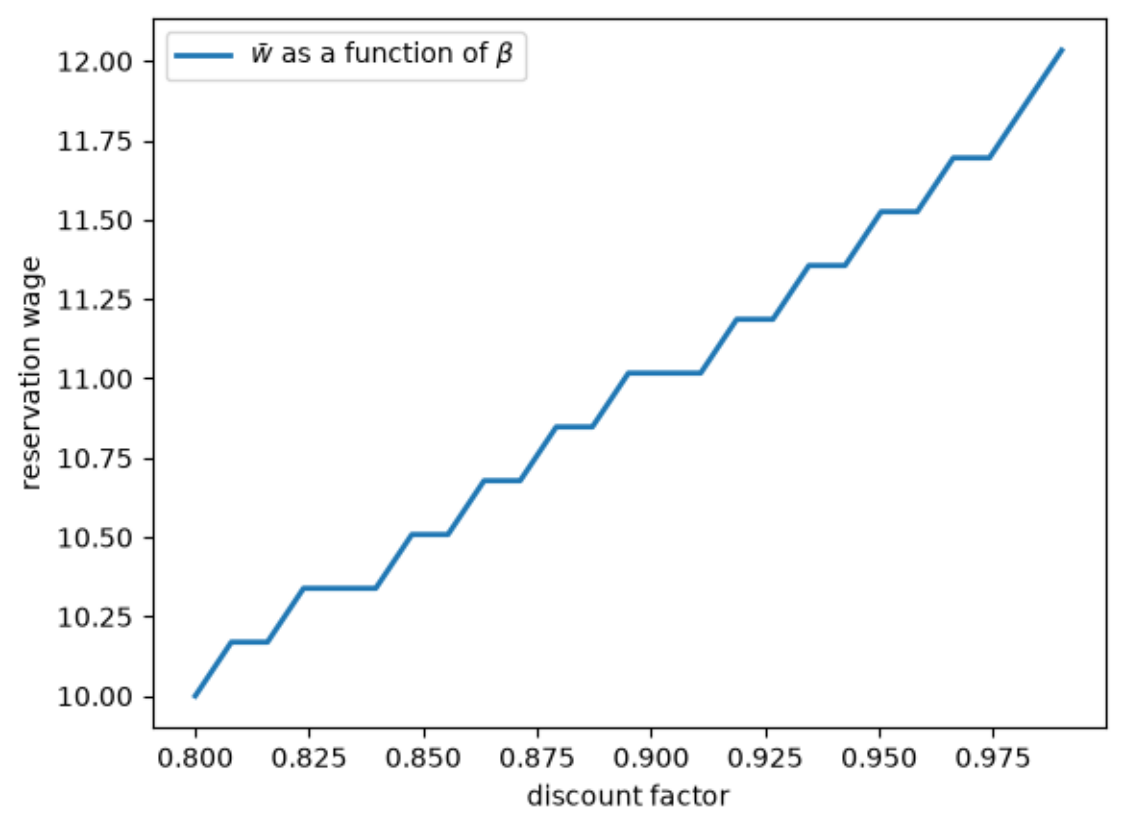
Solution

Here's the first figure.

```
def compute_res_wage_given_c(c):
    model = Model(c=c)
    w_bar = compute_reservation_wage(model)
    return w_bar

w_bar_vals = jax.vmap(compute_res_wage_given_c)(c_vals)

fig, ax = plt.subplots()
ax.set(xlabel='unemployment compensation', ylabel='reservation wage')
ax.plot(c_vals, w_bar_vals, lw=2, label=r'$\bar w$ as a function of $c$')
ax.legend()
glue("mccall_resw_c", fig, display=False)
plt.show()
```



Here's the second one.

```
def compute_res_wage_given_beta(β):
    model = Model(β=β)
    w_bar = compute_reservation_wage(model)
    return w_bar

w_bar_vals = jax.vmap(compute_res_wage_given_beta)(β_vals)

fig, ax = plt.subplots()
ax.set(xlabel='discount factor', ylabel='reservation wage')
ax.plot(β_vals, w_bar_vals, lw=2, label=r'$\bar w$ as a function of $\beta$')

JOB SEARCH III: SEARCH WITH SEPARATION AND MARKOV WAGES

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

  - *Cross-sectional analysis*
  - *Lower unemployment compensation (c=0.5)*
  - *Exercises*

This lecture builds on the job search model with separation presented in the *previous lecture*.

The key difference is that wage offers now follow a *Markov chain* rather than being IID.

This modification adds persistence to the wage offer process, meaning that today's wage offer provides information about tomorrow's offer.

This feature makes the model more realistic, as labor market conditions tend to exhibit serial correlation over time.

In addition to what's in Anaconda, this lecture will need the following libraries

```
!pip install quantecon jax
```

We use the following imports:

```
from quantecon.markov import tauchen
import jax.numpy as jnp
import jax
from jax import lax
from typing import NamedTuple
import matplotlib.pyplot as plt
from functools import partial
```

57.1 Model setup

The setting is as follows:

- Each unemployed agent receives a wage offer w from a finite set $\mathbb{W}$
- Wage offers follow a Markov chain with transition matrix P
- Jobs terminate with probability α each period (separation rate)
- Unemployed workers receive compensation c per period
- Future payoffs are discounted by factor $\beta \in (0, 1)$

57.1.1 Decision problem

When unemployed and receiving wage offer w, the agent chooses between:

1. Accept offer w: Become employed at wage w
2. Reject offer: Remain unemployed, receive c, get new offer next period

The wage updates are as follows:

- If an unemployed agent rejects offer w, then their next offer is drawn from $P(w, \cdot)$
- If an employed agent loses a job in which they were paid wage w, then their next offer is drawn from $P(w, \cdot)$

57.1.2 The wage offer process

To construct the wage offer process we start with an AR1 process.

$$X_{t+1} = \rho X_t + \nu Z_{t+1}$$

where $\{Z_t\}$ is IID and standard normal.

Below we will always choose $\rho \in (0, 1)$.

This means that the wage process will be positively correlated: the higher the current wage offer, the more likely we are to get a high offer tomorrow.

To go from the AR1 process to the wage offer process, we set $W_t = \exp(X_t)$.

Actually, in practice, we approximate this wage process as follows:

- discretize the AR1 process using *Tauchen's method* and

- take the exponential of the resulting wage offer values.

57.1.3 Value functions

We let

- $v_u(w)$ be the value of being unemployed when current wage offer is w
- $v_e(w)$ be the value of being employed at wage w

The Bellman equations are obvious modifications of the *IID case*.

The only change is that expectations for next period are computed using the transition matrix P conditioned on current wage w, instead of being drawn independently from q.

The unemployed worker's value function satisfies the Bellman equation

$$v_u(w) = \max \left\{ v_e(w), u(c) + \beta \sum_{w'} v_u(w') P(w, w') \right\}$$

The employed worker's value function satisfies the Bellman equation

$$v_e(w) = u(w) + \beta \left[\alpha \sum_{w'} v_u(w') P(w, w') + (1 - \alpha) v_e(w) \right]$$

As a matter of notation, given a function h assigning values to wages, it is common to set

$$(Ph)(w) = \sum_{w'} h(w') P(w, w')$$

(To understand this expression, think of P as a matrix, h as a column vector, and w as a row index.)

With this notation, the Bellman equations become

$$v_u(w) = \max\{v_e(w), u(c) + \beta (P v_u)(w)\}$$

and

$$v_e(w) = u(w) + \beta \left[\alpha (P v_u)(w) + (1 - \alpha) v_e(w)\right]$$

57.1.4 Optimal policy

Once we have the solutions v_e and v_u to these Bellman equations, we can compute the optimal policy: accept at current wage offer w if

$$v_e(w) \geq u(c) + \beta (P v_u)(w)$$

The optimal policy turns out to be a reservation wage strategy: accept all wages above some threshold.

57.2 Code

Let's now implement the model.

57.2.1 Set up

The default utility function is a CRRA utility function

```
def u(x, γ):
    return (x**(1 - γ) - 1) / (1 - γ)
```

Let's set up a `Model` class to store information needed to solve the model.

We include `P_cumsum`, the row-wise cumulative sum of the transition matrix, to optimize simulation – the details are explained below.

```
class Model(NamedTuple):
    n: int
    w_vals: jnp.ndarray
    P: jnp.ndarray
    P_cumsum: jnp.ndarray
    β: float
    c: float
    α: float
    γ: float
```

The next function holds default values and creates a `Model` instance:

```
def create_js_with_sep_model(
        n: int = 200,           # wage grid size
        ρ: float = 0.9,         # wage persistence
        ν: float = 0.2,         # wage volatility
        β: float = 0.96,        # discount factor
        α: float = 0.05,        # separation rate
        c: float = 1.0,         # unemployment compensation
        γ: float = 1.5          # utility parameter
    ) -> Model:
    """
    Creates an instance of the job search model with separation.

    """
    mc = tauchen(n, ρ, ν)
    w_vals, P = jnp.exp(jnp.array(mc.state_values)), jnp.array(mc.P)
    P_cumsum = jnp.cumsum(P, axis=1)
    return Model(n, w_vals, P, P_cumsum, β, c, α, γ)
```

57.2.2 Solution: first pass

Let's put together a (not very efficient) routine for calculating the reservation wage.

(We will think carefully about efficiency below.)

It works by starting with guesses for v_e and v_u and iterating to convergence.

Here are Bellman operators that update v_u and v_e respectively.

```
def T_u(model, v_u, v_e):
    """
    Apply the unemployment Bellman update rule and return new guess of v_u.

    """
```

(continues on next page)

(continued from previous page)

```
    n, w_vals, P, P_cumsum, β, c, α, γ = model
    h = u(c, γ) + β * P @ v_u
    v_u_new = jnp.maximum(v_e, h)
    return v_u_new
```

```
def T_e(model, v_u, v_e):
    """
    Apply the employment Bellman update rule and return new guess of v_e.

    """
    n, w_vals, P, P_cumsum, β, c, α, γ = model
    v_e_new = u(w_vals, γ) + β * ((1 - α) * v_e + α * P @ v_u)
    return v_e_new
```

Here's a routine to iterate to convergence and then compute the reservation wage.

```
def solve_model_first_pass(
        model: Model,           # instance containing default parameters
        v_u_init: jnp.ndarray,  # initial condition for v_u
        v_e_init: jnp.ndarray,  # initial condition for v_e
        tol: float=1e-6,        # error tolerance
        max_iter: int=1_000,    # maximum number of iterations for loop
    ):
    n, w_vals, P, P_cumsum, β, c, α, γ = model
    i = 0
    error = tol + 1
    v_u = v_u_init
    v_e = v_e_init

    while i < max_iter and error > tol:
        v_u_next = T_u(model, v_u, v_e)
        v_e_next = T_e(model, v_u, v_e)
        error_u = jnp.max(jnp.abs(v_u_next - v_u))
        error_e = jnp.max(jnp.abs(v_e_next - v_e))
        error = jnp.maximum(error_u, error_e)
        v_u = v_u_next
        v_e = v_e_next
        i += 1

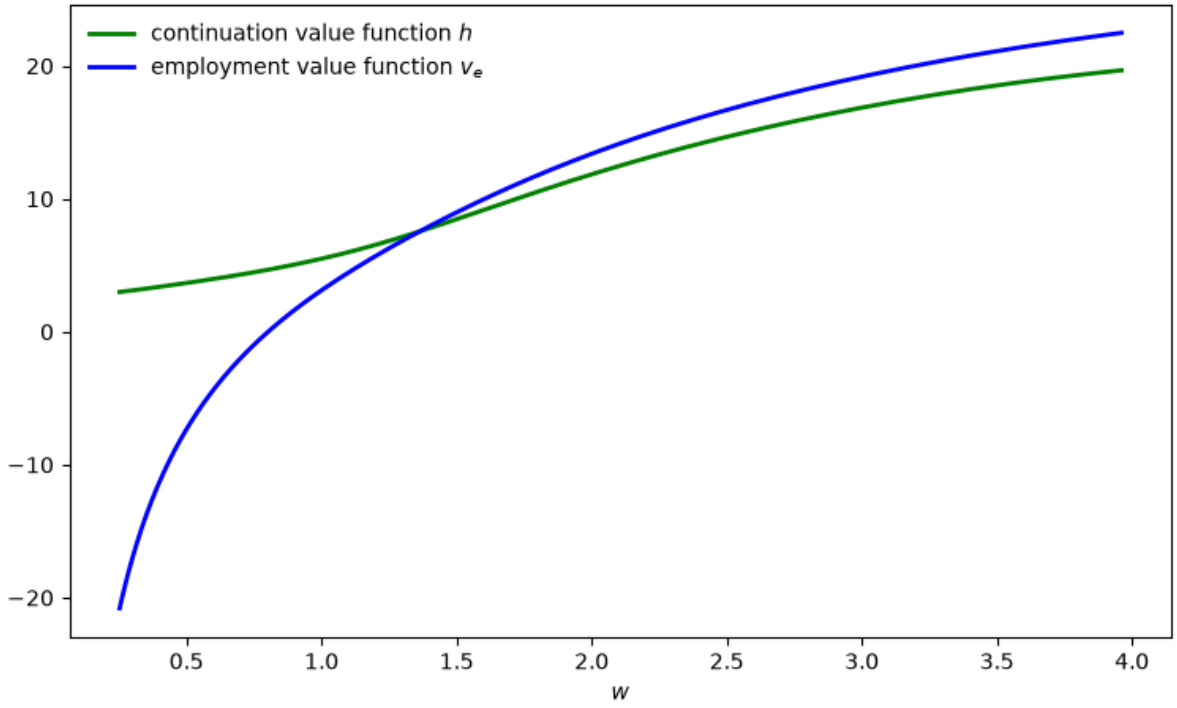
    # Compute accept and reject values
    continuation_values = u(c, γ) + β * P @ v_u

    # Find where acceptance becomes optimal
    accept_indices = v_e >= continuation_values
    first_accept_idx = jnp.argmax(accept_indices)  # index of first True

    # If no acceptance (all False), return infinity
    # Otherwise return the wage at the first acceptance index
    w_bar = jnp.where(
        jnp.any(accept_indices), w_vals[first_accept_idx], jnp.inf
    )
    return v_u, v_e, w_bar
```

57.2.3 Road test

Let's solve the model:



```
model = create_js_with_sep_model()
n, w_vals, P, P_cumsum, β, c, α, γ = model
v_u_init = jnp.zeros(n)
v_e_init = jnp.zeros(n)
v_u, v_e, w_bar_first = solve_model_first_pass(model, v_u_init, v_e_init)
```

Next we compute the continuation values.

```
h = u(c, γ) + β * P @ v_u
```

Let's plot our results.

```
fig, ax = plt.subplots(figsize=(9, 5.2))
ax.plot(w_vals, h, 'g-', linewidth=2,
        label="continuation value function $h$")
ax.plot(w_vals, v_e, 'b-', linewidth=2,
        label="employment value function $v_e$")
ax.legend(frameon=False)
ax.set_xlabel(r"$w$")
plt.show()
```

The reservation wage is at the intersection of v_e, and the continuation value function, which is the value of rejecting.

57.3 Improving efficiency

The solution method described above works fine but we can do much better.

First, we use the employed worker's Bellman equation to express v_e in terms of Pv_u

$$v_e(w) = \frac{1}{1-\beta(1-\alpha)} \cdot (u(w) + \alpha\beta(Pv_u)(w))$$

Next we substitute into the unemployed agent's Bellman equation to get

$$v_u(w) = \max\left\{\frac{1}{1-\beta(1-\alpha)} \cdot (u(w) + \alpha\beta(Pv_u)(w)), u(c) + \beta(Pv_u)(w)\right\}$$

Then we use value function iteration to solve for v_u.

With v_u in hand, we can recover v_e through the equations above and then compute the reservation wage.

Here's the new Bellman operator for the unemployed worker's value function:

```
def T(v: jnp.ndarray, model: Model) -> jnp.ndarray:
    """
    The Bellman operator for v_u.

    """
    n, w_vals, P, P_cumsum, β, c, α, γ = model
    d = 1 / (1 - β * (1 - α))
    v_e = d * (u(w_vals, γ) + α * β * P @ v)
    h = u(c, γ) + β * P @ v
    return jnp.maximum(v_e, h)
```

Here's a routine for value function iteration.

```
@jax.jit
def vfi(
        model: Model,
        tolerance: float = 1e-6,    # Error tolerance
        max_iter: int = 100_000,    # Max iteration bound
    ):

    v_init = jnp.zeros(model.w_vals.shape)

    def cond(loop_state):
        v, error, i = loop_state
        return (error > tolerance) & (i <= max_iter)

    def update(loop_state):
        v, error, i = loop_state
        v_new = T(v, model)
        error = jnp.max(jnp.abs(v_new - v))
        new_loop_state = v_new, error, i + 1
        return new_loop_state

    initial_state = (v_init, tolerance + 1, 1)
    final_loop_state = lax.while_loop(cond, update, initial_state)
    v_final, error, i = final_loop_state

    return v_final
```

Here is a routine that computes the reservation wage from the value function.

```
@jax.jit
def get_reservation_wage(v: jnp.ndarray, model: Model) -> float:
    """
    Calculate the reservation wage from the unemployed agents
    value function v := v_u.

    The reservation wage is the lowest wage w where accepting (v_e(w))
    is at least as good as rejecting (u(c) + β(Pv_u)(w)).

    """
    n, w_vals, P, P_cumsum, β, c, α, γ = model

    # Compute accept and reject values
    d = 1 / (1 - β * (1 - α))
    v_e = d * (u(w_vals, γ) + α * β * P @ v)
    continuation_values = u(c, γ) + β * P @ v

    # Find where acceptance becomes optimal
    accept_indices = v_e >= continuation_values
    first_accept_idx = jnp.argmax(accept_indices)  # index of first True

    # If no acceptance (all False), return infinity
    # Otherwise return the wage at the first acceptance index
    return jnp.where(jnp.any(accept_indices), w_vals[first_accept_idx], jnp.inf)
```

Let's solve the model using our new method:

```
model = create_js_with_sep_model()
n, w_vals, P, P_cumsum, β, c, α, γ = model
v_u = vfi(model)
w_bar = get_reservation_wage(v_u, model)
```

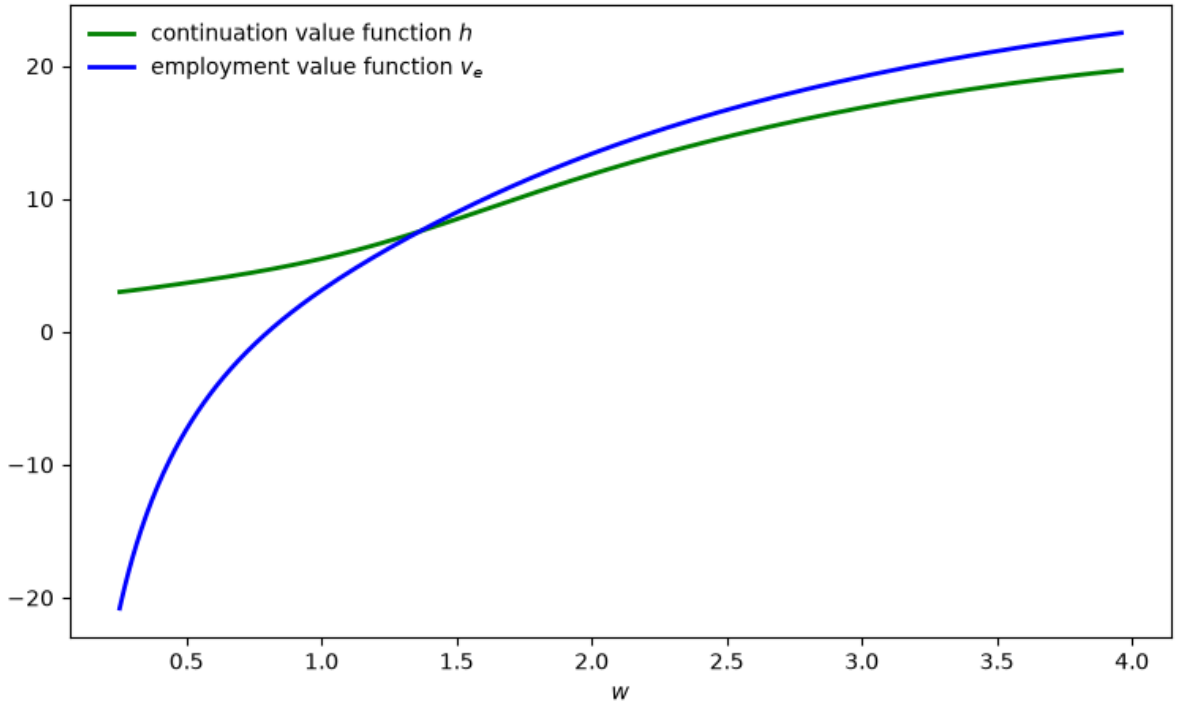
Let's verify that both methods produce the same reservation wage:

```
print(f"Reservation wage (first method):  {w_bar_first:.6f}")
print(f"Reservation wage (second method): {w_bar:.6f}")
print(f"Difference: {abs(w_bar - w_bar_first):.2e}")
```

```
Reservation wage (first method):  1.365155
Reservation wage (second method): 1.365155
Difference: 0.00e+00
```

Next we compute some related quantities for plotting.

```
d = 1 / (1 - β * (1 - α))
v_e = d * (u(w_vals, γ) + α * β * P @ v_u)
h = u(c, γ) + β * P @ v_u
```



Let's plot our results.

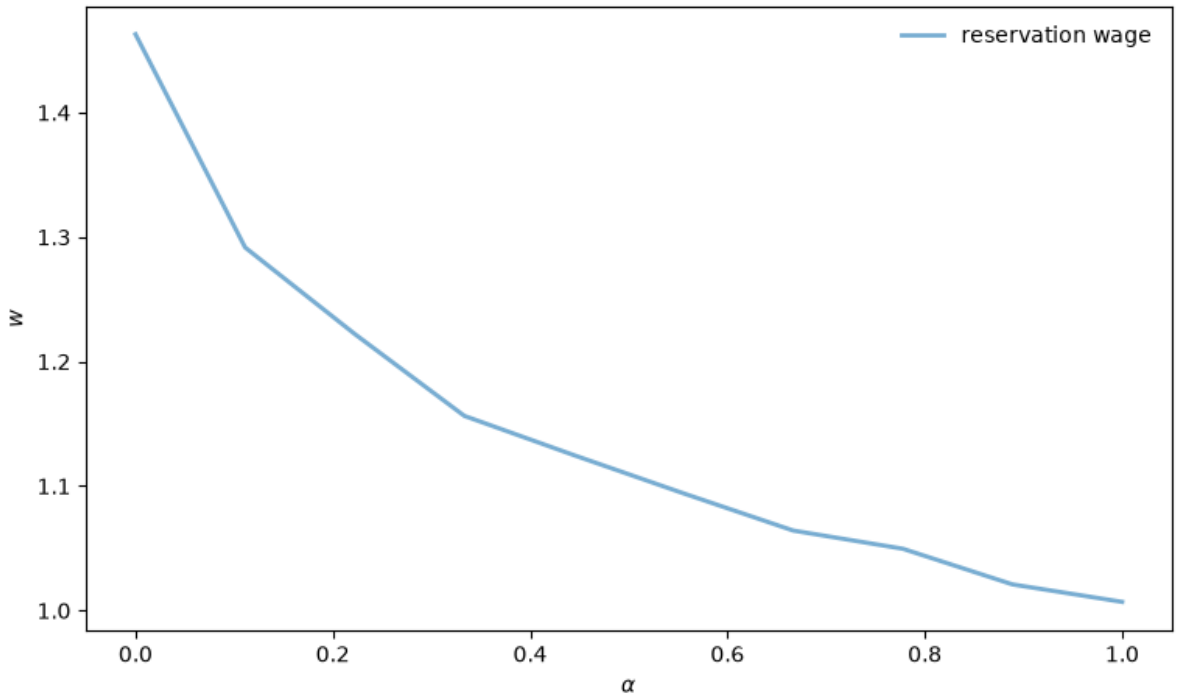
```
fig, ax = plt.subplots(figsize=(9, 5.2))
ax.plot(w_vals, h, 'g-', linewidth=2,
        label="continuation value function $h$")
ax.plot(w_vals, v_e, 'b-', linewidth=2,
        label="employment value function $v_e$")
ax.legend(frameon=False)
```

(continues on next page)

(continued from previous page)

```
ax.set_xlabel(r"$w$")
plt.show()
```

The result is the same as before but we only iterate on one array — and also our JAX code is more efficient.



57.4 Sensitivity analysis

Let's examine how reservation wages change with the separation rate.

```
α_vals: jnp.ndarray = jnp.linspace(0.0, 1.0, 10)

w_bar_vec = []
for α in α_vals:
    model = create_js_with_sep_model(α=α)
    v_u = vfi(model)
    w_bar = get_reservation_wage(v_u, model)
    w_bar_vec.append(w_bar)

fig, ax = plt.subplots(figsize=(9, 5.2))
ax.plot(
    α_vals, w_bar_vec, linewidth=2, alpha=0.6, label="reservation wage"
)
ax.legend(frameon=False)
ax.set_xlabel(r"$\alpha$")
ax.set_ylabel(r"$w$")
plt.show()
```

Can you provide an intuitive economic story behind the outcome that you see in this figure?

57.5 Employment simulation

Now let's simulate the employment dynamics of a single agent under the optimal policy.

Note that, when simulating the Markov chain for wage offers, we need to draw from the distribution in each row of P many times.

To do this, we use the inverse transform method: draw a uniform random variable and find where it falls in the cumulative distribution.

This is implemented via `jnp.searchsorted` on the precomputed cumulative sum `P_cumsum`, which is much faster than recomputing the cumulative sum each time.

The function `update_agent` advances the agent's state by one period.

The agent's state is a pair (S_t, W_t), where S_t is employment status (0 if unemployed, 1 if employed) and W_t is

- their current wage offer, if unemployed, or
- their current wage, if employed.

```
def update_agent(key, status, wage_idx, model, w_bar):
    """
    Updates an agent's employment status and current wage.

    Parameters:
    - key: JAX random key
    - status: Current employment status (0 or 1)
    - wage_idx: Current wage, recorded as an array index
    - model: Model instance
    - w_bar: Reservation wage
```

(continues on next page)

(continued from previous page)

```
    """
    n, w_vals, P, P_cumsum, β, c, α, γ = model

    key1, key2 = jax.random.split(key)
    # Use precomputed cumulative sum for efficient sampling
    # via the inverse transform method.
    new_wage_idx = jnp.searchsorted(
        P_cumsum[wage_idx, :], jax.random.uniform(key1)
    )
    separation_occurs = jax.random.uniform(key2) < α
    # Accept if current wage meets or exceeds reservation wage
    accepts = w_vals[wage_idx] >= w_bar

    # If employed: status = 1 if no separation, 0 if separation
    # If unemployed: status = 1 if accepts, 0 if rejects
    next_status = jnp.where(
        status,
        1 - separation_occurs.astype(jnp.int32),  # employed path
        accepts.astype(jnp.int32)                 # unemployed path
    )

    # If employed: wage = current if no separation, new if separation
    # If unemployed: wage = current if accepts, new if rejects
    next_wage = jnp.where(
        status,
        jnp.where(separation_occurs, new_wage_idx, wage_idx),  # employed path
        jnp.where(accepts, wage_idx, new_wage_idx)             # unemployed path
    )

    return next_status, next_wage
```

Here's a function to simulate the employment path of a single agent.

```
def simulate_employment_path(
        model: Model,      # Model details
        w_bar: float,     # Reservation wage
        T: int = 2_000,    # Simulation length
        seed: int = 42     # Set seed for simulation
    ):
    """
    Simulate employment path for T periods starting from unemployment.

    """
    key = jax.random.key(seed)
    # Unpack model
    n, w_vals, P, P_cumsum, β, c, α, γ = model

    # Initial conditions
    status = 0
    wage_idx = 0

    wage_path = []
    status_path = []

    for t in range(T):
        wage_path.append(w_vals[wage_idx])
```

(continues on next page)

(continued from previous page)

```
        status_path.append(status)

        key, subkey = jax.random.split(key)
        status, wage_idx = update_agent(
            subkey, status, wage_idx, model, w_bar
        )

    return jnp.array(wage_path), jnp.array(status_path)
```

Let's create a comprehensive plot of the employment simulation:

```
model = create_js_with_sep_model()

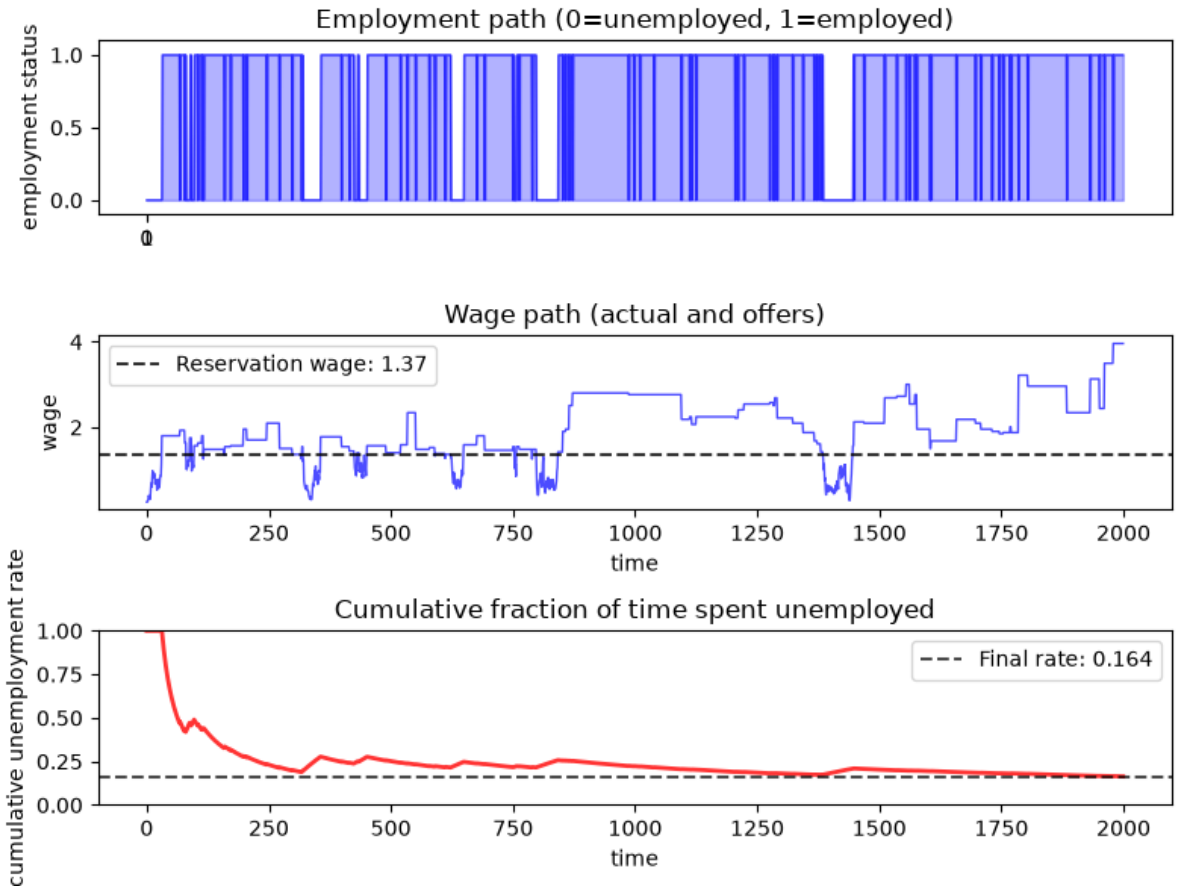
# Calculate reservation wage for plotting
v_u = vfi(model)
w_bar = get_reservation_wage(v_u, model)

wage_path, employment_status = simulate_employment_path(model, w_bar)

fig, (ax1, ax2, ax3) = plt.subplots(3, 1, figsize=(8, 6))

# Plot employment status
ax1.plot(employment_status, 'b-', alpha=0.7, linewidth=1)
ax1.fill_between(
    range(len(employment_status)), employment_status, alpha=0.3, color='blue'
)
ax1.set_ylabel('employment status')
ax1.set_title('Employment path (0=unemployed, 1=employed)')
ax1.set_xticks((0, 1))
ax1.set_ylim(-0.1, 1.1)

# Plot wage path with employment status coloring
ax2.plot(wage_path, 'b-', alpha=0.7, linewidth=1)
ax2.axhline(y=w_bar, color='black', linestyle='--', alpha=0.8,
           label=f'Reservation wage: {w_bar:.2f}')
ax2.set_xlabel('time')
ax2.set_ylabel('wage')
ax2.set_title('Wage path (actual and offers)')
ax2.legend()



# Plot cumulative fraction of time unemployed
unemployed_indicator = (employment_status == 0).astype(int)
cumulative_unemployment = (
    jnp.cumsum(unemployed_indicator) /
    jnp.arange(1, len(employment_status) + 1)
)

ax3.plot(cumulative_unemployment, 'r-', alpha=0.8, linewidth=2)
ax3.axhline(y=jnp.mean(unemployed_indicator), color='black',
            linestyle='--', alpha=0.7,
            label=f'Final rate: {jnp.mean(unemployed_indicator):.3f}')
ax3.set_xlabel('time')
ax3.set_ylabel('cumulative unemployment rate')
ax3.set_title('Cumulative fraction of time spent unemployed')
ax3.legend()
ax3.set_ylim(0, 1)
```

(continues on next page)

(continued from previous page)

```
plt.tight_layout()
plt.show()
```

The simulation helps to visualize outcomes associated with this model.

The agent follows a reservation wage strategy.

Often the agent loses her job and immediately takes another job at a different wage.

This is because she uses the wage w from her last job to draw a new wage offer via $P(w, \cdot)$, and positive correlation means that a high current w is often leads a high new draw.

57.6 Ergodic property

Below we examine cross-sectional unemployment.

In particular, we will look at the unemployment rate in a cross-sectional simulation and compare it to the time-average unemployment rate, which is the fraction of time an agent spends unemployed over a long time series.

We will see that these two values are approximately equal – in fact they are exactly equal in the limit.

The reason is that the process (S_t, W_t), where

- S_t is the employment status and
- W_t is the wage

is Markovian, since the next pair depends only on the current pair and iid randomness, and ergodic.

Ergodicity holds as a result of irreducibility.

Indeed, from any (status, wage) pair, an agent can eventually reach any other (status, wage) pair.

This holds because:

- Unemployed agents can become employed by accepting offers
- Employed agents can become unemployed through separation (probability α)
- The wage process can transition between all wage states (because P is itself irreducible)

These properties ensure the chain is ergodic with a unique stationary distribution π over states (s, w).

For an ergodic Markov chain, the ergodic theorem guarantees that time averages = cross-sectional averages.

In particular, the fraction of time a single agent spends unemployed (across all wage states) converges to the cross-sectional unemployment rate:

$$\lim_{T\to\infty} \frac{1}{T}\sum_{t=1}^{T} \mathbb{1}\{S_t = \text{unemployed}\} = \sum_{w=1}^{n} \pi(\text{unemployed}, w)$$

This holds regardless of initial conditions – provided that we burn in the cross-sectional distribution (run it forward in time from a given initial cross section in order to remove the influence of that initial condition).

As a result, we can study steady-state unemployment either by:

- Following one agent for a long time (time average), or
- Observing many agents at a single point in time (cross-sectional average)

Often the second approach is better for our purposes, since it's easier to parallelize.

57.7 Cross-sectional analysis

Now let's simulate many agents simultaneously to examine the cross-sectional unemployment rate.

To do this efficiently, we need a different approach than `simulate_employment_path` defined above.

The key differences are:

- `simulate_employment_path` records the entire history (all T periods) for a single agent, which is useful for visualization but memory-intensive
- The new function `sim_agent` below only tracks and returns the final state, which is all we need for cross-sectional statistics
- `sim_agent` uses `lax.fori_loop` instead of a Python loop, making it JIT-compilable and suitable for vectorization across many agents

We first define a function that simulates a single agent forward T time steps:

```
@jax.jit
def sim_agent(key, initial_status, initial_wage_idx, model, w_bar, T):
    """
    Simulate a single agent forward T time steps using lax.fori_loop.

    Uses fold_in to generate a new key at each time step.

    Parameters:
```

(continues on next page)

(continued from previous page)

```
    - key: JAX random key for this agent
    - initial_status: Initial employment status (0 or 1)
    - initial_wage_idx: Initial wage index
    - model: Model instance
    - w_bar: Reservation wage
    - T: Number of time periods to simulate

    Returns:
    - final_status: Employment status after T periods
    - final_wage_idx: Wage index after T periods
    """
    def update(t, loop_state):
        status, wage_idx = loop_state
        step_key = jax.random.fold_in(key, t)
        status, wage_idx = update_agent(step_key, status, wage_idx, model, w_bar)
        return status, wage_idx

    initial_loop_state = (initial_status, initial_wage_idx)
    final_loop_state = lax.fori_loop(0, T, update, initial_loop_state)
    final_status, final_wage_idx = final_loop_state
    return final_status, final_wage_idx

# Create vectorized version of sim_agent to process multiple agents in parallel
sim_agents_vmap = jax.vmap(sim_agent, in_axes=(0, 0, 0, None, None, None))

def simulate_cross_section(
        model: Model,               # Model instance with parameters
        n_agents: int = 100_000,    # Number of agents to simulate
        T: int = 200,               # Length of burn-in
        seed: int = 42              # For reproducibility
    ) -> float:
    """
    Simulate cross-section of agents and return unemployment rate.

    This approach:
    1. Generates n_agents random keys
    2. Calls sim_agent for each agent (vectorized via vmap)
    3. Collects the final states to produce the cross-section

    Returns the cross-sectional unemployment rate.
    """
    key = jax.random.key(seed)

    # Solve for optimal reservation wage
    v_u = vfi(model)
    w_bar = get_reservation_wage(v_u, model)

    # Initialize arrays
    initial_wage_indices = jnp.zeros(n_agents, dtype=jnp.int32)
    initial_status_vec = jnp.zeros(n_agents, dtype=jnp.int32)

    # Generate n_agents random keys
    agent_keys = jax.random.split(key, n_agents)

    # Simulate each agent forward T steps (vectorized)
```

(continues on next page)

(continued from previous page)

```
    final_status, final_wage_idx = sim_agents_vmap(
        agent_keys, initial_status_vec, initial_wage_indices, model, w_bar, T
    )

    unemployment_rate = 1 - jnp.mean(final_status)
    return unemployment_rate
```

This function generates a histogram showing the distribution of employment status across many agents:

```
def plot_cross_sectional_unemployment(
        model: Model,
        t_snapshot: int = 200,     # Time of cross-sectional snapshot
        n_agents: int = 20_000     # Number of agents to simulate
    ):
    """
    Generate histogram of cross-sectional unemployment at a specific time.

    """
    # Get final employment state directly
    key = jax.random.key(42)
    v_u = vfi(model)
    w_bar = get_reservation_wage(v_u, model)

    # Initialize arrays
    initial_wage_indices = jnp.zeros(n_agents, dtype=jnp.int32)
    initial_status_vec = jnp.zeros(n_agents, dtype=jnp.int32)

    # Generate n_agents random keys
    agent_keys = jax.random.split(key, n_agents)

    # Simulate each agent forward T steps (vectorized)
    final_status, _ = sim_agents_vmap(
        agent_keys, initial_status_vec, initial_wage_indices, model, w_bar, t_snapshot
    )

    # Calculate unemployment rate
    unemployment_rate = 1 - jnp.mean(final_status)

    fig, ax = plt.subplots(figsize=(8, 5))

    # Plot histogram as density (bars sum to 1)
    weights = jnp.ones_like(final_status) / len(final_status)
    ax.hist(final_status, bins=[-0.5, 0.5, 1.5],
            alpha=0.7, color='blue', edgecolor='black',
            density=True, weights=weights)

    ax.set_xlabel('employment status (0=unemployed, 1=employed)')
    ax.set_ylabel('density')
    ax.set_title(f'Cross-sectional distribution at t={t_snapshot}, ' +
                 f'unemployment rate = {unemployment_rate:.3f}')
    ax.set_xticks([0, 1])

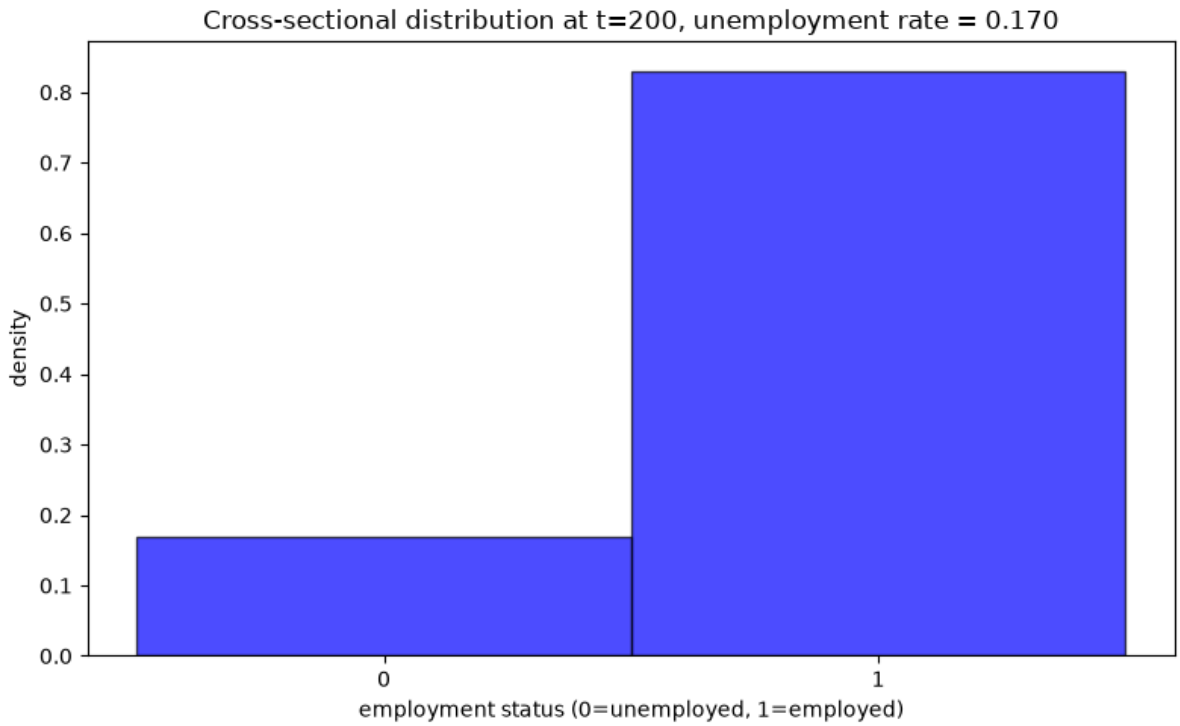
    plt.tight_layout()
    plt.show()
```

Now let's compare the time-average unemployment rate (from a single agent's long simulation) with the cross-sectional unemployment rate (from many agents at a single point in time).

We claimed above that these numbers will be approximately equal in large samples, due to ergodicity.

Let's see if that's true.

```
model = create_js_with_sep_model()
cross_sectional_unemp = simulate_cross_section(
    model, n_agents=20_000, T=200
)

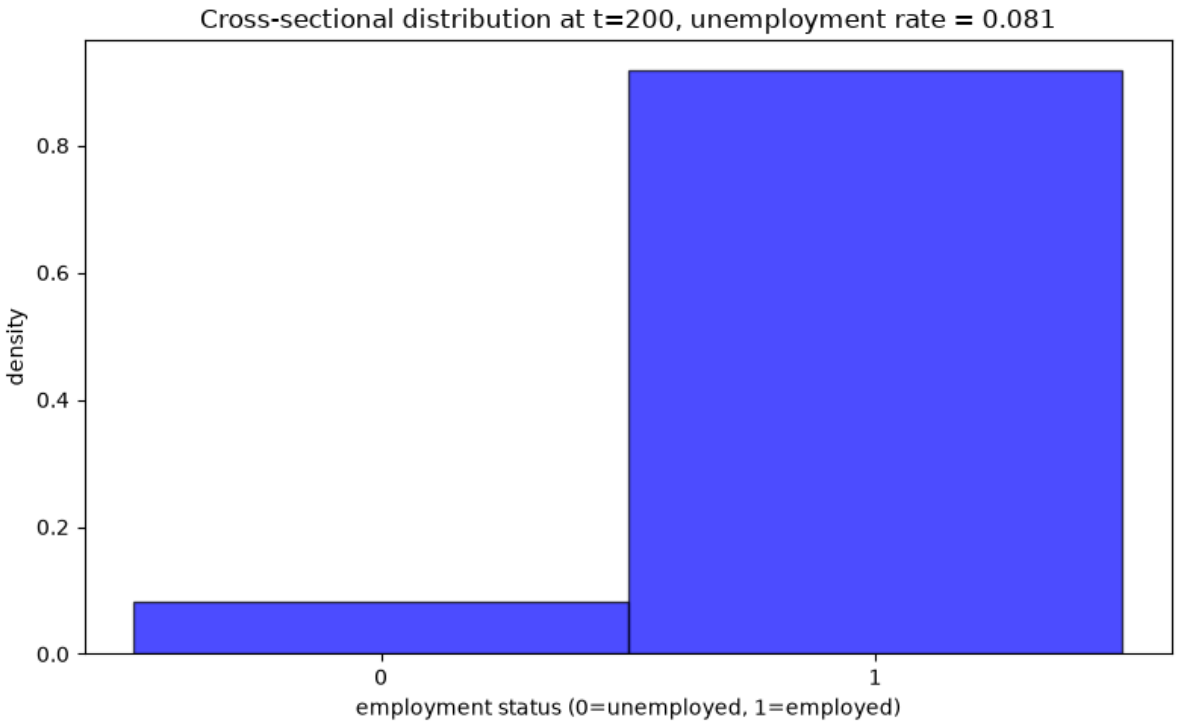


time_avg_unemp = jnp.mean(unemployed_indicator)
print(f"Time-average unemployment rate (single agent): "
      f"{time_avg_unemp:.4f}")
print(f"Cross-sectional unemployment rate (at t=200): "
      f"{cross_sectional_unemp:.4f}")
print(f"Difference: {abs(time_avg_unemp - cross_sectional_unemp):.4f}")
```

```
Time-average unemployment rate (single agent): 0.1640
Cross-sectional unemployment rate (at t=200): 0.1696
Difference: 0.0056
```

Indeed, they are very close.

Now let's visualize the cross-sectional distribution:



```
plot_cross_sectional_unemployment(model)
```

57.8 Lower unemployment compensation (c=0.5)

What happens to the cross-sectional unemployment rate with lower unemployment compensation?

```
model_low_c = create_js_with_sep_model(c=0.5)
plot_cross_sectional_unemployment(model_low_c)
```

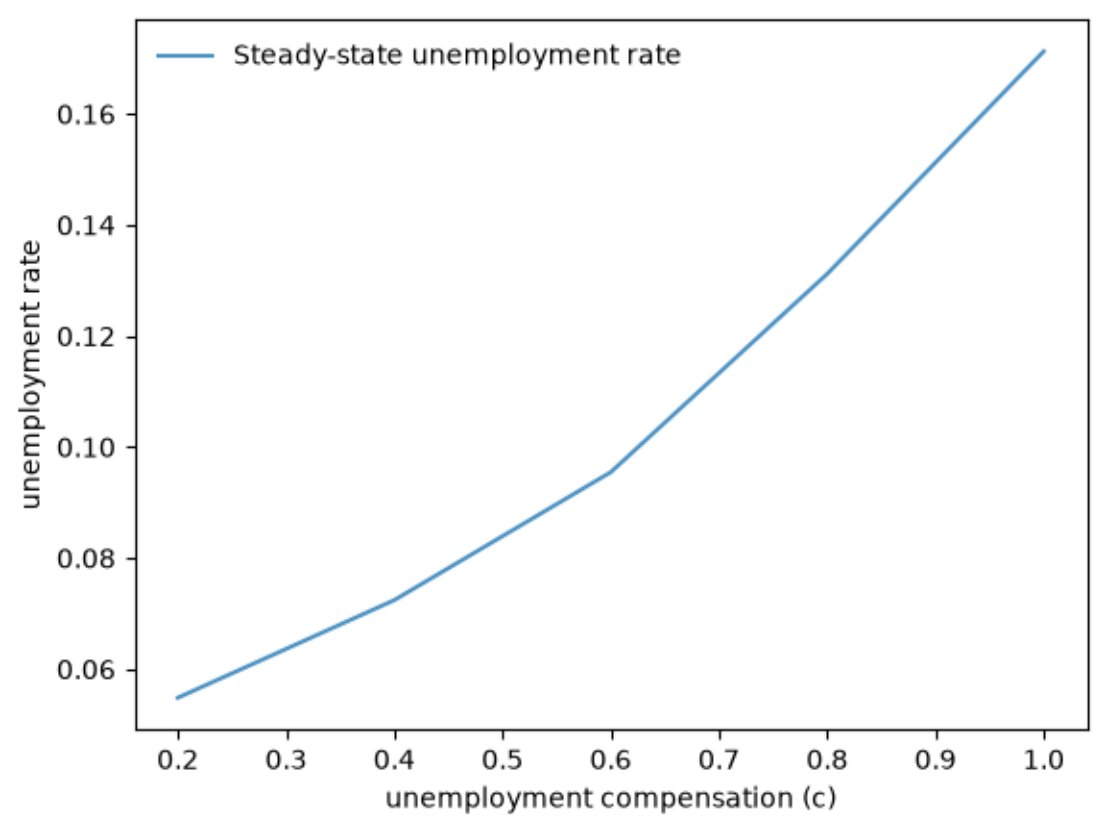
57.9 Exercises

Exercise 57.9.1

Create a plot that investigates more carefully how the steady state cross-sectional unemployment rate changes with unemployment compensation.

Try a range of values for unemployment compensation `c`, such as `c = 0.2, 0.4, 0.6, 0.8, 1.0`. For each value, compute the steady-state cross-sectional unemployment rate and plot it against `c`.

What relationship do you observe between unemployment compensation and the unemployment rate?



Solution

We compute the steady-state unemployment rate for different values of unemployment compensation:

```
c_values = 1.0, 0.8, 0.6, 0.4, 0.2
rates = []
for c in c_values:
    model = create_js_with_sep_model(c=c)
```

```
    unemployment_rate = simulate_cross_section(model)
    rates.append(unemployment_rate)

fig, ax = plt.subplots()
ax.plot(
    c_values, rates, alpha=0.8,
    linewidth=1.5, label='Steady-state unemployment rate'
)
ax.set_xlabel('unemployment compensation (c)')
ax.set_ylabel('unemployment rate')
ax.legend(frameon=False)
plt.show()
```

JOB SEARCH IV: FITTED VALUE FUNCTION ITERATION

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

Contents

- *Job Search IV: Fitted Value Function Iteration*
  - *Overview*
  - *Model*
  - *Solution method*
  - *Implementation*
  - *Simulation*
  - *Exercises*

58.1 Overview

This lecture follows on from the job search model with separation presented in the *previous lecture*.

That lecture combined exogenous job separation events and a Markov wage offer process.

In this lecture we continue with this set and, in addition, allow the wage offer process to be continuous rather than discrete.

In particular,

$$W_t = \exp(X_t) \quad \text{where} \quad X_{t+1} = \rho X_t + \nu Z_{t+1}$$

and $\{Z_t\}$ is IID and standard normal.

While we already considered continuous wage distributions briefly in *Job Search I: The McCall Search Model*, the change was relatively trivial in that case.

The reason is that we were able to reduce the problem to solving for a single scalar value (the continuation value).

Here, in our Markov setting, the change is less trivial, since a continuous wage distribution leads to an uncountably infinite state space.

The infinite state space leads to additional challenges, particularly when it comes to applying value function iteration (VFI).

These challenges will lead us to modify VFI by adding an interpolation step.

The combination of VFI and this interpolation step is called **fitted value function iteration** (fitted VFI).

Fitted VFI is very common in practice, so we will take some time to work through the details.

In addition to what's in Anaconda, this lecture will need the following libraries

```
!pip install quantecon jax
```

We will use the following imports:

```
import matplotlib.pyplot as plt
import jax
import jax.numpy as jnp
from jax import lax
from typing import NamedTuple
from functools import partial
import quantecon as qe
```

58.2 Model

Assuming that readers are familiar with the content of *Job Search III: Search with Separation and Markov Wages*, the model can be summarized as follows.

- Wage offers follow a continuous Markov process: $W_t = \exp(X_t)$ where $X_{t+1} = \rho X_t + \nu Z_{t+1}$
- $\{Z_t\}$ is IID and standard normal
- Jobs terminate with probability α each period (separation rate)
- Unemployed workers receive compensation c per period
- Workers have CRRA utility $u(x) = \frac{x^{1-\gamma}-1}{1-\gamma}$
- Future payoffs are discounted by factor $\beta \in (0, 1)$

58.3 Solution method

Let's discuss how we can solve this model.

The only real change from *Job Search III: Search with Separation and Markov Wages* is that we replace sums with integrals.

58.3.1 Value function iteration

In the *discrete case*, we ended up iterating on the Bellman operator

$$(Tv_u)(w) = \max\left\{\frac{1}{1-\beta(1-\alpha)} \cdot (u(w) + \alpha\beta(Pv_u)(w)), u(c) + \beta(Pv_u)(w)\right\} \tag{58.1}$$

where

$$(Pv_u)(w) := \sum_{w'} v_u(w')P(w, w')$$

Here we iterate on the same law after changing the definition of the P operator to

$$(Pv_u)(w) := \int v_u(w')p(w, w')dw'$$

where $p(w, \cdot)$ is the conditional density of w' given w.

Here we are thinking of v_u as a function on all of $\mathbb{R}_+$.

After taking ψ to be the standard normal density, we can write the expression above more explicitly as

$$(Pv_u)(w) := \int v_u(w^\rho \exp(\nu z))\psi(z)dz,$$

To understand this expression, recall that $W_t = \exp(X_t)$ where $X_{t+1} = \rho X_t + \nu Z_{t+1}$.

As a result $W_{t+1} = \exp(X_{t+1}) = \exp(\rho \log(W_t) + \nu Z_{t+1}) = W_t^\rho \exp(\nu Z_{t+1})$.

The integral above regards the current wage W_t as fixed at w and takes the expectation of $v_u(w^\rho \exp(\nu Z_{t+1}))$.

58.3.2 Fitting

In theory, we should now proceed as follows:

1. Begin with a guess v
2. Applying T to obtain the update $v' = Tv$
3. Unless some stopping condition is satisfied, set $v = v'$ and go to step 2.

However, there is a problem we must confront before we implement this procedure: The iterates of the value function can neither be calculated exactly nor stored on a computer.

To see the issue, consider (58.1).

Even if v is a known function, the only way to store its update v' is to record its value $v'(w)$ for every $w \in \mathbb{R}_+$.

Clearly, this is impossible.

58.3.3 Fitted value function iteration

What we will do instead is use **fitted value function iteration**.

The procedure is as follows:

Let a current guess v be given.

Now we record the value of the function v' at only finitely many "grid" points $w_1 < w_2 < \cdots < w_I$ and then reconstruct v' from this information when required.

More precisely, the algorithm will be

1. Begin with an array **v** representing the values of an initial guess of the value function on some grid points $\{w_i\}$.
2. Build a function v on the state space $\mathbb{R}_+$ by interpolation or approximation, based on **v** and $\{w_i\}$.
3. Obtain and record the samples of the updated function $v'(w_i)$ on each grid point w_i.
4. Unless some stopping condition is satisfied, take this as the new array and go to step 1.

How should we go about step 2?

This is a problem of function approximation, and there are many ways to approach it.

What's important here is that the function approximation scheme must not only produce a good approximation to each v, but also that it combines well with the broader iteration algorithm described above.

One good choice from both respects is continuous piecewise linear interpolation.

This method

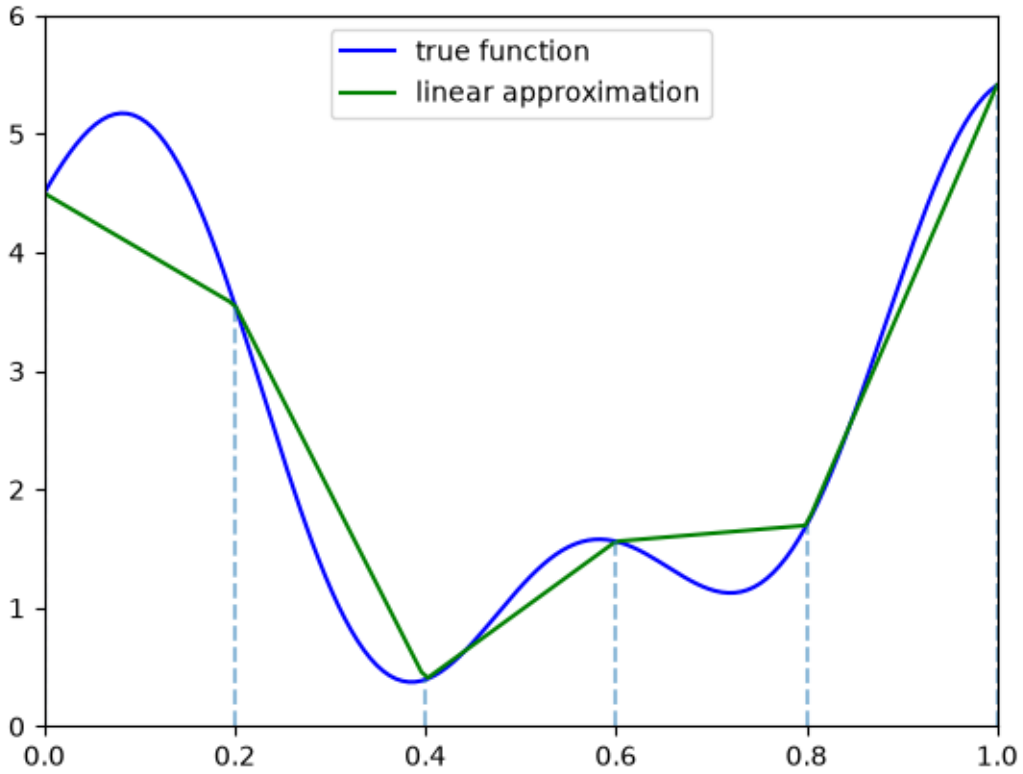
1. combines well with value function iteration (see, e.g., [Gordon, 1995] or [Stachurski, 2008]) and
2. preserves useful shape properties such as monotonicity and concavity/convexity.

Linear interpolation will be implemented using JAX's interpolation function `jnp.interp`.

The next figure illustrates piecewise linear interpolation of an arbitrary function on grid points $0, 0.2, 0.4, 0.6, 0.8, 1$.

```
def f(x):
    y1 = 2 * jnp.cos(6 * x) + jnp.sin(14 * x)
    return y1 + 2.5

c_grid = jnp.linspace(0, 1, 6)
f_grid = jnp.linspace(0, 1, 150)



def Af(x):
    return jnp.interp(x, c_grid, f(c_grid))

fig, ax = plt.subplots()

ax.plot(f_grid, f(f_grid), 'b-', label='true function')
ax.plot(f_grid, Af(f_grid), 'g-', label='linear approximation')
ax.vlines(c_grid, c_grid * 0, f(c_grid), linestyle='dashed', alpha=0.5)

ax.legend(loc="upper center")

ax.set(xlim=(0, 1), ylim=(0, 6))
plt.show()
```

58.4 Implementation

Let's code up and solve the model.

58.4.1 Setup

The first step is to build a JAX-compatible structure for the McCall model with separation and a continuous wage offer distribution.

The key computational challenge is evaluating the conditional expectation $(Pv_u)(w) = \int v_u(w')p(w,w')dw'$ at each wage grid point.

Recall that we have:

$$(Pv_u)(w) = \int v_u(w^\rho \exp(\nu z))\psi(z)dz$$

where ψ is the standard normal density.

We will approximate this integral using Monte Carlo integration with draws $\{Z_i\}$ from the standard normal distribution:

$$(Pv_u)(w) \approx \frac{1}{N}\sum_{i=1}^{N} v_u(w^\rho \exp(\nu Z_i))$$

For this reason, our data structure will include a fixed set of IID $N(0,1)$ draws $\{Z_i\}$.

```
class Model(NamedTuple):
    c: float              # unemployment compensation
    α: float              # job separation rate
    β: float              # discount factor
    ρ: float              # wage persistence
    ν: float              # wage volatility
    γ: float              # utility parameter
    w_grid: jnp.ndarray   # grid of points for fitted VFI
    z_draws: jnp.ndarray  # draws from the standard normal distribution

def create_mccall_model(
        c: float = 1.0,
        α: float = 0.05,
        β: float = 0.96,
        ρ: float = 0.9,
        ν: float = 0.2,
        γ: float = 1.5,
        grid_size: int = 100,
        mc_size: int = 1000,
        seed: int = 1234
    ):
    """Factory function to create a McCall model instance."""

    key = jax.random.key(seed)
    z_draws = jax.random.normal(key, (mc_size,))

    # Discretize just to get a suitable wage grid for interpolation
    mc = qe.markov.tauchen(grid_size, ρ, ν)
    w_grid = jnp.exp(jnp.array(mc.state_values))

    return Model(c, α, β, ρ, ν, γ, w_grid, z_draws)
```

We use the same CRRA utility function as in the discrete case:

```
def u(x, γ):
    return (x**(1 - γ) - 1) / (1 - γ)
```

58.4.2 Iteration

Here is the Bellman operator, where we use Monte Carlo integration to evaluate the expectation.

```
def T(model, v):
    """Update the value function."""

    # Unpack model parameters
    c, α, β, ρ, ν, γ, w_grid, z_draws = model

    # Interpolate array represented value function
    vf = lambda x: jnp.interp(x, w_grid, v)

    def compute_expectation(w):
        # Use Monte Carlo to evaluate integral (P v)(w) = E[v(W' | w)]
        # where W' = w^ρ * exp(ν * Z)
        w_next = w**ρ * jnp.exp(ν * z_draws)
        return jnp.mean(vf(w_next))
```

(continues on next page)

(continued from previous page)

```
    compute_exp_on_grid = jax.vmap(compute_expectation)
    Pv = compute_exp_on_grid(w_grid)

    d = 1 / (1 - β * (1 - α))
    v_e = d * (u(w_grid, γ) + α * β * Pv)
    continuation_values = u(c, γ) + β * Pv
    return jnp.maximum(v_e, continuation_values)
```

Here's the solver, which computes an approximate fixed point v_u of T.

```
@jax.jit
def vfi(
        model: Model,
        tolerance: float = 1e-6,    # Error tolerance
        max_iter: int = 100_000,    # Max iteration bound
    ):
    """
    Compute the fixed point v_u of T.

    """

    v_init = jnp.zeros(model.w_grid.shape)

    def cond(loop_state):
        v, error, i = loop_state
        return (error > tolerance) & (i <= max_iter)

    def update(loop_state):
        v, error, i = loop_state
        v_new = T(model, v)
        error = jnp.max(jnp.abs(v_new - v))
        new_loop_state = v_new, error, i + 1
        return new_loop_state

    initial_state = (v_init, tolerance + 1, 1)
    final_loop_state = lax.while_loop(cond, update, initial_state)
    v_final, error, i = final_loop_state

    return v_final
```

Here's a function that uses a solution v_u to compute the remaining functions of interest: v_e, and the continuation value function h.

We use the same expressions as we did in the *discrete case*, after replacing sums with integrals.

```
def compute_solution_functions(model, v_u):

    # Unpack model parameters
    c, α, β, ρ, ν, γ, w_grid, z_draws = model

    # Interpolate v_u on the wage grid
    vf = lambda x: jnp.interp(x, w_grid, v_u)

    def compute_expectation(w):
        # Use Monte Carlo to evaluate integral (P v)(w)
        # Compute E[v(w' | w)] where w' = w^ρ * exp(ν * z)
        w_next = w**ρ * jnp.exp(ν * z_draws)
```

(continues on next page)

(continued from previous page)

```
        return jnp.mean(vf(w_next))

    compute_exp_on_grid = jax.vmap(compute_expectation)
    Pv = compute_exp_on_grid(w_grid)

    d = 1 / (1 - β * (1 - α))
    v_e = d * (u(w_grid, γ) + α * β * Pv)
    h = u(c, γ) + β * Pv

    return v_e, h
```

Let's try solving the model:

```
model = create_mccall_model()
c, α, β, ρ, ν, γ, w_grid, z_draws = model
v_u = vfi(model)
v_e, h = compute_solution_functions(model, v_u)
```

Let's plot our results.

```
fig, ax = plt.subplots(figsize=(9, 5.2))
ax.plot(w_grid, h, 'g-', linewidth=2,
        label="continuation value function $h$")
ax.plot(w_grid, v_e, 'b-', linewidth=2,
        label="employment value function $v_e$")
ax.legend(frameon=False)
ax.set_xlabel(r"$w$")
plt.show()
```

The reservation wage is at the intersection of the employment value function v_e and the continuation value function h.

Here's a function to compute it explicitly.

```
@jax.jit
def get_reservation_wage(model: Model) -> float:
    """
    Calculate the reservation wage for a given model.

    """
    c, α, β, ρ, ν, γ, w_grid, z_draws = model

    v_u = vfi(model)
    v_e, h = compute_solution_functions(model, v_u)

    # Compute optimal policy (acceptance indices)
    σ = v_e >= h

    # Find first index where policy indicates acceptance
    first_accept_idx = jnp.argmax(σ) # returns first True value

    # If no acceptance (all False), return infinity
    # Otherwise return the wage at the first acceptance index
    return jnp.where(jnp.any(σ), w_grid[first_accept_idx], jnp.inf)
```

Let's repeat our plot, but now inserting the reservation wage.

```
w_bar = get_reservation_wage(model)

fig, ax = plt.subplots(figsize=(9, 5.2))
ax.plot(w_grid, h, 'g-', linewidth=2,
        label="continuation value function $h$")
ax.plot(w_grid, v_e, 'b-', linewidth=2,
        label="employment value function $v_e$")
ax.axvline(x=w_bar, color='black', linestyle='--', alpha=0.8,
           label=f'reservation wage $\\bar{{w}}$')
ax.legend(frameon=False)
ax.set_xlabel(r"$w$")
plt.show()
```

58.5 Simulation

Now we run some simulations with a focus on unemployment rate.

58.5.1 Single agent dynamics

Let's simulate the employment path of a single agent under the optimal policy.

We need a function to update the agent's state by one period.

```
def update_agent(key, status, wage, model, w_bar):
    """
    Updates an agent's employment status and current wage by one period.

    Parameters:
    - key: JAX random key
    - status: Current employment status (0 or 1)
    - wage: Current wage if employed, current offer if unemployed
    - model: Model instance
    - w_bar: Reservation wage

    """
    c, α, β, ρ, ν, γ, w_grid, z_draws = model

    # Draw new wage offer based on current wage
    key1, key2 = jax.random.split(key)
    z = jax.random.normal(key1)
    new_wage = wage**ρ * jnp.exp(ν * z)
```

(continues on next page)

(continued from previous page)

```
    # Check if separation occurs (for employed workers)
    separation_occurs = jax.random.uniform(key2) < α

    # Accept if current wage meets or exceeds reservation wage
    accepts = wage >= w_bar

    # If employed: status = 1 if no separation, 0 if separation
    # If unemployed: status = 1 if accepts, 0 if rejects
    next_status = jnp.where(
        status,
        1 - separation_occurs.astype(jnp.int32),  # employed path
        accepts.astype(jnp.int32)                 # unemployed path
    )

    # If employed: wage = current if no separation, new if separation
    # If unemployed: wage = current if accepts, new if rejects
    next_wage = jnp.where(
        status,
        jnp.where(separation_occurs, new_wage, wage),  # employed path
        jnp.where(accepts, wage, new_wage)             # unemployed path
    )

    return next_status, next_wage
```

Here's a function to simulate the employment path of a single agent.

```
def simulate_employment_path(
        model: Model,      # Model details
        w_bar: float,      # Reservation wage
        T: int = 2_000,    # Simulation length
        seed: int = 42     # Set seed for simulation
    ):
    """
    Simulate employment path for T periods starting from unemployment.

    """
    key = jax.random.key(seed)
    c, α, β, ρ, ν, γ, w_grid, z_draws = model

    # Initial conditions: start unemployed with initial wage draw
    status = 0
    key, subkey = jax.random.split(key)
    wage = jnp.exp(jax.random.normal(subkey) * ν)

    wage_path = []
    status_path = []

    for t in range(T):
        wage_path.append(wage)
        status_path.append(status)

        key, subkey = jax.random.split(key)
        status, wage = update_agent(
            subkey, status, wage, model, w_bar
        )

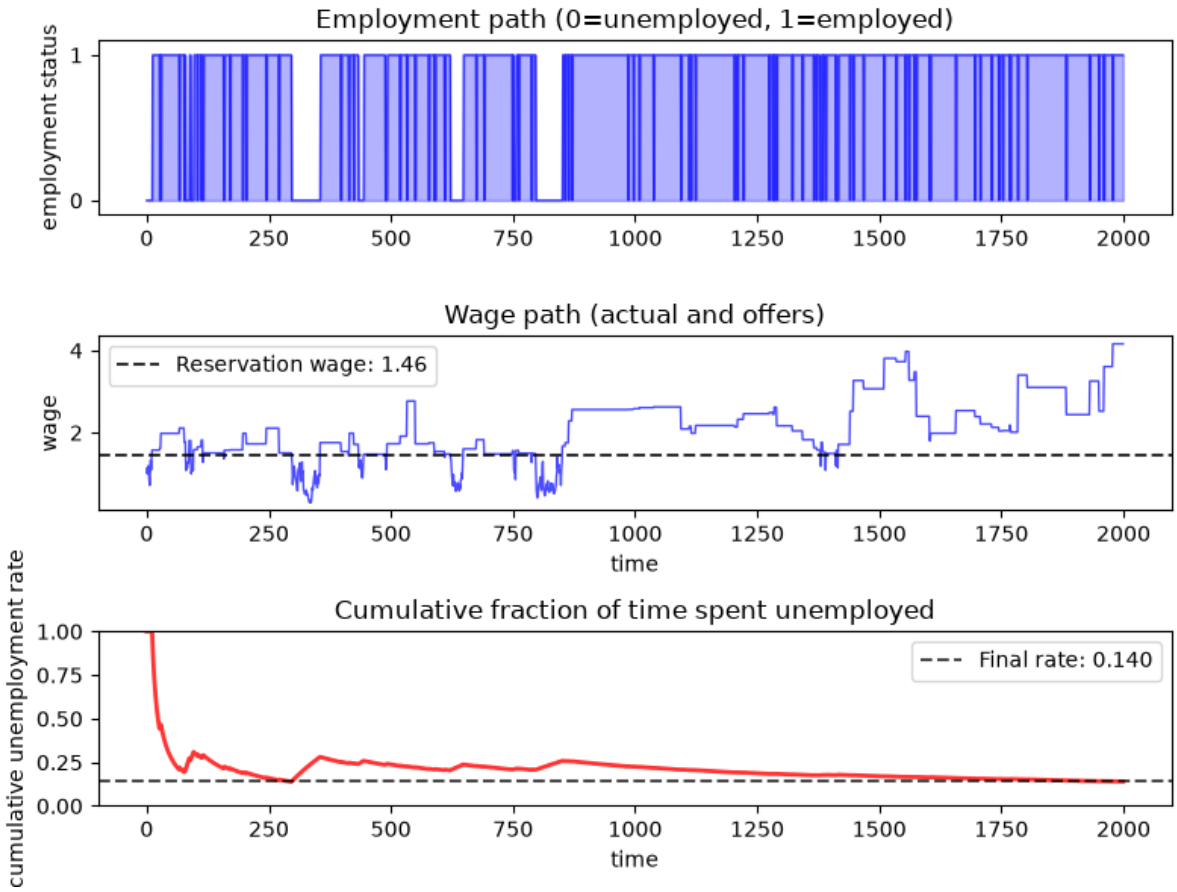
    return jnp.array(wage_path), jnp.array(status_path)
```

Let's create a comprehensive plot of the employment simulation:

```
model = create_mccall_model()
w_bar = get_reservation_wage(model)

wage_path, employment_status = simulate_employment_path(model, w_bar)

fig, (ax1, ax2, ax3) = plt.subplots(3, 1, figsize=(8, 6))



# Plot employment status
ax1.plot(employment_status, 'b-', alpha=0.7, linewidth=1)
ax1.fill_between(
    range(len(employment_status)), employment_status, alpha=0.3, color='blue'
)
ax1.set_ylabel('employment status')
ax1.set_title('Employment path (0=unemployed, 1=employed)')
ax1.set_yticks((0, 1))
ax1.set_ylim(-0.1, 1.1)

# Plot wage path with reservation wage
ax2.plot(wage_path, 'b-', alpha=0.7, linewidth=1)
ax2.axhline(y=w_bar, color='black', linestyle='--', alpha=0.8,
           label=f'Reservation wage: {w_bar:.2f}')
ax2.set_xlabel('time')
ax2.set_ylabel('wage')
ax2.set_title('Wage path (actual and offers)')
ax2.legend()

# Plot cumulative fraction of time unemployed
unemployed_indicator = (employment_status == 0).astype(int)
cumulative_unemployment = (
    jnp.cumsum(unemployed_indicator) /
    jnp.arange(1, len(employment_status) + 1)
)

ax3.plot(cumulative_unemployment, 'r-', alpha=0.8, linewidth=2)
ax3.axhline(y=jnp.mean(unemployed_indicator), color='black',
            linestyle='--', alpha=0.7,
            label=f'Final rate: {jnp.mean(unemployed_indicator):.3f}')
ax3.set_xlabel('time')
ax3.set_ylabel('cumulative unemployment rate')
ax3.set_title('Cumulative fraction of time spent unemployed')
ax3.legend()
ax3.set_ylim(0, 1)

plt.tight_layout()
plt.show()
```

The simulation shows the agent cycling between employment and unemployment.

The agent starts unemployed and receives wage offers according to the Markov process.

When unemployed, the agent accepts offers that exceed the reservation wage.

When employed, the agent faces job separation with probability α each period.

58.5.2 Cross-sectional analysis

Now let's simulate many agents simultaneously to examine the cross-sectional unemployment rate.

To do this efficiently, we need a different approach than `simulate_employment_path` defined above.

The key differences are:

- `simulate_employment_path` records the entire history (all T periods) for a single agent, which is useful for visualization but memory-intensive
- The new function `sim_agent` below only tracks and returns the final state, which is all we need for cross-sectional statistics
- `sim_agent` uses `lax.fori_loop` instead of a Python loop, making it JIT-compilable and suitable for vectorization across many agents

We first define a function that simulates a single agent forward T time steps:

```
@jax.jit
def sim_agent(key, initial_status, initial_wage, model, w_bar, T):
    """
    Simulate a single agent forward T time steps using lax.fori_loop.

    Uses fold_in to generate a new key at each time step.

    Parameters:
    - key: JAX random key for this agent
    - initial_status: Initial employment status (0 or 1)
    - initial_wage: Initial wage
    - model: Model instance
    - w_bar: Reservation wage
    - T: Number of time periods to simulate

    Returns:
    - final_status: Employment status after T periods
    - final_wage: Wage after T periods
    """
    def update(t, loop_state):
        status, wage = loop_state
        step_key = jax.random.fold_in(key, t)
        status, wage = update_agent(step_key, status, wage, model, w_bar)
        return status, wage

    initial_loop_state = (initial_status, initial_wage)
    final_loop_state = lax.fori_loop(0, T, update, initial_loop_state)
    final_status, final_wage = final_loop_state
    return final_status, final_wage

# Create vectorized version of sim_agent to process multiple agents in parallel
sim_agents_vmap = jax.vmap(sim_agent, in_axes=(0, 0, 0, None, None, None))

def simulate_cross_section(
        model: Model,
        n_agents: int = 100_000,
        T: int = 200,
        seed: int = 42
    ) -> float:
    """
    Simulate cross-section of agents and return unemployment rate.

    This approach:
    1. Generates n_agents random keys
    2. Calls sim_agent for each agent (vectorized via vmap)
    3. Collects the final states to produce the cross-section

    Returns the cross-sectional unemployment rate.
    """
    c, α, β, ρ, ν, γ, w_grid, z_draws = model

    key = jax.random.key(seed)

    # Solve for optimal reservation wage
    w_bar = get_reservation_wage(model)
```

(continues on next page)

(continued from previous page)

```
    # Initialize arrays
    init_key, subkey = jax.random.split(key)
    initial_wages = jnp.exp(jax.random.normal(subkey, (n_agents,)) * v)
    initial_status_vec = jnp.zeros(n_agents, dtype=jnp.int32)

    # Generate n_agents random keys
    agent_keys = jax.random.split(init_key, n_agents)

    # Simulate each agent forward T steps (vectorized)
    final_status, final_wages = sim_agents_vmap(
        agent_keys, initial_status_vec, initial_wages, model, w_bar, T
    )

    unemployment_rate = 1 - jnp.mean(final_status)
    return unemployment_rate
```

Now let's compare the time-average unemployment rate (from a single agent's long simulation) with the cross-sectional unemployment rate (from many agents at a single point in time).

```
model = create_mccall_model()
cross_sectional_unemp = simulate_cross_section(
    model, n_agents=20_000, T=200
)

time_avg_unemp = jnp.mean(unemployed_indicator)
print(f"Time-average unemployment rate (single agent, T=2000): "
      f"{time_avg_unemp:.4f}")
print(f"Cross-sectional unemployment rate (at t=200): "
      f"{cross_sectional_unemp:.4f}")
print(f"Difference: {abs(time_avg_unemp - cross_sectional_unemp):.4f}")
```

```
Time-average unemployment rate (single agent, T=2000): 0.1395
Cross-sectional unemployment rate (at t=200): 0.2029
Difference: 0.0634
```

The difference above can be further reduced by increasing the simulation length for the single agent.

```
wage_path_long, employment_status_long = simulate_employment_path(model, w_bar, T=10_
↪000)
unemployed_indicator_long = (employment_status_long == 0).astype(int)
time_avg_unemp_long = jnp.mean(unemployed_indicator_long)

print(f"Time-average unemployment rate (single agent, T=10000): "
      f"{time_avg_unemp_long:.4f}")
print(f"Cross-sectional unemployment rate (at t=200): "
      f"{cross_sectional_unemp:.4f}")
print(f"Difference: {abs(time_avg_unemp_long - cross_sectional_unemp):.4f}")
```

```
Time-average unemployment rate (single agent, T=10000): 0.2071
Cross-sectional unemployment rate (at t=200): 0.2029
Difference: 0.0042
```

58.5.3 Visualization

This function generates a histogram showing the distribution of employment status across many agents:

```
def plot_cross_sectional_unemployment(
        model: Model,            # Model instance with parameters
        t_snapshot: int = 200,   # Time for cross-sectional snapshot
        n_agents: int = 20_000   # Number of agents to simulate
    ):
    """
    Generate histogram of cross-sectional unemployment at a specific time.

    """
    c, α, β, ρ, ν, γ, w_grid, z_draws = model

    # Get final employment state directly
    key = jax.random.key(42)
    w_bar = get_reservation_wage(model)

    # Initialize arrays
    init_key, subkey = jax.random.split(key)
    initial_wages = jnp.exp(jax.random.normal(subkey, (n_agents,)) * ν)
    initial_status_vec = jnp.zeros(n_agents, dtype=jnp.int32)

    # Generate n_agents random keys
    agent_keys = jax.random.split(init_key, n_agents)

    # Simulate each agent forward T steps (vectorized)
    final_status, _ = sim_agents_vmap(
        agent_keys, initial_status_vec, initial_wages, model, w_bar, t_snapshot
    )

    # Calculate unemployment rate
    unemployment_rate = 1 - jnp.mean(final_status)

    fig, ax = plt.subplots(figsize=(8, 5))

    # Plot histogram as density (bars sum to 1)
    weights = jnp.ones_like(final_status) / len(final_status)
    ax.hist(final_status, bins=[-0.5, 0.5, 1.5],
            alpha=0.7, color='blue', edgecolor='black',
            density=True, weights=weights)

    ax.set_xlabel('employment status (0=unemployed, 1=employed)')
    ax.set_ylabel('density')
    ax.set_title(f'Cross-sectional distribution at t={t_snapshot}, ' +
                 f'unemployment rate = {unemployment_rate:.3f}')
    ax.set_xticks([0, 1])

    plt.tight_layout()
    plt.show()
```

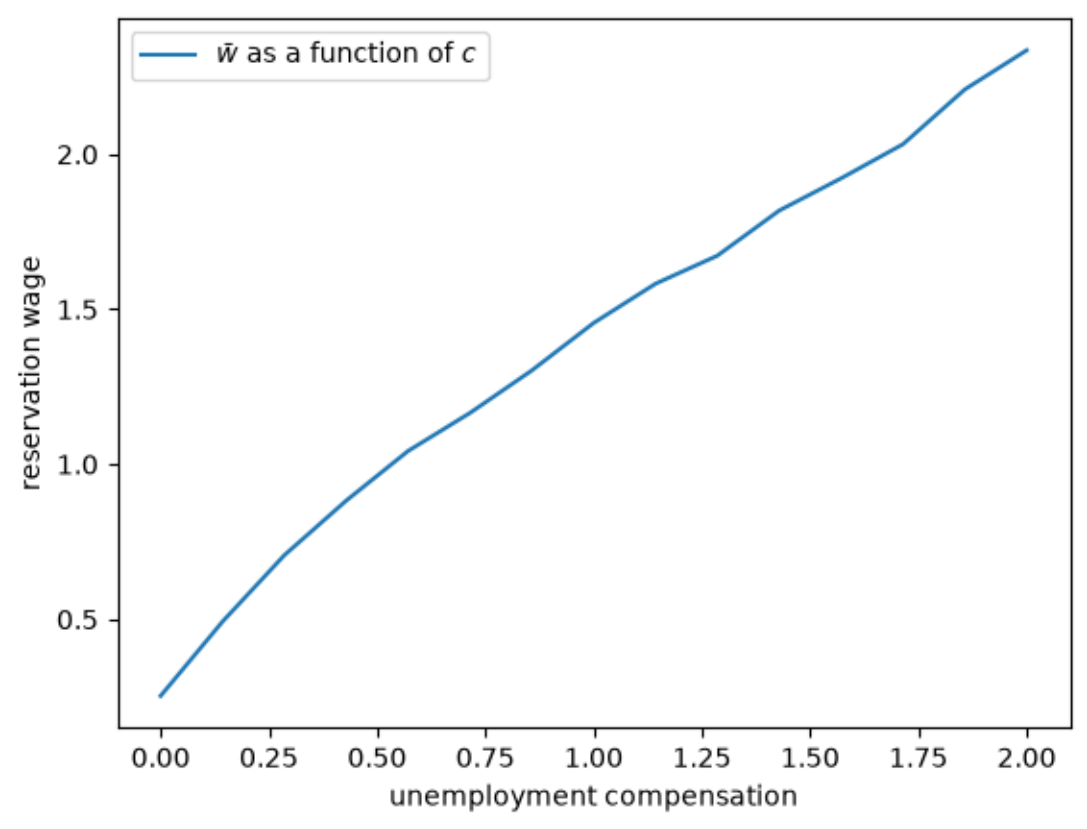
Let's plot the cross-sectional distribution:

```
plot_cross_sectional_unemployment(model)
```

58.6 Exercises

Exercise 58.6.1

Use the code above to explore what happens to the reservation wage when c changes.



Solution

Here is one solution

```
def compute_res_wage_given_c(c):
    model = create_mccall_model(c=c)
    w_bar = get_reservation_wage(model)
    return w_bar

c_vals = jnp.linspace(0.0, 2.0, 15)
w_bar_vals = jax.vmap(compute_res_wage_given_c)(c_vals)

fig, ax = plt.subplots()
ax.set(xlabel='unemployment compensation', ylabel='reservation wage')
ax.plot(c_vals, w_bar_vals, label=r'$\bar w$ as a function of $c$')
ax.legend()
plt.show()
```

As unemployment compensation increases, the reservation wage also increases.

This makes economic sense: when the value of being unemployed rises (through higher c), workers become more selective about which job offers to accept.

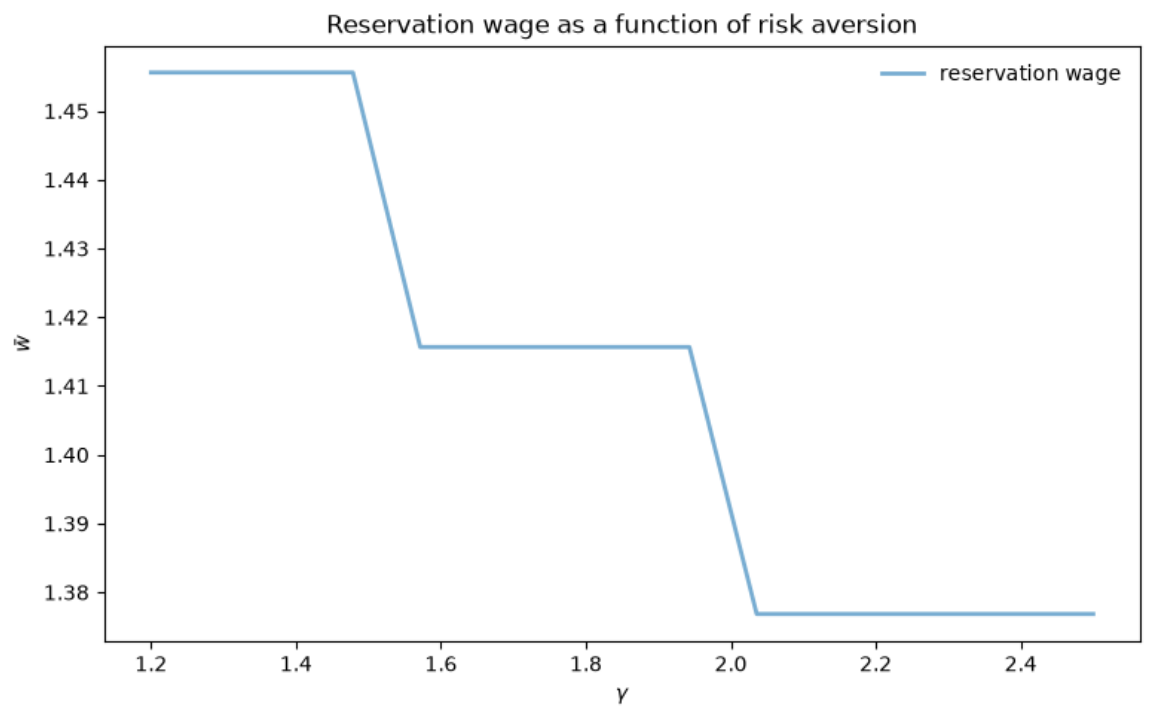
Exercise 58.6.2

Create a plot that shows how the reservation wage changes with the risk aversion parameter γ.

Use `γ_vals = jnp.linspace(1.2, 2.5, 15)` and keep all other parameters at their default values.

How do you expect the reservation wage to vary with γ? Why?

Solution



We compute the reservation wage for different values of the risk aversion parameter:

```
γ_vals = jnp.linspace(1.2, 2.5, 15)
w_bar_vec = jnp.empty_like(γ_vals)

for i, γ in enumerate(γ_vals):
    model = create_mccall_model(γ=γ)
    w_bar = get_reservation_wage(model)
    w_bar_vec = w_bar_vec.at[i].set(w_bar)

fig, ax = plt.subplots(figsize=(9, 5.2))
```

```
ax.plot(γ_vals, w_bar_vec, linewidth=2, alpha=0.6,
        label='reservation wage')
ax.legend(frameon=False)
ax.set_xlabel(r'$\gamma$')
ax.set_ylabel(r'$\bar{w}$')
ax.set_title('Reservation wage as a function of risk aversion')
plt.show()
```

As risk aversion (γ) increases, the reservation wage decreases.

This occurs because more risk-averse workers place higher value on the security of employment relative to the uncertainty of continued search.

With higher γ, the utility cost of unemployment (foregone consumption) becomes more severe, making workers more willing to accept lower wages rather than continue searching.

CHAPTER

FIFTYNINE

JOB SEARCH V: RISK-SENSITIVE PREFERENCES

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

Contents

- *Job Search V: Risk-Sensitive Preferences*
  - *Overview*
  - *Outline*
  - *Introduction to risk-sensitivity*
  - *Back to job search*

59.1 Overview

Risk-sensitive preferences are a common addition to various types of dynamic programming problems.

This lecture gives an introduction to risk-sensitive recursive preferences via job search.

Some motivation is given below.

59.2 Outline

In real-world job-related decisions, individuals and households care about risk.

For example, some individuals might prefer to take a moderate offer already in hand over the risky possibility of a higher offer in the next period, even without discounting future payoffs.

(A bird in the hand is worth two in the bush, etc.)

In previous job search lectures in this series, we inserted some degree of risk aversion by adding a concave flow utility function u.

Unfortunately, this strategy does not isolate preferences over the kind of risk we described above.

This is because adding a concave utility function changes the agent's preferences in other ways, such as in their desire for consumption smoothing.

Hence, if we want to study the pure effects of risk, we need a different solution.

One possibility is to add risk-sensitive preferences.

Here we show how this can be done and study what effects it has on agent choices.

We'll use JAX and the QuantEcon library:

```
!pip install quantecon
```

We use the following imports.

```
import jax
import jax.numpy as jnp
from jax import lax
import quantecon as qe
from typing import NamedTuple
import numpy as np
import matplotlib.pyplot as plt
```

59.3 Introduction to risk-sensitivity

Let's start our discussion in a static environment.

If Y is a random payoff and an agent's evaluation of the payoff is $e := \mathbb{E}Y$, then we say that the agent is **risk neutral**.

Sometimes we want to model agents as risk averse.

One way to do this is to change their evaluation of the payoff Y to

$$e_\theta = \frac{1}{\theta} \ln \left(\mathbb{E}[\exp(\theta Y)] \right)$$

where θ is a number satisfying $\theta < 0$.

The value e_θ is sometimes called the **entropic risk-adjusted expectation** of Y.

59.3.1 A Gaussian example

One way to see the impact is to suppose that Y has the normal distribution $N(\mu, \sigma^2)$, so that its mean is μ and its variance is σ^2.

For this Y we aim to compute the risk-adjusted expectation.

This becomes straightforward if we recognize that $\mathbb{E}[\exp(\theta Y)]$ is the moment generating function (MGF) of the normal distribution.

Using the well-known expression for the MGF of the normal distribution, we get

$$\mathbb{E}[\exp(\theta Y)] = \exp\left(\theta\mu + \frac{\theta^2\sigma^2}{2}\right)$$

Therefore,

$$e_\theta = \frac{1}{\theta}\ln\left(\exp\left(\theta\mu + \frac{\theta^2\sigma^2}{2}\right)\right) = \frac{1}{\theta}\left(\theta\mu + \frac{\theta^2\sigma^2}{2}\right)$$

Simplifying yields

$$e_\theta = \mu + \frac{\theta\sigma^2}{2}$$

We see immediately that the agent prefers a higher average payoff μ.

At the same time, given that $\theta < 0$, the risk-adjusted expectation decreases in σ.

In particular, e_θ decreases as risk increases.

Here is a visualization of e_θ as a function of μ and σ using a contour plot, with $\theta = -1$.

```
θ = -1

μ_vals = np.linspace(-2, 5, 200)
σ_vals = np.linspace(0.1, 3, 200)
μ_grid, σ_grid = np.meshgrid(μ_vals, σ_vals)

e_θ = μ_grid + (θ * σ_grid**2) / 2

# Create contour plot
fig, ax = plt.subplots()
contour = ax.contour(
    μ_grid, σ_grid, e_θ, levels=20, colors='black', linewidths=0.5
)
contourf = ax.contourf(
    μ_grid, σ_grid, e_θ, levels=20, cmap='viridis'
)
ax.clabel(contour, inline=True)
cbar = plt.colorbar(contourf, ax=ax)
cbar.set_label(r'$e_\theta$', rotation=0)

ax.set_xlabel(r'$\mu$ (mean)')
ax.set_ylabel(r'$\sigma$ (standard deviation)')
plt.tight_layout()
plt.show()
```

Again, we see that the agent prefers a higher average payoff but dislikes risk.

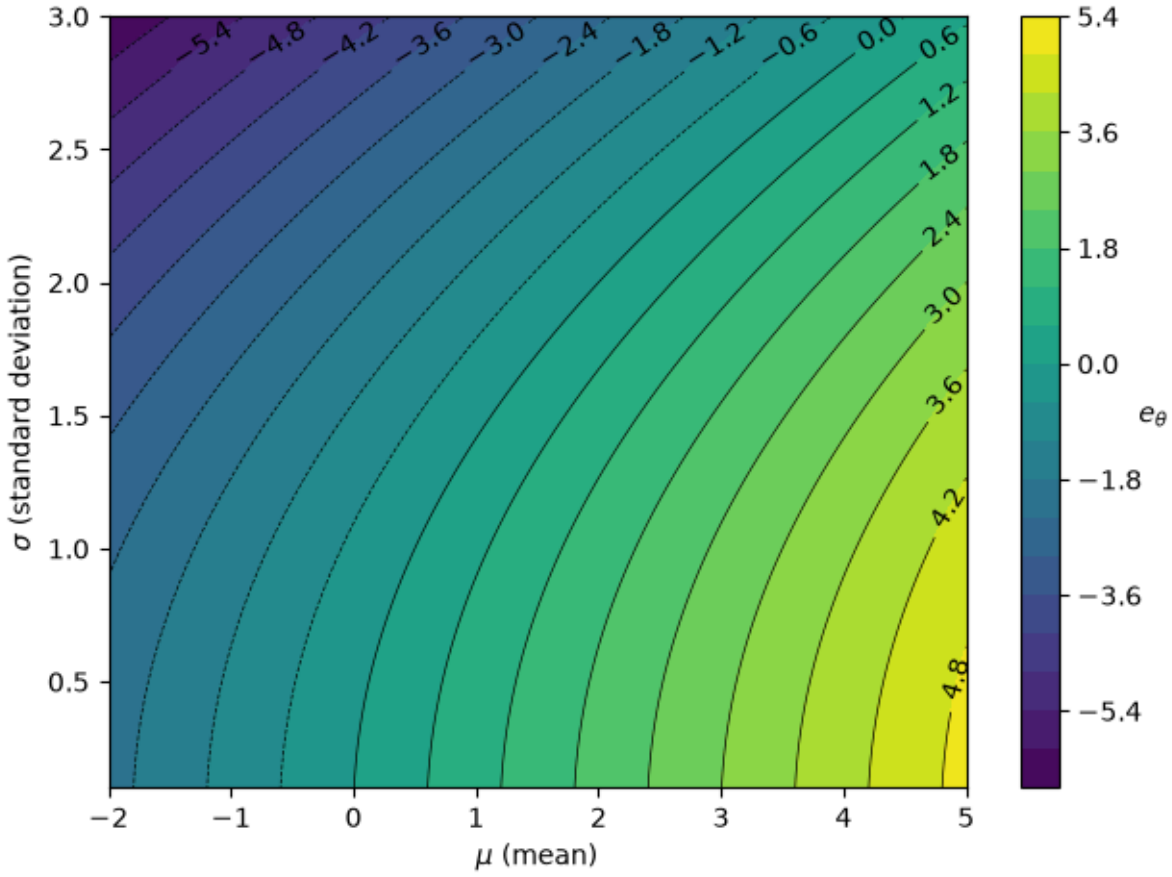


Fig. 59.1: Entropic risk-adjusted expectation, Gaussian case

59.3.2 A more general case

The preceding analysis relies on the Gaussian (normal) assumption to get an analytical solution.

We can investigate all other cases using simulation.

For example, suppose that Y has the Beta(a, b) distribution.

Here we set $a = b = 2.0$ and calculate e_θ using Monte Carlo

The method is:

1. sample $Y_1, \ldots, Y_n$ from Beta$(2, 2)$
2. replace $\mathbb{E}$ with an average over $\exp(\theta Y_i)$

We do this for θ in a grid of 100 points between -2 and -0.1.

Here is a plot of e_θ against θ.

```
# Set parameters
a, b = 2.0, 2.0
mc_size = 1_000_000  # Large number of Monte Carlo samples
θ_grid = jnp.linspace(-2, -0.1, 100)

# Draw samples from Beta(2, 2) distribution using JAX
key = jax.random.key(1234)
Y_samples = jax.random.beta(key, a, b, shape=(mc_size,))

# Define function to compute e_θ for a single θ value
def compute_e_θ(θ):
    """Compute e_θ = (1/θ) * ln(E[exp(θ * Y)])"""
    expectation = jnp.mean(jnp.exp(θ * Y_samples))
    return (1 / θ) * jnp.log(expectation)

# Vectorize over θ_grid using vmap
compute_e_θ_vec = jax.vmap(compute_e_θ)
e_θ_values = compute_e_θ_vec(θ_grid)

# Plot results
fig, ax = plt.subplots()
ax.plot(θ_grid, e_θ_values, lw=2)
ax.set_xlabel(r'$\theta$')
ax.set_ylabel(r'$e_\theta$')
ax.axhline(y=0.5, color='black', linestyle='--',
           linewidth=1, label=r'$\mathbb{E}[Y] = 0.5$')
ax.legend()
plt.tight_layout()
plt.show()
```

The plot shows how the risk-adjusted evaluation e_θ changes with the risk aversion parameter θ.

As $\theta \to 0$, the value e_θ approaches the expected value of Y, which is $\mathbb{E}[Y] = \frac{a}{a+b} = \frac{2}{4} = 0.5$ for Beta(2,2).

This makes sense because when $\theta \to 0$, the agent becomes risk neutral.

As θ becomes more negative, e_θ decreases.

This reflects that a more risk-averse agent values the uncertain payoff Y less than its expected value.

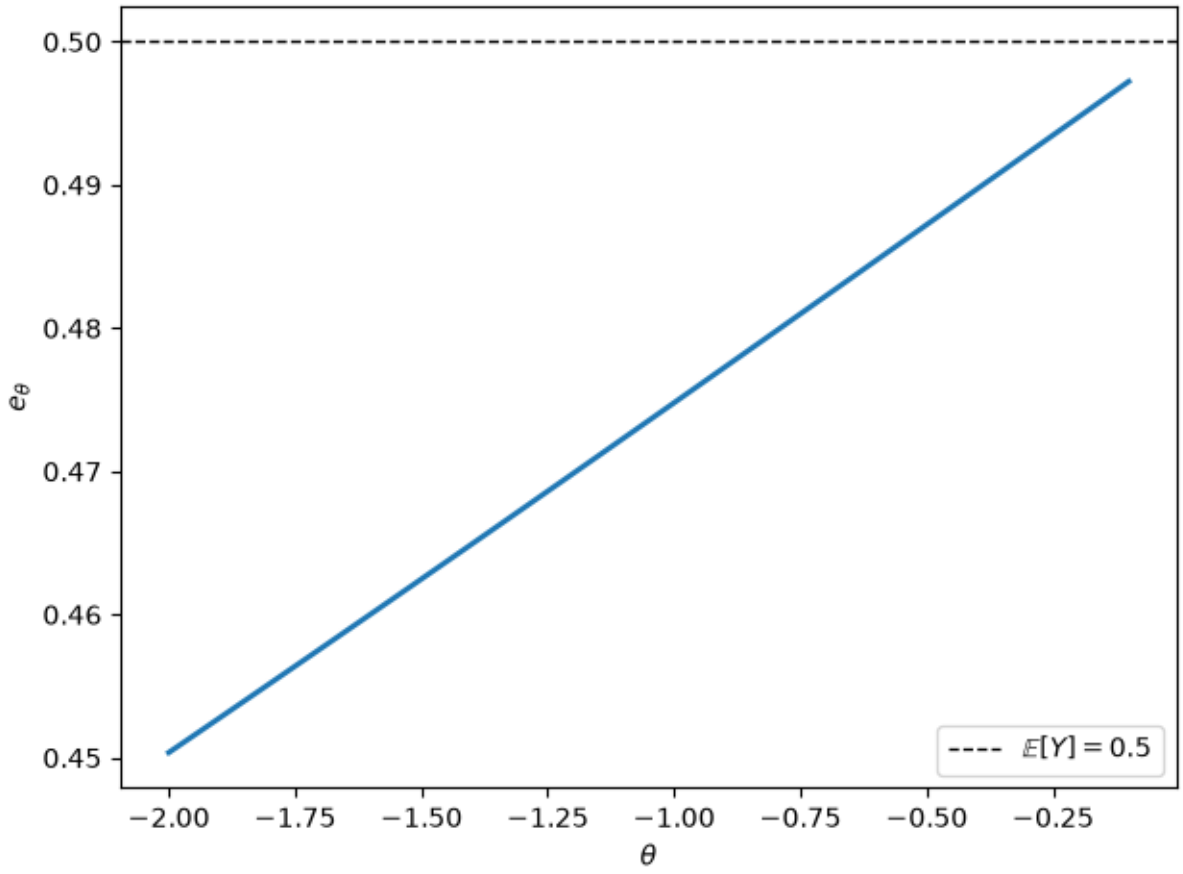

Fig. 59.2: Risk-adjusted evaluation against risk aversion

59.3.3 A mean preserving spread

The next exercise asks you to study the impact of a mean-preserving spread on the risk-adjusted expectation.

Exercise 59.3.1

Keep $Y \sim \text{Beta}(2, 2)$ and fix $\theta = -2$.

Using Monte Carlo again, calculate

$$e_\theta = \frac{1}{\theta} \ln \left(\mathbb{E}[\exp(\theta X)] \right)$$

where $X = Y + \sigma Z$ and Z is standard normal.

How does e_θ change with σ?

Can you provide some intuition for what is happening (given that the agent is risk averse)?

Use a plot to illustrate your results.

Solution

Here's our solution.

```
a, b = 2.0, 2.0
θ = -2.0
mc_size = 1_000_000  # Large number of Monte Carlo samples
σ_grid = jnp.linspace(0.0, 1.0, 50)

# Set random seed for reproducibility
key = jax.random.key(1234)
key_y, key_z = jax.random.split(key)

# Draw samples from Beta(2, 2) distribution
Y_samples = jax.random.beta(key_y, a, b, shape=(mc_size,))

# Draw standard normal samples (reused for all σ values)
Z_samples = jax.random.normal(key_z, shape=(mc_size,))

# Define function to compute e_θ for a single σ value
def compute_e_θ(σ):
    """Compute e_θ for X = Y + σ * Z"""
    # Compute X = Y + σ * Z
    X_samples = Y_samples + σ * Z_samples

    # Calculate E[exp(θ * X)] using Monte Carlo
    expectation = jnp.mean(jnp.exp(θ * X_samples))

    # Calculate e_θ
    return (1 / θ) * jnp.log(expectation)

# Vectorize over σ_grid using vmap
compute_e_θ_vec = jax.vmap(compute_e_θ)
e_θ_values = compute_e_θ_vec(σ_grid)

# Plot results
fig, ax = plt.subplots()
```

```
ax.plot(σ_grid, e_θ_values, lw=2, label=r'$e_\theta(\sigma)$')
ax.set_xlabel(r'$\sigma$ (noise level)')
ax.set_ylabel(r'$e_\theta$')
ax.set_title(r'Risk-adjusted evaluation as noise increases')
ax.axhline(y=e_θ_values[0], color='black', linestyle='--', linewidth=1,
           label=f'No noise: $e_\\theta$ = {e_θ_values[0]:.3f}')
ax.legend()
plt.tight_layout()
plt.show()
```

The plot clearly shows that e_θ decreases monotonically as σ increases.

Since the agent is risk averse ($\theta = -2 < 0$), she dislikes uncertainty.

As we increase σ, we get more volatility, since

$$\text{Var}(X) = \text{Var}(Y) + \sigma^2 \text{Var}(Z) = \text{Var}(Y) + \sigma^2$$

At the same time, the expected value is unchanged, since

$$\mathbb{E}[X] = \mathbb{E}[Y + \sigma Z] = \mathbb{E}[Y] + \sigma \mathbb{E}[Z] = \mathbb{E}[Y] = 0.5$$

Hence the mean payoff doesn't change with σ.

In other words, the risk averse agent is not compensated for bearing additional risk.

This is why the valuation of the random payoff goes down.

59.4 Back to job search

In the lecture *Job Search IV: Fitted Value Function Iteration* we studied a job search model with separation, Markov wage draws and fitted value function iteration.

The wage offer process is continuous and obeys

$$W_t = \exp(X_t) \quad \text{where} \quad X_{t+1} = \rho X_t + \nu Z_{t+1}$$

and $\{Z_t\}$ is IID and standard normal.

Let's now study the same model but replacing the assumption of risk neutral expectations with risk averse expectations.

In particular, the conditional expectation

$$(Pv_u)(w) = \mathbb{E} v_u(w^\rho \exp(\nu Z))$$

from that lecture is replaced with

$$(P_\theta v_u)(w) = \frac{1}{\theta} \ln \left[\mathbb{E} \exp(\theta v_u(w^\rho \exp(\nu Z))) \right]$$

Otherwise the model is the same.

We now solve the dynamic program and study the impact of θ on the reservation wage.

59.4.1 Setup

Here's a class to store parameters and default parameter values.

```
class Model(NamedTuple):
    c: float              # unemployment compensation
    α: float              # job separation rate
    β: float              # discount factor
    ρ: float              # wage persistence
    ν: float              # wage volatility
    θ: float              # risk aversion parameter
    w_grid: jnp.ndarray   # grid of points for fitted VFI
    z_draws: jnp.ndarray  # draws from the standard normal distribution

def create_mccall_model(
        c: float = 1.0,
        α: float = 0.1,
        β: float = 0.96,
        ρ: float = 0.9,
        ν: float = 0.2,
        θ: float = -1.5,
        grid_size: int = 100,
        mc_size: int = 1000,
        seed: int = 1234
    ):
    """Factory function to create a McCall model instance."""

    key = jax.random.key(seed)
    z_draws = jax.random.normal(key, (mc_size,))

    # Discretize just to get a suitable wage grid for interpolation
```

(continues on next page)

(continued from previous page)

```
    mc = qe.markov.tauchen(grid_size, ρ, ν)
    w_grid = jnp.exp(jnp.array(mc.state_values))

    return Model(c, α, β, ρ, ν, θ, w_grid, z_draws)
```

59.4.2 Bellman equations

Our construction is a direct extension of the Bellman equations in *Job Search IV: Fitted Value Function Iteration*.

First we use the employed worker's Bellman equation to express $v_e(w)$ in terms of $(P_\theta v_u)(w)$:

$$v_e(w) = \frac{1}{1-\beta(1-\alpha)} \cdot (u(w) + \alpha\beta(P_\theta v_u)(w))$$

We substitute into the unemployed agent's Bellman equation to get:

$$v_u(w) = \max\left\{\frac{1}{1-\beta(1-\alpha)} \cdot (u(w) + \alpha\beta(P_\theta v_u)(w)), u(c) + \beta(P_\theta v_u)(w)\right\}$$

We use value function iteration to solve for v_u.

Then we compute the optimal policy: accept if $v_e(w) \geq u(c) + \beta(P_\theta v_u)(w)$

Here's the Bellman operator that updates v_u.

```
def T(model, v):
    # Unpack model parameters
    c, α, β, ρ, ν, θ, w_grid, z_draws = model

    # Interpolate array represented value function
    vf = lambda x: jnp.interp(x, w_grid, v)

    def compute_expectation(w):
        # Use Monte Carlo to evaluate integral (P_θ v)(w)
        inner = jnp.mean(jnp.exp(θ * vf(w**ρ * jnp.exp(ν * z_draws))))
        return (1 / θ) * jnp.log(inner)

    compute_exp_all = jax.vmap(compute_expectation)
    P_θ_v = compute_exp_all(w_grid)

    d = 1 / (1 - β * (1 - α))
    accept = d * (w_grid + α * β * P_θ_v)
    reject = c + β * P_θ_v
    return jnp.maximum(accept, reject)
```

Here's the solver:

```
@jax.jit
def vfi(
        model: Model,
        tolerance: float = 1e-6,    # Error tolerance
        max_iter: int = 100_000,    # Max iteration bound
    ):

    v_init = jnp.zeros(model.w_grid.shape)
```

(continues on next page)

(continued from previous page)

```
    def cond(loop_state):
        v, error, i = loop_state
        return (error > tolerance) & (i <= max_iter)

    def update(loop_state):
        v, error, i = loop_state
        v_new = T(model, v)
        error = jnp.max(jnp.abs(v_new - v))
        new_loop_state = v_new, error, i + 1
        return new_loop_state

    initial_state = (v_init, tolerance + 1, 1)
    final_loop_state = lax.while_loop(cond, update, initial_state)
    v_final, error, i = final_loop_state

    return v_final
```

The next function computes the optimal policy under the assumption that v is the value function:

```
def get_greedy(v: jnp.ndarray, model: Model) -> jnp.ndarray:
    """Get a v-greedy policy."""
    c, α, β, ρ, ν, θ, w_grid, z_draws = model

    # Interpolate array represented value function
    vf = lambda x: jnp.interp(x, w_grid, v)

    def compute_expectation(w):
        # Use Monte Carlo to evaluate integral (P_θ v)(w)
        inner = jnp.mean(jnp.exp(θ * vf(w**ρ * jnp.exp(ν * z_draws))))
        return (1 / θ) * jnp.log(inner)

    compute_exp_all = jax.vmap(compute_expectation)
    P_θ_v = compute_exp_all(w_grid)

    d = 1 / (1 - β * (1 - α))
    accept = d * (w_grid + α * β * P_θ_v)
    reject = c + β * P_θ_v
    σ = accept >= reject
    return σ
```

Here's a function that takes an instance of `Model` and returns the associated reservation wage.

```
@jax.jit
def get_reservation_wage(σ: jnp.ndarray, model: Model) -> float:
    """
    Calculate the reservation wage from a given policy.

    Parameters:
    - σ: Policy array where σ[i] = True means accept wage w_grid[i]
    - model: Model instance containing wage values

    Returns:
    - Reservation wage (lowest wage for which policy indicates acceptance)
    """
    c, α, β, ρ, ν, θ, w_grid, z_draws = model

    # Find the first index where policy indicates acceptance
```

(continues on next page)

(continued from previous page)

```
    # σ is a boolean array, argmax returns the first True value
    first_accept_idx = jnp.argmax(σ)

    # If no acceptance (all False), return infinity
    # Otherwise return the wage at the first acceptance index
    return jnp.where(jnp.any(σ), w_grid[first_accept_idx], jnp.inf)
```

Let's solve the model at the default parameters:

```
# First, let's solve for the default θ = -1.5
model = create_mccall_model()
c, α, β, ρ, ν, θ, w_grid, z_draws = model

print(f"Solving model with θ = {θ}")
v_star = vfi(model)
σ_star = get_greedy(v_star, model)
w_bar = get_reservation_wage(σ_star, model)
print(f"Reservation wage at default parameters: {w_bar:.4f}")
```

```
Solving model with θ = -1.5
Reservation wage at default parameters: 1.0720
```

59.4.3 How does the reservation wage vary with θ?

Now let's examine how the reservation wage changes as we vary the risk aversion parameter.

```
# Create a grid of θ values (all negative for risk aversion)
θ_grid = jnp.linspace(-3.0, -0.1, 25)

# Define function to compute reservation wage for a single θ value
def compute_res_wage_for_theta(θ):
    """Compute reservation wage for a given θ value"""
    model = create_mccall_model(θ=θ)
    v = vfi(model)
    σ = get_greedy(v, model)
    w_bar = get_reservation_wage(σ, model)
    return w_bar

# Vectorize over θ_grid using vmap
compute_res_wages_vec = jax.vmap(compute_res_wage_for_theta)
reservation_wages = compute_res_wages_vec(θ_grid)

# Plot the results
fig, ax = plt.subplots()
ax.plot(θ_grid, reservation_wages,
        lw=2, marker='o', markersize=4)
ax.set_xlabel(r'$\theta$ (risk aversion parameter)')
ax.set_ylabel('Reservation wage')
ax.axvline(x=-1.5, color='black', ls='--',
           linewidth=1, label=r'Default $\theta = -1.5$')
ax.legend()
plt.tight_layout()
plt.show()
```

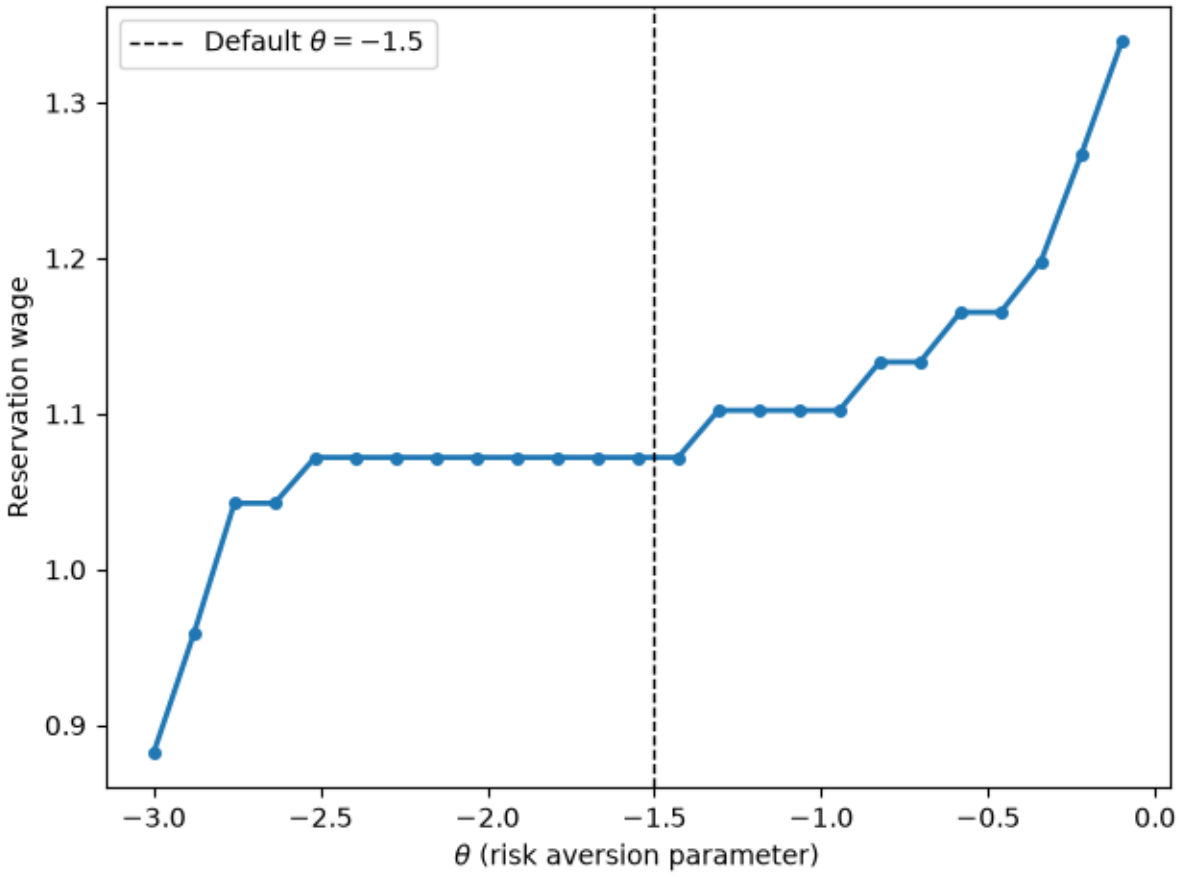

Fig. 59.3: Reservation wage against risk aversion

The reservation wage increases as θ becomes less negative (moves toward zero)

Equivalently, the reservation wage decreases as the agent becomes more risk averse (more negative θ).

The reason is that a more risk-averse agent values the certain income from employment more highly relative to the uncertain future prospects of continued search.

Therefore, they are willing to accept lower wages to escape unemployment.

Exercise 59.4.1

Use simulation to investigate how the long-run unemployment rate varies with θ.

Use the parameters from the previous section, where we studied how the reservation wage varies with θ.

You can use code for simulation from *Job Search IV: Fitted Value Function Iteration*, suitably modified.

Solution

To compute the long-run unemployment rate, we first write a function to update a single agent.

```
@jax.jit
def simulate_single_agent(key, model, w_star, num_periods=200):
    """
    Simulate a single agent for num_periods periods.
    Returns final employment status (1 if employed, 0 if unemployed).
    """
    c, α, β, ρ, ν, θ, w_grid, z_draws = model

    # Start from arbitrary initial conditions
    w = 1.0
    status = 1

    def update(t, loop_state):
        w, status, key = loop_state
        key, k1, k2 = jax.random.split(key, 3)

        # Update wage
        z = jax.random.normal(k2)
        w_new = w**ρ * jnp.exp(ν * z)

        # Employment transitions
        sep_draw = jax.random.uniform(k1)
        becomes_unemployed = sep_draw < α

        # Check if unemployed worker accepts wage
        accepts_job = w >= w_star

        # Update employment status
        new_status = jnp.where(
            status,
            1 - becomes_unemployed,    # employed path
            accepts_job                # unemployed path
        )

        new_wage = jnp.where(
            status,
            jnp.where(becomes_unemployed, w_new, w),   # employed path
```

```
            jnp.where(accepts_job, w, w_new)          # unemployed path
        )

        return (new_wage, new_status, key)

    init_state = (w, status, key)
    final_state = lax.fori_loop(0, num_periods, update, init_state)
    _, final_status, _ = final_state
    return final_status

def compute_unemployment_rate(model, w_star, num_agents=1000, num_periods=200,␣
↪seed=12345):
    """
    Compute unemployment rate via cross-sectional simulation.

    Instead of simulating one agent for a long time series, we simulate
    many agents in parallel for a shorter time period. This is much more
    efficient with JAX parallelization.

    The steady state satisfies:
    - Employed workers lose jobs at rate α
    - Unemployed workers find acceptable jobs at rate (1 - F(w*))

    We simulate num_agents agents for num_periods each, then compute
    the fraction unemployed at the end.
    """
    # Create keys for each agent
    key = jax.random.key(seed)
    keys = jax.random.split(key, num_agents)

    # Vectorize simulation across agents (parallelization!)
    simulate_agents = jax.vmap(
        lambda k: simulate_single_agent(k, model, w_star, num_periods)
    )

    # Run all agents in parallel
    status_cross_section = simulate_agents(keys)

    # Unemployment rate is 1 - mean(status) since status=1 means employed
    unemployment_rate = 1 - jnp.mean(status_cross_section)

    return unemployment_rate

# Define function to compute unemployment rate for a single θ value
def compute_u_rate_for_theta(θ):
    """Compute unemployment rate for a given θ value"""
    model = create_mccall_model(θ=θ)
    v = vfi(model)
    σ = get_greedy(v, model)
    w_star = get_reservation_wage(σ, model)
    u_rate = compute_unemployment_rate(
        model, w_star, num_agents=5000, num_periods=200
    )
    return u_rate
```

```
# Vectorize over θ_grid using vmap
compute_u_rates_vec = jax.vmap(compute_u_rate_for_theta)
unemployment_rates = compute_u_rates_vec(θ_grid)

# Plot the results
fig, ax = plt.subplots()
ax.plot(θ_grid, unemployment_rates * 100,
        lw=2, marker='s', markersize=4)
ax.set_xlabel(r'$\theta$ (risk aversion parameter)')
ax.set_ylabel('Long-run unemployment rate (%)')
ax.set_title('Unemployment rate as a function of risk aversion')
ax.axvline(x=-1.5, color='black', ls='--', linewidth=1, label=r'Default $\theta = -
↪1.5$')
ax.legend()
plt.tight_layout()
plt.show()
```

We see that the unemployment rate decreases as the agent becomes more risk averse (more negative θ).

This is because more risk-averse workers have lower reservation wages, so they accept a wider range of job offers.

As a result, they spend less time unemployed searching for better opportunities

CHAPTER

SIXTY

JOB SEARCH VI: PERSISTENT AND TRANSITORY WAGE SHOCKS

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

Contents

- *Job Search VI: Persistent and Transitory Wage Shocks*
  - *Overview*
  - *The model*
  - *Implementation*
  - *Unemployment duration*
  - *Exercises*

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon jax
```

60.1 Overview

In this lecture we extend the *McCall job search model* by decomposing wage offers into **persistent** and **transitory** components.

In the *baseline model*, wage offers are IID over time, which is unrealistic.

In *Job Search III*, we introduced correlated wage draws using a Markov chain, but we also added job separation.

Here we take a different approach: we model wage dynamics through an AR(1) process for the persistent component plus a transitory shock, while returning to the assumption that jobs are permanent (as in the *baseline model*).

This persistent-transitory decomposition is:

- More realistic for modeling actual wage processes
- Commonly used in labor economics (see, e.g., [MaCurdy, 1982], [Meghir and Pistaferri, 2004])
- Simple enough to analyze while capturing key features of wage dynamics

By keeping jobs permanent, we can focus on understanding how persistent and transitory wage shocks affect search behavior and reservation wages.

We will solve the model using fitted value function iteration with linear interpolation, as introduced in *Job Search IV*.

We will use the following imports:

```
import matplotlib.pyplot as plt
import jax
import jax.numpy as jnp
import jax.random
import quantecon as qe
from typing import NamedTuple
```

60.2 The model

Wages at each point in time are given by

$$W_t = \exp(Z_t) + Y_t$$

where

$$Y_t \sim \exp(\mu + s\zeta_t) \quad \text{and} \quad Z_{t+1} = d + \rho Z_t + \sigma \epsilon_{t+1}$$

Here $\{\zeta_t\}$ and $\{\epsilon_t\}$ are both IID and standard normal.

Here $\{Y_t\}$ is a transitory component and $\{Z_t\}$ is persistent.

As before, the worker can either

1. accept an offer and work permanently at that wage, or
2. take unemployment compensation c and wait till next period.

The value function satisfies the Bellman equation

$$v^*(w, z) = \max \left\{ \frac{u(w)}{1-\beta}, u(c) + \beta \, \mathbb{E}_z v^*(w', z') \right\}$$

In this expression, u is a utility function and $\mathbb{E}_z$ is the expectation of next period variables given current z.

The variable z enters as a state in the Bellman equation because its current value helps predict future wages.

60.2.1 A simplification

There is a way that we can reduce dimensionality in this problem, which greatly accelerates computation.

To start, let f^* be the continuation value function, defined by

$$f^*(z) := u(c) + \beta \, \mathbb{E}_z v^*(w', z')$$

The Bellman equation can now be written

$$v^*(w, z) = \max \left\{ \frac{u(w)}{1-\beta}, \, f^*(z) \right\}$$

Combining the last two expressions, we see that the continuation value function satisfies

$$f^*(z) = u(c) + \beta \, \mathbb{E}_z \max \left\{ \frac{u(w')}{1-\beta}, f^*(z') \right\}$$

We'll solve this functional equation for f^* by introducing the operator

$$Qf(z) = u(c) + \beta \, \mathbb{E}_z \max \left\{ \frac{u(w')}{1-\beta}, f(z') \right\}$$

By construction, f^* is a fixed point of Q, in the sense that $Qf^* = f^*$.

Under mild assumptions, it can be shown that Q is a contraction mapping over a suitable space of continuous functions on $\mathbb{R}$.

By Banach's contraction mapping theorem, this means that f^* is the unique fixed point and we can calculate it by iterating with Q from any reasonable initial condition.

Once we have f^*, we can solve the search problem by stopping when the reward for accepting exceeds the continuation value, or

$$\frac{u(w)}{1-\beta} \geq f^*(z)$$

For utility, we take $u(x) = \ln(x)$.

The reservation wage is the wage where equality holds in the last expression.

That is,

$$\bar{w}(z) := \exp(f^*(z)(1-\beta)) \tag{60.1}$$

Our main aim is to solve for the reservation rule and study its properties and implications.

60.3 Implementation

Let f be our initial guess of f^*.

When we iterate, we use the *fitted value function iteration* algorithm.

In particular, f and all subsequent iterates are stored as a vector of values on a grid.

These points are interpolated into a function as required, using piecewise linear interpolation.

The integral in the definition of Qf is calculated by Monte Carlo.

Here's a `NamedTuple` that stores the model parameters and data.

Default parameter values are embedded in the model.

```
class Model(NamedTuple):
    μ: float     # transient shock log mean
    s: float     # transient shock log variance
    d: float     # shift coefficient of persistent state
    ρ: float     # correlation coefficient of persistent state
    σ: float     # state volatility
    β: float     # discount factor
    c: float     # unemployment compensation
    z_grid: jnp.ndarray
    e_draws: jnp.ndarray

def create_job_search_model(μ=0.0, s=1.0, d=0.0, ρ=0.9, σ=0.1, β=0.98, c=5.0,
                            mc_size=1000, grid_size=100, key=jax.random.key(1234)):
    """
    Create a Model with computed grid and draws.
    """
    # Set up grid
    z_mean = d / (1 - ρ)
    z_sd = σ / jnp.sqrt(1 - ρ**2)
    k = 3  # std devs from mean
    a, b = z_mean - k * z_sd, z_mean + k * z_sd
    z_grid = jnp.linspace(a, b, grid_size)

    # Draw and store shocks
    e_draws = jax.random.normal(key, (2, mc_size))

    return Model(μ, s, d, ρ, σ, β, c, z_grid, e_draws)
```

Next, we implement the Q operator.

```
def Q(model, f_in):
    """
    Apply the operator Q.

        * model is an instance of Model
        * f_in is an array that represents f
        * returns Qf

    """
    μ, s, d = model.μ, model.s, model.d
    ρ, σ, β, c = model.ρ, model.σ, model.β, model.c
    z_grid, e_draws = model.z_grid, model.e_draws
    M = e_draws.shape[1]

    def compute_expectation(z):
        def evaluate_shock(e):
            e1, e2 = e[0], e[1]
            z_next = d + ρ * z + σ * e1
            go_val = jnp.interp(z_next, z_grid, f_in)  # f(z')
            y_next = jnp.exp(μ + s * e2)               # y' draw
            w_next = jnp.exp(z_next) + y_next          # w' draw
            stop_val = jnp.log(w_next) / (1 - β)
            return jnp.maximum(stop_val, go_val)

        expectations = jax.vmap(evaluate_shock)(e_draws.T)
        return jnp.mean(expectations)
```

(continues on next page)

(continued from previous page)

```
    expectations = jax.vmap(compute_expectation)(z_grid)
    f_out = jnp.log(c) + β * expectations
    return f_out
```

Here's a function to compute an approximation to the fixed point of Q.

```
@jax.jit
def compute_fixed_point(model, tol=1e-4, max_iter=1000):
    """
    Compute an approximation to the fixed point of Q.
    """

    def cond_fun(loop_state):
        f, i, error = loop_state
        return jnp.logical_and(error > tol, i < max_iter)

    def body_fun(loop_state):
        f, i, error = loop_state
        f_new = Q(model, f)
        error_new = jnp.max(jnp.abs(f_new - f))
        return f_new, i + 1, error_new

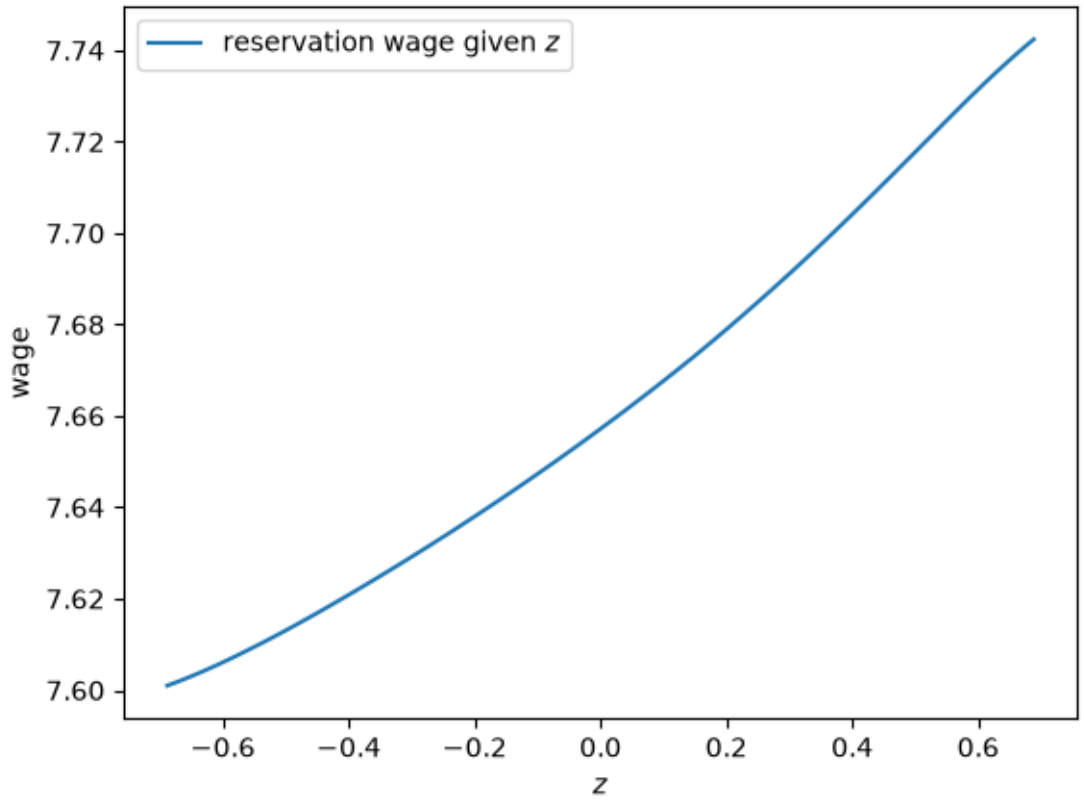
    # Initial state
    f_init = jnp.full(len(model.z_grid), jnp.log(model.c))
    init_state = (f_init, 0, tol + 1)

    # Run iteration
    f_final, iterations, final_error = jax.lax.while_loop(
        cond_fun, body_fun, init_state
    )

    return f_final
```

Let's try generating an instance and solving the model.

```
model = create_job_search_model()



with qe.Timer():
    f_star = compute_fixed_point(model).block_until_ready()
```

```
0.5147 seconds elapsed
```

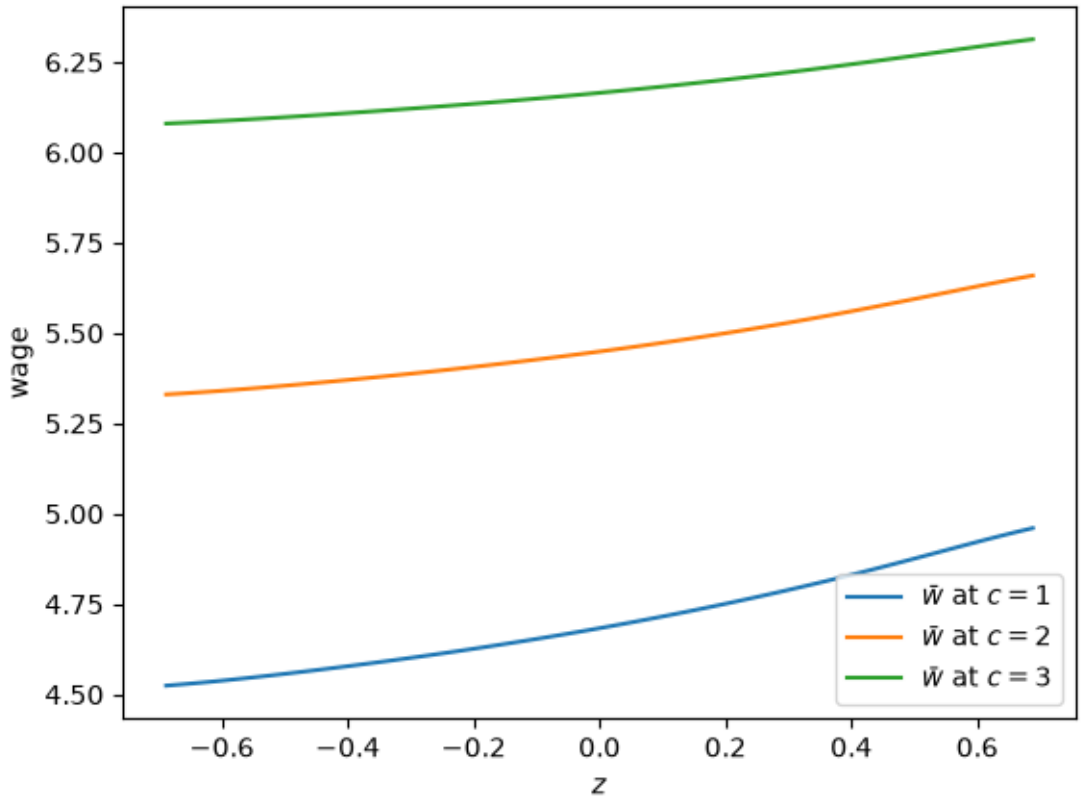
Next, we will compute and plot the reservation wage function defined in (60.1).

```
res_wage_function = jnp.exp(f_star * (1 - model.β))

fig, ax = plt.subplots()
ax.plot(
    model.z_grid, res_wage_function, label="reservation wage given $z$"
)
ax.set(xlabel="$z$", ylabel="wage")
ax.legend()
plt.show()
```

Notice that the reservation wage is increasing in the current state z.

This is because a higher state leads the agent to predict higher future wages, increasing the option value of waiting.



Let's try changing unemployment compensation and looking at its impact on the reservation wage:

```
c_vals = 1, 2, 3

fig, ax = plt.subplots()

for c in c_vals:
    model = create_job_search_model(c=c)
    f_star = compute_fixed_point(model)
    res_wage_function = jnp.exp(f_star * (1 - model.β))
    ax.plot(model.z_grid, res_wage_function,
                label=rf"$\bar w$ at $c = {c}$")

ax.set(xlabel="$z$", ylabel="wage")
ax.legend()
plt.show()
```

As expected, higher unemployment compensation shifts the reservation wage up at all state values.

60.4 Unemployment duration

Next, we study how mean unemployment duration varies with unemployment compensation.

For simplicity, we'll fix the initial state at $Z_0 = 0$.

```
@jax.jit
def draw_duration(key, μ, s, d, ρ, σ, β, z_grid, f_star, t_max=10_000):
    """
    Draw unemployment duration for a single simulation.

    """
    def f_star_function(z):
        return jnp.interp(z, z_grid, f_star)

    def cond_fun(loop_state):
        z, t, unemployed, key = loop_state
        return jnp.logical_and(unemployed, t < t_max)

    def body_fun(loop_state):
        z, t, unemployed, key = loop_state
        key1, key2, key = jax.random.split(key, 3)

        # Draw current wage
        y = jnp.exp(μ + s * jax.random.normal(key1))
```

(continues on next page)

(continued from previous page)

```
        w = jnp.exp(z) + y
        res_wage = jnp.exp(f_star_function(z) * (1 - β))

        # Check if optimal to stop
        accept = w >= res_wage
        τ = jnp.where(accept, t, t_max)

        # Update state if not accepting
        z_new = jnp.where(accept, z,
                          ρ * z + d + σ * jax.random.normal(key2))
        t_new = t + 1
        unemployed_new = jnp.logical_not(accept)

        return z_new, t_new, unemployed_new, key

    # Initial loop_state: (z, t, unemployed, key)
    init_state = (0.0, 0, True, key)
    z_final, t_final, unemployed_final, _ = jax.lax.while_loop(
        cond_fun, body_fun, init_state)

    # Return final time if job found, otherwise t_max
    return jnp.where(unemployed_final, t_max, t_final)

def compute_unemployment_duration(
        model, key=jax.random.key(1234), num_reps=100_000
    ):
    """
    Compute expected unemployment duration.

    """
    f_star = compute_fixed_point(model)
    μ, s, d = model.μ, model.s, model.d
    ρ, σ, β = model.ρ, model.σ, model.β
    z_grid = model.z_grid

    # Generate keys for all simulations
    keys = jax.random.split(key, num_reps)

    # Vectorize over simulations
    τ_vals = jax.vmap(
        lambda k: draw_duration(k, μ, s, d, ρ, σ, β, z_grid, f_star)
    )(keys)

    return jnp.mean(τ_vals)
```

Let's test this out with some possible values for unemployment compensation.

```
c_vals = jnp.linspace(1.0, 10.0, 8)
durations = []
for i, c in enumerate(c_vals):
    model = create_job_search_model(c=c)
    τ = compute_unemployment_duration(model, num_reps=10_000)
    durations.append(τ)
durations = jnp.array(durations)
```

Here is a plot of the results.

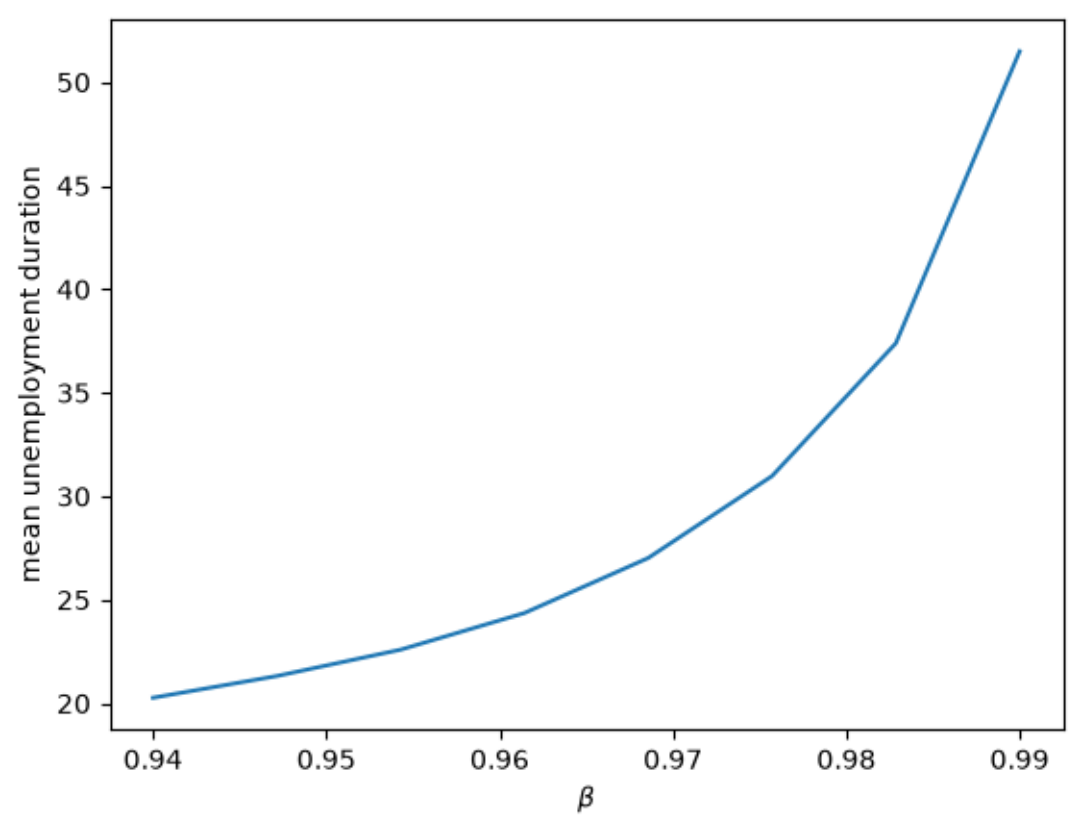
```
fig, ax = plt.subplots()
ax.plot(c_vals, durations)
ax.set_xlabel("unemployment compensation")
ax.set_ylabel("mean unemployment duration")
plt.show()
```

Not surprisingly, unemployment duration increases when unemployment compensation is higher.

This is because the value of waiting increases with unemployment compensation.

60.5 Exercises

Exercise 60.5.1



Investigate how mean unemployment duration varies with the discount factor β.

- What is your prior expectation?
- Do your results match up?

Solution

Here is one solution:

```
beta_vals = jnp.linspace(0.94, 0.99, 8)
durations = []
for i, β in enumerate(beta_vals):
    model = create_job_search_model(β=β)
    τ = compute_unemployment_duration(model, num_reps=10_000)
    durations.append(τ)
durations = jnp.array(durations)
fig, ax = plt.subplots()
ax.plot(beta_vals, durations)
ax.set_xlabel(r"$\beta$")
ax.set_ylabel("mean unemployment duration")
plt.show()
```

The figure shows that more patient individuals tend to wait longer before accepting an offer.

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon jax
```

61.1 Overview

Next, we study a computational problem concerning career and job choices.

The model is originally due to Derek Neal [Neal, 1999].

This exposition draws on the presentation in [Ljungqvist and Sargent, 2018], section 6.5.

We begin with some imports:

```
from typing import NamedTuple
```

(continues on next page)

(continued from previous page)

```
import matplotlib.pyplot as plt
from matplotlib import cm
from mpl_toolkits.mplot3d.axes3d import Axes3D
import jax
import jax.numpy as jnp
import jax.random as jr
from quantecon.distributions import BetaBinomial
```

61.1.1 Model Features

- Career and job within career both chosen to maximize expected discounted wage flow.
- Infinite horizon dynamic programming with two state variables.

61.2 Model

In what follows we distinguish between a career and a job, where

- a **career** is understood to be a general field encompassing many possible jobs, and
- a **job** is understood to be a position with a particular firm

For workers, wages can be decomposed into the contribution of job and career

- $w_t = \theta_t + \epsilon_t$, where
  - θ_t is the contribution of career at time t
  - ϵ_t is the contribution of the job at time t

At the start of time t, a worker has the following options

- retain a current (career, job) pair (θ_t, ϵ_t) — referred to hereafter as "stay put"
- retain a current career θ_t but redraw a job ϵ_t — referred to hereafter as "new job"
- redraw both a career θ_t and a job ϵ_t — referred to hereafter as "new life"

Draws of θ and ϵ are independent of each other and past values, with

- $\theta_t \sim F$
- $\epsilon_t \sim G$

Notice that the worker does not have the option to retain a job but redraw a career — starting a new career always requires starting a new job.

A young worker aims to maximize the expected sum of discounted wages

$$\mathbb{E} \sum_{t=0}^{\infty} \beta^t w_t \tag{61.1}$$

subject to the choice restrictions specified above.

Let $v(\theta, \epsilon)$ denote the value function, which is the maximum of (61.1) overall feasible (career, job) policies, given the initial state (θ, ϵ).

The value function obeys

$$v(\theta, \epsilon) = \max\{I, II, III\}$$

where

$$I = \theta + \epsilon + \beta v(\theta, \epsilon)$$
$$II = \theta + \int \epsilon' G(d\epsilon') + \beta \int v(\theta, \epsilon') G(d\epsilon')$$
$$III = \int \theta' F(d\theta') + \int \epsilon' G(d\epsilon') + \beta \int \int v(\theta', \epsilon') G(d\epsilon') F(d\theta')$$

Evidently I, II and III correspond to "stay put", "new job" and "new life", respectively.

61.2.1 Parameterization

As in [Ljungqvist and Sargent, 2018], section 6.5, we will focus on a discrete version of the model, parameterized as follows:

- both θ and ϵ take values in the set `jnp.linspace(0, B, grid_size)` — an even grid of points between 0 and B inclusive
- `grid_size = 50`
- `B = 5`
- `β = 0.95`

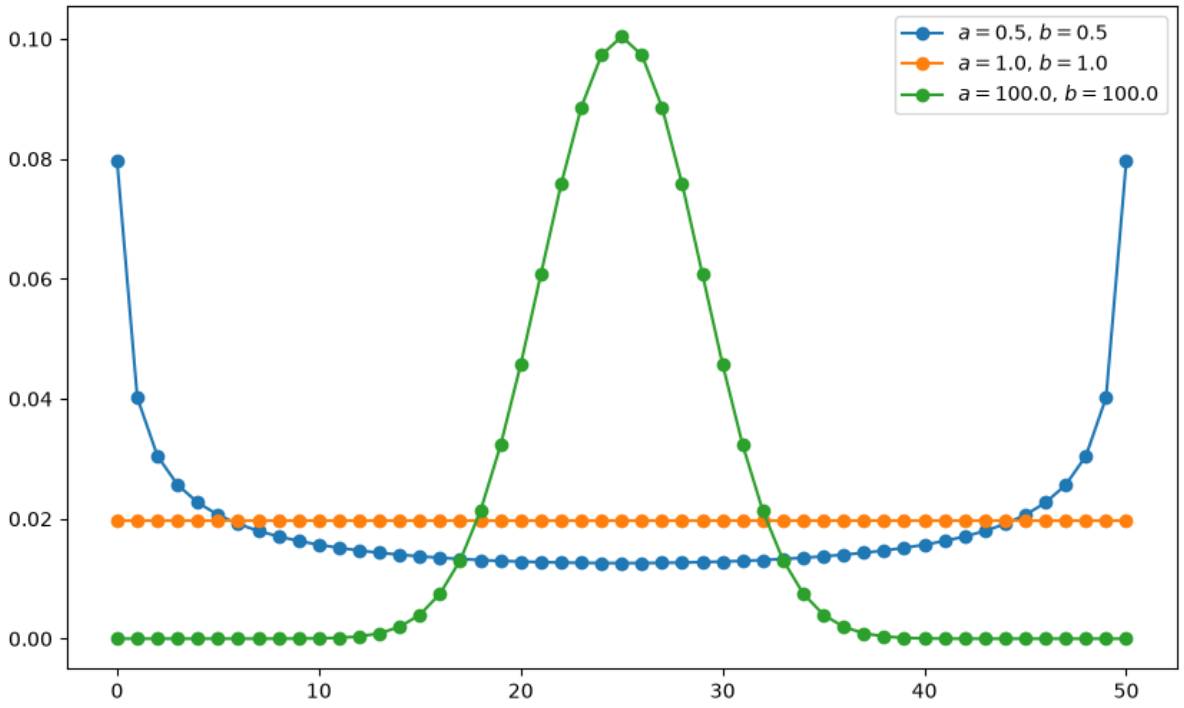
The distributions F and G are discrete distributions generating draws from the grid points `jnp.linspace(0, B, grid_size)`.

A very useful family of discrete distributions is the Beta-binomial family, with probability mass function

$$p(k \mid n, a, b) = \binom{n}{k} \frac{B(k + a, n - k + b)}{B(a, b)}, \qquad k = 0, \ldots, n$$

Interpretation:

- draw q from a Beta distribution with shape parameters (a, b)
- run n independent binary trials, each with success probability q
- $p(k \mid n, a, b)$ is the probability of k successes in these n trials



Nice properties:

- very flexible class of distributions, including uniform, symmetric unimodal, etc.
- only three parameters

Here's a figure showing the effect on the pmf of different shape parameters when $n = 50$.

```
n = 50
a_vals = [0.5, 1, 100]
b_vals = [0.5, 1, 100]

fig, ax = plt.subplots(figsize=(10, 6))
for a, b in zip(a_vals, b_vals):
    ab_label = f'$a = {a:.1f}$, $b = {b:.1f}$'
    ax.plot(range(n + 1), BetaBinomial(n, a, b).pdf(), '-o', label=ab_label)
ax.legend()
plt.show()
```

61.3 Implementation

We store the model primitives in a `NamedTuple`, built by a factory function.

```
class CareerWorkerProblem(NamedTuple):
    β: float                    # Discount factor
    θ: jnp.ndarray              # Set of θ values (career)
    ϵ: jnp.ndarray              # Set of ϵ values (job)
    F_probs: jnp.ndarray        # Distribution over new career draws
    G_probs: jnp.ndarray        # Distribution over new job draws
    F_mean: float               # Mean of F
    G_mean: float               # Mean of G

def create_career_worker_problem(B=5.0,          # Upper bound
                                 β=0.95,         # Discount factor
                                 grid_size=50,   # Grid size
                                 F_a=1,
                                 F_b=1,
                                 G_a=1,
                                 G_b=1):
    "Create an instance of the career choice model."
    θ = jnp.linspace(0, B, grid_size)
    ϵ = jnp.linspace(0, B, grid_size)

    F_probs = jnp.array(BetaBinomial(grid_size - 1, F_a, F_b).pdf())
    G_probs = jnp.array(BetaBinomial(grid_size - 1, G_a, G_b).pdf())

    return CareerWorkerProblem(β=β, θ=θ, ϵ=ϵ,
                               F_probs=F_probs, G_probs=G_probs,
```

(continues on next page)

(continued from previous page)

```
                                F_mean=θ @ F_probs, G_mean=ϵ @ G_probs)
```

The Bellman operator is $Tv(\theta, \epsilon) = \max\{I, II, III\}$, where I, II and III are as given in (61.2).

We start by writing those three values for a **single** state (θ_i, ϵ_j), so that the code sits close to the equation.

```
def _B(v, cw, i, j):
    """
    The values of the three options available at state (θ_i, ϵ_j), in the
    order they appear in the Bellman equation.
    """
    stay_put = cw.θ[i] + cw.ϵ[j] + cw.β * v[i, j]                          # I
    new_job = cw.θ[i] + cw.G_mean + cw.β * v[i, :] @ cw.G_probs             # II
    new_life = cw.G_mean + cw.F_mean + cw.β * cw.F_probs @ v @ cw.G_probs # III
    return jnp.array([stay_put, new_job, new_life])
```

Now we evaluate `_B` at every state.

Rather than write two nested loops over i and j, we apply `jax.vmap` twice.

In `in_axes`, a `0` marks the argument being mapped over, while `None` holds an argument fixed.

```
# The argument order of _B is  (v,    cw,   i,    j)
_B_j  = jax.vmap(_B,   in_axes=(None, None, None, 0))   # over j
_B_ij = jax.vmap(_B_j, in_axes=(None, None, 0,    None))  # then over i

@jax.jit
def B(v, cw):
    "Value of each option at each state; shape (grid_size, grid_size, 3)."
    n = len(cw.θ)
    return _B_ij(v, cw, jnp.arange(n), jnp.arange(n))
```

The Bellman operator and the greedy policy are now the maximum and the maximizer of the same array.

```
@jax.jit
def T(v, cw):
    "The Bellman operator."
    return jnp.max(B(v, cw), axis=-1)

@jax.jit
def get_greedy(v, cw):
    "The v-greedy policy, coded as 1 = stay put, 2 = new job, 3 = new life."
    return jnp.argmax(B(v, cw), axis=-1) + 1
```

Lastly, `solve_model` iterates the Bellman operator to find the fixed point.

We use `jax.lax.while_loop` so that the whole iteration compiles into a single operation, and bound the number of steps so the loop always terminates.

```
@jax.jit
def solve_model(cw, tol=1e-4, max_iter=1_000):
    """
    Solve the model by value function iteration.

    Returns the value function, the number of iterations taken and the final
    error, so that the caller can check convergence.
```

(continues on next page)

(continued from previous page)

```
    """
    def condition(loop_state):
        i, v, error = loop_state
        return (error > tol) & (i < max_iter)

    def update(loop_state):
        i, v, error = loop_state
        v_new = T(v, cw)
        return i + 1, v_new, jnp.max(jnp.abs(v_new - v))

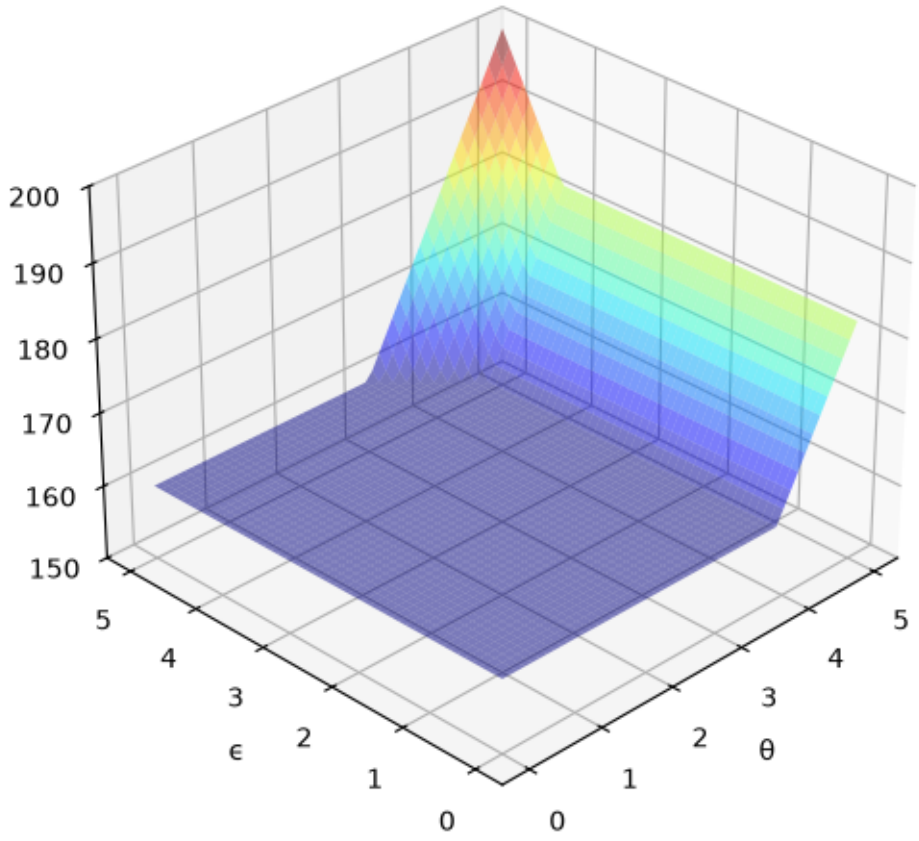
    n = len(cw.θ)
    v_init = jnp.full((n, n), 100.0)
    i, v, error = jax.lax.while_loop(condition, update, (0, v_init, tol + 1))
    return v, i, error
```

Note

The grid here is small, and this model would also run perfectly well in NumPy.

We use JAX because the code is almost as readable as the NumPy equivalent while scaling far better — to finer grids, or to richer versions of the model with more state variables, where the same code will make full use of a GPU.

The gain is already visible in Exercise 61.4.2, where we simulate 25,000 independent careers at once.



Here's the solution to the model – an approximate value function

```
cw = create_career_worker_problem()
v_star, num_iter, error = solve_model(cw)
greedy_star = get_greedy(v_star, cw)

print(f"Converged in {num_iter} iterations with error {error:.2e}.")

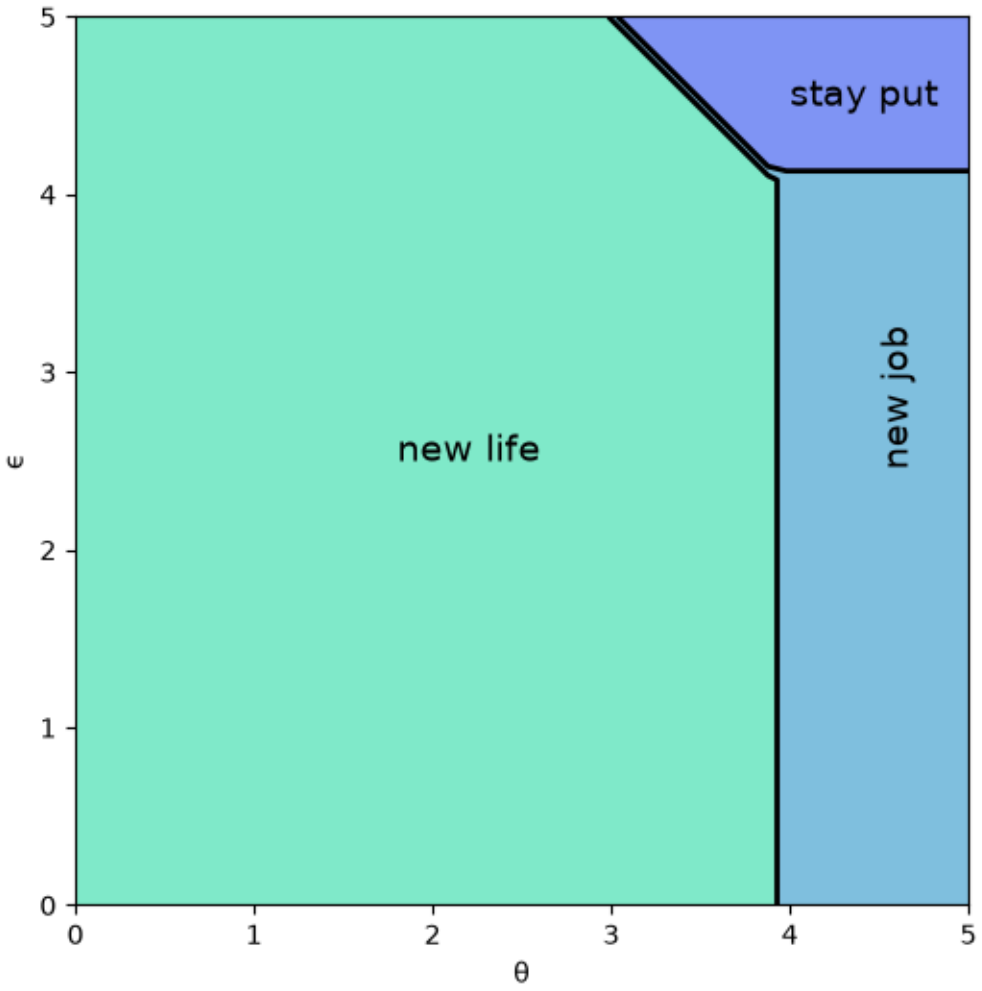


fig = plt.figure(figsize=(8, 6))
ax = fig.add_subplot(111, projection='3d')
tg, eg = jnp.meshgrid(cw.θ, cw.ϵ)
ax.plot_surface(tg,
                eg,
                v_star.T,
                cmap=cm.jet,
                alpha=0.5,
                linewidth=0.25)
ax.set(xlabel='θ', ylabel='ϵ', zlim=(150, 200))
ax.view_init(ax.elev, 225)
plt.show()
```

```
Converged in 213 iterations with error 9.16e-05.
```

And here is the optimal policy

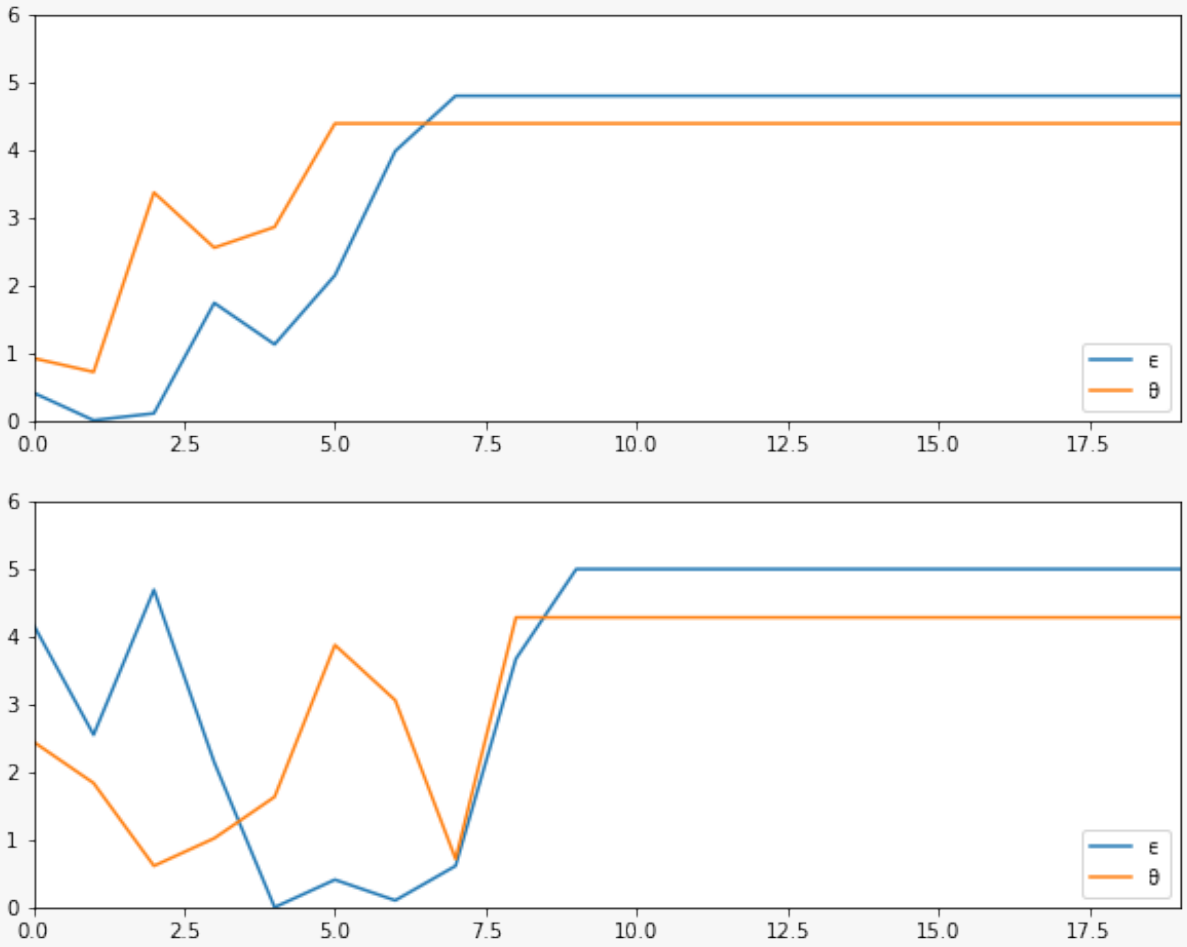
```
fig, ax = plt.subplots(figsize=(6, 6))
tg, eg = jnp.meshgrid(cw.θ, cw.ϵ)
lvls = (0.5, 1.5, 2.5, 3.5)
ax.contourf(tg, eg, greedy_star.T, levels=lvls, cmap=cm.winter, alpha=0.5)
ax.contour(tg, eg, greedy_star.T, colors='k', levels=lvls, linewidths=2)
ax.set(xlabel='θ', ylabel='ϵ')
ax.text(1.8, 2.5, 'new life', fontsize=14)
ax.text(4.5, 2.5, 'new job', fontsize=14, rotation='vertical')
ax.text(4.0, 4.5, 'stay put', fontsize=14)
plt.show()
```

Interpretation:

- If both job and career are poor or mediocre, the worker will experiment with a new job and new career.
- If career is sufficiently good, the worker will hold it and experiment with new jobs until a sufficiently good one is found.
- If both job and career are good, the worker will stay put.

Notice that the worker will always hold on to a sufficiently good career, but not necessarily hold on to even the best paying job.

The reason is that high lifetime wages require both a good job and a good career, but the worker cannot change careers without changing jobs.



- Sometimes a good job must be sacrificed in order to change to a better career.

61.4 Exercises

Exercise 61.4.1

Using the default parameterization in the function `create_career_worker_problem`, generate and plot typical sample paths for θ and ϵ when the worker follows the optimal policy.

In particular, modulo randomness, reproduce the following figure (where the horizontal axis represents time)

Hint

To draw from F and G, invert their cdfs with `jnp.searchsorted`.

Solution

Simulate job/career paths.

In reading the code, recall that `greedy_star[i, j]` = policy at (θ_i, ϵ_j) = either 1, 2 or 3; meaning 'stay put', 'new job' and 'new life'.

```
def draw(key, cdf):
```

```
    "Draw an index from the distribution with the given cdf."
    return jnp.searchsorted(cdf, jr.uniform(key), side="right")

def simulate_path(cw, greedy_star, key, t=20):
    "Simulate a career/job path of length t under the greedy policy."
    F_cdf, G_cdf = jnp.cumsum(cw.F_probs), jnp.cumsum(cw.G_probs)

    def update(state, key):
        i, j = state
        action = greedy_star[i, j]
        key_F, key_G = jr.split(key)
        # Career changes only under 'new life'; the job changes unless we stay put
        i_new = jnp.where(action == 3, draw(key_F, F_cdf), i)
        j_new = jnp.where(action == 1, j, draw(key_G, G_cdf))
        return (i_new, j_new), (i_new, j_new)

    _, (i_path, j_path) = jax.lax.scan(update, (0, 0), jr.split(key, t))
    return cw.θ[i_path], cw.ϵ[j_path]

cw = create_career_worker_problem()
v_star, _, _ = solve_model(cw)
greedy_star = get_greedy(v_star, cw)

key = jr.key(42)
fig, axes = plt.subplots(2, 1, figsize=(10, 8))

for ax in axes:
    key, subkey = jr.split(key)
    θ_path, ϵ_path = simulate_path(cw, greedy_star, subkey)
    ax.plot(ϵ_path, label='ϵ')
    ax.plot(θ_path, label='θ')
    ax.set_ylim(0, 6)
    ax.legend()

plt.show()
```

Exercise 61.4.2

Let's now consider how long it takes for the worker to settle down to a permanent job, given a starting point of $(\theta, \epsilon) = (0, 0)$.

In other words, we want to study the distribution of the random variable

$$T^* := \text{the first point in time from which the worker's job no longer changes}$$

Evidently, the worker's job becomes permanent if and only if (θ_t, ϵ_t) enters the "stay put" region of (θ, ϵ) space.

Letting S denote this region, T^* can be expressed as the first passage time to S under the optimal policy:

$$T^* := \inf\{t \geq 0 \,|\, (\theta_t, \epsilon_t) \in S\}$$

Collect 25,000 draws of this random variable and compute the median (which should be about 7).

Repeat the exercise with $\beta = 0.99$ and interpret the change.

Solution

The median for the original parameterization can be computed as follows.

Each simulation is an independent sequential search, so we write one with `jax.lax.while_loop` and then run 25,000 of them at once with `jax.vmap`.

```
def passage_time(cw, greedy_star, key, max_t=1_000):
    "Time until the worker first chooses to stay put."
    F_cdf, G_cdf = jnp.cumsum(cw.F_probs), jnp.cumsum(cw.G_probs)

    def condition(state):
        i, j, t, key = state
        return (greedy_star[i, j] != 1) & (t < max_t)

    def update(state):
        i, j, t, key = state
        action = greedy_star[i, j]
        key, key_F, key_G = jr.split(key, 3)
        i_new = jnp.where(action == 3, draw(key_F, F_cdf), i)
        j_new = jnp.where(action == 1, j, draw(key_G, G_cdf))
        return i_new, j_new, t + 1, key

    _, _, t, _ = jax.lax.while_loop(condition, update, (0, 0, 0, key))
    return t

@jax.jit
def median_passage_time(cw, greedy_star, key, M=25_000):
    "Median time to settle down, over M independent simulations."
    keys = jr.split(key, M)
    times = jax.vmap(passage_time, in_axes=(None, None, 0))(cw, greedy_star, keys)
    return jnp.median(times)

median_passage_time(cw, greedy_star, jr.key(42))
```

```
Array(7., dtype=float32)
```

To compute the median with $\beta = 0.99$ instead of the default value $\beta = 0.95$, we create a new instance and solve it again.

```
cw_patient = create_career_worker_problem(β=0.99)
v_patient, _, _ = solve_model(cw_patient)
greedy_patient = get_greedy(v_patient, cw_patient)

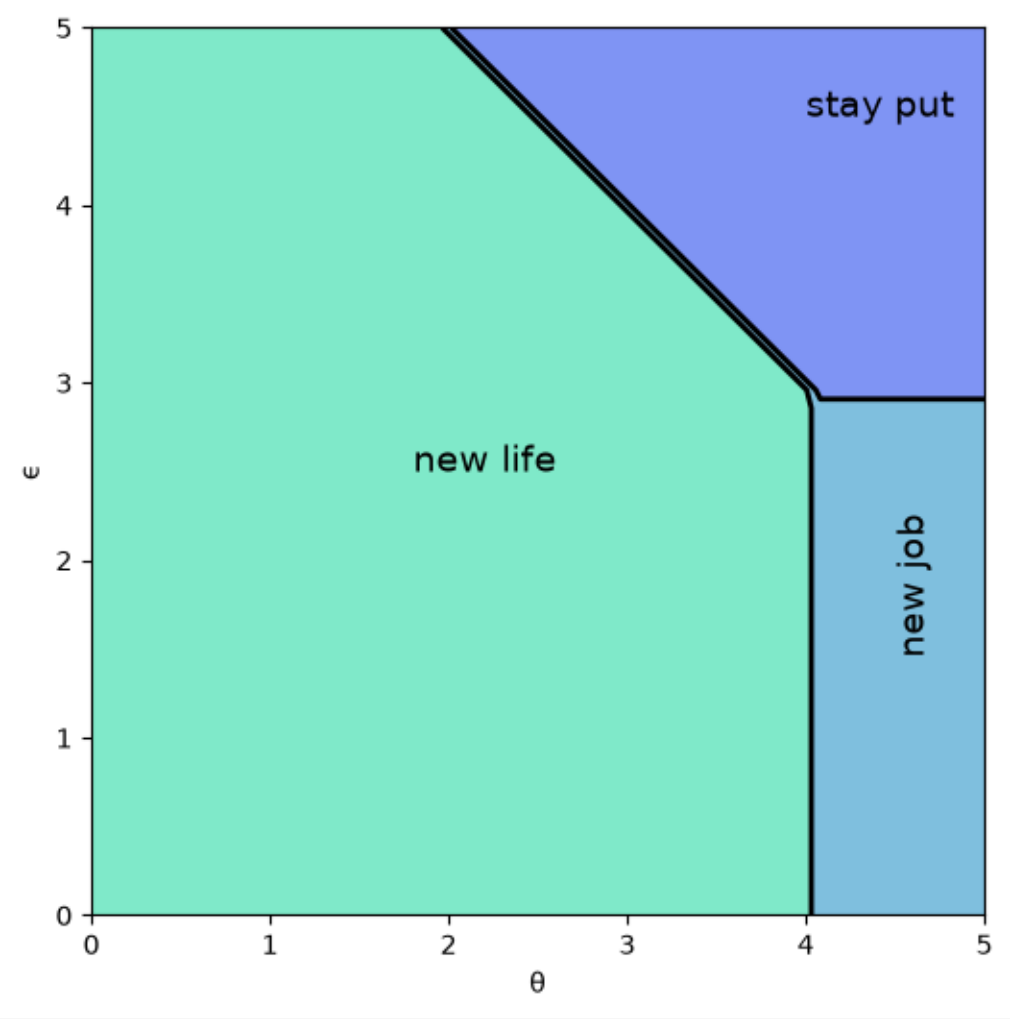
median_passage_time(cw_patient, greedy_patient, jr.key(42))
```

```
Array(14., dtype=float32)
```

The medians are subject to randomness but should be about 7 and 14 respectively.

Not surprisingly, more patient workers will wait longer to settle down to their final job.

Exercise 61.4.3



Set the parameterization to `G_a = G_b = 100` and generate a new optimal policy figure – interpret.

Solution

Here is one solution

```
cw = create_career_worker_problem(G_a=100, G_b=100)
v_star, _, _ = solve_model(cw)
greedy_star = get_greedy(v_star, cw)

fig, ax = plt.subplots(figsize=(6, 6))
tg, eg = jnp.meshgrid(cw.θ, cw.ϵ)
lvls = (0.5, 1.5, 2.5, 3.5)
ax.contourf(tg, eg, greedy_star.T, levels=lvls, cmap=cm.winter, alpha=0.5)
ax.contour(tg, eg, greedy_star.T, colors='k', levels=lvls, linewidths=2)
ax.set(xlabel='θ', ylabel='ϵ')
ax.text(1.8, 2.5, 'new life', fontsize=14)
ax.text(4.5, 1.5, 'new job', fontsize=14, rotation='vertical')
ax.text(4.0, 4.5, 'stay put', fontsize=14)
plt.show()
```

In the new figure, you see that the region for which the worker stays put has grown because the distribution for ϵ has become more concentrated around the mean, making high-paying jobs less realistic.

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install jax
```

62.1 Overview

In this section, we solve a simple on-the-job search model

- based on [Ljungqvist and Sargent, 2018], exercise 6.18, and [Jovanovic, 1979]

Let's start with some imports:

```
from typing import NamedTuple
```

(continues on next page)

(continued from previous page)

```
import matplotlib.pyplot as plt
import scipy.stats as stats
import jax
import jax.numpy as jnp
import jax.random as jr
```

62.1.1 Model Features

- job-specific human capital accumulation combined with on-the-job search
- infinite-horizon dynamic programming with one state variable and two controls

62.2 Model

Let x_t denote the time-t job-specific human capital of a worker employed at a given firm and let w_t denote current wages.

Let $w_t = x_t(1 - s_t - \phi_t)$, where

- ϕ_t is investment in job-specific human capital for the current role and
- s_t is search effort, devoted to obtaining new offers from other firms.

For as long as the worker remains in the current job, evolution of $\{x_t\}$ is given by $x_{t+1} = g(x_t, \phi_t)$.

When search effort at t is s_t, the worker receives a new job offer with probability $\pi(s_t) \in [0, 1]$.

The value of the offer, measured in job-specific human capital, is u_{t+1}, where $\{u_t\}$ is IID with common distribution f.

The worker can reject the current offer and continue with existing job.

Hence $x_{t+1} = u_{t+1}$ if he/she accepts and $x_{t+1} = g(x_t, \phi_t)$ otherwise.

Let $b_{t+1} \in \{0, 1\}$ be a binary random variable, where $b_{t+1} = 1$ indicates that the worker receives an offer at the end of time t.

We can write

$$x_{t+1} = (1 - b_{t+1})g(x_t, \phi_t) + b_{t+1} \max\{g(x_t, \phi_t), u_{t+1}\} \tag{62.1}$$

Agent's objective: maximize expected discounted sum of wages via controls $\{s_t\}$ and $\{\phi_t\}$.

Taking the expectation of $v(x_{t+1})$ and using (62.1), the Bellman equation for this problem can be written as

$$v(x) = \max_{s+\phi \leq 1} \left\{ x(1 - s - \phi) + \beta(1 - \pi(s))v[g(x, \phi)] + \beta\pi(s) \int v[g(x, \phi) \vee u]f(du) \right\} \tag{62.2}$$

Here nonnegativity of s and ϕ is understood, while $a \vee b := \max\{a, b\}$.

62.2.1 Parameterization

In the implementation below, we will focus on the parameterization

$$g(x, \phi) = A(x\phi)^\alpha, \quad \pi(s) = \sqrt{s} \quad \text{and} \quad f = \text{Beta}(2, 2)$$

with default parameter values

- $A = 1.4$
- $\alpha = 0.6$
- $\beta = 0.96$

The Beta$(2, 2)$ distribution is supported on $(0, 1)$ - it has a unimodal, symmetric density peaked at 0.5.

62.2.2 Back-of-the-Envelope Calculations

Before we solve the model, let's make some quick calculations that provide intuition on what the solution should look like.

To begin, observe that the worker has two instruments to build capital and hence wages:

1. invest in capital specific to the current job via ϕ
2. search for a new job with better job-specific capital match via s

Since wages are $x(1 - s - \phi)$, marginal cost of investment via either ϕ or s is identical.

Our risk-neutral worker should focus on whatever instrument has the highest expected return.

The relative expected return will depend on x.

For example, suppose first that $x = 0.05$

- If $s = 1$ and $\phi = 0$, then since $g(x, \phi) = 0$, taking expectations of (62.1) gives expected next period capital equal to $\pi(s)\mathbb{E}u = \mathbb{E}u = 0.5$.
- If $s = 0$ and $\phi = 1$, then next period capital is $g(x, \phi) = g(0.05, 1) \approx 0.23$.

Both rates of return are good, but the return from search is better.

Next, suppose that $x = 0.4$

- If $s = 1$ and $\phi = 0$, then expected next period capital is again 0.5
- If $s = 0$ and $\phi = 1$, then $g(x, \phi) = g(0.4, 1) \approx 0.8$

Return from investment via ϕ dominates expected return from search.

Combining these observations gives us two informal predictions:

1. At any given state x, the two controls ϕ and s will function primarily as substitutes — worker will focus on whichever instrument has the higher expected return.
2. For sufficiently small x, search will be preferable to investment in job-specific human capital. For larger x, the reverse will be true.

Now let's turn to implementation, and see if we can match our predictions.

62.3 Implementation

We solve the model with JAX, using a `NamedTuple` to hold the parameters and grids.

```
class JVWorker(NamedTuple):
    A: float                # Scale parameter in g
    α: float                # Curvature parameter in g
    β: float                # Discount factor
    x_grid: jnp.ndarray     # Grid of human capital values
    s_grid: jnp.ndarray     # Grid of search effort values
    ϕ_grid: jnp.ndarray     # Grid of investment values
    f_rvs: jnp.ndarray      # Draws from f, for Monte Carlo integration

def create_jv_worker(A=1.4,                # Scale parameter in g
                     α=0.6,                # Curvature parameter in g
                     β=0.96,               # Discount factor
                     a=2,                  # Parameter of f
                     b=2,                  # Parameter of f
                     grid_size=50,         # Size of the state grid
                     mc_size=100,          # Number of draws from f
                     search_grid_size=15,  # Size of each action grid
                     ε=1e-4,
                     seed=1234):
    """
    Create an instance of the on-the-job search model.
    """
    f_rvs = jr.beta(jr.key(seed), a, b, (mc_size,))

    # Max of grid is the max of a large quantile value for f and the
    # fixed point y = g(y, 1)
    grid_max = max(A**(1 / (1 - α)), stats.beta(a, b).ppf(1 - ε))

    x_grid = jnp.linspace(ε, grid_max, grid_size)
    s_grid = jnp.linspace(ε, 1, search_grid_size)
    ϕ_grid = jnp.linspace(ε, 1, search_grid_size)

    return JVWorker(A=A, α=α, β=β, x_grid=x_grid, s_grid=s_grid,
                    ϕ_grid=ϕ_grid, f_rvs=f_rvs)
```

Here are the transition function g and the offer probability π.

```
@jax.jit
def g(jv, x, ϕ):
    "Transition function for job-specific human capital."
    return jv.A * (x * ϕ)**jv.α

@jax.jit
def π(s):
    "Probability of receiving an offer when search effort is s."
    return jnp.sqrt(s)
```

Next we write the right-hand side of the Bellman equation (62.2), before maximization:

$$B(x, s, \phi) := x(1 - s - \phi) + \beta(1 - \pi(s))v[g(x, \phi)] + \beta\pi(s) \int v[g(x, \phi) \vee u]f(du) \tag{62.3}$$

We represent v by an array giving its values on `x_grid`, and recover a function from it by linear interpolation.

The integral is replaced by a Monte Carlo average over the draws in `f_rvs`.

The function below is written for a **single** state x and a **single** action pair (s, ϕ) — so it reads much like (62.3) itself.

```
def _B(v, jv, x, s, ϕ):
    """
    The right-hand side of the Bellman equation before maximization, for one
    state x and one action pair (s, ϕ).

    Infeasible pairs, where s + ϕ > 1, are given value -∞ so that they are
    never selected by the maximization step.
    """
    v_func = lambda z: jnp.interp(z, jv.x_grid, v)
    gxϕ = g(jv, x, ϕ)

    # Monte Carlo estimate of ∫ v[g(x, ϕ) ∨ u] f(du)
    integral = jnp.mean(v_func(jnp.maximum(gxϕ, jv.f_rvs)))

    q = π(s) * integral + (1 - π(s)) * v_func(gxϕ)
    return jnp.where(s + ϕ <= 1, x * (1 - s - ϕ) + jv.β * q, -jnp.inf)
```

Now we evaluate `_B` at every combination of state and action.

Rather than write three nested loops, we apply `jax.vmap` three times.

Each application vectorizes over one argument, so the stack below plays the role of a triple loop — but the whole thing compiles to code that runs in parallel.

In `in_axes`, a `0` marks the argument being mapped over, while `None` holds an argument fixed.

```
# The argument order of _B is     (v,     jv,    x,     s,     ϕ)
_B_ϕ   = jax.vmap(_B,    in_axes=(None, None, None, None, 0))     # over ϕ
_B_sϕ  = jax.vmap(_B_ϕ,  in_axes=(None, None, None, 0,    None))  # then over s
_B_xsϕ = jax.vmap(_B_sϕ, in_axes=(None, None, 0,    None, None))  # then over x
```

The result is a fully vectorized version of B.

```
@jax.jit
def B(v, jv):
    """
    Evaluate B at every (state, action) combination.

    Returns an array of shape (len(x_grid), len(s_grid), len(ϕ_grid)) where
    entry [i, j, k] holds the value of choosing (s_j, ϕ_k) in state x_i.
    """
    return _B_xsϕ(v, jv, jv.x_grid, jv.s_grid, jv.ϕ_grid)
```

With `B` in hand, the Bellman operator and the greedy policy are both one-liners — we maximize over the two action axes, taking the maximum in one case and the maximizer in the other.

```
@jax.jit
def T(v, jv):
    "The Bellman operator."
    return jnp.max(B(v, jv), axis=(1, 2))

@jax.jit
def get_greedy(v, jv):
    "Compute the v-greedy policy, returned as a pair (s_policy, ϕ_policy)."
```

(continues on next page)

(continued from previous page)

```
    vals = B(v, jv)

    # Flatten the two action axes so that a single argmax picks out the best
    # pair at each state, then convert the flat index back to a (s, ϕ) pair
    n_s, n_ϕ = len(jv.s_grid), len(jv.ϕ_grid)
    best = jnp.argmax(vals.reshape(len(jv.x_grid), n_s * n_ϕ), axis=1)
    j, k = jnp.unravel_index(best, (n_s, n_ϕ))

    return jv.s_grid[j], jv.ϕ_grid[k]
```

To solve the model we iterate T to convergence.

We use `jax.lax.while_loop` so that the entire iteration compiles into a single operation, and bound the number of steps so that the loop always terminates.

```
@jax.jit
def solve_model(jv, tol=1e-4, max_iter=1_000):
    """
    Solve the model by value function iteration.

    Returns the value function, the number of iterations taken, and the final
    error, so that the caller can check convergence.
    """
    def condition(loop_state):
        i, v, error = loop_state
        return (error > tol) & (i < max_iter)

    def update(loop_state):
        i, v, error = loop_state
        v_new = T(v, jv)
        return i + 1, v_new, jnp.max(jnp.abs(v_new - v))

    v_init = jv.x_grid * 0.5
    i, v, error = jax.lax.while_loop(condition, update, (0, v_init, tol + 1))
    return v, i, error
```

Note

The grids here are small, and this model would also run perfectly well in NumPy.

We use JAX because the code is almost as readable as the NumPy equivalent, while scaling far better — to finer grids, or to richer versions of the model with additional state variables, where the same code will make full use of a GPU.

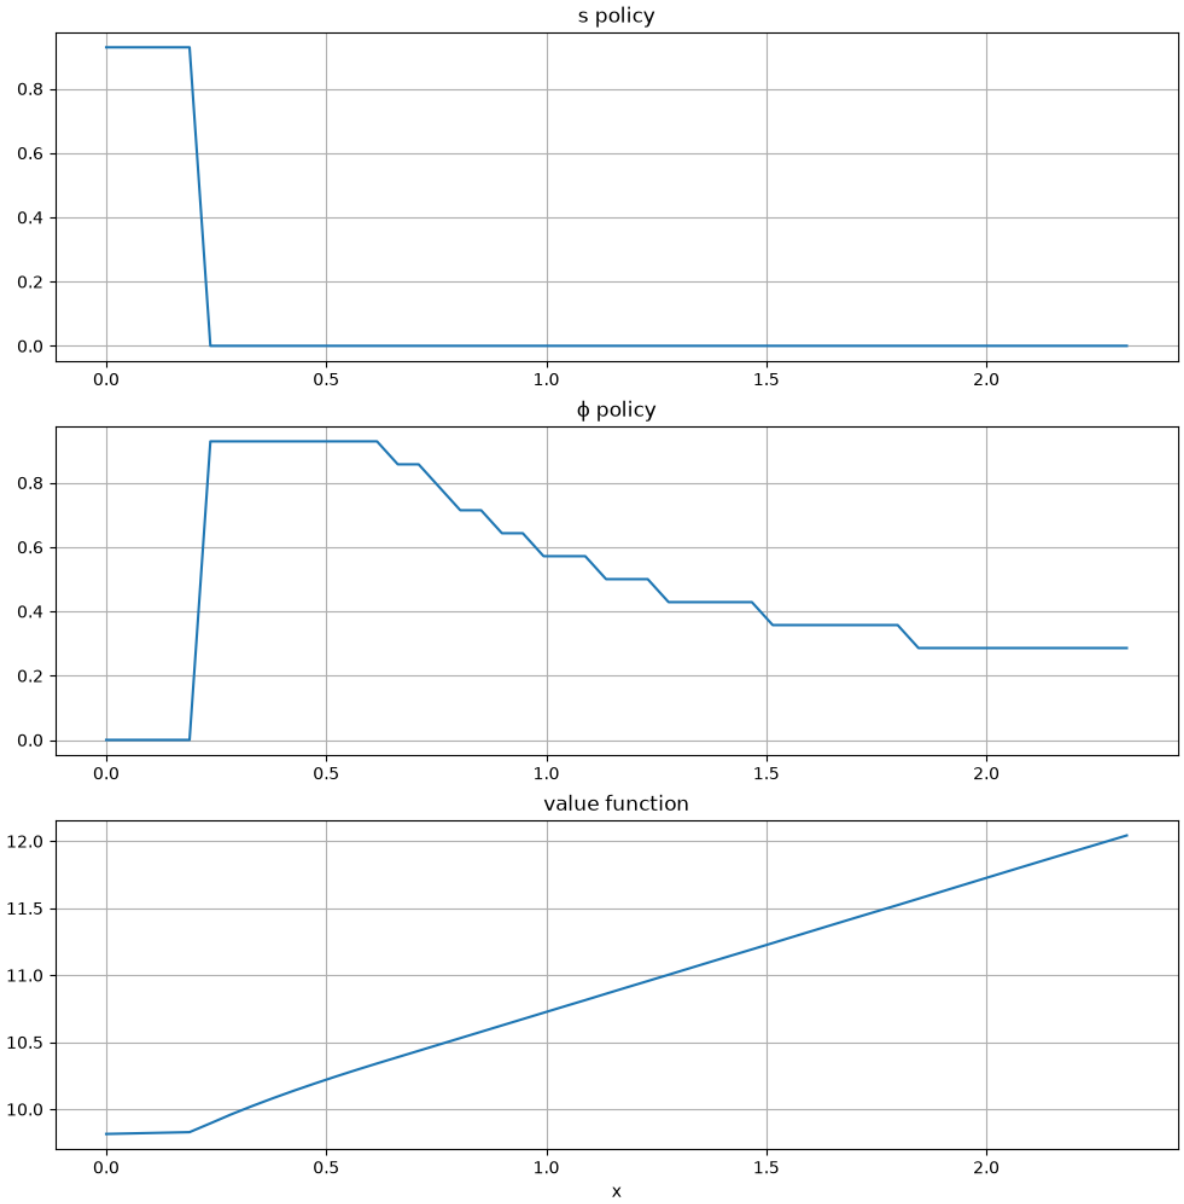
62.4 Solving for Policies

Let's generate the optimal policies and see what they look like.

```
jv = create_jv_worker()
v_star, num_iter, error = solve_model(jv)
s_star, ϕ_star = get_greedy(v_star, jv)

print(f"Converged in {num_iter} iterations with error {error:.2e}.")
```

```
Converged in 205 iterations with error 9.92e-05.
```



Here are the plots:

```
plots = [s_star, ϕ_star, v_star]
titles = ["s policy", "ϕ policy",  "value function"]

fig, axes = plt.subplots(3, 1, figsize=(12, 12))

for ax, plot, title in zip(axes, plots, titles):
    ax.plot(jv.x_grid, plot)
    ax.set(title=title)
    ax.grid()

axes[-1].set_xlabel("x")
plt.show()
```

The horizontal axis is the state x, while the vertical axis gives $s(x)$ and $\phi(x)$.

Overall, the policies match well with our predictions from *above*

- Worker switches from one investment strategy to the other depending on relative return.
- For low values of x, the best option is to search for a new job.
- Once x is larger, worker does better by investing in human capital specific to the current position.

62.5 Exercises

Exercise 62.5.1

Let's look at the dynamics for the state process $\{x_t\}$ associated with these policies.

The dynamics are given by (62.1) when ϕ_t and s_t are chosen according to the optimal policies, and $\mathbb{P}\{b_{t+1} = 1\} = \pi(s_t)$.

Since the dynamics are random, analysis is a bit subtle.

One way to do it is to plot, for each x in a relatively fine grid called `plot_grid`, a large number K of realizations of x_{t+1} given $x_t = x$.

Plot this with one dot for each realization, in the form of a 45 degree diagram, setting

```
jv = create_jv_worker(grid_size=25, mc_size=50)
plot_grid_max, plot_grid_size = 1.2, 100
plot_grid = jnp.linspace(0, plot_grid_max, plot_grid_size)
fig, ax = plt.subplots()
ax.set_xlim(0, plot_grid_max)
ax.set_ylim(0, plot_grid_max)
```

By examining the plot, argue that under the optimal policies, the state x_t will converge to a constant value $\bar{x}$ close to unity.

Argue that at the steady state, $s_t \approx 0$ and $\phi_t \approx 0.6$.

Solution

Here's code to produce the 45 degree diagram.

Note that we draw all of the realizations at once, rather than looping over states and draws.

```
jv = create_jv_worker(grid_size=25, mc_size=50)
v_star, _, _ = solve_model(jv)
s_policy, ϕ_policy = get_greedy(v_star, jv)

# Turn the policy function arrays into actual functions
s = lambda y: jnp.interp(y, jv.x_grid, s_policy)
ϕ = lambda y: jnp.interp(y, jv.x_grid, ϕ_policy)

plot_grid_max, plot_grid_size = 1.2, 100
plot_grid = jnp.linspace(0, plot_grid_max, plot_grid_size)

@jax.jit
def simulate_next(key, plot_grid):
    """
    Draw realizations of next period capital for every x in plot_grid,
    following the law of motion for x_{t+1} given above.  Returns an array of␣
↪shape (len(plot_grid), mc_size).
    """
    K = len(jv.f_rvs)
    gxϕ = g(jv, plot_grid, ϕ(plot_grid))[:, jnp.newaxis]    # Shape (n, 1)
    u = jv.f_rvs[jnp.newaxis, :]                            # Shape (1, K)

    # An offer arrives with probability π(s(x)), independently across draws
```

```
    b = jr.uniform(key, (len(plot_grid), K)) < π(s(plot_grid))[:, jnp.newaxis]

    return jnp.where(b, jnp.maximum(gxϕ, u), gxϕ)

x_next = simulate_next(jr.key(1234), plot_grid)

fig, ax = plt.subplots(figsize=(8, 8))
ticks = (0.25, 0.5, 0.75, 1.0)
ax.set(xticks=ticks, yticks=ticks,
       xlim=(0, plot_grid_max),
       ylim=(0, plot_grid_max),
       xlabel='$x_t$', ylabel='$x_{t+1}$')

ax.plot(plot_grid, plot_grid, 'k--', alpha=0.6)  # 45 degree line
ax.plot(jnp.repeat(plot_grid, x_next.shape[1]), x_next.ravel(),
        'go', alpha=0.25)

plt.show()
```

Looking at the dynamics, we can see that

- If x_t is below about 0.2 the dynamics are random, but $x_{t+1} > x_t$ is very likely.
- As x_t increases the dynamics become deterministic, and x_t converges to a steady state value close to 1.

Referring back to the figure *here* we see that $x_t \approx 1$ means that $s_t = s(x_t) \approx 0$ and $\phi_t = \phi(x_t) \approx 0.6$.

Exercise 62.5.2

In Exercise 62.5.1, we found that s_t converges to zero and ϕ_t converges to about 0.6.

Since these results were calculated at a value of β close to one, let's compare them to the best choice for an *infinitely* patient worker.

Intuitively, an infinitely patient worker would like to maximize steady state wages, which are a function of steady state capital.

You can take it as given—it's certainly true—that the infinitely patient worker does not search in the long run (i.e., $s_t = 0$ for large t).

Thus, given ϕ, steady state capital is the positive fixed point $x^*(\phi)$ of the map $x \mapsto g(x, \phi)$.

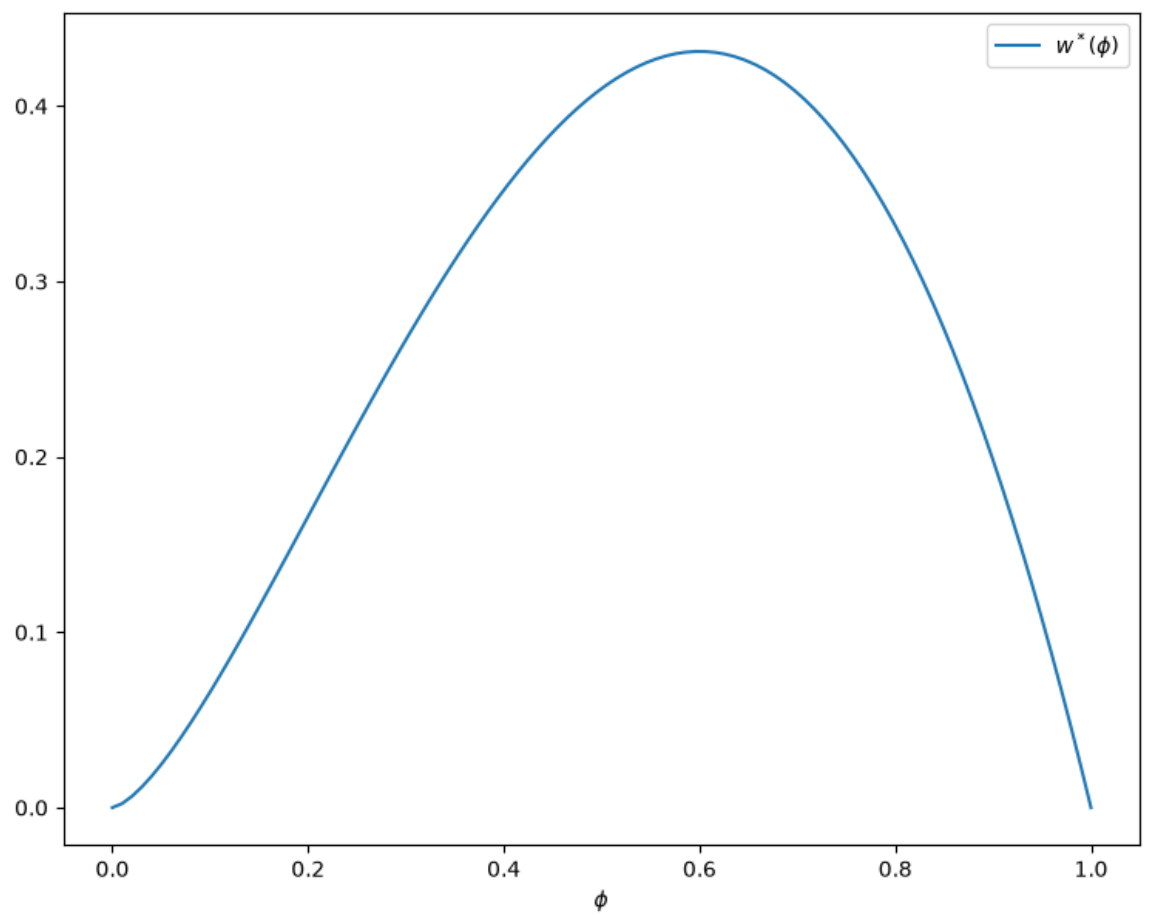
Steady state wages can be written as $w^*(\phi) = x^*(\phi)(1 - \phi)$.

Graph $w^*(\phi)$ with respect to ϕ, and examine the best choice of ϕ.

Can you give a rough interpretation for the value that you see?

Solution

The figure can be produced as follows



```
jv = create_jv_worker()

def xbar(ϕ):
    return (jv.A * ϕ**jv.α)**(1 / (1 - jv.α))

ϕ_grid = jnp.linspace(0, 1, 100)

fig, ax = plt.subplots(figsize=(9, 7))
ax.set(xlabel=r'$\phi$')
ax.plot(ϕ_grid, xbar(ϕ_grid) * (1 - ϕ_grid), label=r'$w^*(\phi)$')
ax.legend()

plt.show()
```

Observe that the maximizer is around 0.6.

This is similar to the long-run value for ϕ obtained in Exercise 62.5.1.

Hence the behavior of the infinitely patent worker is similar to that of the worker with $\beta = 0.96$.

This seems reasonable and helps us confirm that our dynamic programming solutions are probably correct.

```
!pip install interpolation
```

63.1 Overview

In this lecture, we consider an extension of the previously studied job search model of McCall [McCall, 1970].

We'll build on a model of Bayesian learning discussed in this lecture on the topic of exchangeability and its relationship to the concept of IID (identically and independently distributed) random variables and to Bayesian updating.

In the McCall model, an unemployed worker decides when to accept a permanent job at a specific fixed wage, given

- his or her discount factor
- the level of unemployment compensation

- the distribution from which wage offers are drawn

In the version considered below, the wage distribution is unknown and must be learned.

- The following is based on the presentation in [Ljungqvist and Sargent, 2018], section 6.6.

Let's start with some imports

```
import matplotlib.pyplot as plt
from numba import jit, prange, vectorize
from interpolation import mlinterp
from math import gamma
import numpy as np
from matplotlib import cm
import scipy.optimize as op
from scipy.stats import cumfreq, beta
```

63.1.1 Model Features

- Infinite horizon dynamic programming with two states and one binary control.
- Bayesian updating to learn the unknown distribution.

63.2 Model

Let's first review the basic McCall model [McCall, 1970] and then add the variation we want to consider.

63.2.1 The Basic McCall Model

Recall that, *in the baseline model*, an unemployed worker is presented in each period with a permanent job offer at wage W_t.

At time t, our worker either

1. accepts the offer and works permanently at constant wage W_t
2. rejects the offer, receives unemployment compensation c and reconsiders next period

The wage sequence W_t is IID and generated from known density q.

The worker aims to maximize the expected discounted sum of earnings $\mathbb{E} \sum_{t=0}^{\infty} \beta^t y_t$.

Let $v(w)$ be the optimal value of the problem for a previously unemployed worker who has just received offer w and is yet to decide whether to accept or reject the offer.

The value function v satisfies the recursion

$$v(w) = \max \left\{ \frac{w}{1-\beta}, \, c + \beta \int v(w') q(w') dw' \right\} \tag{63.1}$$

The optimal policy has the form $\mathbf{1}\{w \geq \bar{w}\}$, where $\bar{w}$ is a constant called the **reservation wage**.

63.2.2 Offer Distribution Unknown

Now let's extend the model by considering the variation presented in [Ljungqvist and Sargent, 2018], section 6.6.

The model is as above, apart from the fact that

- the density q is unknown
- the worker learns about q by starting with a prior and updating based on wage offers that he/she observes

The worker knows there are two possible distributions F and G.

These two distributions have densities f and g, repectively.

Just before time starts, "nature" selects q to be either f or g.

This is then the wage distribution from which the entire sequence W_t will be drawn.

The worker does not know which distribution nature has drawn, but the worker does know the two possible distributions f and g.

The worker puts a (subjective) prior probability π_0 on f having been chosen.

The worker's time 0 subjective distribution for the distribution of W_0 is

$$\pi_0 f + (1 - \pi_0) g$$

The worker's time t subjective belief about the the distribution of W_t is

$$\pi_t f + (1 - \pi_t) g,$$

where π_t updates via

$$\pi_{t+1} = \frac{\pi_t f(w_{t+1})}{\pi_t f(w_{t+1}) + (1 - \pi_t) g(w_{t+1})} \tag{63.2}$$

This last expression follows from Bayes' rule, which tells us that

$$\mathbb{P}\{q = f \,|\, W = w\} = \frac{\mathbb{P}\{W = w \,|\, q = f\}\mathbb{P}\{q = f\}}{\mathbb{P}\{W = w\}}$$

and

$$\mathbb{P}\{W = w\} = \sum_{\omega \in \{f, g\}} \mathbb{P}\{W = w \,|\, q = \omega\}\mathbb{P}\{q = \omega\}$$

The fact that (63.2) is recursive allows us to progress to a recursive solution method.

Letting

$$q_\pi(w) := \pi f(w) + (1 - \pi) g(w)$$

and

$$\kappa(w, \pi) := \frac{\pi f(w)}{\pi f(w) + (1 - \pi) g(w)}$$

we can express the value function for the unemployed worker recursively as follows

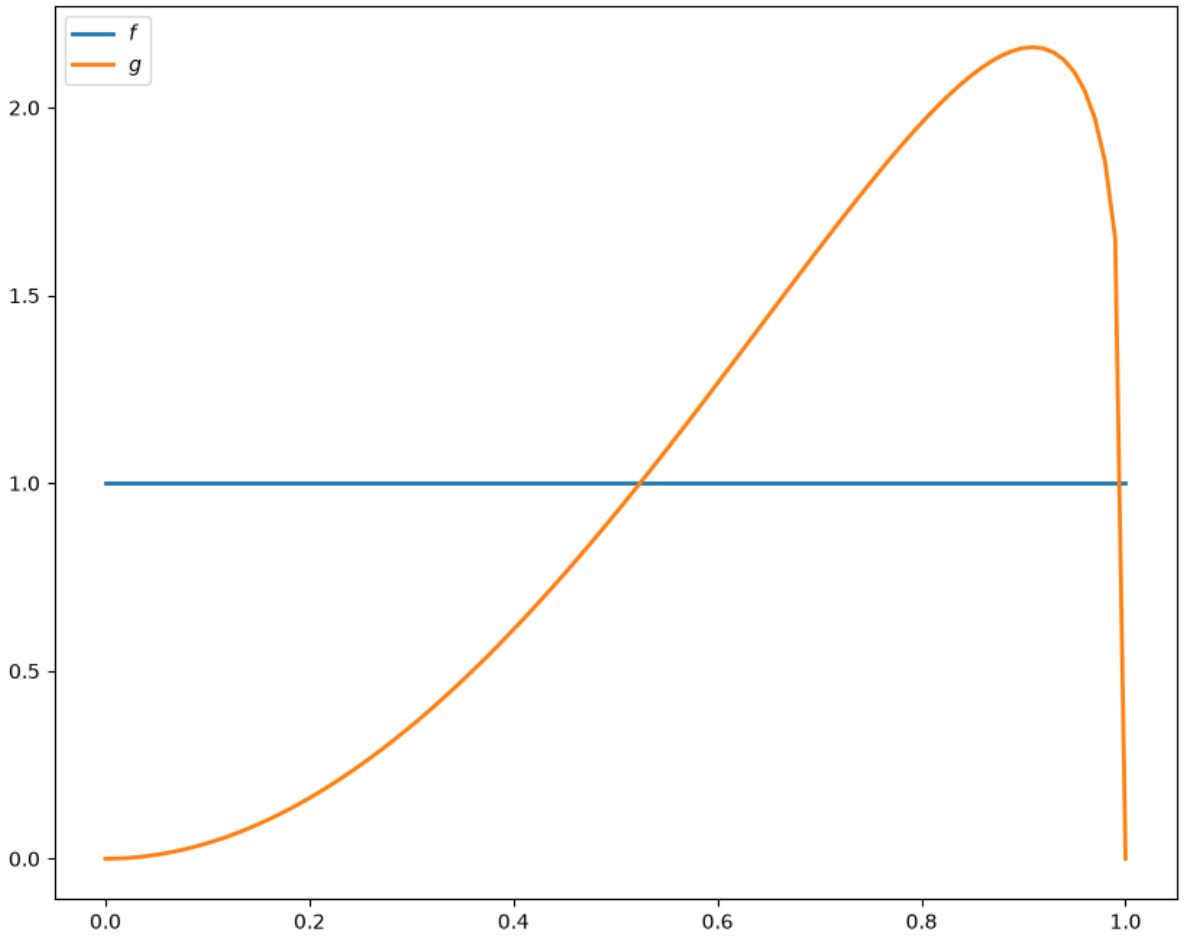
$$v(w, \pi) = \max \left\{ \frac{w}{1 - \beta}, \, c + \beta \int v(w', \pi') \, q_\pi(w') \, dw' \right\} \quad \text{where} \quad \pi' = \kappa(w', \pi) \tag{63.3}$$

Notice that the current guess π is a state variable, since it affects the worker's perception of probabilities for future rewards.

63.2.3 Parameterization

Following section 6.6 of [Ljungqvist and Sargent, 2018], our baseline parameterization will be

- f is Beta$(1, 1)$
- g is Beta$(3, 1.2)$
- $\beta = 0.95$ and $c = 0.3$



The densities f and g have the following shape

```
@vectorize
def p(x, a, b):
    r = gamma(a + b) / (gamma(a) * gamma(b))
    return r * x**(a-1) * (1 - x)**(b-1)

x_grid = np.linspace(0, 1, 100)
f = lambda x: p(x, 1, 1)
g = lambda x: p(x, 3, 1.2)

fig, ax = plt.subplots(figsize=(10, 8))
ax.plot(x_grid, f(x_grid), label='$f$', lw=2)
ax.plot(x_grid, g(x_grid), label='$g$', lw=2)

ax.legend()
plt.show()
```

63.2.4 Looking Forward

What kind of optimal policy might result from (63.3) and the parameterization specified above?

Intuitively, if we accept at w_a and $w_a \leq w_b$, then – all other things being given – we should also accept at w_b.

This suggests a policy of accepting whenever w exceeds some threshold value $\bar{w}$.

But $\bar{w}$ should depend on π – in fact, it should be decreasing in π because

- f is a less attractive offer distribution than g
- larger π means more weight on f and less on g

Thus, larger π depresses the worker's assessment of her future prospects, so relatively low current offers become more attractive.

Summary: We conjecture that the optimal policy is of the form $\mathbb{1}w \geq \bar{w}(\pi)$ for some decreasing function $\bar{w}$.

63.3 Take 1: Solution by VFI

Let's set about solving the model and see how our results match with our intuition.

We begin by solving via value function iteration (VFI), which is natural but ultimately turns out to be second best.

The class `SearchProblem` is used to store parameters and methods needed to compute optimal actions.

```
class SearchProblem:
    """
    A class to store a given parameterization of the "offer distribution
    unknown" model.

    """

    def __init__(self,
                 β=0.95,            # Discount factor
                 c=0.3,             # Unemployment compensation
                 F_a=1,
                 F_b=1,
                 G_a=3,
                 G_b=1.2,
                 w_max=1,           # Maximum wage possible
                 w_grid_size=100,
                 π_grid_size=100,
                 mc_size=500):

        self.β, self.c, self.w_max = β, c, w_max

        self.f = jit(lambda x: p(x, F_a, F_b))
        self.g = jit(lambda x: p(x, G_a, G_b))

        self.π_min, self.π_max = 1e-3, 1-1e-3    # Avoids instability
        self.w_grid = np.linspace(0, w_max, w_grid_size)
        self.π_grid = np.linspace(self.π_min, self.π_max, π_grid_size)

        self.mc_size = mc_size

        self.w_f = np.random.beta(F_a, F_b, mc_size)
        self.w_g = np.random.beta(G_a, G_b, mc_size)
```

The following function takes an instance of this class and returns jitted versions of the Bellman operator `T`, and a `get_greedy()` function to compute the approximate optimal policy from a guess `v` of the value function

```
def operator_factory(sp, parallel_flag=True):

    f, g = sp.f, sp.g
    w_f, w_g = sp.w_f, sp.w_g
    β, c = sp.β, sp.c
    mc_size = sp.mc_size
    w_grid, π_grid = sp.w_grid, sp.π_grid

    @jit
    def v_func(x, y, v):
        return mlinterp((w_grid, π_grid), v, (x, y))

    @jit
    def κ(w, π):
```

(continues on next page)

(continued from previous page)

```
        """
        Updates π using Bayes' rule and the current wage observation w.
        """
        pf, pg = π * f(w), (1 - π) * g(w)
        π_new = pf / (pf + pg)

        return π_new

    @jit(parallel=parallel_flag)
    def T(v):
        """
        The Bellman operator.

        """
        v_new = np.empty_like(v)

        for i in prange(len(w_grid)):
            for j in prange(len(π_grid)):
                w = w_grid[i]
                π = π_grid[j]

                v_1 = w / (1 - β)

                integral_f, integral_g = 0, 0
                for m in prange(mc_size):
                    integral_f += v_func(w_f[m], κ(w_f[m], π), v)
                    integral_g += v_func(w_g[m], κ(w_g[m], π), v)
                integral = (π * integral_f + (1 - π) * integral_g) / mc_size

                v_2 = c + β * integral
                v_new[i, j] = max(v_1, v_2)

        return v_new

    @jit(parallel=parallel_flag)
    def get_greedy(v):
        """"
        Compute optimal actions taking v as the value function.

        """
        σ = np.empty_like(v)

        for i in prange(len(w_grid)):
            for j in prange(len(π_grid)):
                w = w_grid[i]
                π = π_grid[j]

                v_1 = w / (1 - β)

                integral_f, integral_g = 0, 0
                for m in prange(mc_size):
                    integral_f += v_func(w_f[m], κ(w_f[m], π), v)
                    integral_g += v_func(w_g[m], κ(w_g[m], π), v)
                integral = (π * integral_f + (1 - π) * integral_g) / mc_size

                v_2 = c + β * integral
```

(continues on next page)

(continued from previous page)

```
                σ[i, j] = v_1 > v_2  # Evaluates to 1 or 0

        return σ

    return T, get_greedy
```

We will omit a detailed discussion of the code because there is a more efficient solution method that we will use later.

To solve the model we will use the following function that iterates using T to find a fixed point

```
def solve_model(sp,
                use_parallel=True,
                tol=1e-4,
                max_iter=1000,
                verbose=True,
                print_skip=5):

    """
    Solves for the value function

    * sp is an instance of SearchProblem
    """

    T, _ = operator_factory(sp, use_parallel)

    # Set up loop
    i = 0
    error = tol + 1
    m, n = len(sp.w_grid), len(sp.π_grid)

    # Initialize v
    v = np.zeros((m, n)) + sp.c / (1 - sp.β)

    while i < max_iter and error > tol:
        v_new = T(v)
        error = np.max(np.abs(v - v_new))
        i += 1
        if verbose and i % print_skip == 0:
            print(f"Error at iteration {i} is {error}.")
        v = v_new

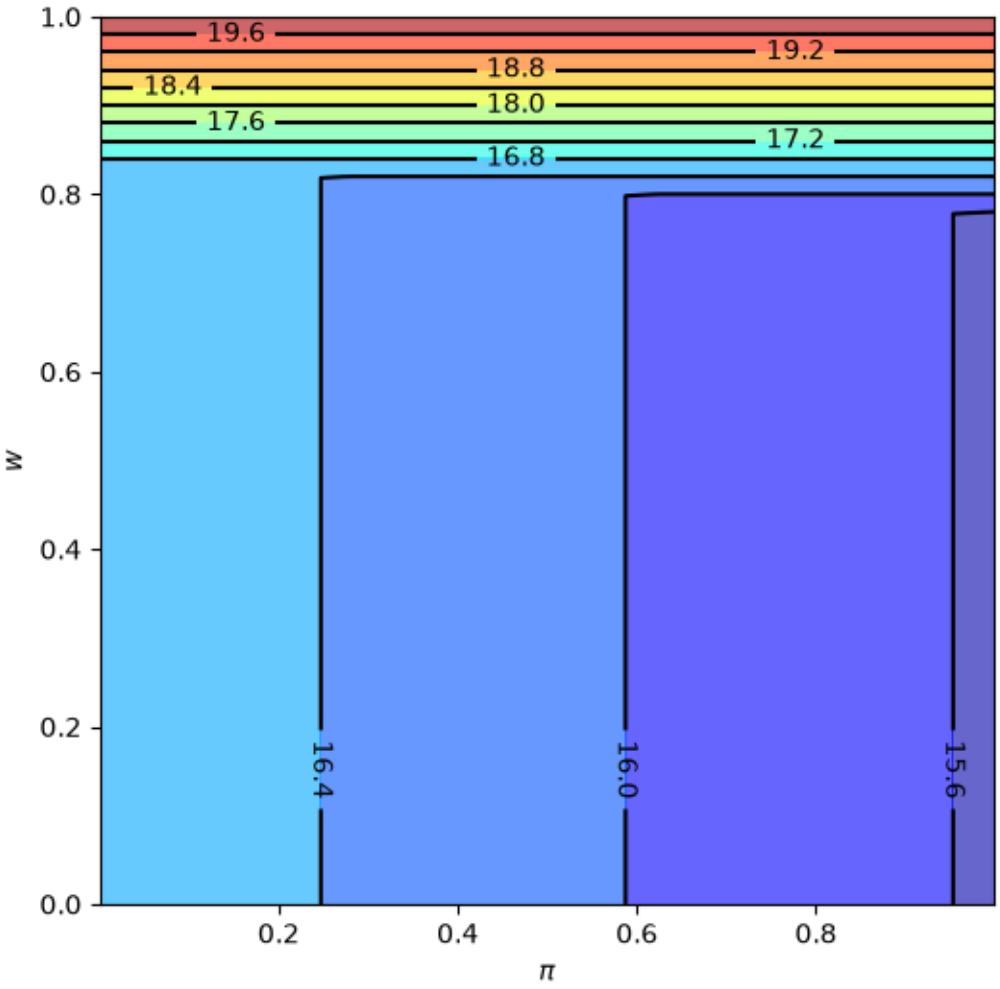
    if error > tol:
        print("Failed to converge!")
    elif verbose:
        print(f"\nConverged in {i} iterations.")

    return v_new
```

Let's look at solutions computed from value function iteration

```
sp = SearchProblem()
v_star = solve_model(sp)
fig, ax = plt.subplots(figsize=(6, 6))
ax.contourf(sp.π_grid, sp.w_grid, v_star, 12, alpha=0.6, cmap=cm.jet)
cs = ax.contour(sp.π_grid, sp.w_grid, v_star, 12, colors="black")
ax.clabel(cs, inline=1, fontsize=10)
```

(continues on next page)



(continued from previous page)

```
ax.set(xlabel=r'$\pi$', ylabel='$w$')

plt.show()
```

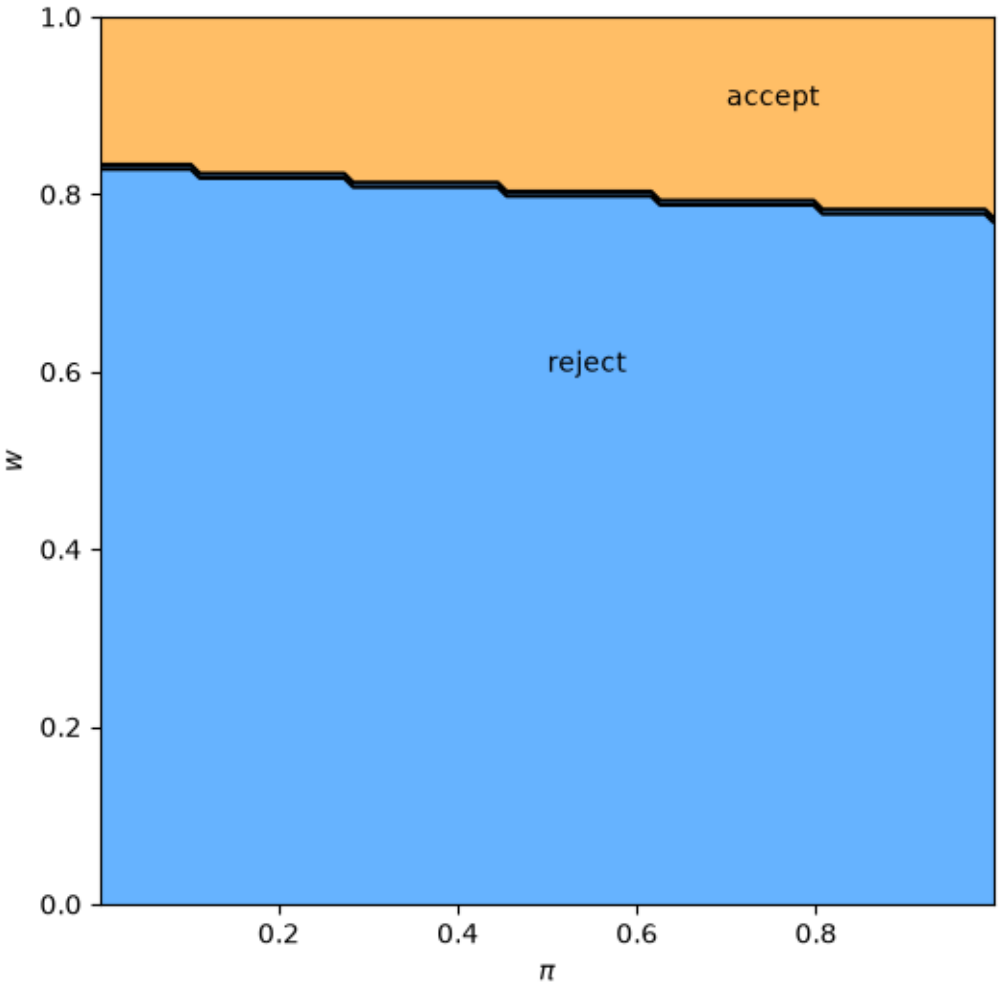
```
Error at iteration 5 is 0.6539433437319566.
Error at iteration 10 is 0.10673633468072907.
Error at iteration 15 is 0.022994332670682738.
Error at iteration 20 is 0.005064115705339489.
Error at iteration 25 is 0.0011238512408109358.
Error at iteration 30 is 0.00024791974615823165.

Converged in 34 iterations.
```

We will also plot the optimal policy

```
T, get_greedy = operator_factory(sp)
σ_star = get_greedy(v_star)

fig, ax = plt.subplots(figsize=(6, 6))
ax.contourf(sp.π_grid, sp.w_grid, σ_star, 1, alpha=0.6, cmap=cm.jet)
ax.contour(sp.π_grid, sp.w_grid, σ_star, 1, colors="black")
```



(continues on next page)

(continued from previous page)

```
ax.set(xlabel=r'$\pi$', ylabel='$w$')

ax.text(0.5, 0.6, 'reject')
ax.text(0.7, 0.9, 'accept')

plt.show()
```

The results fit well with our intuition from section *looking forward*.

- The black line in the figure above corresponds to the function $\bar{w}(\pi)$ introduced there.
- It is decreasing as expected.

63.4 Take 2: A More Efficient Method

Let's consider another method to solve for the optimal policy.

We will use iteration with an operator that has the same contraction rate as the Bellman operator, but

- one dimensional rather than two dimensional
- no maximization step

As a consequence, the algorithm is orders of magnitude faster than VFI.

This section illustrates the point that when it comes to programming, a bit of mathematical analysis goes a long way.

63.5 Another Functional Equation

To begin, note that when $w = \bar{w}(\pi)$, the worker is indifferent between accepting and rejecting.

Hence the two choices on the right-hand side of (63.3) have equal value:

$$\frac{\bar{w}(\pi)}{1-\beta} = c + \beta \int v(w', \pi') \, q_\pi(w') \, dw' \tag{63.4}$$

Together, (63.3) and (63.4) give

$$v(w, \pi) = \max \left\{ \frac{w}{1-\beta}, \, \frac{\bar{w}(\pi)}{1-\beta} \right\} \tag{63.5}$$

Combining (63.4) and (63.5), we obtain

$$\frac{\bar{w}(\pi)}{1-\beta} = c + \beta \int \max \left\{ \frac{w'}{1-\beta}, \, \frac{\bar{w}(\pi')}{1-\beta} \right\} q_\pi(w') \, dw'$$

Multiplying by $1-\beta$, substituting in $\pi' = \kappa(w', \pi)$ and using $\circ$ for composition of functions yields

$$\bar{w}(\pi) = (1-\beta)c + \beta \int \max \left\{ w', \bar{w} \circ \kappa(w', \pi) \right\} \, q_\pi(w') \, dw' \tag{63.6}$$

Equation (63.6) can be understood as a functional equation, where $\bar{w}$ is the unknown function.

- Let's call it the **reservation wage functional equation** (RWFE).
- The solution $\bar{w}$ to the RWFE is the object that we wish to compute.

63.6 Solving the RWFE

To solve the RWFE, we will first show that its solution is the fixed point of a contraction mapping.

To this end, let

- $b[0, 1]$ be the bounded real-valued functions on $[0, 1]$
- $\|\omega\| := \sup_{x \in [0,1]} |\omega(x)|$

Consider the operator Q mapping $\omega \in b[0, 1]$ into $Q\omega \in b[0, 1]$ via

$$(Q\omega)(\pi) = (1-\beta)c + \beta \int \max \left\{ w', \omega \circ \kappa(w', \pi) \right\} \, q_\pi(w') \, dw' \tag{63.7}$$

Comparing (63.6) and (63.7), we see that the set of fixed points of Q exactly coincides with the set of solutions to the RWFE.

- If $Q\bar{w} = \bar{w}$ then $\bar{w}$ solves (63.6) and vice versa.

Moreover, for any $\omega, \omega' \in b[0,1]$, basic algebra and the triangle inequality for integrals tells us that

$$|(Q\omega)(\pi) - (Q\omega')(\pi)| \leq \beta \int |\max\{w', \omega \circ \kappa(w', \pi)\} - \max\{w', \omega' \circ \kappa(w', \pi)\}| \; q_\pi(w') \, dw' \tag{63.8}$$

Working case by case, it is easy to check that for real numbers a, b, c we always have

$$|\max\{a, b\} - \max\{a, c\}| \leq |b - c| \tag{63.9}$$

Combining (63.8) and (63.9) yields

$$|(Q\omega)(\pi) - (Q\omega')(\pi)| \leq \beta \int |\omega \circ \kappa(w', \pi) - \omega' \circ \kappa(w', \pi)| \; q_\pi(w') \, dw' \leq \beta \|\omega - \omega'\| \tag{63.10}$$

Taking the supremum over π now gives us

$$\|Q\omega - Q\omega'\| \leq \beta \|\omega - \omega'\| \tag{63.11}$$

In other words, Q is a contraction of modulus β on the complete metric space $(b[0,1], \|\cdot\|)$.

Hence

- A unique solution $\bar{w}$ to the RWFE exists in $b[0,1]$.
- $Q^k \omega \to \bar{w}$ uniformly as $k \to \infty$, for any $\omega \in b[0,1]$.

63.7 Implementation

The following function takes an instance of `SearchProblem` and returns the operator `Q`

```
def Q_factory(sp, parallel_flag=True):

    f, g = sp.f, sp.g
    w_f, w_g = sp.w_f, sp.w_g
    β, c = sp.β, sp.c
    mc_size = sp.mc_size
    w_grid, π_grid = sp.w_grid, sp.π_grid

    @jit
    def ω_func(p, ω):
        return np.interp(p, π_grid, ω)

    @jit
    def κ(w, π):
        """
        Updates π using Bayes' rule and the current wage observation w.
        """
        pf, pg = π * f(w), (1 - π) * g(w)
        π_new = pf / (pf + pg)

        return π_new

    @jit(parallel=parallel_flag)
    def Q(ω):
        """
```

(continues on next page)

(continued from previous page)

```
        Updates the reservation wage function guess ω via the operator
        Q.

        """
        ω_new = np.empty_like(ω)

        for i in prange(len(π_grid)):
            π = π_grid[i]
            integral_f, integral_g = 0, 0

            for m in prange(mc_size):
                integral_f += max(w_f[m], ω_func(κ(w_f[m], π), ω))
                integral_g += max(w_g[m], ω_func(κ(w_g[m], π), ω))
            integral = (π * integral_f + (1 - π) * integral_g) / mc_size

            ω_new[i] = (1 - β) * c + β * integral

        return ω_new

    return Q
```

In the next exercise, you are asked to compute an approximation to $\bar{w}$.

63.8 Exercises

Exercise 63.8.1

Use the default parameters and `Q_factory` to compute an optimal policy.

Your result should coincide closely with the figure for the optimal policy *shown above*.

Try experimenting with different parameters, and confirm that the change in the optimal policy coincides with your intuition.

63.9 Solutions

Solution

This code solves the "Offer Distribution Unknown" model by iterating on a guess of the reservation wage function.

You should find that the run time is shorter than that of the value function approach.

Similar to above, we set up a function to iterate with `Q` to find the fixed point

```
def solve_wbar(sp,
               use_parallel=True,
               tol=1e-4,
               max_iter=1000,
               verbose=True,
               print_skip=5):

    Q = Q_factory(sp, use_parallel)
```

```
    # Set up loop
    i = 0
    error = tol + 1
    m, n = len(sp.w_grid), len(sp.π_grid)

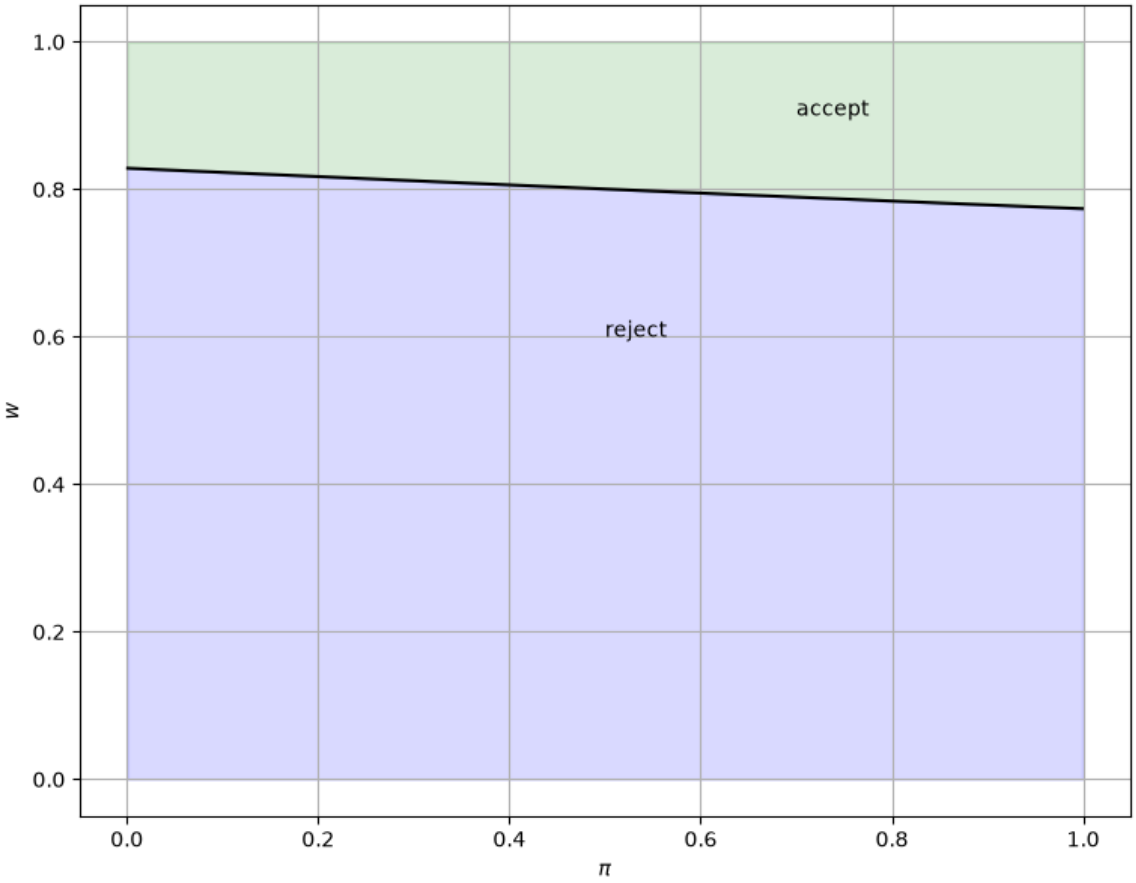
    # Initialize w
    w = np.ones_like(sp.π_grid)

    while i < max_iter and error > tol:
        w_new = Q(w)
        error = np.max(np.abs(w - w_new))
        i += 1
        if verbose and i % print_skip == 0:
            print(f"Error at iteration {i} is {error}.")
        w = w_new

    if error > tol:
        print("Failed to converge!")
    elif verbose:
        print(f"\nConverged in {i} iterations.")

    return w_new
```

The solution can be plotted as follows



```
sp = SearchProblem()
w_bar = solve_wbar(sp)

fig, ax = plt.subplots(figsize=(9, 7))

ax.plot(sp.π_grid, w_bar, color='k')
ax.fill_between(sp.π_grid, 0, w_bar, color='blue', alpha=0.15)
ax.fill_between(sp.π_grid, w_bar, sp.w_max, color='green', alpha=0.15)
ax.text(0.5, 0.6, 'reject')
ax.text(0.7, 0.9, 'accept')
ax.set(xlabel=r'$\pi$', ylabel='$w$')
ax.grid()
plt.show()
```

```
Error at iteration 5 is 0.021726625819358802.
Error at iteration 10 is 0.006988182615050631.

```

63.10 Appendix A

The next piece of code generates a fun simulation to see what the effect of a change in the underlying distribution on the unemployment rate is.

At a point in the simulation, the distribution becomes significantly worse.

It takes a while for agents to learn this, and in the meantime, they are too optimistic and turn down too many jobs.

As a result, the unemployment rate spikes

```
F_a, F_b, G_a, G_b = 1, 1, 3, 1.2

63.11 Appendix B

In this appendix we provide more details about how Bayes' Law contributes to the workings of the model.

We present some graphs that bring out additional insights about how learning works.

We build on graphs proposed in this lecture.

In particular, we'll add actions of our searching worker to a key graph presented in that lecture.

To begin, we first define two functions for computing the empirical distributions of unemployment duration and π at the time of employment.

```
@jit
def empirical_dist(F_a, F_b, G_a, G_b, w_bar, π_grid,
                   N=10000, T=600):
    """
    Simulates population for computing empirical cumulative
    distribution of unemployment duration and π at time when
    the worker accepts the wage offer. For each job searching
    problem, we simulate for two cases that either f or g is
    the true offer distribution.

    Parameters
    ----------
```

(continues on next page)

(continued from previous page)

```
    F_a, F_b, G_a, G_b : parameters of beta distributions F and G.
    w_bar : the reservation wage
    π_grid : grid points of π, for interpolation
    N : number of workers for simulation, optional
    T : maximum of time periods for simulation, optional

    Returns
    -------
    accpet_t : 2 by N ndarray. the empirical distribution of
               unemployment duration when f or g generates offers.
    accept_π : 2 by N ndarray. the empirical distribution of
               π at the time of employment when f or g generates offers.
    """

    accept_t = np.empty((2, N))
    accept_π = np.empty((2, N))

    # f or g generates offers
    for i, (a, b) in enumerate([(F_a, F_b), (G_a, G_b)]):
        # update each agent
        for n in range(N):

            # initial priori
            π = 0.5

            for t in range(T+1):

                # Draw random wage
                w = np.random.beta(a, b)
                lw = p(w, F_a, F_b) / p(w, G_a, G_b)
                π = π * lw / (π * lw + 1 - π)

                # move to next agent if accepts
                if w >= np.interp(π, π_grid, w_bar):
                    break

            # record the unemployment duration
            # and π at the time of acceptance
            accept_t[i, n] = t
            accept_π[i, n] = π

    return accept_t, accept_π

def cumfreq_x(res):
    """
    A helper function for calculating the x grids of
    the cumulative frequency histogram.
    """

    cumcount = res.cumcount
    lowerlimit, binsize = res.lowerlimit, res.binsize

    x = lowerlimit + np.linspace(0, binsize*cumcount.size, cumcount.size)

    return x
```

Now we define a wrapper function for analyzing job search models with learning under different parameterizations.

The wrapper takes parameters of beta distributions and unemployment compensation as inputs and then displays various things we want to know to interpret the solution of our search model.

In addition, it computes empirical cumulative distributions of two key objects.

```
def job_search_example(F_a=1, F_b=1, G_a=3, G_b=1.2, c=0.3):
    """
    Given the parameters that specify F and G distributions,
    calculate and display the rejection and acceptance area,
    the evolution of belief π, and the probability of accepting
    an offer at different π level, and simulate and calculate
    the empirical cumulative distribution of the duration of
    unemployment and π at the time the worker accepts the offer.
    """

    # construct a search problem
    sp = SearchProblem(F_a=F_a, F_b=F_b, G_a=G_a, G_b=G_b, c=c)
    f, g = sp.f, sp.g

    plt.show()
```

We now provide some examples that provide insights about how the model works.

63.12 Examples

63.12.1 Example 1 (Baseline)

F ~ Beta(1, 1), G ~ Beta(3, 1.2), c=0.3.

In the graphs below, the red arrows in the upper right figure show how π_t is updated in response to the new information w_t.

Recall the following formula from this lecture

$$\frac{\pi_{t+1}}{\pi_t} = \frac{l\left(w_{t+1}\right)}{\pi_t l\left(w_{t+1}\right) + \left(1 - \pi_t\right)} \begin{cases} > 1 & \text{if } l\left(w_{t+1}\right) > 1 \\ \leq 1 & \text{if } l\left(w_{t+1}\right) \leq 1 \end{cases}$$

The formula implies that the direction of motion of π_t is determined by the relationship between $l(w_t)$ and 1.

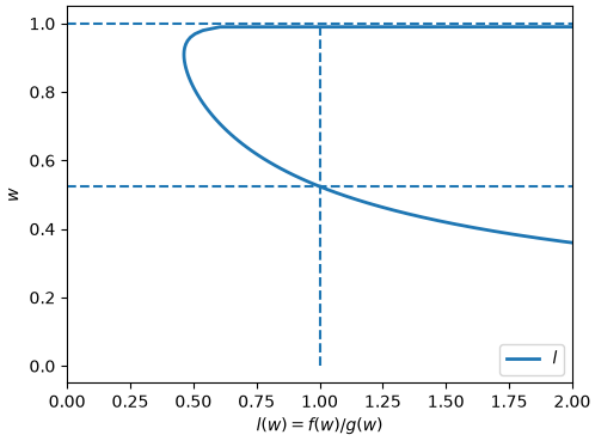
The magnitude is small if

- $l(w)$ is close to 1, which means the new w is not very informative for distinguishing two distributions,
- π_{t-1} is close to either 0 or 1, which means the priori is strong.

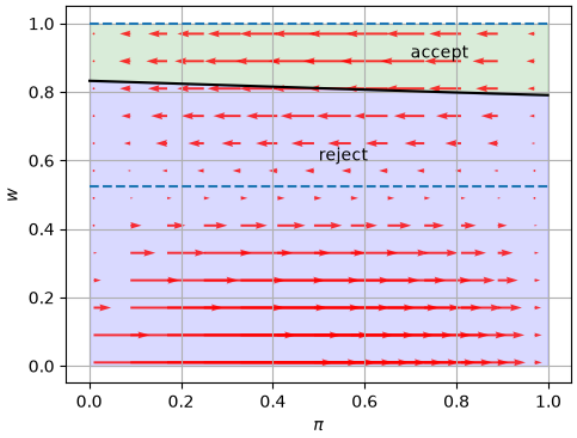
Will an unemployed worker accept an offer earlier or not, when the actual ruling distribution is g instead of f?

Two countervailing effects are at work.

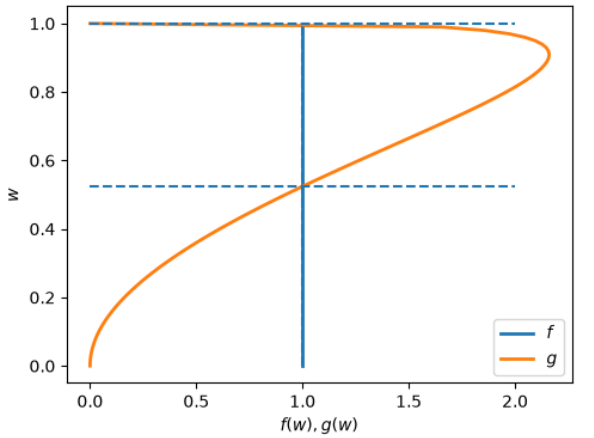
- if f generates successive wage offers, then w is more likely to be low, but π is moving up toward to 1, which lowers the reservation wage, i.e., the worker becomes less selective the longer he or she remains unemployed.
- if g generates wage offers, then w is more likely to be high, but π is moving downward toward 0, increasing the reservation wage, i.e., the worker becomes more selective the longer he or she remains unemployed.



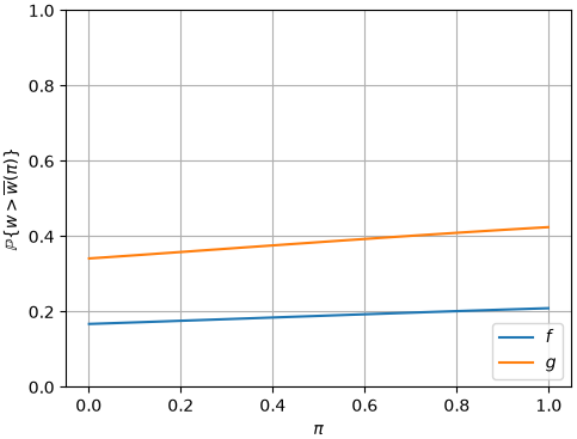
Quantitatively, the lower right figure sheds light on which effect dominates in this example.



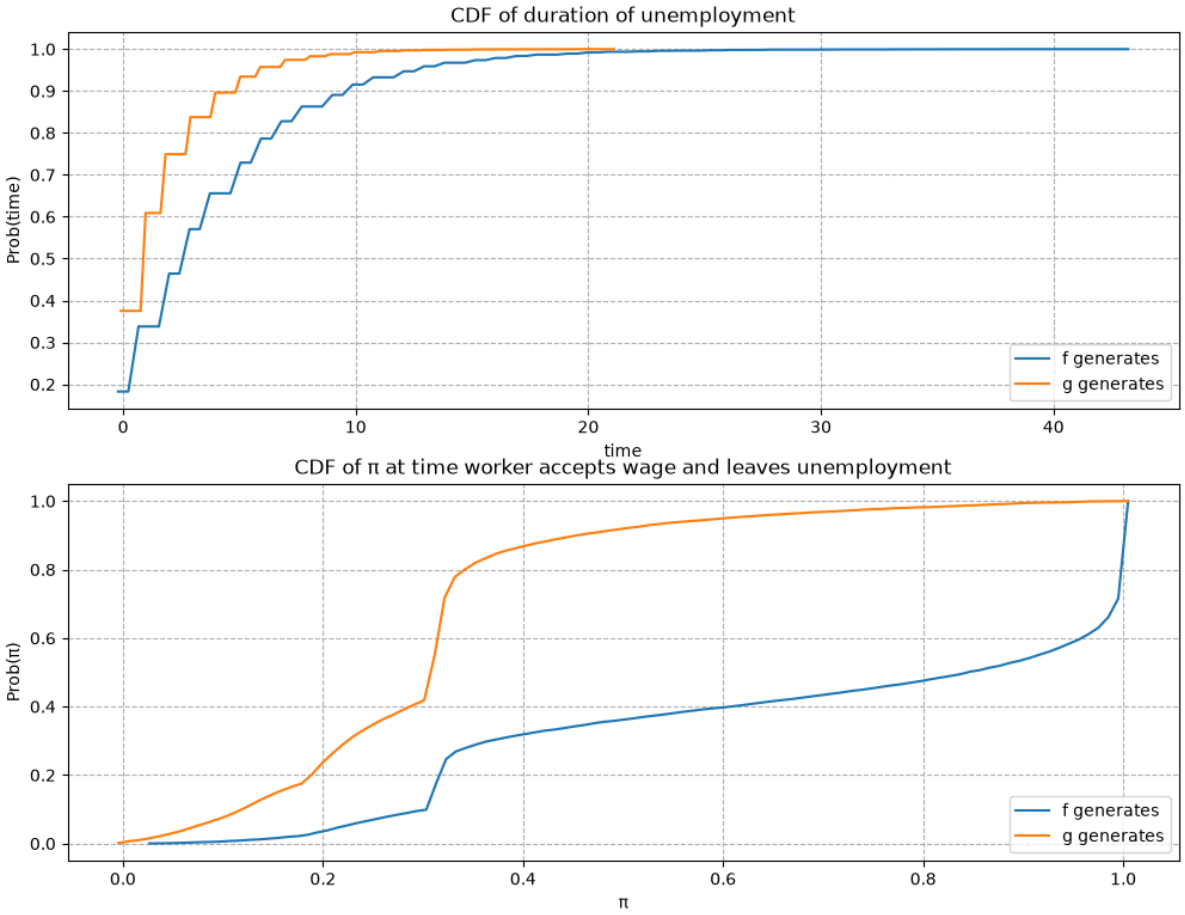
It shows the probability that a previously unemployed worker accepts an offer at different values of π when f or g generates wage offers.



That graph shows that for the particular f and g in this example, the worker is always more likely to accept an offer when f generates the data even when π is close to zero so that the worker believes the true distribution is g and therefore is relatively more selective.



The empirical cumulative distribution of the duration of unemployment verifies our conjecture.



```
job_search_example()
```

w

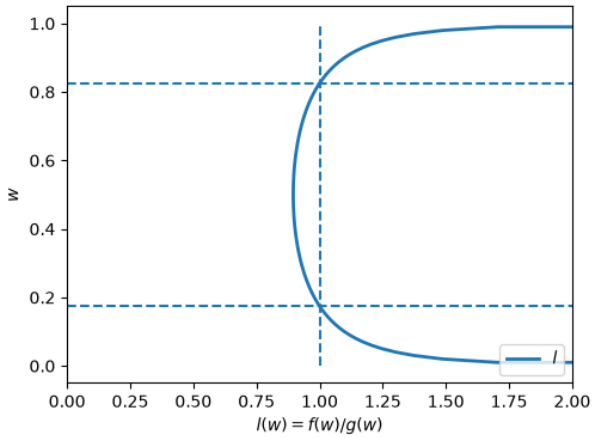
l

accept
reject
w
π

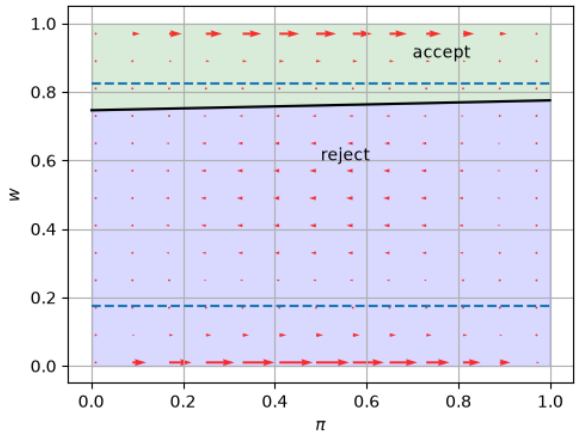
w
f(w), g(w)
f
g

$\mathbb{P}\{w > \overline{w}(\pi)\}$
π
f
g

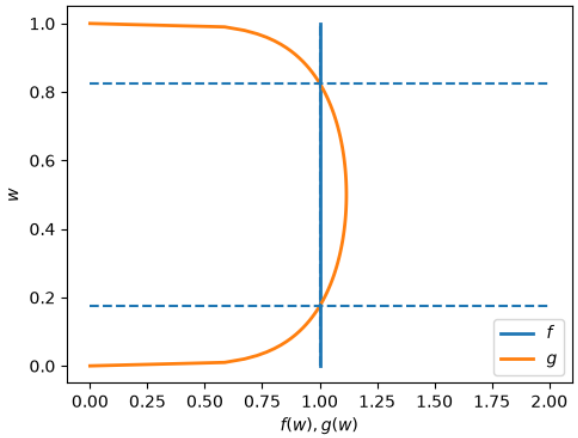
63.12.2 Example 2



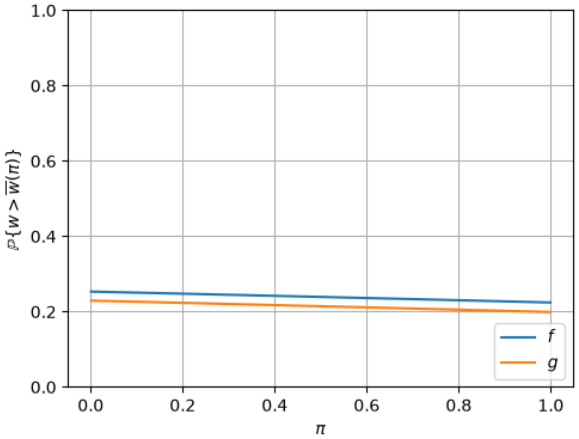
F ~ Beta(1, 1), G ~ Beta(1.2, 1.2), c=0.3.



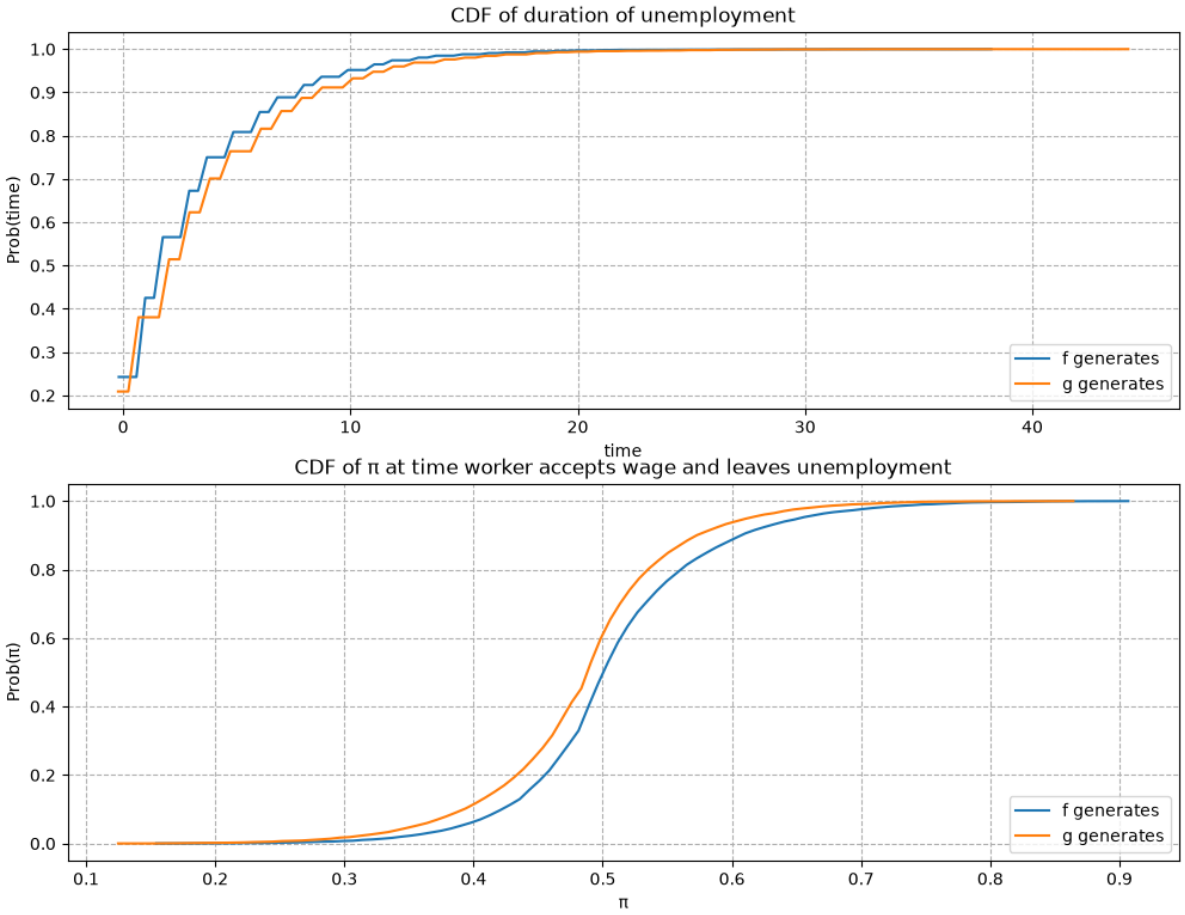
Now G has the same mean as F with a smaller variance.



Since the unemployment compensation c serves as a lower bound for bad wage offers, G is now an "inferior" distribution to F.



Consequently, we observe that the optimal policy $\overline{w}(\pi)$ is increasing in π.



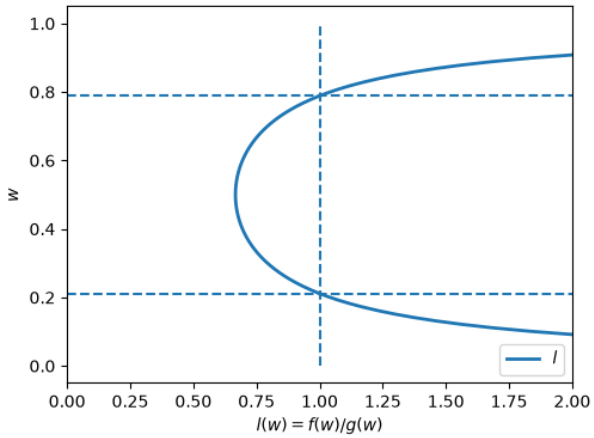
```
job_search_example(1, 1, 1.2, 1.2, 0.3)
```

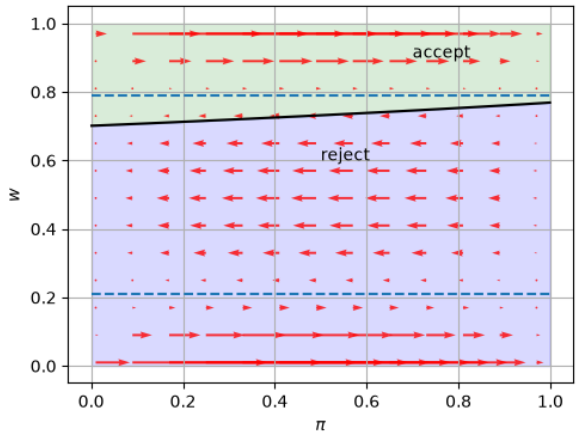
w
l(w) = f(w)/g(w)
l

accept
reject
w
π

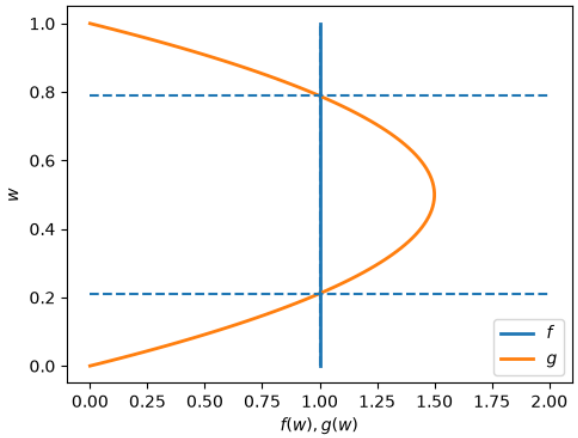
w
f(w), g(w)
f
g

$\mathbb{P}\{w > \overline{w}(\pi)\}$
π
f
g

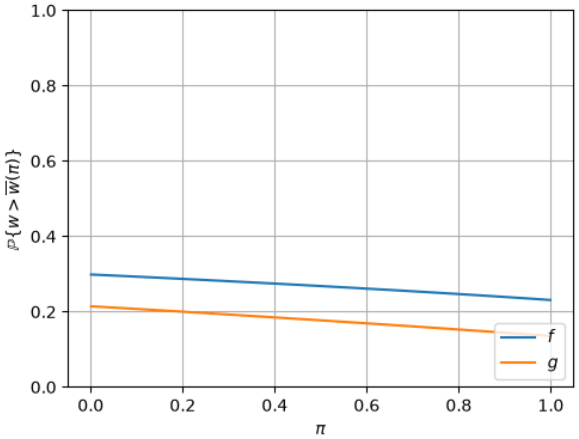




63.12.3 Example 3



F ~ Beta(1, 1), G ~ Beta(2, 2), c=0.3.



If the variance of G is smaller, we observe in the result that G is even more "inferior" and the slope of $\overline{w}(\pi)$ is larger.

```
job_search_example(1, 1, 2, 2, 0.3)
```

w
l(w) = f(w)/g(w)
l

accept
reject
w
π

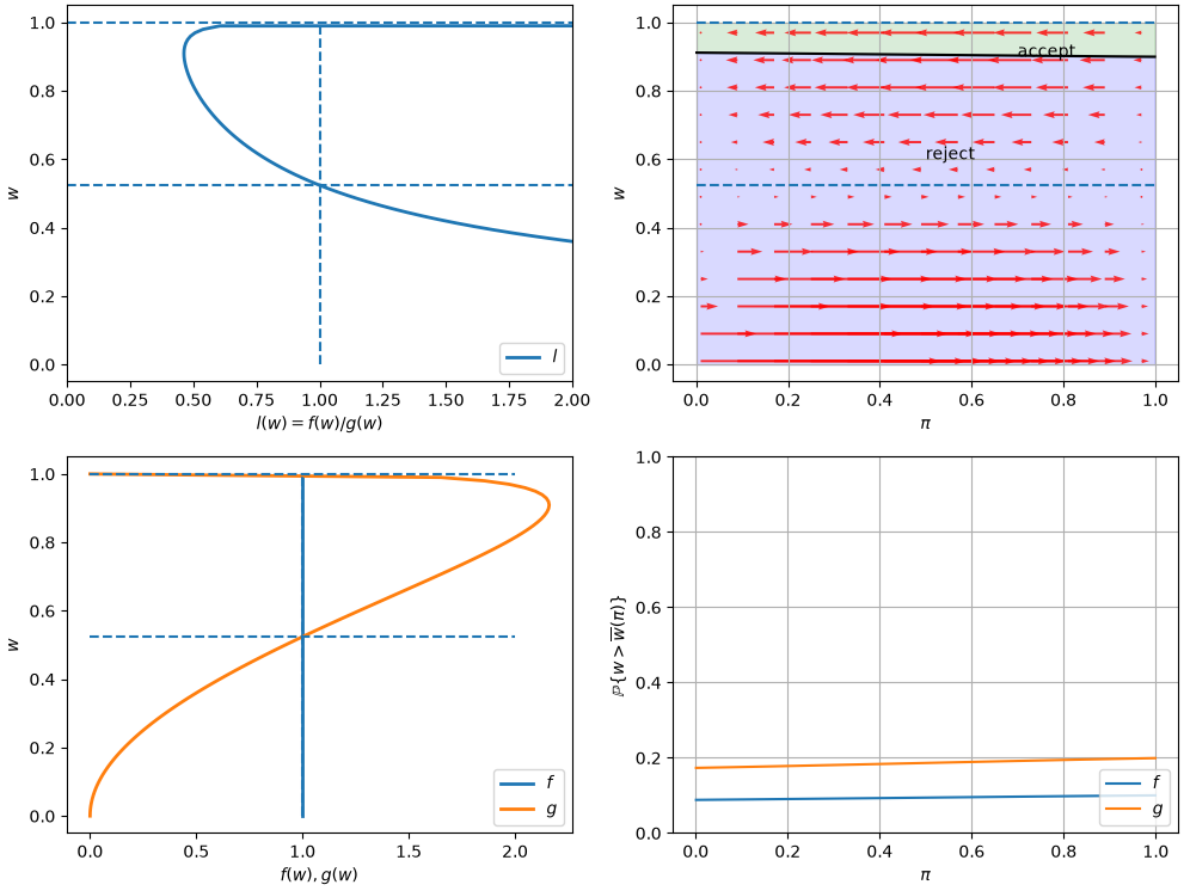
w
f(w), g(w)
f
g

$\mathbb{P}\{w > \overline{w}(\pi)\}$
π
f
g

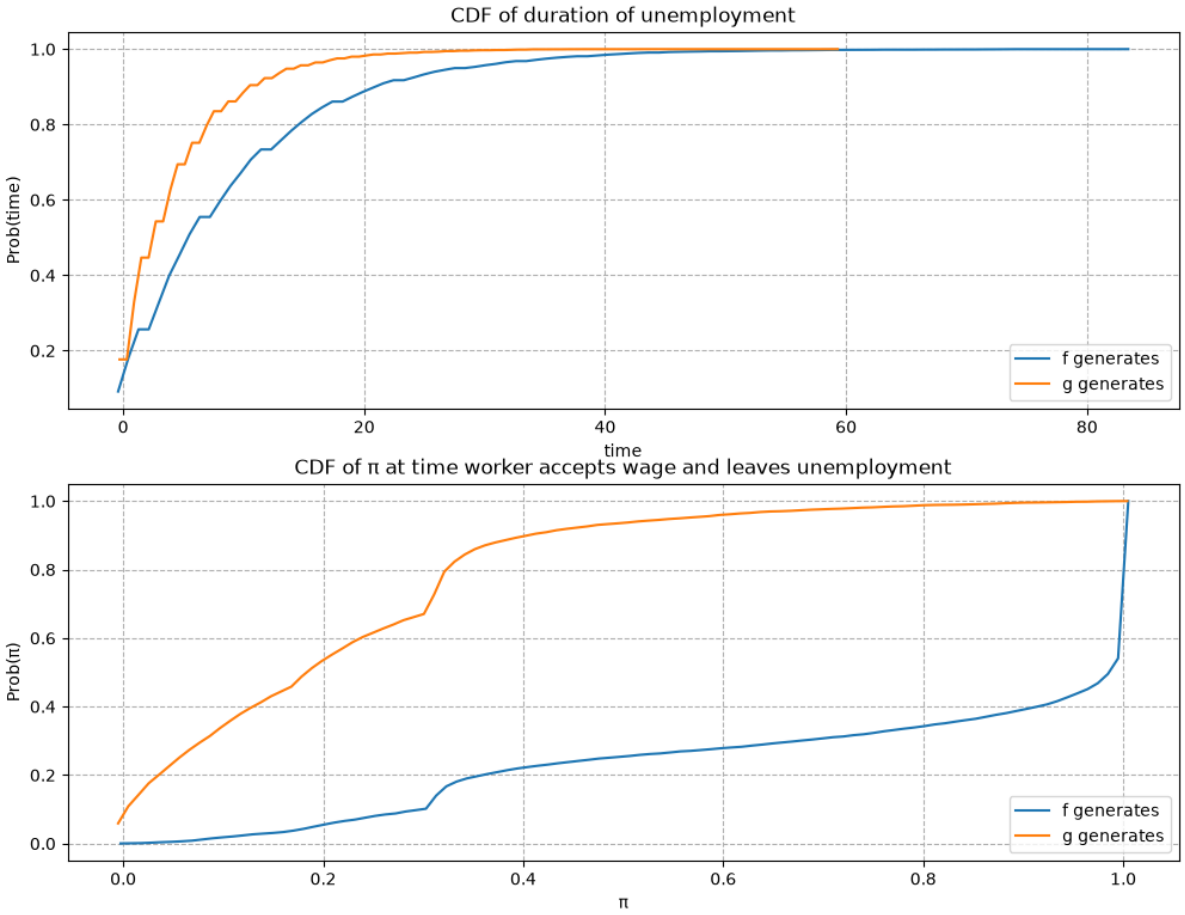
63.12.4 Example 4

F ~ Beta(1, 1), G ~ Beta(3, 1.2), and c=0.8.

In this example, we keep the parameters of beta distributions to be the same with the baseline case but increase the unemployment compensation c.



Comparing outcomes to the baseline case (example 1) in which unemployment compensation if low (c=0.3), now the worker can afford a longer learning period.

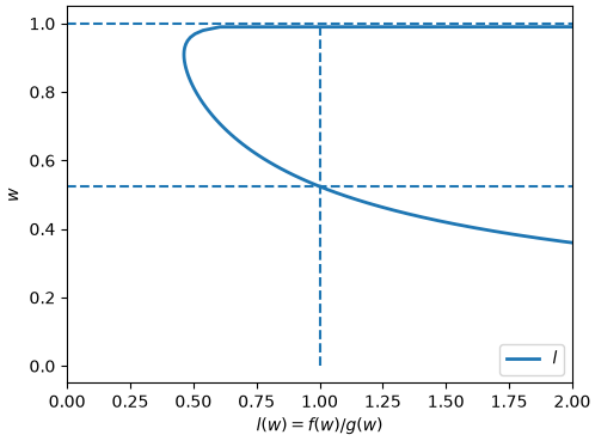


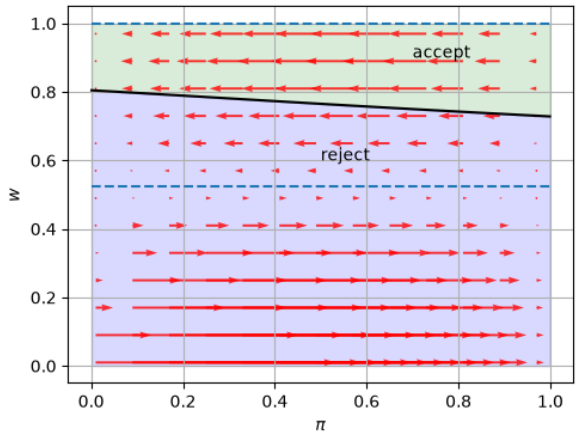
As a result, the worker tends to accept wage offers much later.

Furthermore, at the time of accepting employment, the belief π is closer to either 0 or 1.

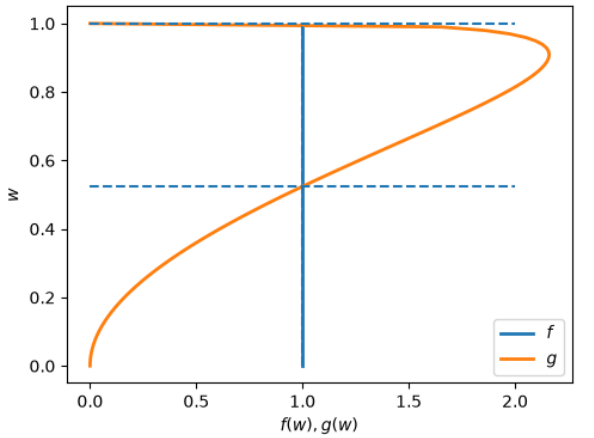
That means that the worker has a better idea about what the true distribution is when he eventually chooses to accept a wage offer.

```
job_search_example(1, 1, 3, 1.2, c=0.8)
```

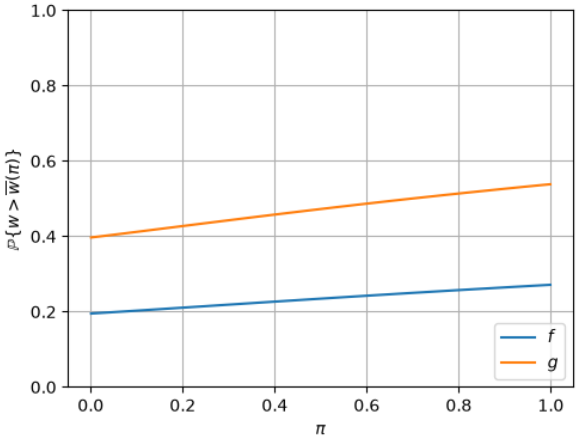




63.12.5 Example 5



F ~ Beta(1, 1), G ~ Beta(3, 1.2), and c=0.1.



As expected, a smaller c makes an unemployed worker accept wage offers earlier after having acquired less information about the wage distribution.

```
job_search_example(1, 1, 3, 1.2, c=0.1)

INVENTORY MANAGEMENT VIA Q-LEARNING

Contents

- *Inventory Management via Q-Learning*
  - *Introduction*
  - *The Model*
  - *Solving via Value Function Iteration*
  - *Q-Learning*

64.1 Introduction

In this lecture we study a classic inventory management problem.

A firm must decide how much stock to order each period, facing uncertain demand and a trade-off between lost sales and ordering costs.

We approach the problem in two ways.

First, we solve it exactly using dynamic programming, assuming full knowledge of the model – the demand distribution, cost parameters, and transition dynamics.

Second, we show how a manager can learn the optimal policy from experience alone, using Q-learning.

In this setting, we assume that the manager observes only

- the inventory level,
- the order placed,
- the resulting profit, and
- the next inventory level.

The manager knows the interest rate – and hence the discount factor – but not any of the other underlying parameters.

A key idea is the *Q-factor* representation, which reformulates the Bellman equation so that the optimal policy can be recovered without knowledge of the transition dynamics.

We show that, given enough experience, the manager's learned policy converges to the optimal one.

The lecture proceeds as follows:

1. We set up the inventory model and solve it exactly via value function iteration.
2. We introduce Q-factors and derive the Q-factor Bellman equation.
3. We implement Q-learning and show the learned policy converges to the optimal one.

A risk-sensitive extension of this model is studied in *Risk-Sensitive Inventory Management via Q-Learning*.

We will use the following imports:

```
import numpy as np
import numba
import matplotlib.pyplot as plt
from typing import NamedTuple
```

64.2 The Model

We study a firm where a manager tries to maximize shareholder value by controlling inventories.

To simplify the problem, we assume that the firm only sells one product.

Letting π_t be profits at time t and $r > 0$ be the interest rate, the value of the firm is

$$V_0 = \mathbb{E} \sum_{t \geq 0} \beta^t \pi_t \qquad \text{where} \qquad \beta := \frac{1}{1+r}.$$

Suppose the firm faces exogenous demand process $(D_t)_{t \geq 0}$.

We assume $(D_t)_{t \geq 0}$ is IID with common distribution ϕ on $\{0, 1, ...\}$.

Inventory $(X_t)_{t \geq 0}$ of the product obeys

$$X_{t+1} = h(X_t, A_t, D_{t+1}) \qquad \text{where} \quad h(x, a, d) := \max(x - d, 0) + a.$$

The term A_t is units of stock ordered this period, which arrive at the start of period $t + 1$, after demand D_{t+1} is realized and served:

- observe $X_t \to$ choose $A_t \to$ demand D_{t+1} arrives $\to$ profit realized $\to X_{t+1}$ determined.

(We use a t subscript in A_t to indicate the information set: it is chosen before D_{t+1} is observed.)

We assume that the firm can store at most K items at one time.

Profits are given by

$$\pi(X_t, A_t, D_{t+1}) := \min(X_t, D_{t+1}) - cA_t - \kappa 1\{A_t > 0\}.$$

Here

- the sales price is set to unity (for convenience)
- revenue is the minimum of current stock and demand because orders in excess of inventory are lost (not back-filled)
- c is unit product cost and κ is a fixed cost of ordering inventory

We can map our inventory problem into a dynamic program with state space $\mathsf{X} := \{0, \ldots, K\}$ and action space $\mathsf{A} := \mathsf{X}$.

The feasible correspondence Γ is

$$\Gamma(x) := \{0, \ldots, K - x\}.$$

This represents the set of feasible orders when the current inventory state is x.

The Bellman equation takes the form

$$v(x) = \max_{a \in \Gamma(x)} \mathbb{E}\left[\pi(x, a, D) + \beta v(h(x, a, D))\right]. \tag{64.1}$$

Here D is a random variable with distribution ϕ.

64.3 Solving via Value Function Iteration

Let's start in a setting where the manager knows all parameters, functional forms, and distributions.

She solves the model numerically using value function iteration (VFI).

The idea is to iterate on the Bellman operator T defined by

$$(Tv)(x) = \max_{a \in \Gamma(x)} \sum_d \phi(d) \left[\pi(x, a, d) + \beta\, v(h(x, a, d))\right]$$

starting from an initial guess v_0.

Then, taking the output v from this iteration process, we compute a v**-greedy policy** σ, which obeys

$$\sigma(x) \in \arg\max_{a \in \Gamma(x)} \sum_d \phi(d) \left[\pi(x, a, d) + \beta\, v(h(x, a, d))\right]$$

When $r > 0$ (equivalently, $\beta < 1$), the sequence $v_{k+1} = Tv_k$ converges to the unique fixed point v^*, which is the value function of the optimal policy (see, e.g., [Sargent and Stachurski, 2025]).

64.3.1 Model specification

We store the model primitives in a `NamedTuple`.

Demand follows a geometric distribution with parameter p, so $\phi(d) = (1-p)^d\, p$ for $d = 0, 1, 2, \ldots$.

```
class Model(NamedTuple):
    x_values: np.ndarray        # Inventory values
    d_values: np.ndarray        # Demand values for summation
    ϕ_values: np.ndarray        # Demand probabilities
    p: float                    # Demand parameter
    c: float                    # Unit cost
    κ: float                    # Fixed cost
    β: float                    # Discount factor
```

The function below constructs a `Model` instance with default parameters.

We truncate the demand distribution at `D_MAX` for computational purposes.

```
def create_sdd_inventory_model(
        K: int = 20,          # Max inventory
        D_MAX: int = 21,      # Demand upper bound for summation
        p: float = 0.7,
        c: float = 0.2,
        κ: float = 0.8,
        β: float = 0.98
    ) -> Model:

    def demand_pdf(p, d):
```

(continues on next page)

(continued from previous page)

```
        return (1 - p)**d * p

    d_values = np.arange(D_MAX)
    ϕ_values = demand_pdf(p, d_values)      # ϕ_0, ϕ_1,...
    x_values = np.arange(K + 1)             # 0, 1, ..., K

    return Model(x_values, d_values, ϕ_values, p, c, κ, β)
```

64.3.2 The Bellman operator

The core computation is the Bellman operator T.

For each inventory level x, we loop over all feasible order quantities $a \in \{0, \ldots, K - x\}$ and compute the expected value

$$\sum_d \phi(d) \left[\min(x, d) - c\,a - \kappa\,\mathbf{1}\{a > 0\} + \beta\, v(\max(x - d, 0) + a) \right].$$

We then take the maximum over a.

The inner loops are compiled with Numba for performance.

```
@numba.jit(nopython=True)
def T_kernel(v, d_values, ϕ_values, c, κ, β, K):
    new_v = np.empty(K + 1)
    for x in range(K + 1):
        best = -np.inf
        for a in range(K - x + 1):           # loop over feasible actions
            val = 0.0
            for i in range(len(d_values)):   # compute expectation over demand
                d = d_values[i]
                x_next = max(x - d, 0) + a
                revenue = min(x, d)
                cost = c * a + κ * (a > 0)
                val += ϕ_values[i] * (revenue - cost + β * v[x_next])
            if val > best:
                best = val
        new_v[x] = best
    return new_v
```

The wrapper function `T` unpacks the model and calls the compiled kernel.

```
def T(v, model):
    """The Bellman operator."""
    x_values, d_values, ϕ_values, p, c, κ, β = model
    K = len(x_values) - 1
    return T_kernel(v, d_values, ϕ_values, c, κ, β, K)
```

64.3.3 Computing the greedy policy

Recall that, given a value function v, the **v-greedy policy** is computed via

$$\sigma(x) = \arg\max_{a \in \Gamma(x)} \sum_d \phi(d) \left[\pi(x, a, d) + \beta \, v(h(x, a, d)) \right].$$

The structure is the same as the Bellman operator, except we record the maximizing action rather than the maximized value.

```
@numba.jit(nopython=True)
def get_greedy_kernel(v, d_values, ϕ_values, c, κ, β, K):
    σ = np.empty(K + 1, dtype=np.int32)
    for x in range(K + 1):
        best = -np.inf
        best_a = 0
        for a in range(K - x + 1):
            val = 0.0
            for i in range(len(d_values)):
                d = d_values[i]
                x_next = max(x - d, 0) + a
                revenue = min(x, d)
                cost = c * a + κ * (a > 0)
                val += ϕ_values[i] * (revenue - cost + β * v[x_next])
            if val > best:
                best = val
                best_a = a
        σ[x] = best_a
    return σ
```

```
def get_greedy(v, model):
    """Get a v-greedy policy."""
    x_values, d_values, ϕ_values, p, c, κ, β = model
    K = len(x_values) - 1
    return get_greedy_kernel(v, d_values, ϕ_values, c, κ, β, K)
```

64.3.4 Value function iteration

We iterate $v_{k+1} = Tv_k$ until convergence, starting from $v_0 = 0$.

Once the value function has converged (to within tolerance `tol`), we extract the optimal policy σ^* via `get_greedy`.

```
def solve_inventory_model(v_init, model, max_iter=10_000, tol=1e-6):
    v = v_init.copy()
    i, error = 0, tol + 1

    while i < max_iter and error > tol:
        new_v = T(v, model)
        error = np.max(np.abs(new_v - v))
        i += 1
        v = new_v

    print(f"Converged in {i} iterations with error {error:.2e}")

    σ = get_greedy(v, model)
    return v, σ
```

64.3.5 Creating and solving an instance

```
model = create_sdd_inventory_model()
x_values, d_values, ϕ_values, p, c, κ, β = model
n_x = len(x_values)
v_init = np.zeros(n_x)
```

```
v_star, σ_star = solve_inventory_model(v_init, model)
```

```
Converged in 623 iterations with error 9.95e-07
```

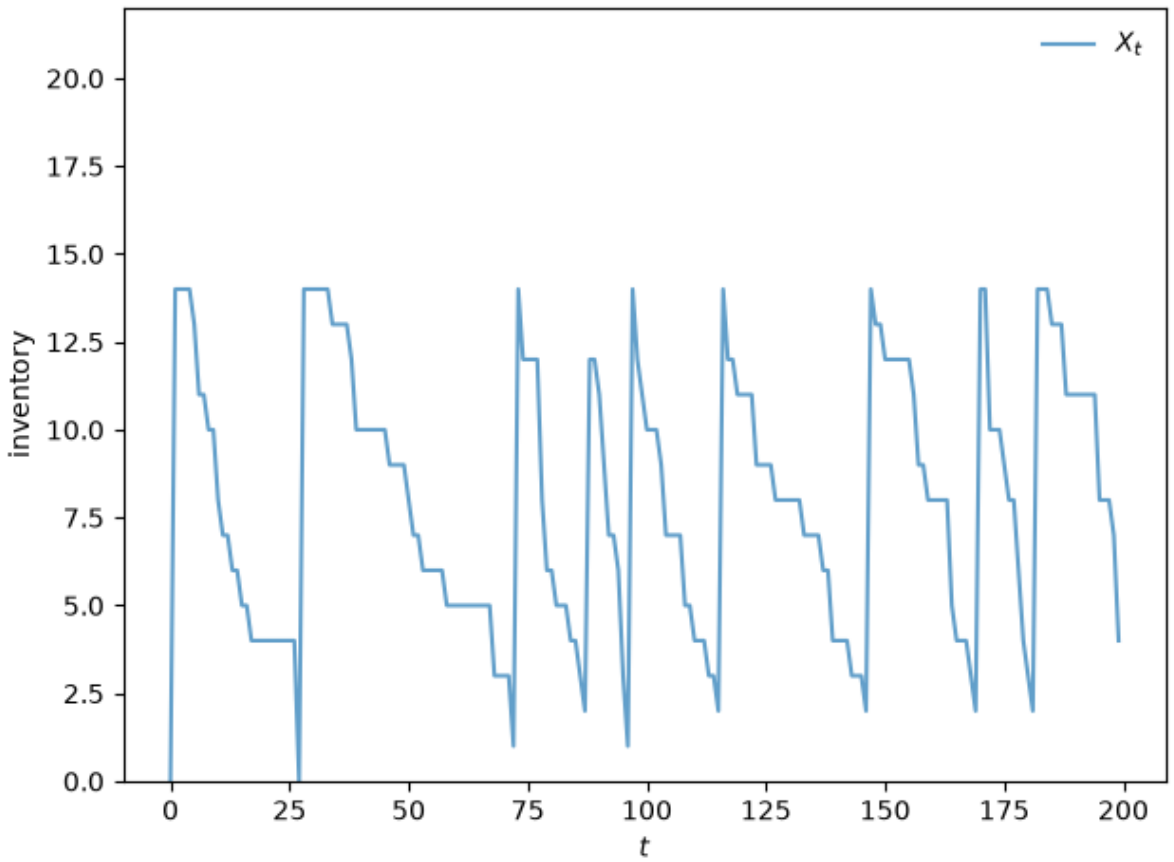
64.3.6 Simulating the optimal policy

To visualize the solution, we simulate the inventory process under the optimal policy σ^*.

At each step, we draw a demand shock from the geometric distribution and update the state via h.

```
@numba.jit(nopython=True)
def sim_inventories(ts_length, σ, p, rng, X_init=0):
    """Simulate inventory dynamics under policy σ."""
    X = np.zeros(ts_length, dtype=np.int32)
    X[0] = X_init
    for t in range(ts_length - 1):
        d = rng.geometric(p) - 1
        X[t+1] = max(X[t] - d, 0) + σ[X[t]]
    return X
```

The plot below shows a typical inventory path under the optimal policy.



Notice the **S-s pattern**: when inventory falls to a low level, the firm places a large order to replenish stock (the upward jumps), after which inventory gradually declines as demand is served.

```
def plot_ts(ts_length=200, fontsize=10, seed=0):
    X = sim_inventories(ts_length, σ_star, p, np.random.default_rng(seed))
    fig, ax = plt.subplots()

    ax.plot(X, label=r"$X_t$", alpha=0.7)
    ax.set_xlabel(r"$t$", fontsize=fontsize)
    ax.set_ylabel("inventory", fontsize=fontsize)
    ax.legend(fontsize=fontsize, frameon=False)
    ax.set_ylim(0, len(σ_star) + 1)

    plt.tight_layout()
    plt.show()
```

```
plot_ts()
```

64.4 Q-Learning

We now ask: can an agent **learn** the optimal policy without knowing the model?

In particular, suppose the agent does not know the demand distribution ϕ, the cost parameters c and κ, or the transition function h.

Instead, the agent only observes the sequence of states, actions, and profits as it interacts with the environment.

64.4.1 The Q-factor Bellman equation

The first step of Q-learning is to modify the Bellman equation, placing it in a form that allows learning from this limited information.

Rather than working with the value function $v(x)$, we work with the **Q-function** (or Q-factor) $q(x, a)$.

We define q in terms of the value function v^* as

$$q(x, a) := \mathbb{E}\left[\pi(x, a, D) + \beta\, v^*(h(x, a, D))\right].$$

In words, $q(x, a)$ is the expected value of taking action a in state x and then following the optimal policy thereafter.

Note that the Bellman equation (64.1) can be written as

$$v^*(x) = \max_{a \in \Gamma(x)} q(x, a).$$

Substituting this back into the definition of q, we can eliminate v^* and obtain a fixed point equation in q alone:

$$q(x,a) = \mathbb{E}\left[\pi(x,a,D) + \beta \max_{a' \in \Gamma(x')} q(x',a')\right]$$

where $x' = h(x,a,D)$.

One advantage of working with q is that the optimal policy can be read off directly as $\sigma(x) = \arg\max_a q(x,a)$, without needing to know the transition function.

64.4.2 The Q-learning update rule

Q-learning approximates the fixed point of the Q-factor Bellman equation using **stochastic approximation**.

At each step, the agent is in state x, takes action a, observes reward $R_{t+1} = \pi(x,a,D_{t+1})$ and next state $X_{t+1} = h(x,a,D_{t+1})$, and updates

$$q_{t+1}(x,a) = (1-\alpha_t) q_t(x,a) + \alpha_t \left(R_{t+1} + \beta \max_{a' \in \Gamma(X_{t+1})} q_t(X_{t+1}, a')\right)$$

where α_t is the learning rate.

The update blends the current estimate $q_t(x,a)$ with a fresh sample of the Bellman target.

64.4.3 What the manager needs to know

Notice what is **not** required to implement the update.

The manager does not need to know the demand distribution ϕ, the unit cost c, the fixed cost κ, or the transition function h.

All the manager needs to observe at each step is:

1. the current inventory level x,
2. the order quantity a, which they choose,
3. the resulting profit R_{t+1} (which appears on the books),
4. the discount factor β, which is determined by the interest rate, and
5. the next inventory level X_{t+1} (which they can read off the warehouse).

These are all directly observable quantities – no model knowledge is required.

64.4.4 The Q-table and the role of the max

It is important to understand how the update rule relates to the manager's actions.

The manager maintains a **Q-table** – a lookup table storing an estimate $q_t(x,a)$ for every state-action pair (x,a).

At each step, the manager is in some state x and must choose a specific action a to take. Whichever a is chosen, the manager observes profit R_{t+1} and next state X_{t+1}, and updates *that one entry* $q_t(x,a)$ of the table using the rule above.

It is tempting to read the $\max_{a'}$ in the update rule as prescribing the manager's next action – that is, to interpret the update as saying "move to state X_{t+1} and take an action in $\arg\max_{a'} q_t(X_{t+1}, a')$."

But the max plays a different role.

The quantity $\max_{a' \in \Gamma(X_{t+1})} q_t(X_{t+1}, a')$ is just an estimate of the value of being in state X_{t+1} under the best possible continuation.

This scalar enters the update as part of the target value for $q_t(x, a)$.

Which action the manager *actually takes* at time $t+1$ is a separate decision.

In short, the max is doing the work of finding the optimum; it does not dictate the action that the manager actually takes.

64.4.5 The behavior policy

The rule governing how the manager chooses actions is called the **behavior policy**.

Because the max in the update target always points toward q^* regardless of how the manager selects actions, the behavior policy affects only which (x, a) entries get visited – and hence updated – over time.

In the reinforcement learning literature, this property is called **off-policy** learning: the convergence target (q^*) does not depend on the behavior policy.

As long as every (x, a) pair is visited infinitely often (so that every entry of the Q-table receives infinitely many updates) and the learning rates satisfy standard conditions (see below), the Q-table converges to q^*.

The behavior policy affects the *speed* of convergence – visiting important state-action pairs more frequently leads to faster learning – but not the *limit*.

In practice, we want the manager to mostly take good actions (to earn reasonable profits while learning), while still occasionally experimenting to discover better alternatives.

64.4.6 Learning rate

We use $\alpha_t = 1/n_t(x, a)^{0.51}$, where $n_t(x, a)$ is the number of times the pair (x, a) has been visited up to time t.

This decays slowly enough to allow learning from later (better-informed) updates, while still satisfying the Robbins–Monro conditions for convergence.

64.4.7 Exploration: epsilon-greedy

For our behavior policy, we use an ε-greedy strategy:

- With probability ε, choose a random feasible action (explore).
- With probability $1 - \varepsilon$, choose the action with the highest current q-value (exploit).

The exploration ensures that every state-action pair is visited, which is needed for convergence.

The exploitation ensures the manager earns reasonable profits while learning.

We decay ε each step: $\varepsilon_{t+1} = \max(\varepsilon_{\min},\ \varepsilon_t \cdot \lambda)$, so the manager experiments widely early on and increasingly relies on learned q-values as experience accumulates.

The stochastic demand shocks naturally drive the manager across different inventory levels, providing exploration over the state space without any artificial resets.

64.4.8 Optimistic initialization

A simple but powerful technique for accelerating learning is **optimistic initialization**: instead of starting the Q-table at zero, we initialize every entry to a value above the true optimum.

Because every untried action looks optimistically good, the agent is "disappointed" whenever it tries one – the update pulls that entry down toward reality. This drives the agent to try other actions (which still look optimistically high), producing broad exploration of the state-action space early in training.

This idea is sometimes called **optimism in the face of uncertainty** and is widely used in both bandit and reinforcement learning settings.

In our problem, the value function v^* ranges from about 13 to 18. We initialize the Q-table at 20 – modestly above the true maximum – to ensure optimistic exploration without being so extreme as to distort learning.

64.4.9 Implementation

We first define a helper to extract the greedy policy from a Q-table.

```
@numba.jit(nopython=True)
def greedy_policy_from_q(q, K):
    """Extract greedy policy from Q-table."""
    σ = np.empty(K + 1, dtype=np.int32)
    for x in range(K + 1):
        best_val = -np.inf
        best_a = 0
        for a in range(K - x + 1):
            if q[x, a] > best_val:
                best_val = q[x, a]
                best_a = a
        σ[x] = best_a
    return σ
```

The Q-learning loop runs for `n_steps` total steps in a single continuous trajectory – just as a real manager would learn from the ongoing stream of data.

At specified step counts (given by `snapshot_steps`), we record the current greedy policy.

```
@numba.jit(nopython=True)
def q_learning_kernel(K, p, c, κ, β, n_steps, X_init,
                      ε_init, ε_min, ε_decay, q_init, snapshot_steps, rng):
    q = np.full((K + 1, K + 1), q_init)
    n = np.zeros((K + 1, K + 1))       # visit counts for learning rate
    ε = ε_init

    n_snaps = len(snapshot_steps)
    snapshots = np.zeros((n_snaps, K + 1), dtype=np.int32)
    snap_idx = 0

    # Initialize state and action
    x = X_init
    a = rng.integers(0, K - x + 1)

    for t in range(n_steps):
        # Record policy snapshot if needed
        if snap_idx < n_snaps and t == snapshot_steps[snap_idx]:
            snapshots[snap_idx] = greedy_policy_from_q(q, K)
```

(continues on next page)

(continued from previous page)

```
            snap_idx += 1

        # === Draw D_{t+1} and observe outcome ===
        d = rng.geometric(p) - 1
        reward = min(x, d) - c * a - κ * (a > 0)
        x_next = max(x - d, 0) + a

        # === Max over next state (scalar value for update target) ===
        # Also record the argmax action for use by the behavior policy.
        best_next = -np.inf
        a_next = 0
        for aa in range(K - x_next + 1):
            if q[x_next, aa] > best_next:
                best_next = q[x_next, aa]
                a_next = aa

        # === Q-learning update (uses best_next, the max value) ===
        n[x, a] += 1
        α = 1.0 / n[x, a] ** 0.51
        q[x, a] = (1 - α) * q[x, a] + α * (reward + β * best_next)

        # === Behavior policy: ε-greedy (uses a_next, the argmax action) ===
        x = x_next
        if rng.random() < ε:
            a = rng.integers(0, K - x + 1)
        else:
            a = a_next
        ε = max(ε_min, ε * ε_decay)

    return q, snapshots
```

The wrapper function unpacks the model and provides default hyperparameters.

```
def q_learning(model, n_steps=20_000_000, X_init=0,
               ε_init=1.0, ε_min=0.01, ε_decay=0.999999,
               q_init=20.0, snapshot_steps=None, seed=1234):
    x_values, d_values, ϕ_values, p, c, κ, β = model
    K = len(x_values) - 1
    if snapshot_steps is None:
        snapshot_steps = np.array([], dtype=np.int64)
    rng = np.random.default_rng(seed)
    return q_learning_kernel(K, p, c, κ, β, n_steps, X_init,
                             ε_init, ε_min, ε_decay, q_init, snapshot_steps, rng)
```

Next we run n = 5 million steps and take policy snapshots at steps 10,000, 1,000,000, and n.

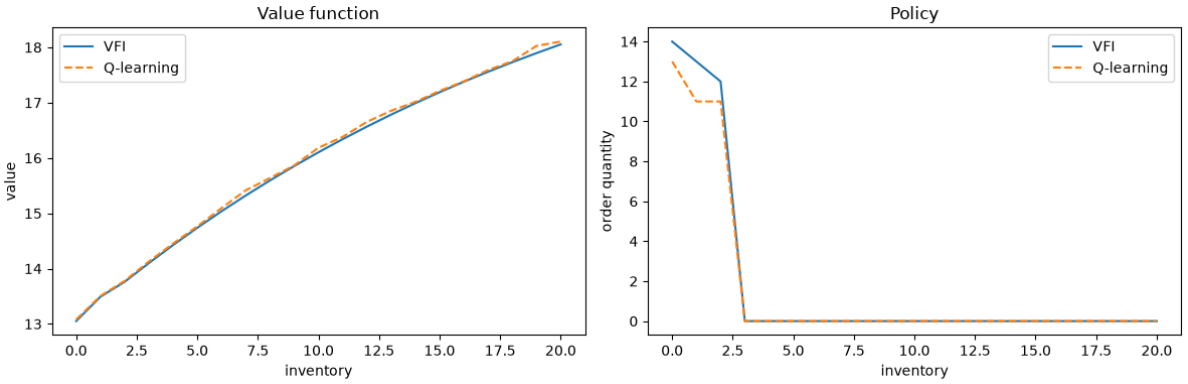
```
n = 5_000_000
snap_steps = np.array([10_000, 1_000_000, n], dtype=np.int64)
q, snapshots = q_learning(model, n_steps=n+1, snapshot_steps=snap_steps)
```

64.4.10 Comparing with the exact solution

We extract the value function and policy from the final Q-table via

$$v_Q(x) = \max_{a \in \Gamma(x)} q(x,a), \qquad \sigma_Q(x) = \arg\max_{a \in \Gamma(x)} q(x,a)$$

and compare them against v^* and σ^* from VFI.



```
K = len(x_values) - 1
# restrict to feasible actions a ∈ {0, ..., K-x}
v_q = np.array([np.max(q[x, :K - x + 1]) for x in range(K + 1)])
σ_q = np.array([np.argmax(q[x, :K - x + 1]) for x in range(K + 1)])
```

```
fig, axes = plt.subplots(1, 2, figsize=(12, 4))

axes[0].plot(x_values, v_star, label="VFI")
axes[0].plot(x_values, v_q, '--', label="Q-learning")
axes[0].set_xlabel("inventory")
axes[0].set_ylabel("value")
axes[0].legend()
axes[0].set_title("Value function")

axes[1].plot(x_values, σ_star, label="VFI")
axes[1].plot(x_values, σ_q, '--', label="Q-learning")
axes[1].set_xlabel("inventory")
axes[1].set_ylabel("order quantity")
axes[1].legend()
axes[1].set_title("Policy")

plt.tight_layout()
plt.show()
```

64.4.11 Visualizing learning over time

The panels below show how the agent's behavior evolves during training.

Each panel simulates an inventory path using the greedy policy extracted from the Q-table at a given training step.

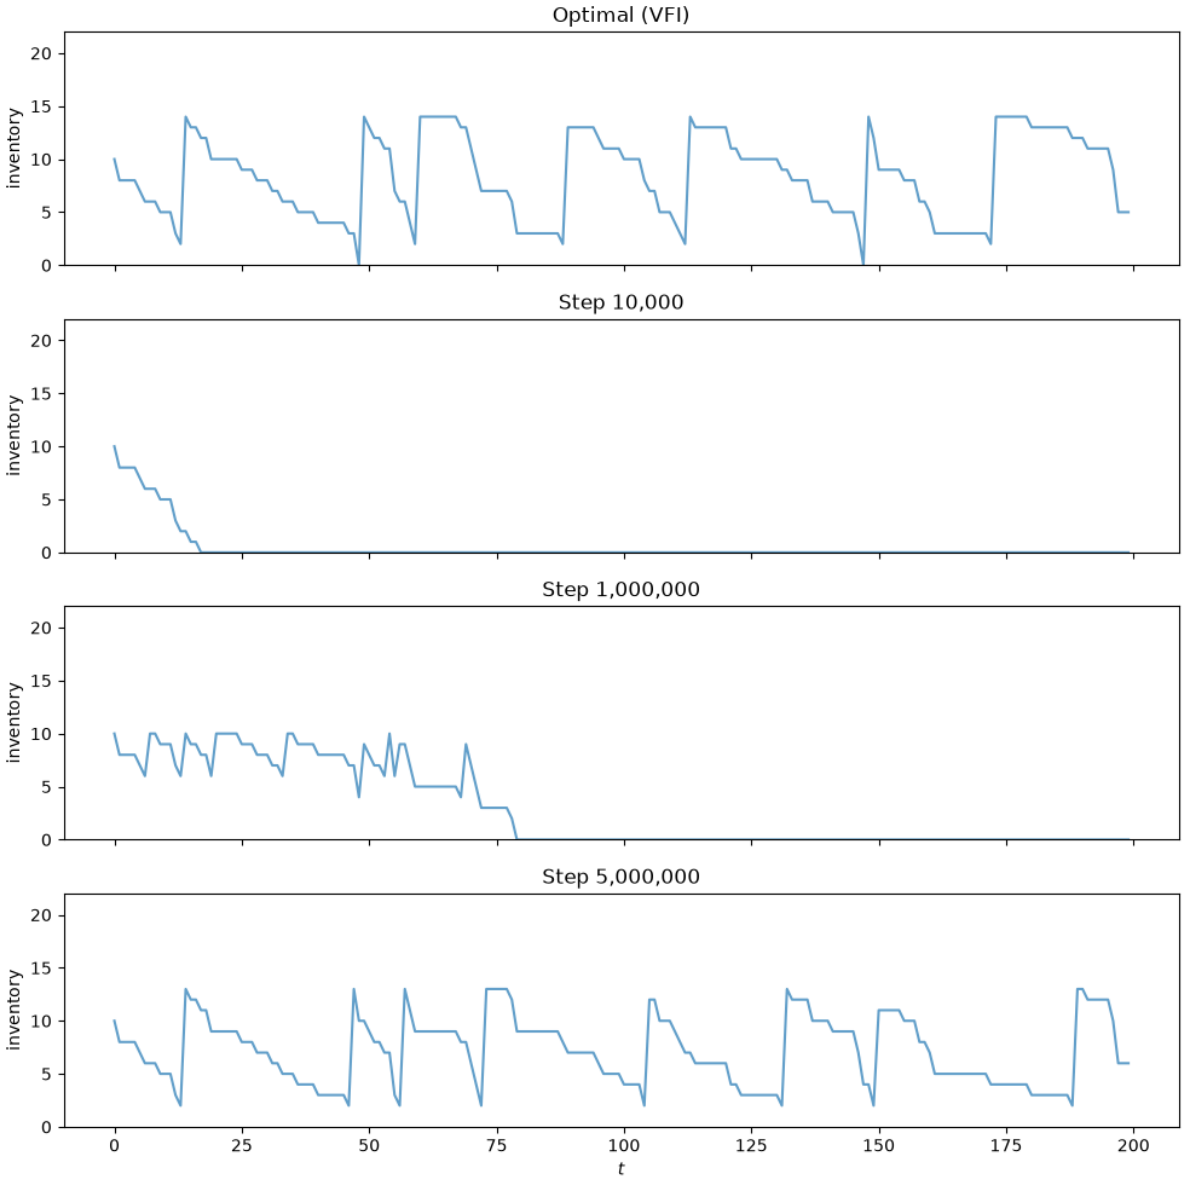
All panels use the **same demand sequence** (via a fixed random seed), so differences reflect only changes in the policy.

The top panel shows the optimal policy from VFI for reference.

After 10,000 steps the agent has barely explored and its policy is poor.

By 1,000,000 steps the policy has improved but still differs noticeably from the optimum.

By step 5 million, the learned policy produces inventory dynamics that closely resemble the S-s pattern of the optimal solution.



```
ts_length = 200
n_snaps = len(snap_steps)
fig, axes = plt.subplots(n_snaps + 1, 1, figsize=(10, 2.5 * (n_snaps + 1)),
                         sharex=True)

RISK-SENSITIVE INVENTORY MANAGEMENT VIA Q-LEARNING

Contents

- *Risk-Sensitive Inventory Management via Q-Learning*
  - *Introduction*
  - *The Model*
  - *Solving via Value Function Iteration*
  - *Interpreting the Outcomes*
  - *Q-Learning*
  - *Conclusion*

65.1 Introduction

In *Inventory Management via Q-Learning*, we looked at an inventory management problem and solved it with both value function iteration and Q-learning.

In this lecture, we consider a risk-sensitive variation.

Injection of risk-sensitivity acknowledges the fact that, in incomplete markets with financial and informational frictions, firms typically take risk into account in their decision making.

In other words, the actions of firms are not, in general, risk neutral.

One natural way to handle this is to use a risk-sensitive version of the Bellman equation.

We show how the model can be solved using value function iteration.

We then investigate how risk sensitivity affects the optimal policy.

```
import numpy as np
import numba
import matplotlib.pyplot as plt
from typing import NamedTuple
```

65.2 The Model

The Bellman equation for the inventory management problem in *Inventory Management via Q-Learning* has the form

$$v(x) = \max_{a \in \Gamma(x)} \mathbb{E}\left[\pi(x, a, D) + \beta v(h(x, a, D))\right].$$

Here D is a random variable with distribution ϕ.

(Primitives and definitions are the same as in *Inventory Management via Q-Learning*.)

The risk-sensitive version of this Bellman equation has the form

$$v(x) = \max_{a \in \Gamma(x)} \psi^{-1}\left\{\mathbb{E}\psi\left[\pi(x, a, D) + \beta v(h(x, a, D))\right]\right\},$$

where $\psi(t) = \exp(-\gamma t)$ for fixed $\gamma > 0$.

Since $\psi^{-1}(y) = -\frac{1}{\gamma}\ln(y)$, the Bellman equation becomes

$$v(x) = \max_{a \in \Gamma(x)} \left(-\frac{1}{\gamma}\right) \ln\left\{\sum_d \phi(d) \exp\left[-\gamma\left(\pi(x, a, d) + \beta\, v(h(x, a, d))\right)\right]\right\}.$$

Here $\phi(d)$ denotes the demand probability mass function, as in *Inventory Management via Q-Learning*.

The parameter γ controls the degree of risk sensitivity.

As $\gamma \to 0$, the certainty equivalent reduces to the ordinary expectation and we recover the risk-neutral case.

Larger γ means more aversion to downside risk.

The Bellman operator, greedy policy, and VFI algorithm all carry over from the risk-neutral case, with the expectation replaced by the certainty equivalent.

65.3 Solving via Value Function Iteration

65.3.1 Model specification

We reuse the same model primitives as in *Inventory Management via Q-Learning*, adding γ as a parameter.

```
class RSModel(NamedTuple):
    x_values: np.ndarray        # Inventory values
    d_values: np.ndarray        # Demand values for summation
    ϕ_values: np.ndarray        # Demand probabilities
    p: float                    # Demand parameter

```

65.3.2 The Bellman operator

The risk-sensitive Bellman operator replaces the expected value with the certainty equivalent.

For numerical stability, we use the log-sum-exp trick: given values $z_i = \pi(x, a, d_i) + \beta\, v(h(x, a, d_i))$, we compute

$$-\frac{1}{\gamma} \ln \sum_i \phi(d_i) \exp(-\gamma z_i) \;=\; -\frac{1}{\gamma} \left(m + \ln \sum_i \phi(d_i) \exp(-\gamma z_i - m) \right),$$

where $m = \max_i(-\gamma z_i)$.

```
@numba.jit(nopython=True)
def T_rs_kernel(v, d_values, ϕ_values, c, κ, β, γ, K):
    new_v = np.empty(K + 1)
    n_d = len(d_values)
    for x in range(K + 1):
        best = -np.inf
        for a in range(K - x + 1):
            # Compute -γ * z_i for each demand realization
            exponents = np.empty(n_d)
            for i in range(n_d):
                d = d_values[i]
                x_next = max(x - d, 0) + a
                revenue = min(x, d)
                cost = c * a + κ * (a > 0)
                z_i = revenue - cost + β * v[x_next]
                exponents[i] = -γ * z_i

K = len(x_values) - 1

for i, γ in enumerate(γ_values):
    v, σ = results[γ]
    X = sim_inventories(ts_length, σ, model.p,
                        np.random.default_rng(sim_seed), X_init=K // 2)
    axes[i].plot(X, alpha=0.7)
    axes[i].set_ylabel("inventory")
    axes[i].set_title(f"$\\gamma = {γ}$")
    axes[i].set_ylim(0, K + 2)

axes[-1].set_xlabel(r"$t$")
plt.tight_layout()
plt.show()
```

65.4 Interpreting the Outcomes

The plots above show that a more risk-sensitive firm (larger γ) orders less inventory and maintains lower stock levels.

At first glance this may seem surprising: wouldn't holding more inventory reduce variance by ensuring the firm can always meet demand?

The key is to identify where the randomness in profits actually comes from.

Recall that per-period profit is $\pi(x, a, d) = \min(x, d) - ca - \kappa \mathbf{1}\{a > 0\}$.

The ordering cost $ca + \kappa \mathbf{1}\{a > 0\}$ is **deterministic** – it is chosen before the demand shock is realized.

So higher ordering shifts the level of profits down but does not affect their variance.

The variance comes from **revenue**: $\min(x, D)$.

When inventory x is high, $\min(x, D) \approx D$ for most demand realizations – revenue inherits the full variance of demand.

When inventory x is low, $\min(x, D) \approx x$ for most realizations – revenue is nearly deterministic, capped at the inventory level.

A risk-sensitive agent therefore prefers lower inventory because it **caps the randomness of revenue**.

The agent accepts lower expected sales in exchange for more predictable profits.

There is also a continuation value channel: next-period inventory $\max(x - D, 0) + a$ varies with D, and higher x means $x - D$ tracks D more closely, propagating that variance forward through v.

65.5 Q-Learning

We now ask whether the optimal policy can be learned without knowledge of the model, as we did in the risk-neutral case in *Inventory Management via Q-Learning*.

65.5.1 The Q-factor

The first step is to define the Q-factor in a way that is compatible with the risk-sensitive Bellman equation.

We define

$$q(x,a) := \mathbb{E}\left[\exp(-\gamma\,(\pi(x,a,D) + \beta\, v^*(h(x,a,D))))\right].$$

In words, $q(x,a)$ applies the risk-sensitivity transformation $\psi(t) = \exp(-\gamma t)$ inside the expectation, evaluated at the return from taking action a in state x and following the optimal policy thereafter.

65.5.2 Deriving the Q-factor Bellman equation

Our goal is to obtain a fixed point equation in q alone, eliminating v^*.

Step 1. Express v^* in terms of q.

The risk-sensitive Bellman equation says $v^*(x) = \max_{a\in\Gamma(x)} \psi^{-1}(q(x,a))$.

Since $\psi^{-1}(y) = -\frac{1}{\gamma}\ln(y)$ is a **decreasing** function, the maximum over a of $\psi^{-1}(q(x,a))$ corresponds to the **minimum** over a of $q(x,a)$:

$$v^*(x) = \psi^{-1}\left(\min_{a\in\Gamma(x)} q(x,a)\right) = -\frac{1}{\gamma}\ln\left(\min_{a\in\Gamma(x)} q(x,a)\right).$$

Equivalently,

$$\exp(-\gamma\, v^*(x)) = \min_{a\in\Gamma(x)} q(x,a).$$

Step 2. Substitute back into the definition of q to eliminate v^*.

Expanding the exponential in the definition of q,

$$q(x,a) = \mathbb{E}\left[\exp(-\gamma\,\pi(x,a,D)) \;\cdot\; \exp(-\gamma\beta\, v^*(x'))\right]$$

where $x' = h(x,a,D)$.

From Step 1, $\exp(-\gamma\, v^*(x')) = \min_{a'\in\Gamma(x')} q(x',a')$, so $\exp(-\gamma\beta\, v^*(x')) = \left[\min_{a'\in\Gamma(x')} q(x',a')\right]^{\beta}$.

Substituting,

$$q(x,a) = \mathbb{E}\left[\exp(-\gamma\,\pi(x,a,D)) \;\cdot\; \left(\min_{a'\in\Gamma(x')} q(x',a')\right)^{\beta}\right].$$

This is a fixed point equation in q alone – v^* has been eliminated.

65.5.3 The Q-learning update rule

As in the risk-neutral case, we approximate the fixed point using stochastic approximation.

At each step, the agent is in state x, takes action a, observes profit $R_{t+1} = \pi(x, a, D_{t+1})$ and next state $X_{t+1} = h(x, a, D_{t+1})$, and updates

$$q_{t+1}(x,a) = (1-\alpha_t)\, q_t(x,a) + \alpha_t \left[\exp(-\gamma\, R_{t+1}) \cdot \left(\min_{a' \in \Gamma(X_{t+1})} q_t(X_{t+1}, a') \right)^{\beta} \right].$$

The term in brackets is a single-sample estimate of the right-hand side of the Q-factor Bellman equation.

The update blends the current estimate with this fresh sample, just as in standard Q-learning.

Notice several differences from the risk-neutral case:

- The Q-values are **positive** (expectations of exponentials) rather than signed.
- The optimal policy is $\sigma(x) = \arg\min_a q(x,a)$ – we **minimize** rather than maximize, because ψ^{-1} is decreasing.
- The observed profit enters through $\exp(-\gamma R_{t+1})$ rather than additively.
- The continuation value enters as a **power** $(\min_{a'} q_t)^{\beta}$ rather than a scaled sum $\beta \cdot \max_{a'} q_t$.

As before, the agent needs only to observe x, a, R_{t+1}, and X_{t+1} – no model knowledge is required.

65.5.4 Implementation plan

Our implementation follows the same structure as the risk-neutral Q-learning in *Inventory Management via Q-Learning*, with the modifications above:

1. **Initialize** the Q-table q optimistically (see below) and visit counts n to zeros.
2. **At each step:**
   - Draw demand D_{t+1} and compute observed profit R_{t+1} and next state X_{t+1}.
   - Compute $\min_{a'} q_t(X_{t+1}, a')$ over feasible actions (this is a scalar for the update target, and the arg min action is used by the ε-greedy behavior policy).
   - Update $q_t(x,a)$ using the rule above, with learning rate $\alpha_t = 1/n_t(x,a)^{0.51}$.
   - Choose the next action via ε-greedy: with probability ε pick a random feasible action, otherwise pick the arg min action.
   - Decay ε.
3. **Extract the greedy policy** from the final Q-table via $\sigma(x) = \arg\min_{a \in \Gamma(x)} q(x,a)$.
4. **Compare** the learned policy against the VFI solution.

65.5.5 Optimistic initialization

As in *Inventory Management via Q-Learning*, we use optimistic initialization to accelerate learning.

The logic is the same – initialize the Q-table so that every untried action looks attractive, driving the agent to explore broadly – but the direction is reversed.

Since the optimal policy *minimizes* q, "optimistic" means initializing the Q-table *below* the true values. When the agent tries an action, the update pushes q upward toward reality, making that entry look worse and prompting the agent to try other actions that still appear optimistically good.

The true Q-values are on the order of $\exp(-\gamma\, v^*) \approx 10^{-8}$ to 10^{-6}. We initialize the Q-table at 10^{-9}, modestly below this range.

65.5.6 Implementation

We first define a helper to extract the greedy policy from the Q-table.

Since the optimal policy minimizes q, we use arg min rather than arg max.

```
@numba.jit(nopython=True)
def greedy_policy_from_q_rs(q, K):
    """Extract greedy policy from risk-sensitive Q-table (argmin)."""
    σ = np.empty(K + 1, dtype=np.int32)
    for x in range(K + 1):
        best_val = np.inf
        best_a = 0
        for a in range(K - x + 1):
            if q[x, a] < best_val:
                best_val = q[x, a]
                best_a = a
        σ[x] = best_a
    return σ
```

The Q-learning loop mirrors the risk-neutral version, with the key changes: the update target uses $\exp(-\gamma R_{t+1}) \cdot (\min_{a'} q_t)^\beta$, and the behavior policy follows the arg min.

```
@numba.jit(nopython=True)
def q_learning_rs_kernel(K, p, c, κ, β, γ, n_steps, X_init,
                         ε_init, ε_min, ε_decay, q_init, snapshot_steps, rng):
    q = np.full((K + 1, K + 1), q_init)  # optimistic initialization
    n = np.zeros((K + 1, K + 1))         # visit counts for learning rate
    ε = ε_init

    n_snaps = len(snapshot_steps)
    snapshots = np.zeros((n_snaps, K + 1), dtype=np.int32)
    snap_idx = 0

    # Initialize state and action
    x = X_init
    a = rng.integers(0, K - x + 1)

    for t in range(n_steps):
        # Record policy snapshot if needed
        if snap_idx < n_snaps and t == snapshot_steps[snap_idx]:
            snapshots[snap_idx] = greedy_policy_from_q_rs(q, K)
            snap_idx += 1

        # === Draw D_{t+1} and observe outcome ===
        d = rng.geometric(p) - 1
        reward = min(x, d) - c * a - κ * (a > 0)
        x_next = max(x - d, 0) + a

        # === Min over next state (scalar value for update target) ===
        # Also record the argmin action for use by the behavior policy.
        best_next = np.inf
        a_next = 0
        for aa in range(K - x_next + 1):
```

(continues on next page)

(continued from previous page)

```
            if q[x_next, aa] < best_next:
                best_next = q[x_next, aa]
                a_next = aa

        # === Risk-sensitive Q-learning update ===
        target = np.exp(-γ * reward) * best_next ** β
        n[x, a] += 1
        α = 1.0 / n[x, a] ** 0.51
        q[x, a] = (1 - α) * q[x, a] + α * target

        # === Behavior policy: ε-greedy (uses a_next, the argmin action) ===
        x = x_next
        if rng.random() < ε:
            a = rng.integers(0, K - x + 1)
        else:
            a = a_next
        ε = max(ε_min, ε * ε_decay)

    return q, snapshots
```

The wrapper function unpacks the model and provides default hyperparameters.

```
def q_learning_rs(model, n_steps=20_000_000, X_init=0,
                  ε_init=1.0, ε_min=0.01, ε_decay=0.999999,
                  q_init=1e-9, snapshot_steps=None, seed=1234):
    x_values, d_values, ϕ_values, p, c, κ, β, γ = model
    K = len(x_values) - 1
    if snapshot_steps is None:
        snapshot_steps = np.array([], dtype=np.int64)
    rng = np.random.default_rng(seed)
    return q_learning_rs_kernel(K, p, c, κ, β, γ, n_steps, X_init,
                                ε_init, ε_min, ε_decay, q_init, snapshot_steps, rng)
```

65.5.7 Running Q-learning

We run n = 5 million steps and take policy snapshots at steps 10,000, 1,000,000, and n.

```
n = 5_000_000
snap_steps = np.array([10_000, 1_000_000, n], dtype=np.int64)
q_table, snapshots = q_learning_rs(model, n_steps=n+1, snapshot_steps=snap_steps)
```

65.5.8 Comparing with the exact solution

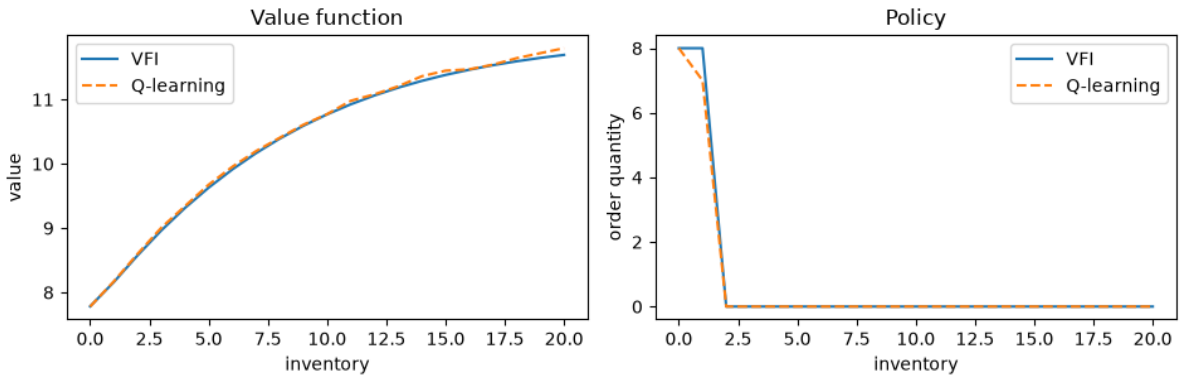
We extract the value function and policy from the final Q-table.

Since Q-values represent $\mathbb{E}[\exp(-\gamma(\cdots))]$, we recover the value function via $v_Q(x) = -\frac{1}{\gamma}\ln(\min_a q(x,a))$ and the policy via $\sigma_Q(x) = \arg\min_a q(x,a)$.

```
K = len(x_values) - 1
γ_base = model.γ
# restrict to feasible actions a ∈ {0, ..., K-x}
v_q = np.array([-(1/γ_base) * np.log(np.min(q_table[x, :K - x + 1]))
                for x in range(K + 1)])
```

(continues on next page)

(continued from previous page)



```
σ_q = np.array([np.argmin(q_table[x, :K - x + 1])
                for x in range(K + 1)])
```

```
fig, axes = plt.subplots(1, 2, figsize=(9.6, 3.2))

axes[0].plot(x_values, v_star, label="VFI")
axes[0].plot(x_values, v_q, '--', label="Q-learning")
axes[0].set_xlabel("inventory")
axes[0].set_ylabel("value")
axes[0].legend()
axes[0].set_title("Value function")

axes[1].plot(x_values, σ_star, label="VFI")
axes[1].plot(x_values, σ_q, '--', label="Q-learning")
axes[1].set_xlabel("inventory")
axes[1].set_ylabel("order quantity")
axes[1].legend()
axes[1].set_title("Policy")

plt.tight_layout()
plt.show()
```

65.5.9 Visualizing learning over time

The panels below show how the agent's policy evolves during training.

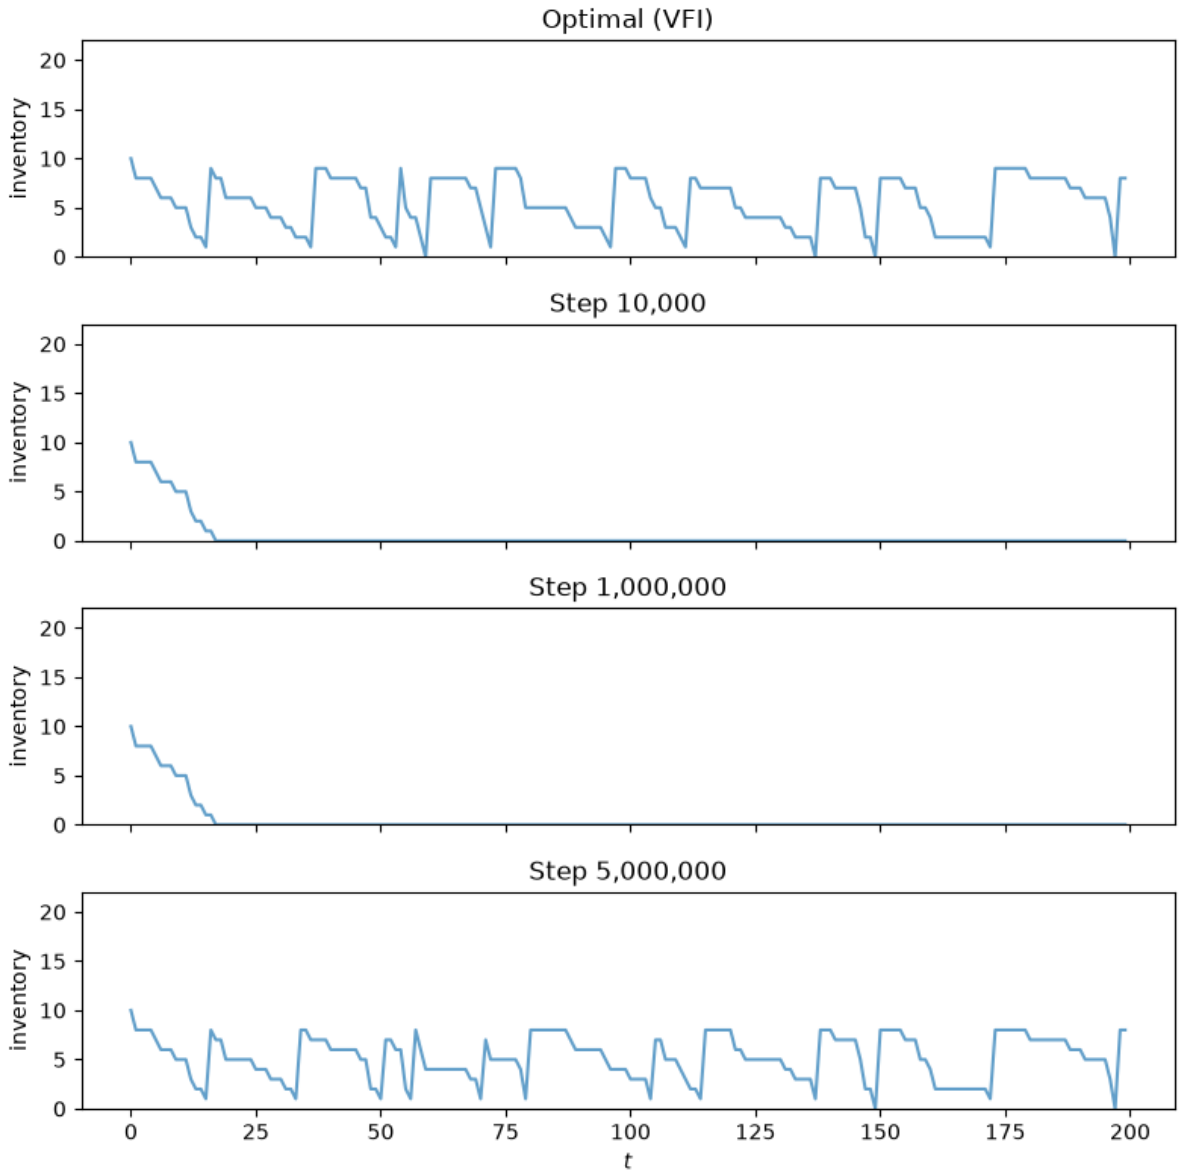
Each panel simulates an inventory path using the greedy policy extracted from the Q-table at a given training step, with the same demand sequence throughout.

The top panel shows the optimal policy from VFI for reference.

```
ts_length = 200
n_snaps = len(snap_steps)
fig, axes = plt.subplots(n_snaps + 1, 1, figsize=(8, 2.0 * (n_snaps + 1)),
                         sharex=True)

X_init = K // 2
sim_seed = 5678

# Optimal policy
X_opt = sim_inventories(ts_length, σ_star, model.p,
```



(continues on next page)

(continued from previous page)

```
                        np.random.default_rng(sim_seed), X_init)
axes[0].plot(X_opt, alpha=0.7)
axes[0].set_ylabel("inventory")
axes[0].set_title("Optimal (VFI)")
axes[0].set_ylim(0, K + 2)

# Q-learning snapshots
for i in range(n_snaps):
    σ_snap = snapshots[i]
    X = sim_inventories(ts_length, σ_snap, model.p,
                        np.random.default_rng(sim_seed), X_init)
    axes[i + 1].plot(X, alpha=0.7)
    axes[i + 1].set_ylabel("inventory")
    axes[i + 1].set_title(f"Step {snap_steps[i]:,}")
    axes[i + 1].set_ylim(0, K + 2)

axes[-1].set_xlabel(r"$t$")
plt.tight_layout()
plt.show()
```

After 10,000 steps, the agent has barely explored and its policy is erratic.

By 1,000,000 steps the learned policy has improved but still differs noticeably from the optimum.

By step 5 million the inventory dynamics are nearly indistinguishable from the VFI solution.

Note that the converged policy maintains lower inventory levels than in the risk-neutral case (compare with *Inventory Management via Q-Learning*), consistent with the mechanism discussed above: a risk-sensitive agent caps its exposure to demand variance by holding less stock.

65.6 Conclusion

We extended the inventory management problem from *Inventory Management via Q-Learning* to incorporate risk sensitivity via the certainty equivalent operator $\psi^{-1}(\mathbb{E}[\psi(\cdot)])$ with $\psi(t) = \exp(-\gamma t)$.

Value function iteration confirms that risk-sensitive firms order less aggressively, preferring predictable profits over higher but more volatile returns.

We then showed that Q-learning can be adapted to the risk-sensitive setting by working with the transformed Q-factor $q(x, a) = \mathbb{E}[\exp(-\gamma(\pi + \beta v^*))]$.

The resulting update rule replaces addition with multiplication and max with min, but retains the key property of model-free learning: the agent needs only to observe states, actions, and profits.

CHAPTER

SIXTYSIX

JOB SEARCH X: SEARCH WITH Q-LEARNING

66.1 Overview

This lecture illustrates a powerful machine learning technique called Q-learning.

[Sutton and Barto, 2018] presents Q-learning and a variety of other statistical learning procedures.

The Q-learning algorithm combines ideas from

- dynamic programming
- a recursive version of least squares known as temporal difference learning.

This lecture applies a Q-learning algorithm to the situation faced by a McCall worker.

This lecture also considers the case where a McCall worker is given an option to quit the current job.

Relative to the dynamic programming formulation of the McCall worker model that we studied in *quantecon lecture*, a Q-learning algorithm gives the worker less knowledge about

- the random process that generates a sequence of wages
- the reward function that tells consequences of accepting or rejecting a job

The Q-learning algorithm invokes a statistical learning model to learn about these things.

Statistical learning often comes down to some version of least squares, and it will be here too.

Any time we say **statistical learning**, we have to say what object is being learned.

For Q-learning, the object that is learned is not the **value function** that is a focus of dynamic programming.

But it is something that is closely affiliated with it.

In the finite-action, finite state context studied in this lecture, the object to be learned statistically is a **Q-table**, an instance of a **Q-function** for finite sets.

Sometimes a Q-function or Q-table is called a quality-function or quality-table.

The rows and columns of a Q-table correspond to possible states that an agent might encounter, and possible actions that he can take in each state.

An equation that resembles a Bellman equation plays an important role in the algorithm.

It differs from the Bellman equation for the McCall model that we have seen in *this quantecon lecture*

In this lecture, we'll learn a little about

- the **Q-function** or **quality function** that is affiliated with any Markov decision problem whose optimal value function satisfies a Bellman equation
- **temporal difference learning**, a key component of a Q-learning algorithm

As usual, let's import some Python modules.

```
!pip install quantecon
```

```
import numpy as np

from numba import jit, float64, int64
from numba.experimental import jitclass
from quantecon.distributions import BetaBinomial

import matplotlib.pyplot as plt

rng = np.random.default_rng(123)
```

66.2 Review of McCall model

We begin by reviewing the McCall model described in *this quantecon lecture*.

We'll compute an optimal value function and a policy that attains it.

We'll eventually compare that optimal policy to what the Q-learning McCall worker learns.

The McCall model is characterized by parameters β, c and a known distribution of wage offers F.

A McCall worker wants to maximize an expected discounted sum of lifetime incomes

$$\mathbb{E}\sum_{t=0}^{\infty}\beta^t y_t$$

The worker's income y_t equals his wage w if he is employed, and unemployment compensation c if he is unemployed.

An optimal value $V(w)$ for a McCall worker who has just received a wage offer w and is deciding whether to accept or reject it satisfies the Bellman equation

$$V(w) = \max_{\text{accept, reject}}\left\{\frac{w}{1-\beta}, c+\beta\int V(w')\,dF(w')\right\} \tag{66.1}$$

To form a benchmark to compare with results from Q-learning, we first approximate the optimal value function.

With possible states residing in a finite discrete state space indexed by $\{1, 2, ..., n\}$, we make an initial guess for the value function of $v \in \mathbb{R}^n$ and then iterate on the Bellman equation:

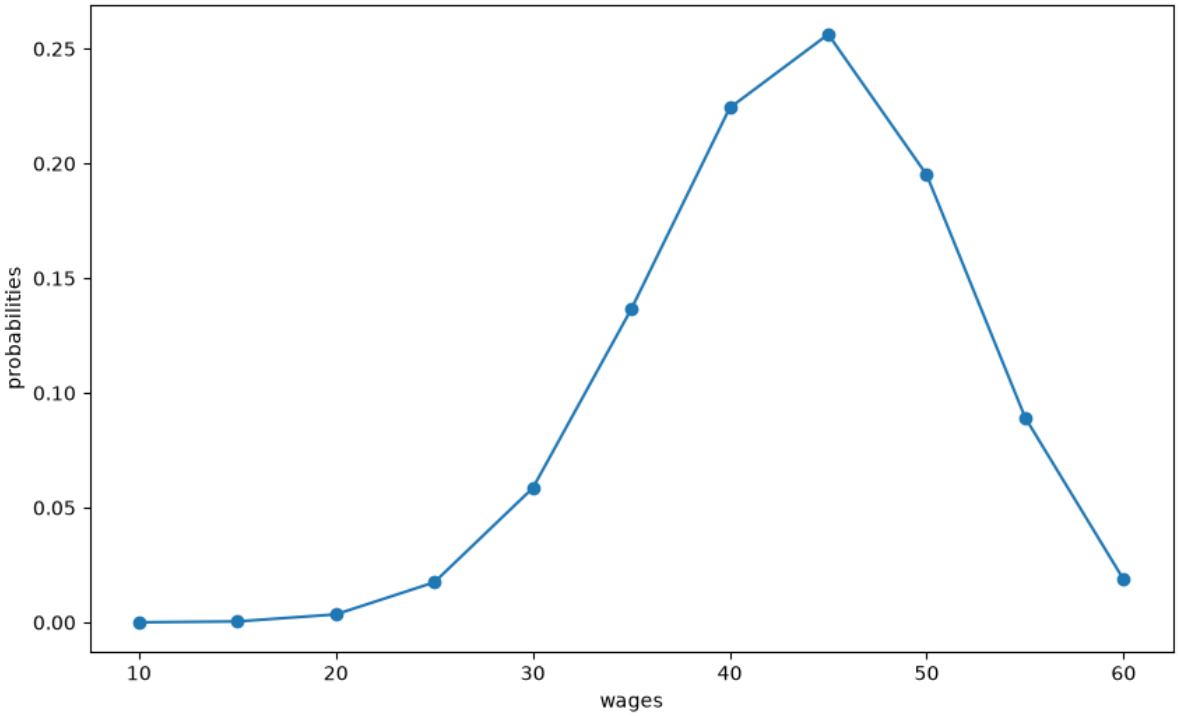
$$v'(i) = \max\left\{\frac{w(i)}{1-\beta}, c+\beta\sum_{1\le j\le n} v(j)q(j)\right\} \quad \text{for } i = 1, \dots, n$$

Let's use Python code from *this quantecon lecture*.

We use a Python method called `VFI` to compute the optimal value function using value function iterations.

We construct an assumed distribution of wages and plot it with the following Python code

```
n, a, b = 10, 200, 100                       # default parameters
q_default = BetaBinomial(n, a, b).pdf()      # default choice of q



w_min, w_max = 10, 60
w_default = np.linspace(w_min, w_max, n+1)
```

(continues on next page)

(continued from previous page)

```
# plot distribution of wage offer
fig, ax = plt.subplots(figsize=(10,6))
ax.plot(w_default, q_default, '-o', label='$q(w(i))$')
ax.set_xlabel('wages')
ax.set_ylabel('probabilities')

plt.show()
```

Next we'll compute the worker's optimal value function by iterating to convergence on the Bellman equation.

Then we'll plot various iterates on the Bellman operator.

```
mccall_data = [
    ('c', float64),      # unemployment compensation
    ('β', float64),      # discount factor
    ('w', float64[::1]),  # array of wage values, w[i] = wage at state i
    ('q', float64[::1])   # array of probabilities
]

@jitclass(mccall_data)
class McCallModel:

    def __init__(self, c=25, β=0.99, w=w_default, q=q_default):

        self.c, self.β = c, β
        self.w, self.q = w, q

    def state_action_values(self, i, v):
        """
        The values of state-action pairs.
```

(continues on next page)

(continued from previous page)

```
        """
        # Simplify names
        c, β, w, q = self.c, self.β, self.w, self.q
        # Evaluate value for each state-action pair
        # Consider action = accept or reject the current offer
        accept = w[i] / (1 - β)
        reject = c + β * (v @ q)

        return np.array([accept, reject])

    def VFI(self, eps=1e-5, max_iter=500):
        """
        Find the optimal value function.
        """

        n = len(self.w)
        v = self.w / (1 - self.β)
        v_next = np.empty_like(v)
        flag=0

        for i in range(max_iter):
            for j in range(n):
                v_next[j] = np.max(self.state_action_values(j, v))

            if np.max(np.abs(v_next - v))<=eps:
                flag=1
                break
            v[:] = v_next

        return v, flag

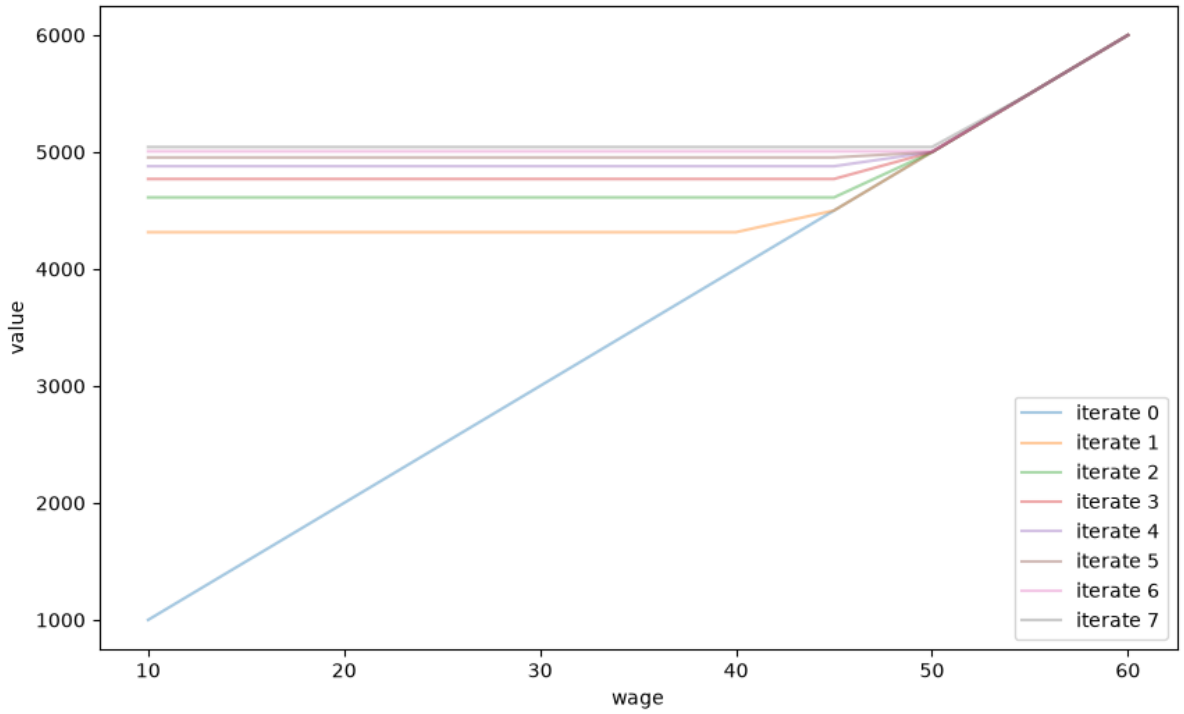
def plot_value_function_seq(mcm, ax, num_plots=8):
    """
    Plot a sequence of value functions.

        * mcm is an instance of McCallModel
        * ax is an axes object that implements a plot method.

    """

    n = len(mcm.w)
    v = mcm.w / (1 - mcm.β)
    v_next = np.empty_like(v)
    for i in range(num_plots):
        ax.plot(mcm.w, v, '-', alpha=0.4, label=f"iterate {i}")
        # Update guess
        for i in range(n):
            v_next[i] = np.max(mcm.state_action_values(i, v))
        v[:] = v_next  # copy contents into v

    ax.legend(loc='lower right')
```



```
mcm = McCallModel()
valfunc_VFI, flag = mcm.VFI()

fig, ax = plt.subplots(figsize=(10,6))
```

(continues on next page)

(continued from previous page)

```
ax.set_xlabel('wage')
ax.set_ylabel('value')
plot_value_function_seq(mcm, ax)
plt.show()
```

Next we'll print out the limit of the sequence of iterates.

This is the approximation to the McCall worker's value function that is produced by value function iteration.

We'll use this value function as a benchmark later after we have done some Q-learning.

```
print(valfunc_VFI)
```

```

 5322.27935875 5322.27935875 5322.27935875 5322.27935875 5500.
 6000.        ]
```

66.3 Implied quality function Q

A **quality function** Q maps state-action pairs into optimal values.

They are tightly linked to optimal value functions.

But value functions are functions just of states, and not actions.

For each given state, the quality function gives a list of optimal values that can be attained starting from that state, with each component of the list indicating one of the possible actions that is taken.

For our McCall worker with a finite set of possible wages

- the state space $\mathcal{W} = \{w_1, w_2, ..., w_n\}$ is indexed by integers $1, 2, ..., n$

- the action space is $\mathcal{A} = \{\text{accept}, \text{reject}\}$

Let $a \in \mathcal{A}$ be one of the two possible actions, i.e., accept or reject.

For our McCall worker, an optimal Q-function $Q(w, a)$ equals the maximum value of that a previously unemployed worker who has offer w in hand can attain if he takes action a.

This definition of $Q(w, a)$ presumes that in subsequent periods the worker takes optimal actions.

An optimal Q-function for our McCall worker satisfies

$$\begin{aligned} Q\left(w, \text{accept}\right) &= \frac{w}{1-\beta} \\ Q\left(w, \text{reject}\right) &= c + \beta \int \max_{\text{accept, reject}} \left\{ \frac{w'}{1-\beta}, Q\left(w', \text{reject}\right) \right\} dF\left(w'\right) \end{aligned} \tag{66.2}$$

Note that the first equation of system (66.2) presumes that after the agent has accepted an offer, he will not have the option to reject that same offer in the future.

These equations are aligned with the Bellman equation for the worker's optimal value function that we studied in *this quantecon lecture*.

Evidently, the optimal value function $V(w)$ described in that lecture is related to our Q-function by

$$V(w) = \max_{\text{accept,reject}} \left\{ Q(w, \text{accept}), Q\left(w, \text{reject}\right) \right\}$$

If we stare at the second equation of system (66.2), we notice that since the wage process is identically and independently distributed over time, $Q\left(w, \text{reject}\right)$, the right side of the equation is independent of the current state w.

So we can denote it as a scalar

$$Q_r := Q\left(w, \text{reject}\right) \quad \forall\, w \in \mathcal{W}.$$

This fact provides us with an an alternative, and as it turns out in this case, a faster way to compute an optimal value function and associated optimal policy for the McCall worker.

Instead of using the value function iterations that we deployed above, we can instead iterate to convergence on a version of the second equation in system (66.2) that maps an estimate of Q_r into an improved estimate Q_r':

$$Q_r' = c + \beta \int \max \left\{ \frac{w'}{1-\beta}, Q_r \right\} dF\left(w'\right)$$

After a Q_r sequence has converged, we can recover the optimal value function $V(w)$ for the McCall worker from

$$V\left(w\right) = \max \left\{ \frac{w}{1-\beta}, Q_r \right\}$$

66.4 From probabilities to samples

We noted above that the optimal Q function for our McCall worker satisfies the Bellman equations

$$\begin{aligned} w + \beta \max_{\text{accept, reject}} \left\{ Q(w, \text{accept}), Q(w, \text{reject}) \right\} - Q(w, \text{accept}) &= 0 \\ c + \beta \int \max_{\text{accept, reject}} \left\{ Q(w', \text{accept}), Q\left(w', \text{reject}\right) \right\} dF\left(w'\right) - Q\left(w, \text{reject}\right) &= 0 \end{aligned} \tag{66.3}$$

Notice the integral over $F(w')$ on the second line.

Erasing the integral sign sets the stage for an illegitimate argument that can get us started thinking about Q-learning.

Thus, construct a difference equation system that keeps the first equation of (66.3) but replaces the second by removing integration over $F(w')$:

$$\begin{aligned} w + \beta \max_{\text{accept, reject}} \{Q(w, \text{accept}), Q(w, \text{reject})\} - Q(w, \text{accept}) = 0 \\ c + \beta \max_{\text{accept, reject}} \{Q(w', \text{accept}), Q\left(w', \text{reject}\right)\} - Q\left(w, \text{reject}\right) \approx 0 \end{aligned} \tag{66.4}$$

The second equation can't hold for all w, w' pairs in the appropriate Cartesian product of our state space.

But maybe an appeal to a Law of Large numbers could let us hope that it would hold **on average** for a long time series sequence of draws of w_t, w_{t+1} pairs, where we are thinking of w_t as w and w_{t+1} as w'.

The basic idea of Q-learning is to draw a long sample of wage offers from F (we know F though we assume that the worker doesn't) and iterate on a recursion that maps an estimate $\hat{Q}_t$ of a Q-function at date t into an improved estimate $\hat{Q}_{t+1}$ at date $t+1$.

To set up such an algorithm, we first define some errors or "differences"

$$\begin{aligned} w + \beta \max_{\text{accept, reject}} \left\{\hat{Q}_t(w_t, \text{accept}), \hat{Q}_t(w_t, \text{reject})\right\} - \hat{Q}_t(w_t, \text{accept}) = \text{diff}_{\text{accept},t} \\ c + \beta \max_{\text{accept, reject}} \left\{\hat{Q}_t(w_{t+1}, \text{accept}), \hat{Q}_t\left(w_{t+1}, \text{reject}\right)\right\} - \hat{Q}_t\left(w_t, \text{reject}\right) = \text{diff}_{\text{reject},t} \end{aligned} \tag{66.5}$$

The adaptive learning scheme would then be some version of

$$\hat{Q}_{t+1} = \hat{Q}_t + \alpha \, \text{diff}_t \tag{66.6}$$

where $\alpha \in (0, 1)$ is a small **gain** parameter that governs the rate of learning and $\hat{Q}_t$ and diff_t are 2×1 vectors corresponding to objects in equation system (66.5).

This informal argument takes us to the threshold of Q-learning.

66.5 Q-learning

Let's first describe a Q-learning algorithm precisely.

Then we'll implement it.

The algorithm works by using a Monte Carlo method to update estimates of a Q-function.

We begin with an initial guess for a Q-function.

In the example studied in this lecture, we have a finite action space and also a finite state space.

That means that we can represent a Q-function as a matrix or Q-table, $\widetilde{Q}(w, a)$.

Q-learning proceeds by updating the Q-function as the decision maker acquires experience along a path of wage draws generated by simulation.

During the learning process, our McCall worker takes actions and experiences rewards that are consequences of those actions.

He learns simultaneously about the environment, in this case the distribution of wages, and the reward function, in this case the unemployment compensation c and the present value of wages.

The updating algorithm is based on a slight modification (to be described soon) of a recursion like

$$\widetilde{Q}^{new}\left(w, a\right) = \widetilde{Q}^{old}\left(w, a\right) + \alpha \widetilde{TD}\left(w, a\right) \tag{66.7}$$

where

$$\begin{aligned}\widetilde{TD}\left(w,\text{accept}\right) &= \left[w+\beta\max_{a'\in\mathcal{A}}\widetilde{Q}^{old}\left(w,a'\right)\right]-\widetilde{Q}^{old}\left(w,\text{accept}\right)\\ \widetilde{TD}\left(w,\text{reject}\right) &= \left[c+\beta\max_{a'\in\mathcal{A}}\widetilde{Q}^{old}\left(w',a'\right)\right]-\widetilde{Q}^{old}\left(w,\text{reject}\right),\ w'\sim F\end{aligned} \tag{66.8}$$

The terms $\widetilde{TD}(w,a)$ for $a=\{\text{accept,reject}\}$ are the **temporal difference errors** that drive the updates.

This system is thus a version of the adaptive system that we sketched informally in equation (66.6).

An aspect of the algorithm not yet captured by equation system (66.8) is random **experimentation** that we add by occasionally randomly replacing

$$\text{argmax}_{a'\in\mathcal{A}}\widetilde{Q}^{old}\left(w,a'\right)$$

with

$$\text{argmin}_{a'\in\mathcal{A}}\widetilde{Q}^{old}\left(w,a'\right)$$

and occasionally replacing

$$\text{argmax}_{a'\in\mathcal{A}}\widetilde{Q}^{old}\left(w',a'\right)$$

with

$$\text{argmin}_{a'\in\mathcal{A}}\widetilde{Q}^{old}\left(w',a'\right)$$

We activate such experimentation with probability ϵ in step 3 of the following pseudo-code for our McCall worker to do Q-learning:

1. Set an arbitrary initial Q-table.
2. Draw an initial wage offer w from F.
3. From the appropriate row in the Q-table, choose an action using the following ϵ-greedy algorithm:
    - with probability $1-\epsilon$, choose the action that maximizes the value, and
    - with probability ϵ, choose the alternative action.
4. Update the state associated with the chosen action and compute $\widetilde{TD}$ according to (66.8) and update $\widetilde{Q}$ according to (66.7).
5. Either draw a new state w' if required or else take the existing wage and update the Q-table again according to (66.7).
6. Stop when the old and new Q-tables are close enough, i.e., $\|\tilde{Q}^{new}-\tilde{Q}^{old}\|_\infty\leq\delta$ for given δ or if the worker keeps accepting for T periods for a prescribed T.
7. Return to step 2 with the updated Q-table.

Repeat this procedure for N episodes or until the updated Q-table has converged.

We call one pass through steps 2 to 7 an "episode" or "epoch" of temporal difference learning.

In our context, each episode starts with an agent drawing an initial wage offer, i.e., a new state.

The agent then takes actions based on the preset Q-table, receives rewards, and then enters a new state implied by this period's actions.

The Q-table is updated via temporal difference learning.

We iterate this until convergence of the Q-table or the maximum length of an episode is reached.

Multiple episodes allow the agent to start afresh and visit states that she was less likely to visit from the terminal state of a previous episode.

For example, an agent who has accepted a wage offer based on her Q-table will be less likely to draw a new offer from other parts of the wage distribution.

By using the ϵ-greedy method and also by increasing the number of episodes, the Q-learning algorithm balances gains from exploration and from exploitation.

Remark: Notice that $\widetilde{TD}$ associated with an optimal Q-table defined in (66.7) automatically above satisfies $\widetilde{TD} = 0$ for all state action pairs. Whether a limit of our Q-learning algorithm converges to an optimal Q-table depends on whether the algorithm visits all state-action pairs often enough.

We implement this pseudo code in a Python class.

For simplicity and convenience, we let `s` represent the state index between 0 and $n = 50$ and $w_s = w[s]$.

The first column of the Q-table represents the value associated with rejecting the wage and the second represents accepting the wage.

We use `numba` compilation to accelerate computations.

The above graphs indicates that

- the Q-learning algorithm has trouble learning the Q-table well for wages that are rarely drawn
- the quality of approximation to the "true" value function computed by value function iteration improves for longer

epochs

66.6 Employed worker can't quit

The preceding version of temporal difference Q-learning described in equation system (66.8) lets an employed worker quit, i.e., reject her wage as an incumbent and instead receive unemployment compensation this period and draw a new offer next period.

This is an option that the McCall worker described in *this quantecon lecture* would not take.

See [Ljungqvist and Sargent, 2018], chapter 6 on search, for a proof.

But in the context of Q-learning, giving the worker the option to quit and get unemployment compensation while unemployed turns out to accelerate the learning process by promoting experimentation versus premature exploitation only.

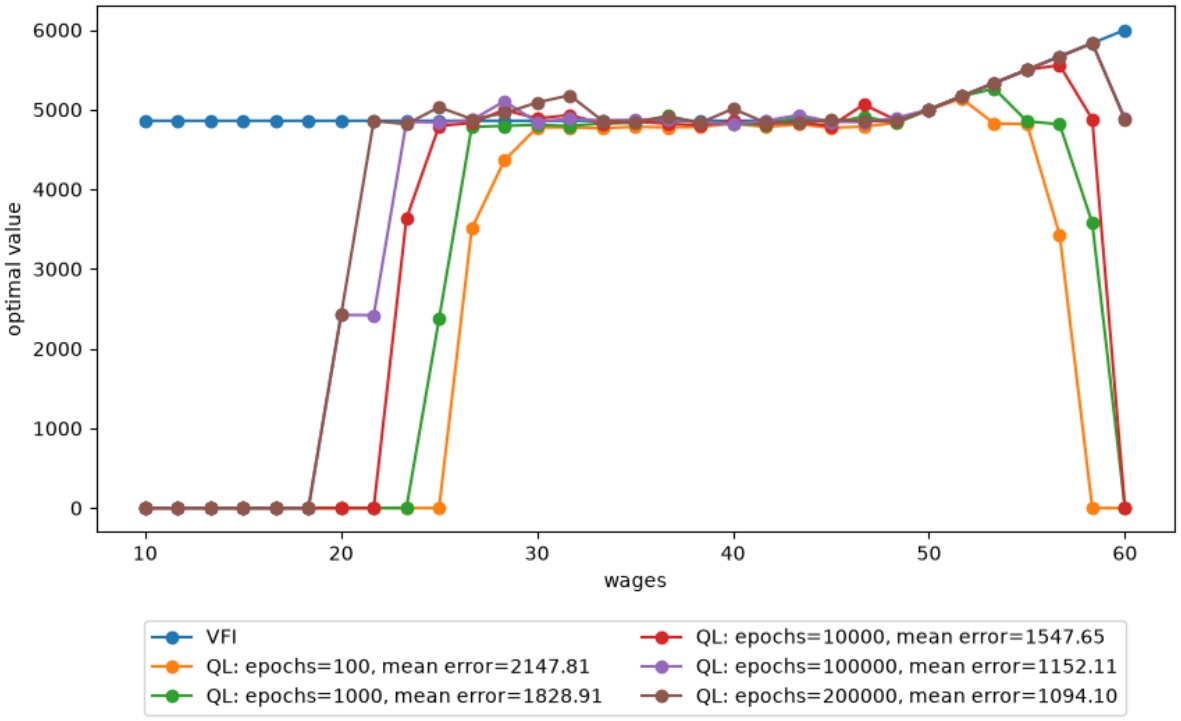
To illustrate this, we'll amend our formulas for temporal differences to forbid an employed worker from quitting a job she had accepted earlier.

With this understanding about available choices, we obtain the following temporal difference values:

$$\begin{aligned} \widetilde{TD}\left(w, \text{accept}\right) &= \left[w + \beta \widetilde{Q}^{old}\left(w, \text{accept}\right)\right] - \widetilde{Q}^{old}\left(w, \text{accept}\right) \\ \widetilde{TD}\left(w, \text{reject}\right) &= \left[c + \beta \max_{a' \in \mathcal{A}} \widetilde{Q}^{old}\left(w', a'\right)\right] - \widetilde{Q}^{old}\left(w, \text{reject}\right), \; w' \sim F \end{aligned} \tag{66.9}$$

It turns out that formulas (66.9) combined with our Q-learning recursion (66.7) can lead our agent to eventually learn the optimal value function as well as in the case where an option to redraw can be exercised.

But learning is slower because an agent who ends up accepting a wage offer prematurely loses the option to explore new states in the same episode and to adjust the value associated with that state.



This can lead to inferior outcomes when the number of epochs/episodes is low.

But if we increase the number of epochs/episodes, we can observe that the error decreases and the outcomes get better.

We illustrate these possibilities with the following code and graph.

```
plot_epochs(epochs_to_plot=[100, 1000, 10000, 100000, 200000], quit_allowed=0)
```

```
Progress: EPOCHs = 0
Progress: EPOCHs = 20000
Progress: EPOCHs = 40000
Progress: EPOCHs = 60000
Progress: EPOCHs = 80000
Progress: EPOCHs = 100000
Progress: EPOCHs = 120000
Progress: EPOCHs = 140000
Progress: EPOCHs = 160000
Progress: EPOCHs = 180000
Progress: EPOCHs = 200000
```

66.7 Possible extensions

To extend the algorithm to handle problems with continuous state spaces, a typical approach is to restrict Q-functions and policy functions to take particular functional forms.

This is the approach in **deep Q-learning** where the idea is to use a multilayer neural network as a good function approximator.

We will take up this topic in a subsequent quantecon lecture.

OPTIMAL SAVINGS I: CAKE EATING

Contents

- *Optimal Savings I: Cake Eating*
  - *Overview*
  - *The model*
  - *The value function*
  - *The optimal policy*
  - *The Euler equation*
  - *Exercises*

67.1 Overview

In this lecture we introduce a simple "cake eating" problem.

The intertemporal problem is: how much to enjoy today and how much to leave for the future?

This trade-off between current and future rewards is at the heart of many savings and consumption problems.

Once we master the ideas in a simple environment, we will apply them to progressively more challenging problems.

The main tool we will use to solve the cake eating problem is dynamic programming.

The following lectures contain background on dynamic programming and might be worth reviewing:

- The shortest paths lecture
- The *basic McCall model*
- The *McCall model with separation*
- The *McCall model with separation and a continuous wage distribution*

We require the following imports:

```
import matplotlib.pyplot as plt
import numpy as np
```

67.2 The model

We consider a discrete time model with an infinite time horizon.

At $t = 0$ the agent is given a complete cake with size $\bar{x}$.

Let x_t denote the size of the cake at the beginning of each period, so that, in particular, $x_0 = \bar{x}$.

We choose how much of the cake to eat in any given period t.

After choosing to consume c_t of the cake in period t, the amount left in period $t + 1$ is

$$x_{t+1} = x_t - c_t$$

Consuming quantity c of the cake gives current utility $u(c)$.

We adopt the CRRA utility function

$$u(c) = \frac{c^{1-\gamma}}{1-\gamma} \qquad (\gamma > 0,\ \gamma \neq 1) \tag{67.1}$$

In Python this is

```
def u(c, γ):

    return c**(1 - γ) / (1 - γ)
```

Future cake consumption utility is discounted according to $\beta \in (0, 1)$.

In particular, consumption of c units t periods hence has present value $\beta^t u(c)$

The agent's problem can be written as

$$\max_{\{c_t\}} \sum_{t=0}^{\infty} \beta^t u(c_t) \tag{67.2}$$

subject to

$$x_{t+1} = x_t - c_t \quad \text{and} \quad 0 \leq c_t \leq x_t \tag{67.3}$$

for all t.

A consumption path $\{c_t\}$ satisfying (67.3) and $x_0 = \bar{x}$ is called **feasible**.

In this problem, the following terminology is standard:

- x_t is called the **state variable**
- c_t is called the **control variable** or the **action**
- β and γ are **parameters**

67.2.1 Trade-off

The key trade-off in the cake-eating problem is this:

- Delaying consumption is costly because of the discount factor.
- But delaying some consumption is also attractive because u is concave.

The concavity of u implies that the consumer gains value from **consumption smoothing**, which means spreading consumption out over time.

This is because concavity implies diminishing marginal utility—a progressively smaller gain in utility for each additional spoonful of cake consumed within one period.

67.2.2 Intuition

The reasoning given above suggests that the discount factor β and the curvature parameter γ will play a key role in determining the rate of consumption.

Here's an educated guess as to what impact these parameters will have.

1. Higher β implies less discounting, and hence the agent is more patient, which should reduce the rate of consumption.
2. Higher γ implies more curvature in u, more desire for consumption smoothing, and hence a lower rate of consumption.

Note

More formally, higher γ implies a lower intertemporal elasticity of substitution, since IES = $1/\gamma$.

This means the consumer is less willing to substitute consumption between periods.

This stronger preference for consumption smoothing results in a lower consumption rate.

In summary, we expect the rate of consumption to be decreasing in both parameters.

Let's see if this is true.

67.3 The value function

The first step of our dynamic programming treatment is to obtain the Bellman equation.

The next step is to use it to calculate the solution.

67.3.1 The Bellman equation

To this end, we let $v(x)$ be maximum lifetime utility attainable from the current time when x units of cake are left.

That is,

$$v(x) = \max \sum_{t=0}^{\infty} \beta^t u(c_t) \tag{67.4}$$

where the maximization is over all paths $\{c_t\}$ that are feasible from $x_0 = x$.

At this point, we do not have an expression for v, but we can still make inferences about it.

For example, as was the case with the *McCall model*, the value function will satisfy a version of the *Bellman equation*.

In the present case, this equation states that v satisfies

$$v(x) = \max_{0 \leq c \leq x} \{u(c) + \beta v(x - c)\} \quad \text{for any given } x \geq 0. \tag{67.5}$$

The intuition here is essentially the same as it was for the McCall model.

Choosing c optimally means trading off current vs future rewards.

Current rewards from choice c are just $u(c)$.

Future rewards given current cake size x, measured from next period and assuming optimal behavior, are $v(x - c)$.

These are the two terms on the right hand side of (67.5), after suitable discounting.

If c is chosen optimally using this trade off strategy, then we obtain maximal lifetime rewards from our current state x.

Hence, $v(x)$ equals the right hand side of (67.5), as claimed.

67.3.2 An analytical solution

It has been shown that, with u as the CRRA utility function in (67.1), the function v^* given by

$$v^*(x) = \left(1 - \beta^{1/\gamma}\right)^{-\gamma} u(x) \tag{67.6}$$

solves the Bellman equation and hence is equal to the value function.

You are asked to confirm that this is true in the exercises below.

Note

The solution (67.6) depends heavily on the CRRA utility function.

In fact, if we move away from CRRA utility, usually there is no analytical solution at all.

In other words, beyond CRRA utility, we know that the value function still satisfies the Bellman equation, but we do not have a way of writing it explicitly, as a function of the state variable and the parameters.

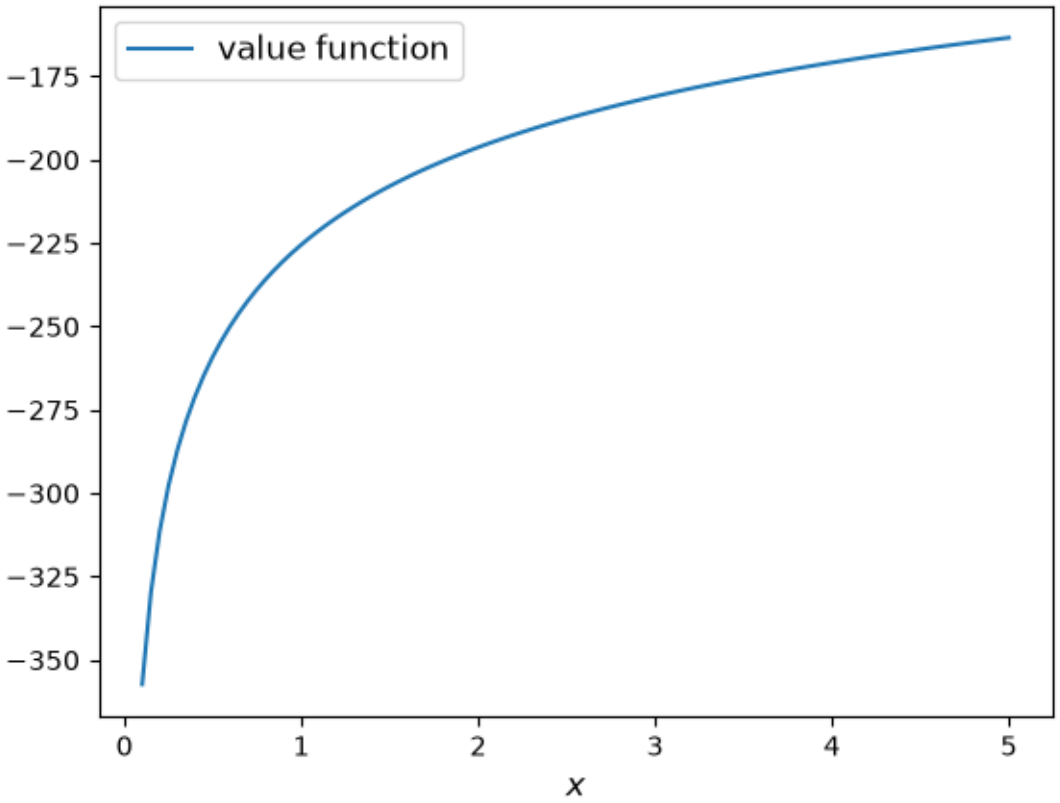
We will deal with that situation numerically in the following lectures.

Here is a Python representation of the value function:

```
def v_star(x, β, γ):

    return (1 - β**(1 / γ))**(-γ) * u(x, γ)
```

And here's a figure showing the function for fixed parameters:



```
β, γ = 0.95, 1.2
x_grid = np.linspace(0.1, 5, 100)

fig, ax = plt.subplots()

ax.plot(x_grid, v_star(x_grid, β, γ), label='value function')

ax.set_xlabel('$x$', fontsize=12)
ax.legend(fontsize=12)

plt.show()
```

67.4 The optimal policy

Now that we have the value function v^*, it is straightforward to calculate the optimal action at each state.

We should choose consumption to maximize the right hand side of the Bellman equation (67.5).

$$c^* = \arg \max_{0 \leq c \leq x} \{u(c) + \beta v^*(x - c)\}$$

We can think of this optimal choice as a *function* of the state x, in which case we call it the **optimal policy**.

We denote the optimal policy by σ^*, so that

$$\sigma^*(x) := \arg \max_c \{u(c) + \beta v^*(x - c)\} \quad \text{for all} \quad x \geq 0$$

If we plug the analytical expression (67.6) for the value function into the right hand side and compute the optimum, we find that

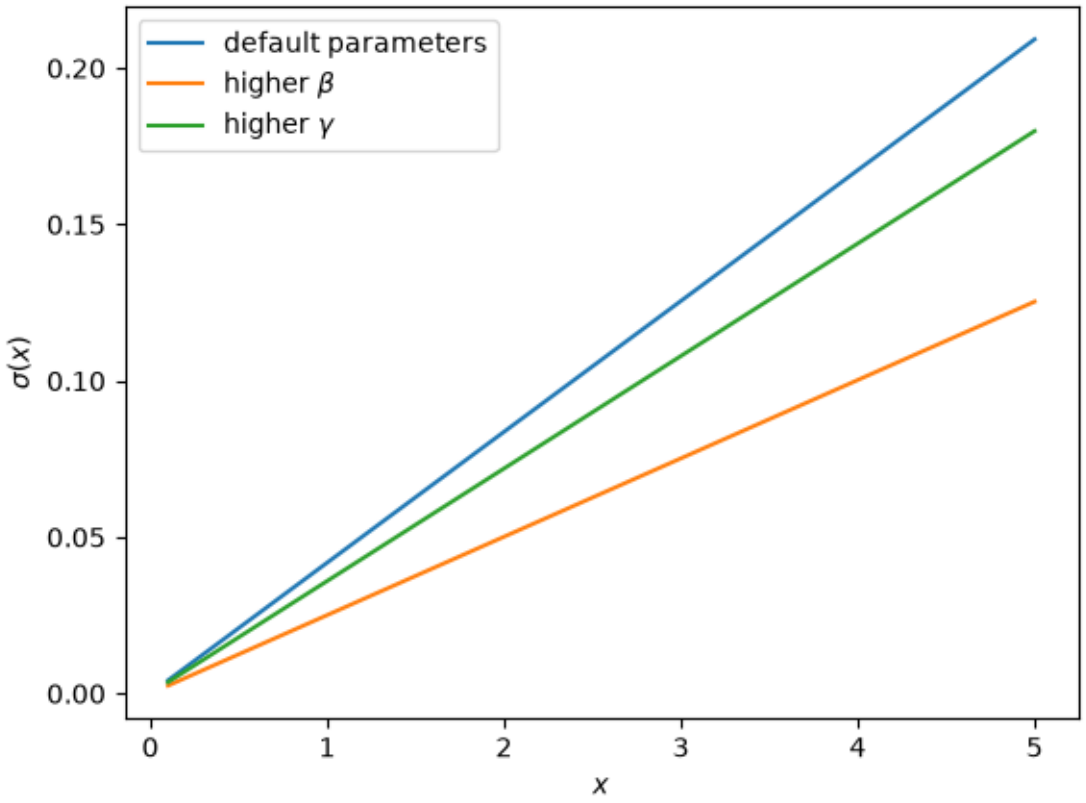
$$\sigma^*(x) = \left(1 - \beta^{1/\gamma}\right) x \tag{67.7}$$

Now let's recall our intuition on the impact of parameters.

We guessed that consumption would be decreasing in both parameters.

This is in fact the case, as can be seen from (67.7).

Here are some plots that illustrate.



```
def c_star(x, β, γ):

    return (1 - β ** (1/γ)) * x
```

Continuing with the values for β and γ used above, the plot is

```
fig, ax = plt.subplots()
ax.plot(x_grid, c_star(x_grid, β, γ), label='default parameters')
ax.plot(x_grid, c_star(x_grid, β + 0.02, γ), label=r'higher $\beta$')
ax.plot(x_grid, c_star(x_grid, β, γ + 0.2), label=r'higher $\gamma$')
ax.set_ylabel(r'$\sigma(x)$')
ax.set_xlabel('$x$')
ax.legend()

plt.show()
```

67.5 The Euler equation

In the discussion above we have provided a complete solution to the cake eating problem in the case of CRRA utility.

There is in fact another way to solve for the optimal policy, based on the so-called **Euler equation**.

Although we already have a complete solution, now is a good time to study the Euler equation.

This is because, for more difficult problems, this equation provides key insights that are hard to obtain by other methods.

67.5.1 Statement and implications

The Euler equation for the present problem can be stated as

$$u'(c_t^*) = \beta u'(c_{t+1}^*) \tag{67.8}$$

This is a necessary condition for an optimal consumption path $\{c_t^*\}_{t\geq 0}$.

It says that, along the optimal path, marginal rewards are equalized across time, after appropriate discounting.

This makes sense: optimality is obtained by smoothing consumption up to the point where no marginal gains remain.

We can also state the Euler equation in terms of the policy function.

A **feasible consumption policy** is a map $x \mapsto \sigma(x)$ satisfying $0 \leq \sigma(x) \leq x$.

(The last restriction says that we cannot consume more than the remaining quantity of cake.)

A feasible consumption policy σ is said to **satisfy the Euler equation** if, for all $x > 0$,

$$u'(\sigma(x)) = \beta u'(\sigma(x - \sigma(x))) \tag{67.9}$$

Evidently (67.9) is just the policy equivalent of (67.8).

It turns out that a feasible policy is optimal if and only if it satisfies the Euler equation.

In the exercises, you are asked to verify that the optimal policy (67.7) does indeed satisfy this functional equation.

Note

A **functional equation** is an equation where the unknown object is a function.

For a proof of sufficiency of the Euler equation in a very general setting, see proposition 2.2 of [Ma *et al.*, 2020].

The following arguments focus on necessity, explaining why an optimal path or policy should satisfy the Euler equation.

67.5.2 Derivation I: a perturbation approach

Let's write c as a shorthand for consumption path $\{c_t\}_{t=0}^{\infty}$.

The overall cake-eating maximization problem can be written as

$$\max_{c \in F} U(c) \quad \text{where } U(c) := \sum_{t=0}^{\infty} \beta^t u(c_t)$$

and F is the set of feasible consumption paths.

We know that differentiable functions have a zero gradient at a maximizer.

So the optimal path $c^* := \{c_t^*\}_{t=0}^{\infty}$ must satisfy $U'(c^*) = 0$.

Note

If you want to know exactly how the derivative $U'(c^*)$ is defined, given that the argument c^* is a vector of infinite length, you can start by learning about Gateaux derivatives. However, such knowledge is not assumed in what follows.

In other words, the rate of change in U must be zero for any infinitesimally small (and feasible) perturbation away from the optimal path.

So consider a feasible perturbation that reduces consumption at time t to $c_t^* - h$ and increases it in the next period to $c_{t+1}^* + h$.

Consumption does not change in any other period.

We call this perturbed path c^h.

By the preceding argument about zero gradients, we have

$$\lim_{h \to 0} \frac{U(c^h) - U(c^*)}{h} = U'(c^*) = 0$$

Recalling that consumption only changes at t and $t+1$, this becomes

$$\lim_{h \to 0} \frac{\beta^t u(c_t^* - h) + \beta^{t+1} u(c_{t+1}^* + h) - \beta^t u(c_t^*) - \beta^{t+1} u(c_{t+1}^*)}{h} = 0$$

After rearranging, the same expression can be written as

$$\lim_{h \to 0} \frac{u(c_t^* - h) - u(c_t^*)}{h} + \beta \lim_{h \to 0} \frac{u(c_{t+1}^* + h) - u(c_{t+1}^*)}{h} = 0$$

or, taking the limit,

$$-u'(c_t^*) + \beta u'(c_{t+1}^*) = 0$$

This is just the Euler equation.

67.5.3 Derivation II: using the Bellman equation

Another way to derive the Euler equation is to use the Bellman equation (67.5).

Note

The argument that follows assumes that the value function is differentiable. A proof of differentiability of the value function can be found in EDTC, theorem 10.1.13.

Taking the derivative on the right hand side of the Bellman equation with respect to c and setting it to zero, we get

$$u'(c) = \beta v'(x - c) \tag{67.10}$$

To obtain $v'(x-c)$, we set $g(c, x) = u(c) + \beta v(x - c)$, so that, at the optimal choice of consumption,

$$v(x) = g(c, x) \tag{67.11}$$

Differentiating both sides while acknowledging that the maximizing consumption will depend on x, we get

$$v'(x) = \frac{\partial}{\partial c} g(c, x) \frac{\partial c}{\partial x} + \frac{\partial}{\partial x} g(c, x)$$

When $g(c, x)$ is maximized at c, we have $\frac{\partial}{\partial c} g(c, x) = 0$.

Hence the derivative simplifies to

$$v'(x) = \frac{\partial g(c, x)}{\partial x} = \frac{\partial}{\partial x} \beta v(x - c) = \beta v'(x - c) \tag{67.12}$$

(This argument is an example of the Envelope Theorem.)

But now an application of (67.10) gives

$$u'(c) = v'(x) \tag{67.13}$$

Thus, the derivative of the value function is equal to marginal utility.

Combining this fact with (67.12) recovers the Euler equation.

67.6 Exercises

Exercise 67.6.1

How does one obtain the expressions for the value function and optimal policy given in (67.6) and (67.7) respectively?

The first step is to make a guess of the functional form for the consumption policy.

So suppose that we do not know the solutions and start with a guess that the optimal policy is linear.

In other words, we conjecture that there exists a positive θ such that setting $c_t^* = \theta x_t$ for all t produces an optimal path.

Starting from this conjecture, try to obtain the solutions (67.6) and (67.7).

In doing so, you will need to use the definition of the value function and the Bellman equation.

Solution

We start with the conjecture $c_t^* = \theta x_t$, which leads to a path for the state variable (cake size) given by

$$x_{t+1} = x_t(1-\theta)$$

Then $x_t = x_0(1-\theta)^t$ and hence

$$\begin{aligned} v(x_0) &= \sum_{t=0}^{\infty} \beta^t u(\theta x_t) \\ &= \sum_{t=0}^{\infty} \beta^t u(\theta x_0 (1-\theta)^t) \\ &= \sum_{t=0}^{\infty} \theta^{1-\gamma} \beta^t (1-\theta)^{t(1-\gamma)} u(x_0) \\ &= \frac{\theta^{1-\gamma}}{1-\beta(1-\theta)^{1-\gamma}} u(x_0) \end{aligned}$$

From the Bellman equation, then,

$$\begin{aligned} v(x) &= \max_{0 \le c \le x} \left\{ u(c) + \beta \frac{\theta^{1-\gamma}}{1-\beta(1-\theta)^{1-\gamma}} \cdot u(x-c) \right\} \\ &= \max_{0 \le c \le x} \left\{ \frac{c^{1-\gamma}}{1-\gamma} + \beta \frac{\theta^{1-\gamma}}{1-\beta(1-\theta)^{1-\gamma}} \cdot \frac{(x-c)^{1-\gamma}}{1-\gamma} \right\} \end{aligned}$$

From the first order condition, we obtain

$$c^{-\gamma} + \beta \frac{\theta^{1-\gamma}}{1-\beta(1-\theta)^{1-\gamma}} \cdot (x-c)^{-\gamma}(-1) = 0$$

or

$$c^{-\gamma} = \beta \frac{\theta^{1-\gamma}}{1-\beta(1-\theta)^{1-\gamma}} \cdot (x-c)^{-\gamma}$$

With $c = \theta x$ we get

$$(\theta x)^{-\gamma} = \beta \frac{\theta^{1-\gamma}}{1-\beta(1-\theta)^{1-\gamma}} \cdot (x(1-\theta))^{-\gamma}$$

Some rearrangement produces

$$\theta = 1 - \beta^{\frac{1}{\gamma}}$$

This confirms our earlier expression for the optimal policy:

$$c_t^* = \left(1 - \beta^{\frac{1}{\gamma}}\right) x_t$$

Substituting θ into the value function above gives

$$v^*(x_t) = \frac{\left(1-\beta^{\frac{1}{\gamma}}\right)^{1-\gamma}}{1-\beta\left(\beta^{\frac{1-\gamma}{\gamma}}\right)} u(x_t)$$

Rearranging gives

$$v^*(x_t) = \left(1-\beta^{\frac{1}{\gamma}}\right)^{-\gamma} u(x_t)$$

Our claims are now verified.

Exercise 67.6.2

Verify that the optimal policy (67.7) satisfies the Euler equation (67.9).

Solution

Recall that the optimal policy is

$$\sigma^*(x) = (1-\beta^{1/\gamma})x$$

and the Euler equation in policy form is

$$u'(\sigma(x)) = \beta u'(\sigma(x-\sigma(x)))$$

With CRRA utility $u(c) = \frac{c^{1-\gamma}}{1-\gamma}$, the marginal utility is

$$u'(c) = c^{-\gamma}$$

Now let's verify the Euler equation. The left-hand side is

$$u'(\sigma^*(x)) = [\sigma^*(x)]^{-\gamma} = [(1-\beta^{1/\gamma})x]^{-\gamma} = (1-\beta^{1/\gamma})^{-\gamma} x^{-\gamma}$$

For the right-hand side, we first compute the state in the next period:

$$x - \sigma^*(x) = x - (1 - \beta^{1/\gamma})x = x\beta^{1/\gamma}$$

Next period's consumption under the optimal policy is

$$\sigma^*(x - \sigma^*(x)) = \sigma^*(x\beta^{1/\gamma}) = (1 - \beta^{1/\gamma}) \cdot x\beta^{1/\gamma}$$

Therefore, the right-hand side of the Euler equation is

$$\begin{aligned}
\beta u'(\sigma^*(x - \sigma^*(x))) &= \beta[(1 - \beta^{1/\gamma}) \cdot x\beta^{1/\gamma}]^{-\gamma} \\
&= \beta(1 - \beta^{1/\gamma})^{-\gamma} x^{-\gamma} (\beta^{1/\gamma})^{-\gamma} \\
&= \beta(1 - \beta^{1/\gamma})^{-\gamma} x^{-\gamma} \beta^{-1} \\
&= (1 - \beta^{1/\gamma})^{-\gamma} x^{-\gamma}
\end{aligned}$$

Since the left-hand side equals the right-hand side, the optimal policy σ^* satisfies the Euler equation.

OPTIMAL SAVINGS II: NUMERICAL CAKE EATING

Contents

- *Optimal Savings II: Numerical Cake Eating*
  - *Overview*
  - *Reviewing the Model*
  - *Value Function Iteration*
  - *Exercises*

68.1 Overview

In this lecture we continue the study of the problem described in *Optimal Savings I: Cake Eating*.

The aim of this lecture is to solve the problem using numerical methods.

At first this might appear unnecessary, since we already obtained the optimal policy analytically.

However, the cake eating problem is too simple to be useful without modifications, and once we start modifying the problem, numerical methods become essential.

Hence it makes sense to introduce numerical methods now, and test them on this simple problem.

Since we know the analytical solution, this will allow us to assess the accuracy of alternative numerical methods.

Note

The code below aims for clarity rather than maximum efficiency.

In the lectures below we will explore best practice for speed and efficiency.

Let's put these algorithm and code optimizations to one side for now.

We will use the following imports:

```
import matplotlib.pyplot as plt
import numpy as np
from scipy.optimize import minimize_scalar, bisect
from typing import NamedTuple
```

68.2 Reviewing the Model

You might like to review the details in *Optimal Savings I: Cake Eating* before we start.

Recall in particular that the Bellman equation is

$$v(x) = \max_{0 \leq c \leq x} \{u(c) + \beta v(x - c)\} \quad \text{for all } x \geq 0. \tag{68.1}$$

where u is the CRRA utility function.

The analytical solutions for the value function and optimal policy were found to be as follows.

```
def c_star(x, β, γ):

    return (1 - β ** (1/γ)) * x

def v_star(x, β, γ):

    return (1 - β**(1 / γ))**(-γ) * (x**(1-γ) / (1-γ))
```

Our first aim is to obtain these analytical solutions numerically.

68.3 Value Function Iteration

The first approach we will take is **value function iteration**.

This is a form of **successive approximation**, and was discussed in our *lecture on job search*.

The basic idea is:

1. Take an arbitrary initial guess of v.
2. Obtain an update $\hat{v}$ defined by

$$\hat{v}(x) = \max_{0 \leq c \leq x} \{u(c) + \beta v(x - c)\}$$

3. Stop if $\hat{v}$ is approximately equal to v, otherwise set $v = \hat{v}$ and go back to step 2.

Let's write this a bit more mathematically.

68.3.1 The Bellman Operator

We introduce the **Bellman operator** T that takes a function v as an argument and returns a new function Tv defined by

$$Tv(x) = \max_{0 \leq c \leq x} \{u(c) + \beta v(x - c)\}$$

From v we get Tv, and applying T to this yields $T^2 v := T(Tv)$ and so on.

This is called **iterating with the Bellman operator** from initial guess v.

As we discuss in more detail in later lectures, one can use Banach's contraction mapping theorem to prove that the sequence of functions $T^n v$ converges to the solution to the Bellman equation.

68.3.2 Fitted Value Function Iteration

Both consumption c and the state variable x are continuous.

This causes complications when it comes to numerical work.

For example, we need to store each function $T^n v$ in order to compute the next iterate $T^{n+1} v$.

But this means we have to store $T^n v(x)$ at infinitely many x, which is, in general, impossible.

To circumvent this issue we will use fitted value function iteration, as discussed previously in *one of the lectures* on job search.

The process looks like this:

1. Begin with an array of values $\{v_0, \ldots, v_I\}$ representing the values of some initial function v on the grid points $\{x_0, \ldots, x_I\}$.
2. Build a function $\hat{v}$ on the state space $\mathbb{R}_+$ by interpolation, based on the interpolation points $\{(x_i, v_i)\}$.
3. Insert $\hat{v}$ into the right hand side of the Bellman equation and obtain and record the value $T\hat{v}(x_i)$ on each grid point x_i.
4. Unless some stopping condition is satisfied, set $\{v_0, \ldots, v_I\} = \{T\hat{v}(x_0), \ldots, T\hat{v}(x_I)\}$ and go to step 2.

In step 2 we'll use piecewise linear interpolation.

68.3.3 Implementation

The `maximize` function below is a small helper function that converts a SciPy minimization routine into a maximization routine.

```
def maximize(g, upper_bound):
    """
    Maximize the function g over the interval [0, upper_bound].

    We use the fact that the maximizer of g on any interval is
    also the minimizer of -g.

    """

    objective = lambda x: -g(x)
    bounds = (0, upper_bound)
    result = minimize_scalar(objective, bounds=bounds, method='bounded')
    maximizer, maximum = result.x, -result.fun
    return maximizer, maximum
```

We'll store the parameters β and γ and the grid in a `NamedTuple` called `Model`.

We'll also create a helper function called `create_cake_eating_model` to store default parameters and build an instance of `Model`.

```
class Model(NamedTuple):
    β: float
    γ: float
    x_grid: np.ndarray

def create_cake_eating_model(
        β: float = 0.96,           # discount factor
        γ: float = 1.5,            # degree of relative risk aversion
```

(continues on next page)

(continued from previous page)

```
        x_grid_min: float = 1e-3,  # exclude zero for numerical stability
        x_grid_max: float = 2.5,   # size of cake
        x_grid_size: int = 120
    ):
    """
    Creates an instance of the cake eating model.

    """
    x_grid = np.linspace(x_grid_min, x_grid_max, x_grid_size)
    return Model(β, γ, x_grid)
```

Here's the CRRA utility function.

```
def u(c, γ):
    return (c ** (1 - γ)) / (1 - γ)
```

To work with the Bellman equation, let's write it as

$$v(x) = \max_{0 \leq c \leq x} B(x, c, v)$$

where

$$B(x, c, v) := u(c) + \beta v(x - c)$$

Now we implement the function B.

```
def B(
        x: float,               # the current state (remaining cake)
        c: float,               # current consumption
        v: np.ndarray,          # current guess of the value function
        model: Model            # instance of cake eating model
    ):
    """
    Right hand side of the Bellman equation given x and c.

    """
    # Unpack (simplify names)
    β, γ, x_grid = model

    # Convert array v into a function by linear interpolation
    vf = lambda x: np.interp(x, x_grid, v)

    # Return B(x, c, v)
    return u(c, γ) + β * vf(x - c)
```

We now define the Bellman operator acting on grid points:

$$Tv(x_i) = \max_{0 \leq c \leq x_i} B(x_i, c, v) \qquad \text{for all } i$$

```
def T(
        v: np.ndarray,          # Current guess of the value function
        model: Model            # Instance of the cake eating model
    ):
    " The Bellman operator.  Updates the guess of the value function. "

    # Allocate memory for the new array v_new = Tv
```

(continues on next page)

(continued from previous page)

```
    v_new = np.empty_like(v)

    # Calculate Tv(x) for all x
    for i, x in enumerate(model.x_grid):
        # Maximize RHS of Bellman equation with respect to c over [0, x]
        _, v_new[i] = maximize(lambda c: B(x, c, v, model), x)

    return v_new
```

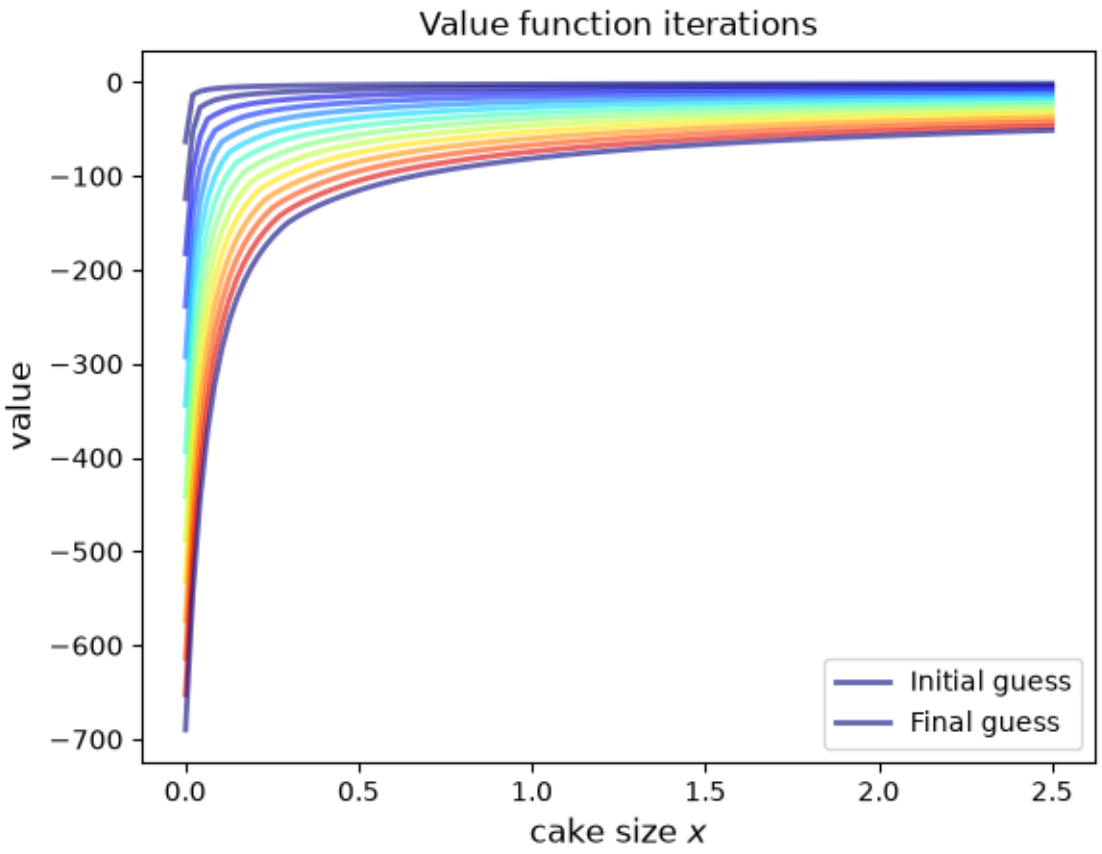
After defining the Bellman operator, we are ready to solve the model.

Let's start by creating a model using the default parameterization.

```
model = create_cake_eating_model()
β, γ, x_grid = model
```

Now let's see iteration of the value function in action.

We start from guess v given by $v(x) = u(x)$ for every x grid point.



```
v = u(x_grid, γ)  # Initial guess
n = 12                  # Number of iterations
fig, ax = plt.subplots()

# Initial plot
ax.plot(x_grid, v, color=plt.cm.jet(0),
        lw=2, alpha=0.6, label='Initial guess')

# Iterate
for i in range(n):
    v = T(v, model)  # Apply the Bellman operator
    ax.plot(x_grid, v, color=plt.cm.jet(i / n), lw=2, alpha=0.6)

# One last update and plot
v = T(v, model)
ax.plot(x_grid, v, color=plt.cm.jet(0),
        lw=2, alpha=0.6, label='Final guess')

ax.legend()
ax.set_ylabel('value', fontsize=12)
ax.set_xlabel('cake size $x$', fontsize=12)
ax.set_title('Value function iterations')
plt.show()
```

To iterate more systematically, we introduce a wrapper function called `compute_value_function`.

It's task is to iterate using T until some convergence conditions are satisfied.

```
def compute_value_function(
        model: Model,
        tol: float = 1e-4,
        max_iter: int = 1_000,
        verbose: bool = True,
        print_skip: int = 25
    ):

    # Set up loop
    v = np.zeros(len(model.x_grid)) # Initial guess
    i = 0
    error = tol + 1

    while i < max_iter and error > tol:
        v_new = T(v, model)

        error = np.max(np.abs(v - v_new))
        i += 1

        if verbose and i % print_skip == 0:
            print(f"Error at iteration {i} is {error}.")

        v = v_new
```

(continues on next page)

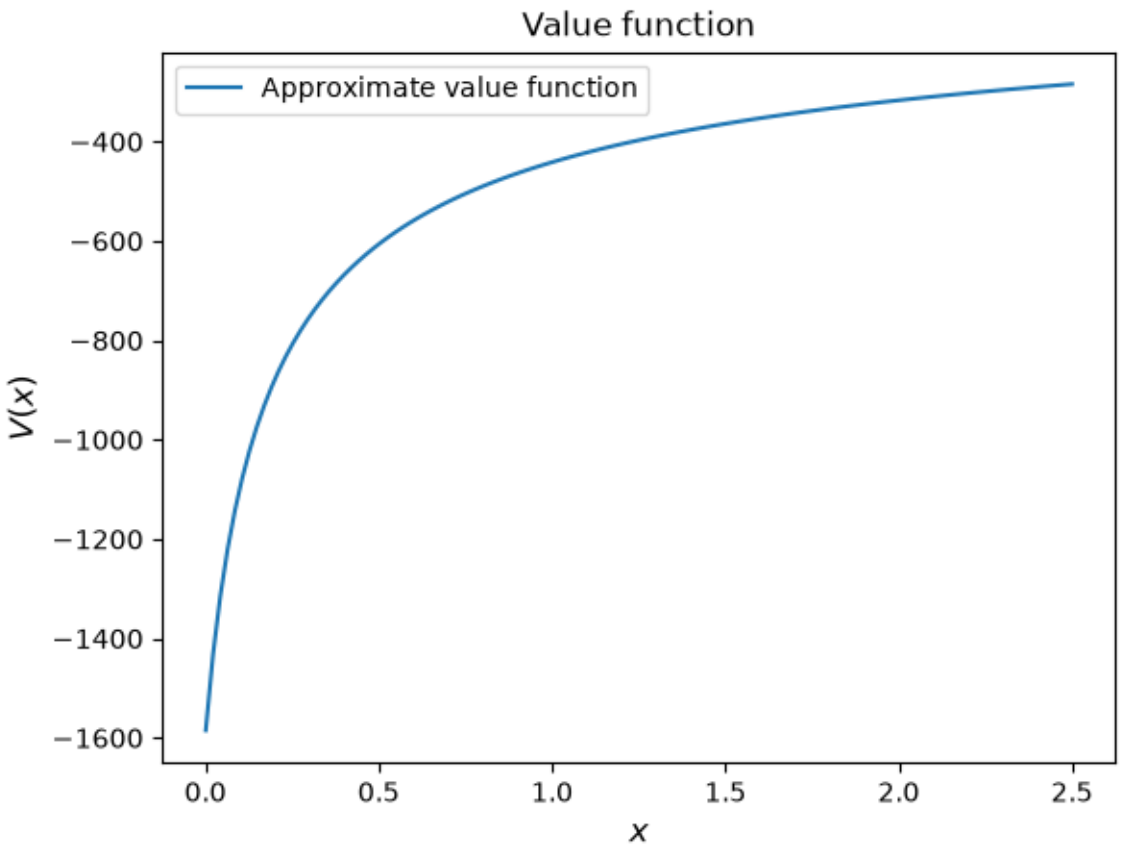
(continued from previous page)

```
    if error > tol:
        print("Failed to converge!")
    elif verbose:
        print(f"\nConverged in {i} iterations.")

    return v_new
```

Now let's call it, noting that it takes a little while to run.

```
v = compute_value_function(model)
```



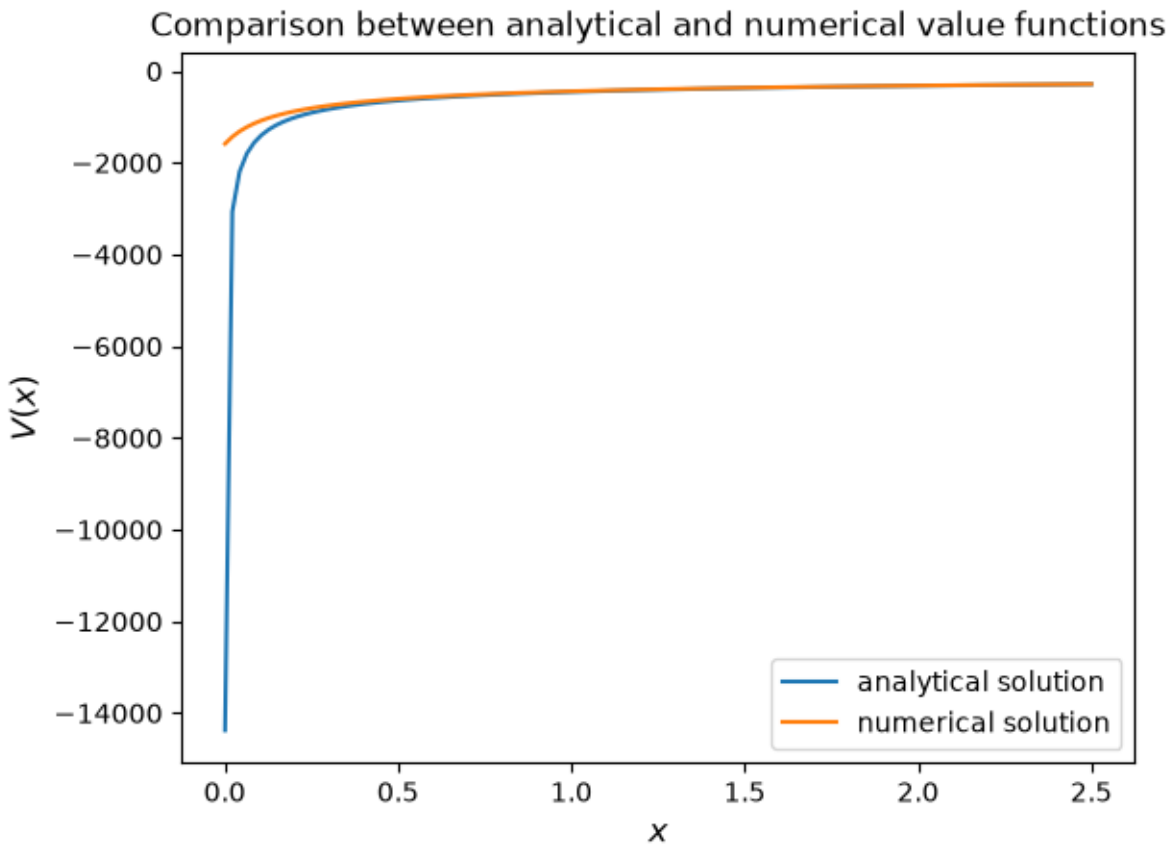
```
Error at iteration 25 is 23.80037552320357.
Error at iteration 50 is 8.577577198550443.
Error at iteration 75 is 3.091330660953872.
Error at iteration 100 is 1.1141054209301728.
Error at iteration 125 is 0.4015199359369035.
Error at iteration 150 is 0.1447064666647293.
Error at iteration 175 is 0.05215173549413521.
Error at iteration 200 is 0.018795314250610318.
Error at iteration 225 is 0.006773769548317432.
Error at iteration 250 is 0.0024412443060555233.
Error at iteration 275 is 0.0008798164330414693.
Error at iteration 300 is 0.0003170829540977138.
Error at iteration 325 is 0.00011427565573285392.

Converged in 329 iterations.
```

Now we can plot and see what the converged value function looks like.

```
fig, ax = plt.subplots()

ax.plot(x_grid, v, label='Approximate value function')
ax.set_ylabel('$V(x)$', fontsize=12)
ax.set_xlabel('$x$', fontsize=12)
ax.set_title('Value function')
ax.legend()
plt.show()
```



Next let's compare it to the analytical solution.

```
v_analytical = v_star(x_grid, β, γ)
```

```
fig, ax = plt.subplots()

ax.plot(x_grid, v_analytical, label='analytical solution')
ax.plot(x_grid, v, label='numerical solution')
ax.set_ylabel('$V(x)$', fontsize=12)
ax.set_xlabel('$x$', fontsize=12)
ax.legend()
ax.set_title('Comparison between analytical and numerical value functions')
plt.show()
```

The quality of approximation is reasonably good for large x, but less so near the lower boundary.

The reason is that the utility function and hence value function is very steep near the lower boundary, and hence hard to approximate.

Note

One way to fix this issue is to use a nonlinear grid, with more points in the neighborhood of zero.

Instead of pursuing this idea, however, we will turn our attention to working with policy functions.

We will see that value function iteration can be avoided by iterating on a guess of the policy function instead.

The policy function has less curvature and hence is easier to interpolate than the value function.

These ideas will be explored over the next few lectures.

68.3.4 Policy Function

Let's try computing the optimal policy.

In *Optimal Savings I: Cake Eating*, the optimal consumption policy was shown to be

$$\sigma^*(x) = \left(1 - \beta^{1/\gamma}\right) x$$

Let's see if our numerical results lead to something similar.

Our numerical strategy will be to compute, for any given v, the policy

$$\sigma(x) = \arg \max_{0 \leq c \leq x} \{u(c) + \beta v(x - c)\}$$

This policy is called the v-**greedy policy**.

In practice we will compute σ on a grid of x points and then interpolate.

For v we will use the approximation of the value function we obtained above.

Here's the function:

```
def get_greedy(
        v: np.ndarray,          # current guess of the value function
        model: Model            # instance of cake eating model
    ):
    " Compute the v-greedy policy on x_grid."

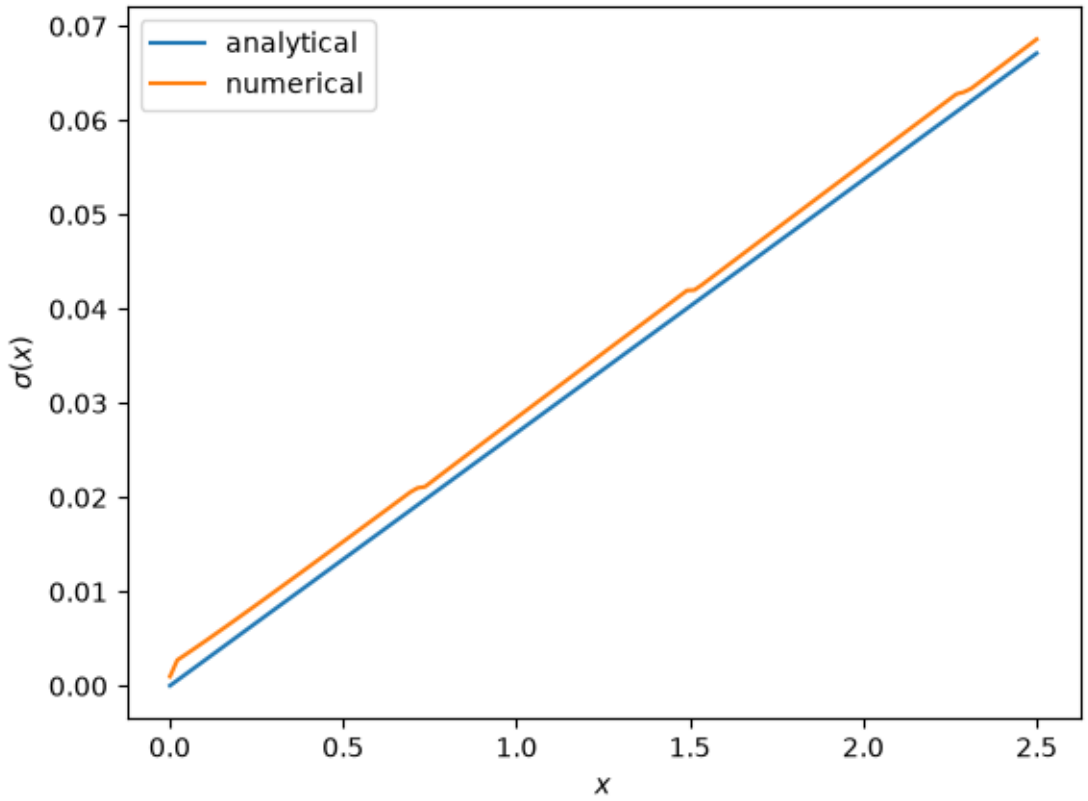
    σ = np.empty_like(v)

    for i, x in enumerate(model.x_grid):
        # Maximize RHS of Bellman equation at state x
        σ[i], _ = maximize(lambda c: B(x, c, v, model), x)

    return σ
```

Now let's pass the approximate value function and compute optimal consumption:

```
σ = get_greedy(v, model)
```



Let's plot this next to the true analytical solution

```
c_analytical = c_star(model.x_grid, model.β, model.γ)

fig, ax = plt.subplots()

ax.plot(model.x_grid, c_analytical, label='analytical')
ax.plot(model.x_grid, σ, label='numerical')
ax.set_ylabel(r'$\sigma(x)$')
ax.set_xlabel('$x$')
ax.legend()

plt.show()
```

The fit is reasonable but not perfect.

We can improve it by increasing the grid size or reducing the error tolerance in the value function iteration routine.

However, both changes will lead to a longer compute time.

Another possibility is to use an alternative algorithm, which offers the possibility of faster compute time and, at the same time, more accuracy.

We explore this in *Optimal Savings IV: Time Iteration*.

68.4 Exercises

Exercise 68.4.1

Try the following modification of the problem.

Instead of the cake size changing according to $x_{t+1} = x_t - c_t$, let it change according to

$$x_{t+1} = (x_t - c_t)^\alpha$$

where α is a parameter satisfying $0 < \alpha < 1$.

(We will see this kind of update rule when we study optimal growth models.)

Make the required changes to value function iteration code and plot the value and policy functions.

Try to reuse as much code as possible.

Solution

We need to create an extended version of our model and state-action value function.

We'll create a new `NamedTuple` for the extended cake model and a helper function.

```
# Create extended cake model data structure
class ExtendedModel(NamedTuple):
    β: float
    γ: float
    α: float
    x_grid: np.ndarray

def create_extended_model(β=0.96,           # discount factor
                          γ=1.5,            # degree of relative risk aversion
                          α=0.4,            # productivity parameter
                          x_grid_min=1e-3,  # exclude zero for numerical stability
                          x_grid_max=2.5,   # size of cake
                          x_grid_size=120):
    """
    Creates an instance of the extended cake eating model.
    """
    x_grid = np.linspace(x_grid_min, x_grid_max, x_grid_size)
    return ExtendedModel(β, γ, α, x_grid)

def extended_B(c, x, v, model):
    """
    Right hand side of the Bellman equation for the extended cake model given x␣
 ↪and c.

    """
    β, γ, α, x_grid = model
    vf = lambda x: np.interp(x, x_grid, v)
    return u(c, γ) + β * vf((x - c)**α)
```

We also need a modified Bellman operator:

```
def extended_T(v, model):
    " The Bellman operator for the extended cake model. "

    v_new = np.empty_like(v)
    for i, x in enumerate(model.x_grid):
        _, v_new[i] = maximize(lambda c: extended_B(c, x, v, model), x)
    return v_new
```

Now create the model:

```
model = create_extended_model()
```

Here's a function to compute the value function.

```
def compute_value_function_extended(model,
                                    tol=1e-4,
                                    max_iter=1000,
                                    verbose=True,
                                    print_skip=25):
    """
    Compute value function for extended cake model.
    """
    v = np.zeros(len(model.x_grid))
    i = 0
    error = tol + 1

    while i < max_iter and error > tol:
        v_new = extended_T(v, model)
        error = np.max(np.abs(v - v_new))
        i += 1
        if verbose and i % print_skip == 0:
            print(f"Error at iteration {i} is {error}.")
        v = v_new

    if error > tol:
        print("Failed to converge!")
    elif verbose:
        print(f"\nConverged in {i} iterations.")

    return v_new

v = compute_value_function_extended(model, verbose=False)

fig, ax = plt.subplots()

ax.plot(model.x_grid, v, lw=2, alpha=0.6)
ax.set_ylabel('value', fontsize=12)
ax.set_xlabel('state $x$', fontsize=12)

plt.show()
```

Here's the computed policy, combined with the solution we derived above for the standard cake eating case $\alpha = 1$.

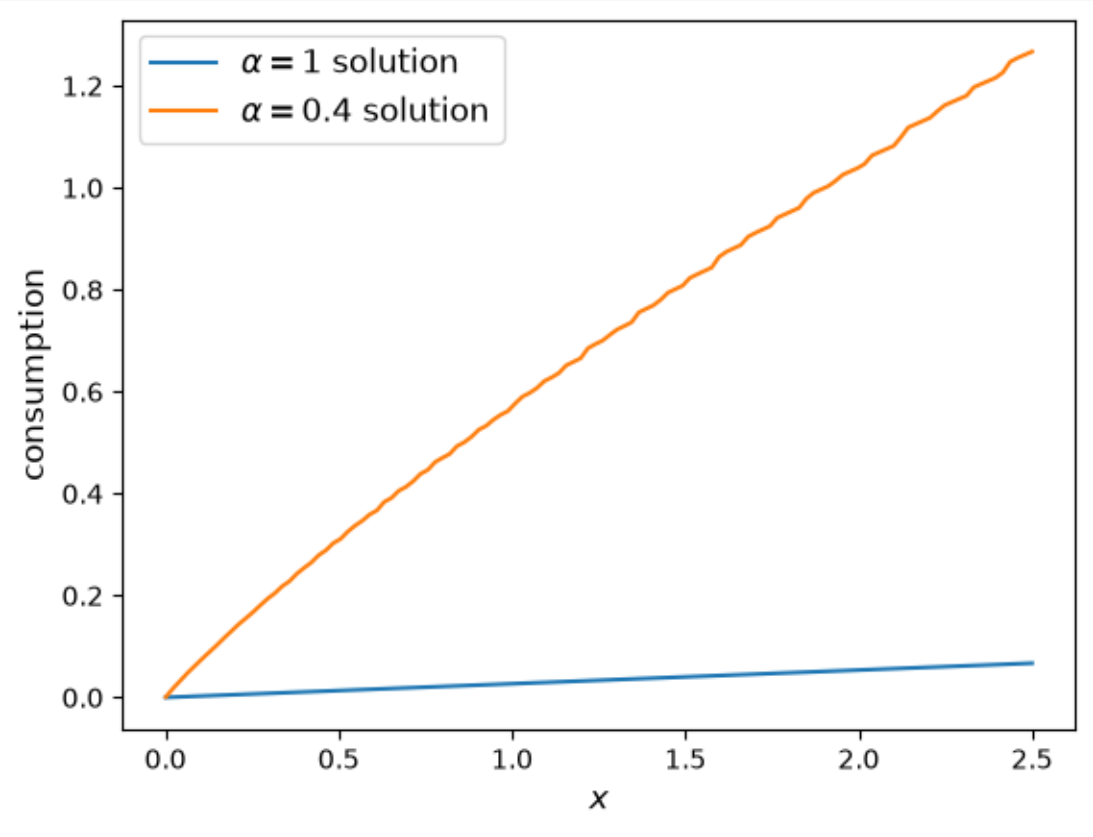
```
def extended_get_greedy(model, v):
    """
    The optimal policy function for the extended cake model.
    """
    σ = np.empty_like(v)

    for i, x in enumerate(model.x_grid):
        # Maximize extended_B with respect to c over [0, x]
        σ[i], _ = maximize(lambda c: extended_B(c, x, v, model), x)

    return σ

σ = extended_get_greedy(model, v)

# Get the baseline model for comparison
baseline_model = create_cake_eating_model()
c_analytical = c_star(baseline_model.x_grid, baseline_model.β, baseline_model.γ)



fig, ax = plt.subplots()

ax.plot(baseline_model.x_grid, c_analytical, label=r'$\alpha=1$ solution')
ax.plot(model.x_grid, σ, label=fr'$\alpha={model.α}$ solution')

ax.set_ylabel('consumption', fontsize=12)
ax.set_xlabel('$x$', fontsize=12)

ax.legend(fontsize=12)

plt.show()
```

Consumption is higher when $\alpha < 1$ because, at least for large x, the return to savings is lower.

CHAPTER

SIXTYNINE

OPTIMAL SAVINGS III: STOCHASTIC RETURNS

Contents

- *Optimal Savings III: Stochastic Returns*
  - *Overview*
  - *The Model*
  - *Computation*
  - *Exercises*

69.1 Overview

In this lecture, we continue our study of optimal savings problems, building on *Optimal Savings I: Cake Eating* and *Optimal Savings II: Numerical Cake Eating*.

The key difference from the previous lectures is that wealth now evolves stochastically.

We can think of wealth as a harvest that regrows if we save some seeds.

Specifically, if we save and invest part of today's harvest x_t, it grows into next period's harvest x_{t+1} according to a stochastic production process.

The extensions in this lecture introduce several new elements:

- nonlinear returns to saving, through a production function, and
- stochastic returns, due to shocks to production.

Despite these additions, the model remains relatively tractable.

As a first pass, we will solve the model using dynamic programming and value function iteration (VFI).

Note

In later lectures we'll explore more efficient methods for this class of problems.

At the same time, VFI is foundational and globally convergent.

Hence we want to be sure we can use this method too.

More information on this savings problem can be found in

- [Ljungqvist and Sargent, 2018], Section 3.1
- EDTC, Chapter 1
- [Sundaram, 1996], Chapter 12

Let's start with some imports:

```
import matplotlib.pyplot as plt
import numpy as np
from scipy.interpolate import interp1d
from scipy.optimize import minimize_scalar
from typing import NamedTuple, Callable
```

69.2 The Model

Here we described the new model and the optimization problem.

69.2.1 Setup

Consider an agent who owns an amount $x_t \in \mathbb{R}_+ := [0, \infty)$ of a consumption good at time t.

This output can either be consumed or saved and used for production.

Production is stochastic, in that it also depends on a shock ξ_{t+1} realized at the end of the current period.

Next period output is

$$x_{t+1} := f(s_t)\xi_{t+1}$$

where $f \colon \mathbb{R}_+ \to \mathbb{R}_+$ is the **production function** and

$$s_t = x_t - c_t \tag{69.1}$$

is **current savings**.

and all variables are required to be nonnegative.

In what follows,

- The sequence $\{\xi_t\}$ is assumed to be IID.
- The common distribution of each ξ_t will be denoted by ϕ.
- The production function f is assumed to be increasing and continuous.

69.2.2 Optimization

Taking x_0 as given, the agent wishes to maximize

$$\mathbb{E} \sum_{t=0}^{\infty} \beta^t u(c_t) \tag{69.2}$$

subject to

$$x_{t+1} = f(x_t - c_t)\xi_{t+1} \quad \text{and} \quad 0 \leq c_t \leq x_t \quad \text{for all } t \tag{69.3}$$

where

- u is a bounded, continuous and strictly increasing utility function and
- $\beta \in (0, 1)$ is a discount factor.

In summary, the agent's aim is to select a path $c_0, c_1, c_2, \ldots$ for consumption that is

1. nonnegative,
2. feasible,
3. optimal, in the sense that it maximizes (69.2) relative to all other feasible consumption sequences, and
4. **adapted**, in the sense that the current action c_t depends only on current and historical outcomes, not on future outcomes such as ξ_{t+1}.

In the present context

- x_t is called the **state** variable — it summarizes the "state of the world" at the start of each period.
- c_t is called the **control** variable — a value chosen by the agent each period after observing the state.

69.2.3 Optimal Policies

Let us look at **policy functions**, each one of which is a map σ from the current state x_t into a current action c_t.

Note

These kinds of policies are called Markov policies (or stationary Markov policies).

For this dynamic program, the optimal policy is always a Markov policy (see, e.g., DP1).

In essence, the current state x_t provides a sufficient statistic for the history in terms of making an optimal decision today.

In what follows, we will call σ a **feasible consumption policy** if it satisfies

$$0 \leq \sigma(x) \leq x \quad \text{for all} \quad x \in \mathbb{R}_+ \tag{69.4}$$

In other words, a feasible policy is a policy function that respects the resource constraint.

The set of all feasible consumption policies will be denoted by Σ.

Each $\sigma \in \Sigma$ determines a Markov dynamics for output $\{x_t\}$ via

$$x_{t+1} = f(x_t - \sigma(x_t))\xi_{t+1}, \quad x_0 \text{ given} \tag{69.5}$$

This is the time path for output when we choose and stick with the policy σ.

We insert this process into the objective function to get

$$\mathbb{E}\sum_{t=0}^{\infty} \beta^t u(c_t) = \mathbb{E}\sum_{t=0}^{\infty} \beta^t u(\sigma(x_t)) \tag{69.6}$$

This is the total expected present value of following policy σ forever, given initial income x_0.

The aim is to select a policy that makes this number as large as possible.

The next section covers these ideas more formally.

69.2.4 Optimality

The lifetime value v_σ associated with a given policy σ is the mapping defined by

$$v_\sigma(x) = \mathbb{E} \sum_{t=0}^{\infty} \beta^t u(\sigma(x_t)) \tag{69.7}$$

when $\{x_t\}$ is given by (69.5) with $x_0 = x$.

In other words, it is the lifetime value of following policy σ forever, starting at initial condition x.

The **value function** is then defined as

$$v^*(x) := \sup_{\sigma \in \Sigma} \; v_\sigma(x) \tag{69.8}$$

The value function gives the maximal value that can be obtained from state x, after considering all feasible policies.

A policy $\sigma \in \Sigma$ is called **optimal** if $v_\sigma(x) = v^*(x)$ for all $x \in \mathbb{R}_+$.

69.2.5 The Bellman Equation

The following equation is called the **Bellman equation** associated with this dynamic programming problem.

$$v(x) = \max_{0 \leq c \leq x} \left\{ u(c) + \beta \int v(f(x-c)z)\phi(dz) \right\} \qquad (x \in \mathbb{R}_+) \tag{69.9}$$

This is a *functional equation in* v, in the sense that a given v can either satisfy it or not satisfy it.

The term $\int v(f(x-c)z)\phi(dz)$ can be understood as the expected next period value when

- v is used to measure value
- the state is x
- consumption is set to c

As shown in DP1 and a range of other texts, the value function v^* satisfies the Bellman equation.

In other words, (69.9) holds when $v = v^*$.

The intuition is that maximal value from a given state can be obtained by optimally trading off

- current reward from a given action, vs
- expected discounted future value of the state resulting from that action

The Bellman equation is important because it

1. gives us more information about the value function and
2. suggests a way of computing the value function, which we discuss below.

69.2.6 Greedy Policies

The value function can be used to compute optimal policies.

Given a continuous function v on $\mathbb{R}_+$, we say that $\sigma \in \Sigma$ is v-**greedy** if

$$\sigma(x) \in \arg\max_{0 \leq c \leq x} \left\{ u(c) + \beta \int v(f(x-c)z)\phi(dz) \right\} \tag{69.10}$$

for every $x \in \mathbb{R}_+$.

In other words, $\sigma \in \Sigma$ is v-greedy if it optimally trades off current and future rewards when v is taken to be the value function.

In our setting, we have the following key result

Theorem 69.2.1

A feasible consumption policy is optimal if and only if it is v^*-greedy.

See, for example, Theorem 10.1.11 of EDTC.

Hence, once we have a good approximation to v^*, we can compute the (approximately) optimal policy by computing the corresponding greedy policy.

The advantage is that we are now solving a much lower dimensional optimization problem.

69.2.7 The Bellman Operator

How, then, should we compute the value function?

One way is to use the so-called **Bellman operator**.

(The term **operator** is usually reserved for functions that send functions into functions!)

The Bellman operator is denoted by T and defined by

$$Tv(x) := \max_{0 \leq c \leq x} \left\{ u(c) + \beta \int v(f(x-c)z)\phi(dz) \right\} \qquad (x \in \mathbb{R}_+) \tag{69.11}$$

In other words, T sends the function v into the new function Tv defined by (69.11).

By construction, the set of solutions to the Bellman equation (69.9) *exactly coincides with* the set of fixed points of T.

For example, if $Tv = v$, then, for any $x \geq 0$,

$$v(x) = Tv(x) = \max_{0 \leq c \leq x} \left\{ u(c) + \beta \int v(f(x-c)z)\phi(dz) \right\}$$

which says precisely that v is a solution to the Bellman equation.

It follows that v^* is a fixed point of T.

69.2.8 Review of Theoretical Results

One can also show that T is a contraction mapping on the set of continuous bounded functions on $\mathbb{R}_+$ under the supremum distance

$$\rho(g, h) = \sup_{x \geq 0} |g(x) - h(x)|$$

See EDTC, Lemma 10.1.18.

Hence, it has exactly one fixed point in this set, which we know is equal to the value function.

It follows that

- The value function v^* is bounded and continuous.
- Starting from any bounded and continuous v, the sequence $v, Tv, T^2v, \ldots$ generated by iteratively applying T converges uniformly to v^*.

This iterative method is called **value function iteration**.

We also know that a feasible policy is optimal if and only if it is v^*-greedy.

It's not too hard to show that a v^*-greedy policy exists.

Hence, at least one optimal policy exists.

Our problem now is how to compute it.

69.2.9 Unbounded Utility

The results stated above assume that u is bounded.

In practice economists often work with unbounded utility functions — and so will we.

In the unbounded setting, various optimality theories exist.

Nevertheless, their main conclusions are usually in line with those stated for the bounded case just above (as long as we drop the word "bounded").

Note

Consult the following references for more on the unbounded case:

- The lecture *The Income Fluctuation Problem V: Stochastic Returns on Assets*.
- Section 12.2 of EDTC.

69.3 Computation

Let's now look at computing the value function and the optimal policy.

Our implementation in this lecture will focus on clarity and flexibility.

(In subsequent lectures we will focus on efficiency and speed.)

We will use fitted value function iteration, which was already described in *Optimal Savings II: Numerical Cake Eating*.

69.3.1 Scalar Maximization

To maximize the right hand side of the Bellman equation (69.9), we are going to use the `minimize_scalar` routine from SciPy.

To keep the interface tidy, we will wrap `minimize_scalar` in an outer function as follows:

```
def maximize(g, upper_bound):
    """
    Maximize the function g over the interval [0, upper_bound].

    We use the fact that the maximizer of g on any interval is
    also the minimizer of -g.

    """

    objective = lambda x: -g(x)
```

(continues on next page)

(continued from previous page)

```
    bounds = (0, upper_bound)
    result = minimize_scalar(objective, bounds=bounds, method='bounded')
    maximizer, maximum = result.x, -result.fun
    return maximizer, maximum
```

69.3.2 Model

We will assume for now that ϕ is the distribution of $\xi := \exp(\mu + \nu\zeta)$ where

- ζ is standard normal,
- μ is a shock location parameter and
- ν is a shock scale parameter.

We will store the primitives of the model in a `NamedTuple`.

```
class Model(NamedTuple):
    u: Callable        # utility function
    f: Callable        # production function
    β: float           # discount factor
    μ: float           # shock location parameter
    ν: float           # shock scale parameter
    x_grid: np.ndarray # state grid
    shocks: np.ndarray # shock draws

def create_model(
        u: Callable,
        f: Callable,
        β: float = 0.96,
        μ: float = 0.0,
        ν: float = 0.1,
        grid_max: float = 4.0,
        grid_size: int = 120,
        shock_size: int = 250,
        seed: int = 1234
    ) -> Model:
    """
    Creates an instance of the optimal savings model.
    """
    # Set up grid
    x_grid = np.linspace(1e-4, grid_max, grid_size)

    # Store shocks (with a seed, so results are reproducible)
    rng = np.random.default_rng(seed)
    shocks = np.exp(μ + ν * rng.standard_normal(shock_size))

    return Model(u, f, β, μ, ν, x_grid, shocks)
```

We set up the right-hand side of the Bellman equation

$$B(x, c, v) := u(c) + \beta \int v(f(x - c)z)\phi(dz)$$

```
def B(
        x: float,               # State
        c: float,               # Action
        v_array: np.ndarray,    # Array representing a guess of the value fn
        model: Model            # An instance of Model containing parameters
    ):

    u, f, β, μ, v, x_grid, shocks = model
    v = interp1d(x_grid, v_array)

    return u(c) + β * np.mean(v(f(x - c) * shocks))
```

In the second last line we are using linear interpolation.

In the last line, the expectation in (69.11) is computed via Monte Carlo, using the approximation

$$\int v(f(x-c)z)\phi(dz) \approx \frac{1}{n}\sum_{i=1}^{n} v(f(x-c)\xi_i)$$

where $\{\xi_i\}_{i=1}^n$ are IID draws from ϕ.

Monte Carlo is not always the most efficient way to compute integrals numerically but it does have some theoretical advantages in the present setting.

(For example, it preserves the contraction mapping property of the Bellman operator — see, e.g., [Pál and Stachurski, 2013].)

69.3.3 The Bellman Operator

The next function implements the Bellman operator.

```
def T(v: np.ndarray, model: Model) -> tuple[np.ndarray, np.ndarray]:
    """
    The Bellman operator.  Updates the guess of the value function.

      * model is an instance of Model
      * v is an array representing a guess of the value function

    """
    x_grid = model.x_grid
    v_new = np.empty_like(v)

    for i in range(len(x_grid)):
        x = x_grid[i]
        _, v_max = maximize(lambda c: B(x, c, v, model), x)
        v_new[i] = v_max

    return v_new
```

Here's the function:

```
def get_greedy(
        v: np.ndarray,          # current guess of the value function
        model: Model            # instance of optimal savings model
    ):
    " Compute the v-greedy policy on x_grid."
```

(continues on next page)

(continued from previous page)

```
    σ = np.empty_like(v)

    for i, x in enumerate(model.x_grid):
        # Maximize RHS of Bellman equation at state x
        σ[i], _ = maximize(lambda c: B(x, c, v, model), x)

    return σ
```

69.3.4 An Example

Let's suppose now that

$$f(x-c) = (x-c)^\alpha \quad \text{and} \quad u(c) = \ln c$$

For this particular problem, an exact analytical solution is available (see [Ljungqvist and Sargent, 2018], section 3.1.2), with

$$v^*(x) = \frac{\ln(1-\alpha\beta)}{1-\beta} + \frac{(\mu + \alpha \ln(\alpha\beta))}{1-\alpha}\left[\frac{1}{1-\beta} - \frac{1}{1-\alpha\beta}\right] + \frac{1}{1-\alpha\beta}\ln x \tag{69.12}$$

and optimal consumption policy

$$\sigma^*(x) = (1-\alpha\beta)x$$

It is valuable to have these closed-form solutions because it lets us check whether our code works for this particular case.

In Python, the functions above can be expressed as:

```
def v_star(x, α, β, μ):
    """
    True value function
    """
    c1 = np.log(1 - α * β) / (1 - β)
    c2 = (μ + α * np.log(α * β)) / (1 - α)
    c3 = 1 / (1 - β)
    c4 = 1 / (1 - α * β)
    return c1 + c2 * (c3 - c4) + c4 * np.log(x)

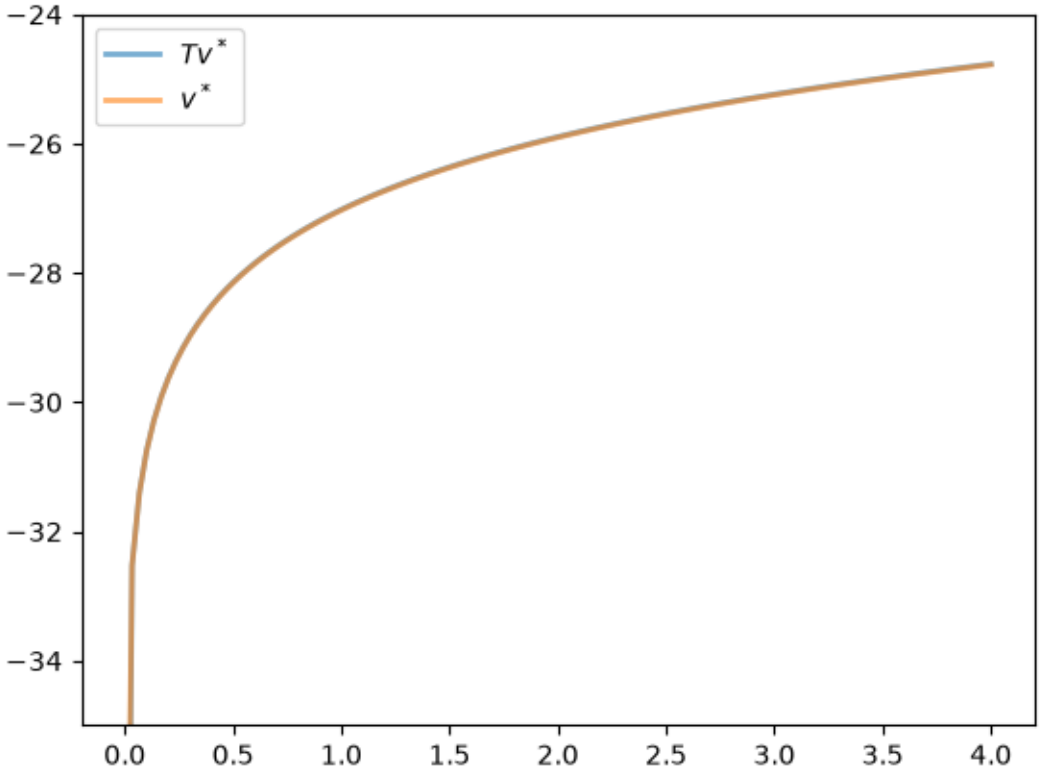
def σ_star(x, α, β):
    """
    True optimal policy
    """
    return (1 - α * β) * x
```

Next let's create an instance of the model with the above primitives and assign it to the variable `model`.

```
α = 0.4
def fcd(s):
    return s**α

model = create_model(u=np.log, f=fcd)
```

Now let's see what happens when we apply our Bellman operator to the exact solution v^* in this case.



In theory, since v^* is a fixed point, the resulting function should again be v^*.

In practice, we expect some small numerical error.

```
x_grid = model.x_grid

v_init = v_star(x_grid, α, model.β, model.μ)     # Start at the solution
v = T(v_init, model)              # Apply T once

fig, ax = plt.subplots()
ax.set_ylim(-35, -24)
ax.plot(x_grid, v, lw=2, alpha=0.6, label='$Tv^*$')
ax.plot(x_grid, v_init, lw=2, alpha=0.6, label='$v^*$')
ax.legend()
plt.show()
```

The two functions are essentially indistinguishable, so we are off to a good start.

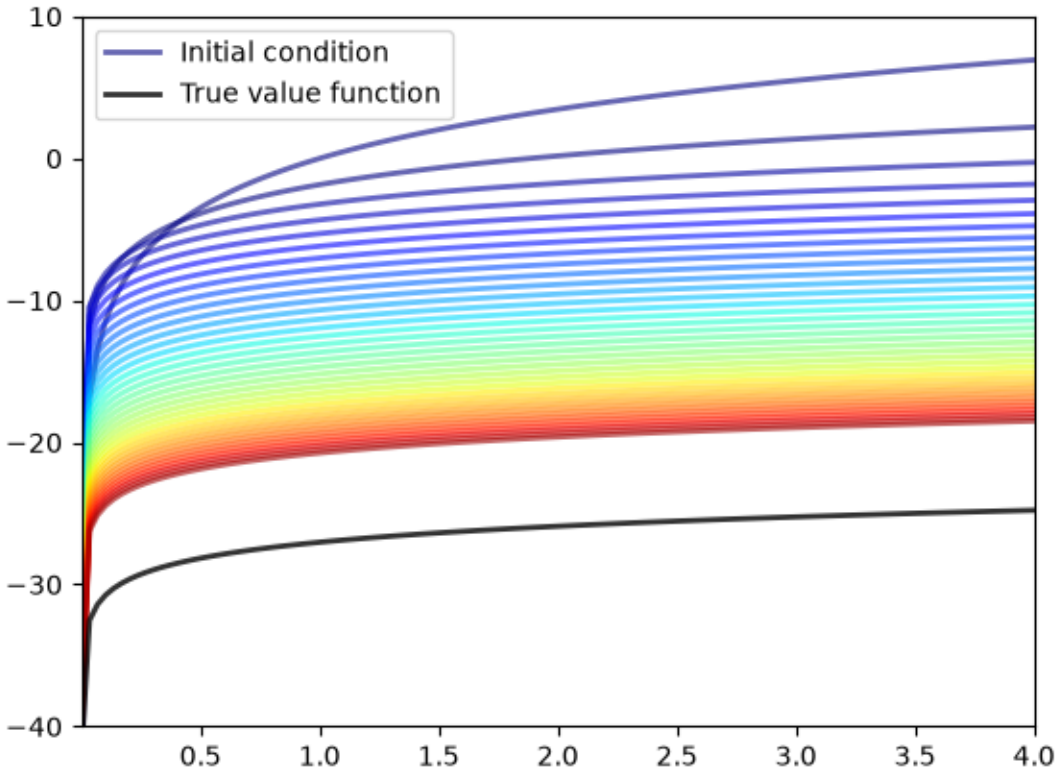
Now let's have a look at iterating with the Bellman operator, starting from an arbitrary initial condition.

The initial condition we'll start with is, somewhat arbitrarily, $v(x) = 5 \ln(x)$.

```
v = 5 * np.log(x_grid)  # An initial condition
n = 35

fig, ax = plt.subplots()

ax.plot(x_grid, v, color=plt.cm.jet(0),
        lw=2, alpha=0.6, label='Initial condition')



for i in range(n):
    v = T(v, model)  # Apply the Bellman operator
    ax.plot(x_grid, v, color=plt.cm.jet(i / n), lw=2, alpha=0.6)
```

(continues on next page)

(continued from previous page)

```
ax.plot(x_grid, v_star(x_grid, α, model.β, model.μ), 'k-', lw=2,
        alpha=0.8, label='True value function')

ax.legend()
ax.set(ylim=(-40, 10), xlim=(np.min(x_grid), np.max(x_grid)))
plt.show()
```

The figure shows

1. the first 36 functions generated by the fitted value function iteration algorithm, with hotter colors given to higher iterates
2. the true value function v^* drawn in black

The sequence of iterates converges towards v^*.

We are clearly getting closer.

69.3.5 Iterating to Convergence

We can write a function that iterates until the difference is below a particular tolerance level.

```
def solve_model(
        model: Model,           # instance of optimal savings model
        tol: float = 1e-4,      # convergence tolerance
        max_iter: int = 1000,   # maximum iterations
        verbose: bool = True,   # print iteration info
        print_skip: int = 25    # iterations between prints
```

(continues on next page)

(continued from previous page)

```
    ):
    " Solve by value function iteration. "

    v = model.u(model.x_grid)  # Initial condition
    i = 0
    error = tol + 1

    while i < max_iter and error > tol:
        v_new = T(v, model)
        error = np.max(np.abs(v - v_new))
        i += 1
        if verbose and i % print_skip == 0:
            print(f"Error at iteration {i} is {error}.")
        v = v_new

    if error > tol:
        print("Failed to converge!")
    elif verbose:
        print(f"\nConverged in {i} iterations.")

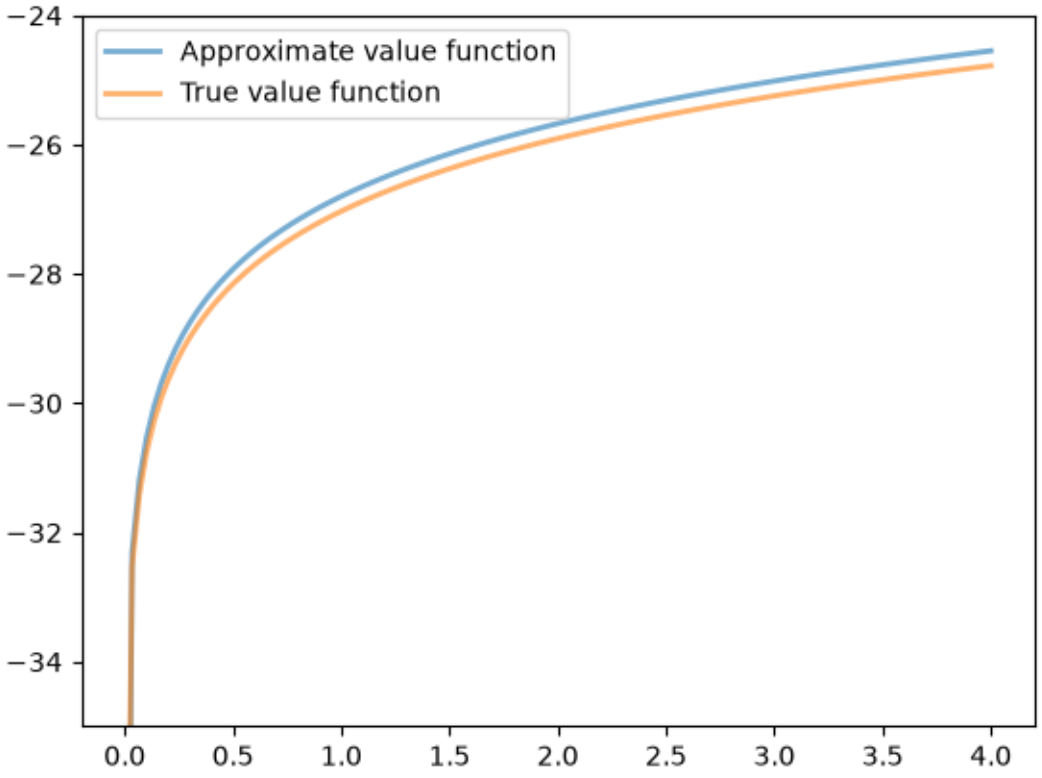
    v_greedy = get_greedy(v_new, model)
    return v_greedy, v_new
```

Let's use this function to compute an approximate solution at the defaults.

```
v_greedy, v_solution = solve_model(model)
```

```
Error at iteration 25 is 0.4089748660600776.
Error at iteration 50 is 0.14739319864069955.
Error at iteration 75 is 0.05312002487731604.
Error at iteration 100 is 0.019144282565221715.
Error at iteration 125 is 0.006899536583134136.
Error at iteration 150 is 0.0024865703324401522.
Error at iteration 175 is 0.0008961517840404554.
Error at iteration 200 is 0.0003229701607807556.
Error at iteration 225 is 0.0001163973856428413.

Converged in 229 iterations.
```



Now we check our result by plotting it against the true value:

```
fig, ax = plt.subplots()

ax.plot(x_grid, v_solution, lw=2, alpha=0.6,
        label='Approximate value function')

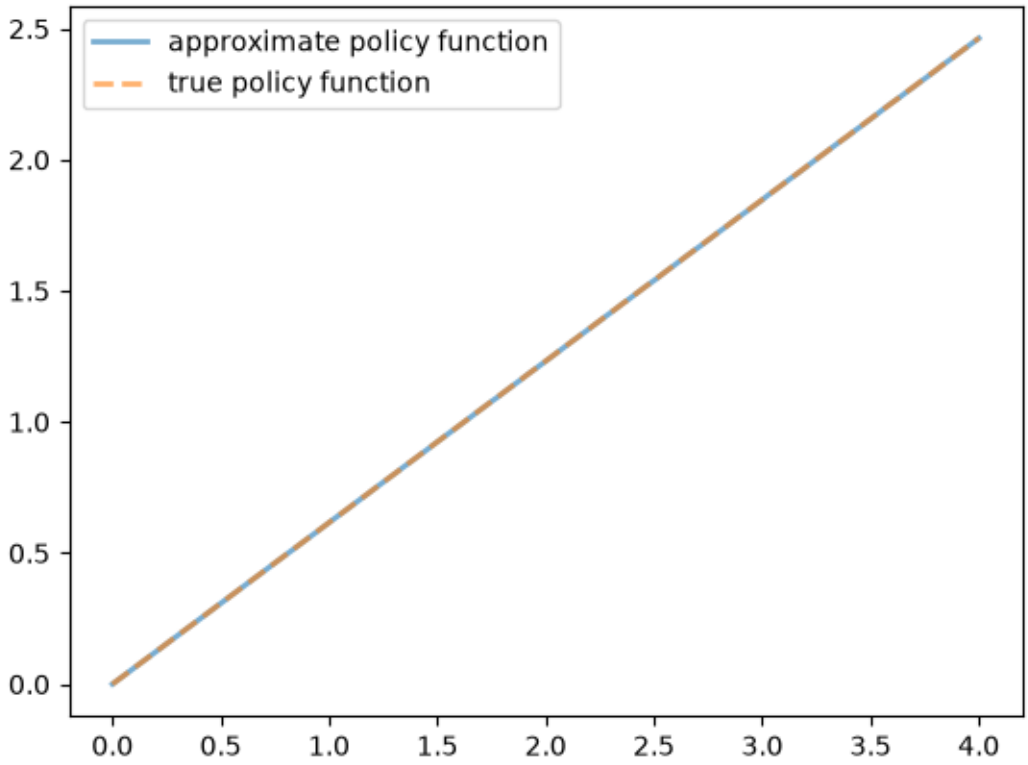
ax.plot(x_grid, v_star(x_grid, α, model.β, model.μ), lw=2,
        alpha=0.6, label='True value function')

ax.legend()
ax.set_ylim(-35, -24)
plt.show()
```

The figure shows that we are pretty much on the money.

69.3.6 The Policy Function

The policy `v_greedy` computed above corresponds to an approximate optimal policy.



The next figure compares it to the exact solution, which, as mentioned above, is $\sigma(x) = (1 - \alpha\beta)x$

```
fig, ax = plt.subplots()

ax.plot(x_grid, v_greedy, lw=2,
        alpha=0.6, label='approximate policy function')

ax.plot(x_grid, σ_star(x_grid, α, model.β), '--',
        lw=2, alpha=0.6, label='true policy function')

ax.legend()
plt.show()
```

The figure shows that we've done a good job in this instance of approximating the true policy.

69.4 Exercises

Exercise 69.4.1

A common choice for utility function in this kind of work is the CRRA specification

$$u(c) = \frac{c^{1-\gamma}}{1-\gamma}$$

Maintaining the other defaults, including the Cobb-Douglas production function, solve the optimal savings model with this utility specification.

Setting $\gamma = 1.5$, compute and plot an estimate of the optimal policy.

Solution

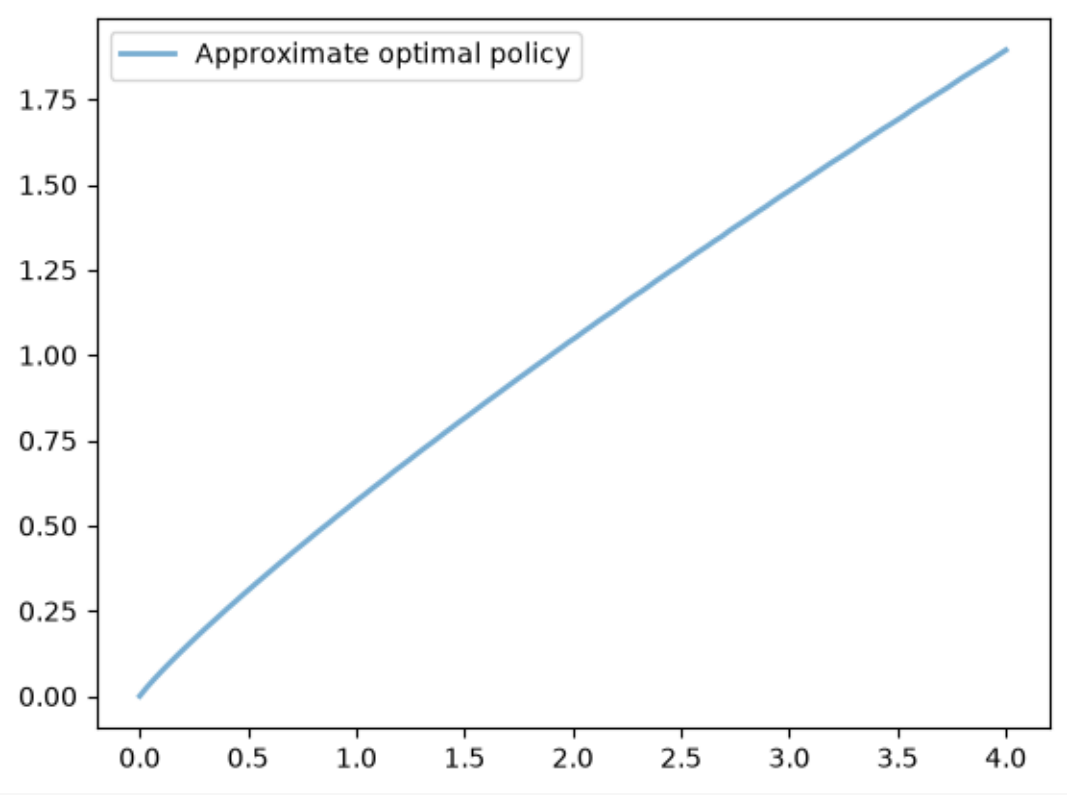
Here we set up the model.

```
γ = 1.5    # Preference parameter

def u_crra(c):
    return (c**(1 - γ) - 1) / (1 - γ)

model = create_model(u=u_crra, f=fcd)
```

Now let's run it, with a timer.



```
%%time
v_greedy, v_solution = solve_model(model)
```

```
Error at iteration 25 is 0.5516510200263269.
Error at iteration 50 is 0.19881274768354373.
Error at iteration 75 is 0.07165146153470658.
Error at iteration 100 is 0.025822951495229063.
Error at iteration 125 is 0.009306506938493442.
Error at iteration 150 is 0.003354034546092066.
Error at iteration 175 is 0.001208783038691763.
Error at iteration 200 is 0.0004356414385711105.
Error at iteration 225 is 0.00015700374421356855.

Converged in 237 iterations.
CPU times: user 27.5 s, sys: 1.99 ms, total: 27.5 s
Wall time: 27.5 s
```

Let's plot the policy function just to see what it looks like:

```
fig, ax = plt.subplots()
ax.plot(x_grid, v_greedy, lw=2,
        alpha=0.6, label='Approximate optimal policy')
ax.legend()
plt.show()
```

OPTIMAL SAVINGS IV: TIME ITERATION

Contents

- *Optimal Savings IV: Time Iteration*
  - *Overview*
  - *The Euler Equation*
  - *Implementation*
  - *Exercises*

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

70.1 Overview

In this lecture, we introduce the core idea of **time iteration**: iterating on a guess of the optimal policy using the Euler equation.

This approach differs from the value function iteration we used in *Optimal Savings III: Stochastic Returns*, where we iterated on the value function itself.

Time iteration exploits the structure of the Euler equation to find the optimal policy directly, rather than computing the value function as an intermediate step.

The key advantage is computational efficiency: by working directly with the policy function, we can often solve problems faster than with value function iteration.

However, time iteration is not the most efficient Euler equation-based method available.

In *Optimal Savings V: The Endogenous Grid Method*, we'll introduce the **endogenous grid method** (EGM), which provides an even more efficient way to solve the problem.

For now, our goal is to understand the basic mechanics of time iteration and how it leverages the Euler equation.

Let's start with some imports:

```
import matplotlib.pyplot as plt
import numpy as np
```

(continues on next page)

(continued from previous page)

```
from scipy.optimize import brentq
from typing import NamedTuple, Callable
```

70.2 The Euler Equation

Our first step is to derive the Euler equation, which is a generalization of the Euler equation we obtained in *Optimal Savings I: Cake Eating*.

We take the model set out in *Optimal Savings III: Stochastic Returns* and add the following assumptions:

1. u and f are continuously differentiable and strictly concave
2. $f(0) = 0$
3. $\lim_{c \to 0} u'(c) = \infty$ and $\lim_{c \to \infty} u'(c) = 0$
4. $\lim_{k \to 0} f'(k) = \infty$ and $\lim_{k \to \infty} f'(k) = 0$

The last two conditions are usually called **Inada conditions**.

Recall the Bellman equation

$$v(x) = \max_{0 \leq c \leq x} \left\{ u(c) + \beta \int v(f(x-c)z)\phi(dz) \right\} \quad \text{for all} \quad x \in \mathbb{R}_+ \tag{70.1}$$

Let v^* be the value function and let σ^* be the optimal consumption policy.

We know that σ^* is a v^*-greedy policy.

The conditions above imply that

- σ^* is the unique optimal policy for the optimal savings problem
- the optimal policy is continuous, strictly increasing and also **interior**, in the sense that $0 < \sigma^*(x) < x$ for all strictly positive x, and
- the value function is strictly concave and continuously differentiable, with

$$(v^*)'(x) = u'(\sigma^*(x)) := (u' \circ \sigma^*)(x) \tag{70.2}$$

The last result is called the **envelope condition** due to its relationship with the envelope theorem.

To see why (70.2) holds, write the Bellman equation in the equivalent form

$$v^*(x) = \max_{0 \leq k \leq x} \left\{ u(x-k) + \beta \int v^*(f(k)z)\phi(dz) \right\},$$

Differentiating with respect to x, and then evaluating at the optimum yields (70.2).

(Section 12.1 of EDTC contains full proofs of these results, and closely related discussions can be found in many other texts.)

Differentiability of the value function and interiority of the optimal policy imply that optimal consumption satisfies the first-order condition associated with (70.1), which is

$$u'(\sigma^*(x)) = \beta \int (v^*)'(f(x - \sigma^*(x))z) f'(x - \sigma^*(x)) z \phi(dz) \tag{70.3}$$

Combining (70.2) and the first-order condition (70.3) gives the **Euler equation**

$$(u' \circ \sigma^*)(x) = \beta \int (u' \circ \sigma^*)(f(x - \sigma^*(x))z) f'(x - \sigma^*(x)) z \phi(dz) \tag{70.4}$$

We can think of the Euler equation as a functional equation

$$(u' \circ \sigma)(x) = \beta \int (u' \circ \sigma)(f(x - \sigma(x))z) f'(x - \sigma(x)) z \phi(dz) \tag{70.5}$$

over interior consumption policies σ, one solution of which is the optimal policy σ^*.

Our aim is to solve the functional equation (70.5) and hence obtain σ^*.

70.2.1 The Coleman-Reffett Operator

Recall the Bellman operator

$$Tv(x) := \max_{0 \leq c \leq x} \left\{ u(c) + \beta \int v(f(x - c)z) \phi(dz) \right\} \tag{70.6}$$

Just as we introduced the Bellman operator to solve the Bellman equation, we will now introduce an operator over policies to help us solve the Euler equation.

This operator K will act on the set of all $\sigma \in \Sigma$ that are continuous, strictly increasing and interior.

Henceforth we denote this set of policies by $\mathcal{P}$

1. The operator K takes as its argument a $\sigma \in \mathcal{P}$ and
2. returns a new function $K\sigma$, where $K\sigma(x)$ is the $c \in (0, x)$ that solves

$$u'(c) = \beta \int (u' \circ \sigma)(f(x - c)z) f'(x - c) z \phi(dz) \tag{70.7}$$

We call this operator the **Coleman-Reffett operator** to acknowledge the work of [Coleman, 1990] and [Reffett, 1996].

In essence, $K\sigma$ is the consumption policy that the Euler equation tells you to choose today when your future consumption policy is σ.

The important thing to note about K is that, by construction, its fixed points coincide with solutions to the functional equation (70.5).

In particular, the optimal policy σ^* is a fixed point.

Indeed, for fixed x, the value $K\sigma^*(x)$ is the c that solves

$$u'(c) = \beta \int (u' \circ \sigma^*)(f(x - c)z) f'(x - c) z \phi(dz)$$

In view of the Euler equation, this is exactly $\sigma^*(x)$.

70.2.2 Is the Coleman-Reffett Operator Well Defined?

In particular, is there always a unique $c \in (0, x)$ that solves (70.7)?

The answer is yes, under our assumptions.

For any $\sigma \in \mathcal{P}$, the right side of (70.7)

- is continuous and strictly increasing in c on $(0, x)$
- diverges to $+\infty$ as $c \uparrow x$

The left side of (70.7)

- is continuous and strictly decreasing in c on $(0, x)$

- diverges to $+\infty$ as $c \downarrow 0$

Sketching these curves and using the information above will convince you that they cross exactly once as c ranges over $(0, x)$.

With a bit more analysis, one can show in addition that $K\sigma \in \mathcal{P}$ whenever $\sigma \in \mathcal{P}$.

70.2.3 Comparison with VFI (Theory)

It is possible to prove that there is a tight relationship between iterates of K and iterates of the Bellman operator.

Mathematically, T and K are **topologically conjugate** under a translation that involves differentiation in one direction and integration in the other.

This conjugacy implies that if iterates of one operator converge then so do iterates of the other, and vice versa.

Moreover, there is a sense in which they converge *at the same rate*, at least in theory.

However, it turns out that the operator K is more stable *numerically* and hence more efficient in the applications we consider.

This is because

- K exploits additional structure because it uses first-order conditions, and
- policies near the optimal policy have less curvature and hence are easier to approximate than value functions near the optimal value function.

Examples are given below.

70.3 Implementation

Let's turn to implementation.

Note

In this lecture we mainly focus on the algorithm, favoring clarity over efficiency in the code.

In later lectures we will optimize both the algorithm and the code.

As in *Optimal Savings III: Stochastic Returns*, we assume that

- $u(c) = \ln c$
- $f(x - c) = (x - c)^\alpha$
- ϕ is the distribution of $\xi := \exp(\mu + \nu\zeta)$ when ζ is standard normal

This allows us to compare our results to the analytical solutions we obtained in that lecture:

```
def v_star(x, α, β, μ):
    """
    True value function
    """
    c1 = np.log(1 - α * β) / (1 - β)
    c2 = (μ + α * np.log(α * β)) / (1 - α)
    c3 = 1 / (1 - β)
    c4 = 1 / (1 - α * β)
```

(continues on next page)

(continued from previous page)

```
    return c1 + c2 * (c3 - c4) + c4 * np.log(x)

def σ_star(x, α, β):
    """
    True optimal policy
    """
    return (1 - α * β) * x
```

As discussed above, our plan is to solve the model using time iteration, which means iterating with the operator K.

For this we need access to the functions u' and f, f'.

We use the same `Model` structure from *Optimal Savings III: Stochastic Returns*.

```
class Model(NamedTuple):
    u: Callable        # utility function
    f: Callable        # production function
    β: float           # discount factor
    μ: float           # shock location parameter
    ν: float           # shock scale parameter
    grid: np.ndarray   # state grid
    shocks: np.ndarray # shock draws
    α: float = 0.4     # production function parameter
    u_prime: Callable = None        # derivative of utility
    f_prime: Callable = None        # derivative of production

def create_model(
        u: Callable,
        f: Callable,
        β: float = 0.96,
        μ: float = 0.0,
        ν: float = 0.1,
        grid_max: float = 4.0,
        grid_size: int = 120,
        shock_size: int = 250,
        seed: int = 1234,
        α: float = 0.4,
        u_prime: Callable = None,
        f_prime: Callable = None
    ) -> Model:
    """
    Creates an instance of the optimal savings model.
    """
    # Set up grid
    grid = np.linspace(1e-4, grid_max, grid_size)

    # Store shocks (with a seed, so results are reproducible)
    rng = np.random.default_rng(seed)
    shocks = np.exp(μ + ν * rng.standard_normal(shock_size))

    return Model(u, f, β, μ, ν, grid, shocks, α, u_prime, f_prime)
```

Now we implement a method called `euler_diff`, which returns

$$u'(c) - \beta \int (u' \circ \sigma)(f(x-c)z) f'(x-c) z \phi(dz) \tag{70.8}$$

```
def euler_diff(c: float, σ: np.ndarray, x: float, model: Model) -> float:
    """
    Set up a function such that the root with respect to c,
    given x and σ, is equal to Kσ(x).

    """

    # Unpack
    u, f, β, μ, ν, grid, shocks, α, u_prime, f_prime = model

    # Turn σ into a function via interpolation
    σ_func = lambda x: np.interp(x, grid, σ)

    # Now set up the function we need to find the root of.
    vals = u_prime(σ_func(f(x - c, α) * shocks)) * f_prime(x - c, α) * shocks
    return u_prime(c) - β * np.mean(vals)
```

The function `euler_diff` evaluates integrals by Monte Carlo and approximates functions using linear interpolation.

We will use a root-finding algorithm to solve (70.8) for c given state x and σ, the current guess of the policy.

Here's the operator K, that implements the root-finding step.

```
def K(σ: np.ndarray, model: Model) -> np.ndarray:
    """
    The Coleman-Reffett operator

    """

    # Unpack
    u, f, β, μ, ν, grid, shocks, α, u_prime, f_prime = model

    σ_new = np.empty_like(σ)
    for i, x in enumerate(grid):
        # Solve for optimal c at x
        c_star = brentq(euler_diff, 1e-10, x-1e-10, args=(σ, x, model))
        σ_new[i] = c_star

    return σ_new
```

70.3.1 Testing

Let's generate an instance and plot some iterates of K, starting from $\sigma(x) = x$.

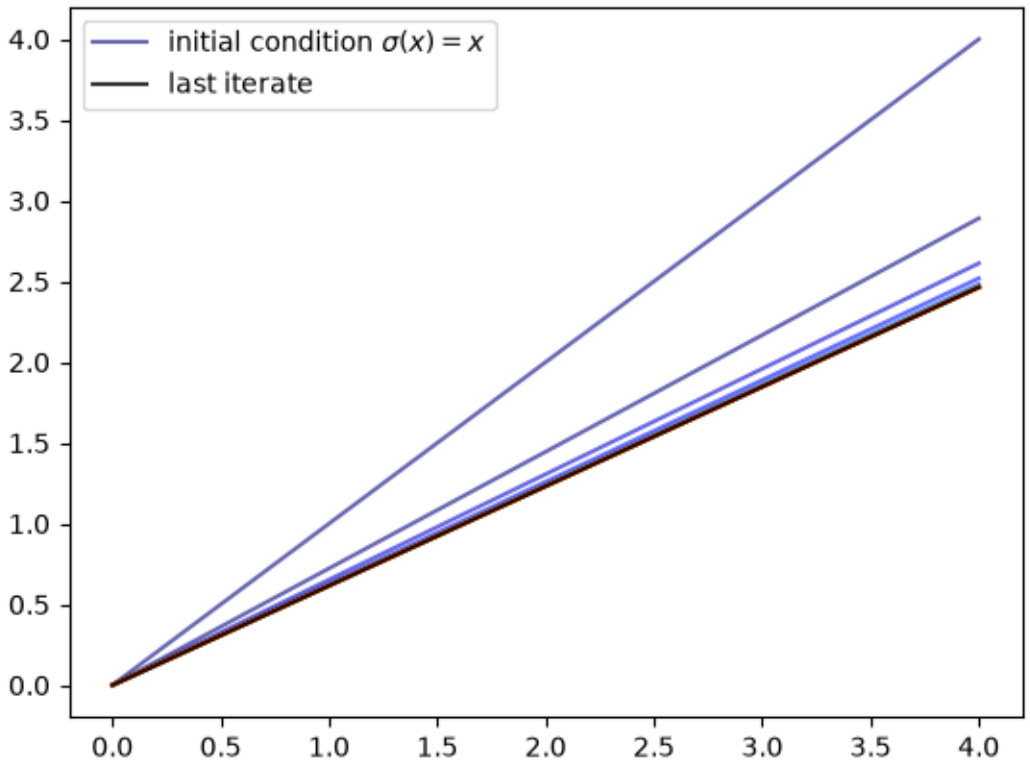
```
# Define utility and production functions with derivatives
α = 0.4
u = lambda c: np.log(c)
u_prime = lambda c: 1 / c
f = lambda k, α: k**α
f_prime = lambda k, α: α * k**(α - 1)

model = create_model(u=u, f=f, α=α, u_prime=u_prime, f_prime=f_prime)
grid = model.grid

n = 15
σ = grid.copy()  # Set initial condition
```

(continues on next page)

(continued from previous page)



```
fig, ax = plt.subplots()
lb = r'initial condition $\sigma(x) = x$'
ax.plot(grid, σ, color=plt.cm.jet(0), alpha=0.6, label=lb)

for i in range(n):
    σ = K(σ, model)
    ax.plot(grid, σ, color=plt.cm.jet(i / n), alpha=0.6)

# Update one more time and plot the last iterate in black
σ = K(σ, model)
ax.plot(grid, σ, color='k', alpha=0.8, label='last iterate')

ax.legend()

plt.show()
```

We see that the iteration process converges quickly to a limit that resembles the solution we obtained in *Optimal Savings III: Stochastic Returns*.

Here is a function called `solve_model_time_iter` that takes an instance of `Model` and returns an approximation to the optimal policy, using time iteration.

```
def solve_model_time_iter(
        model: Model,
        σ_init: np.ndarray,
        tol: float = 1e-5,
        max_iter: int = 1000,
        verbose: bool = True
```

(continues on next page)

(continued from previous page)

```
    ) -> np.ndarray:
    """
    Solve the model using time iteration.

    """
    σ = σ_init
    error = tol + 1
    i = 0

    while error > tol and i < max_iter:
        σ_new = K(σ, model)
        error = np.max(np.abs(σ_new - σ))
        σ = σ_new
        i += 1
        if verbose:
            print(f"Iteration {i}, error = {error}")

    if i == max_iter:
        print("Warning: maximum iterations reached")

    return σ
```

Let's call it:

```
# Unpack
grid = model.grid

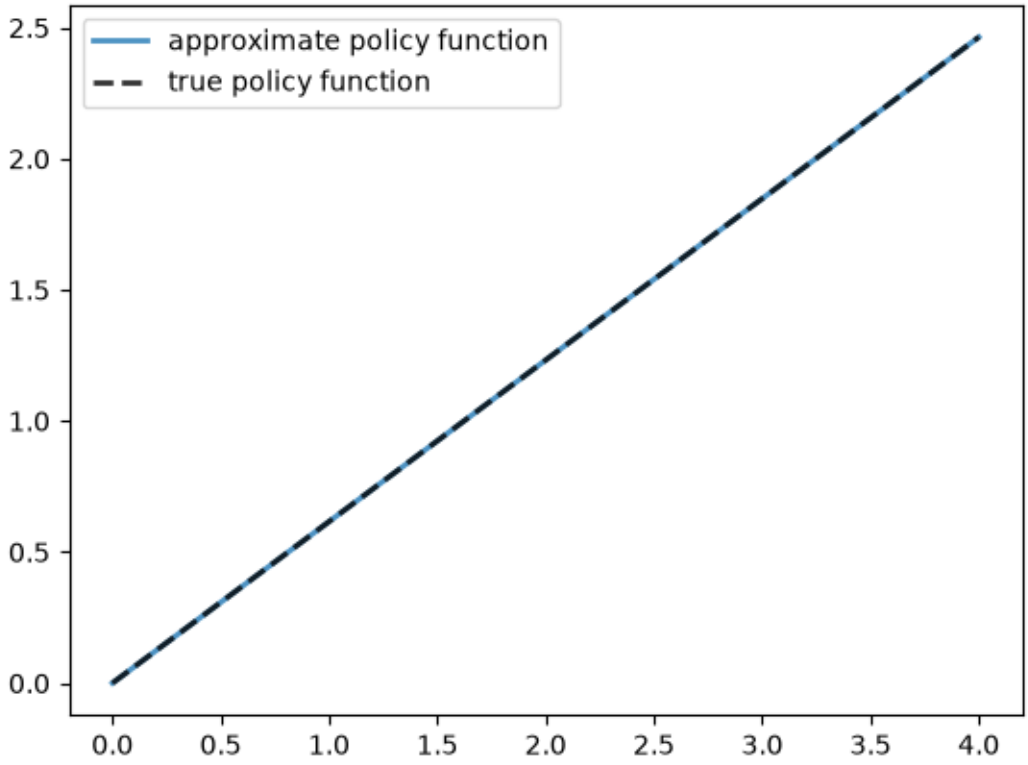
σ_init = np.copy(grid)
σ = solve_model_time_iter(model, σ_init)
```

```
Iteration 1, error = 1.1098265895953756
Iteration 2, error = 0.2782798920795728
Iteration 3, error = 0.09312729948558696
Iteration 4, error = 0.034020038271348696
Iteration 5, error = 0.012820752818721193
Iteration 6, error = 0.00488808156053766
Iteration 7, error = 0.0018718902256100733
Iteration 8, error = 0.0007180512309559184
Iteration 9, error = 0.0002756205293255043
Iteration 10, error = 0.0001058219018155171
Iteration 11, error = 4.063319516767194e-05
Iteration 12, error = 1.560279084245053e-05
Iteration 13, error = 5.991419175899182e-06
```

Here is a plot of the resulting policy, compared with the true policy:

```
# Unpack
grid, α, β = model.grid, model.α, model.β

fig, ax = plt.subplots()



ax.plot(grid, σ, lw=2,
        alpha=0.8, label='approximate policy function')

ax.plot(grid, σ_star(grid, α, β), 'k--',
        lw=2, alpha=0.8, label='true policy function')
```

(continues on next page)

(continued from previous page)

```
ax.legend()
plt.show()
```

Again, the fit is excellent.

The maximal absolute deviation between the two policies is

```
# Unpack
grid, α, β = model.grid, model.α, model.β

np.max(np.abs(σ - σ_star(grid, α, β)))
```

```
np.float64(3.7348959640581825e-06)
```

Time iteration runs faster than value function iteration, as discussed in *Optimal Savings III: Stochastic Returns*.

This is because time iteration exploits differentiability and the first-order conditions, while value function iteration does not use this available structure.

At the same time, there is a variation of time iteration that runs even faster.

This is the endogenous grid method, which we will introduce in *Optimal Savings V: The Endogenous Grid Method*.

70.4 Exercises

Exercise 70.4.1

Solve the optimal savings problem with CRRA utility

$$u(c) = \frac{c^{1-\gamma}}{1-\gamma}$$

Set `γ = 1.5`.

Compute and plot the optimal policy.

Solution

We define the CRRA utility function and its derivative.

```
γ = 1.5

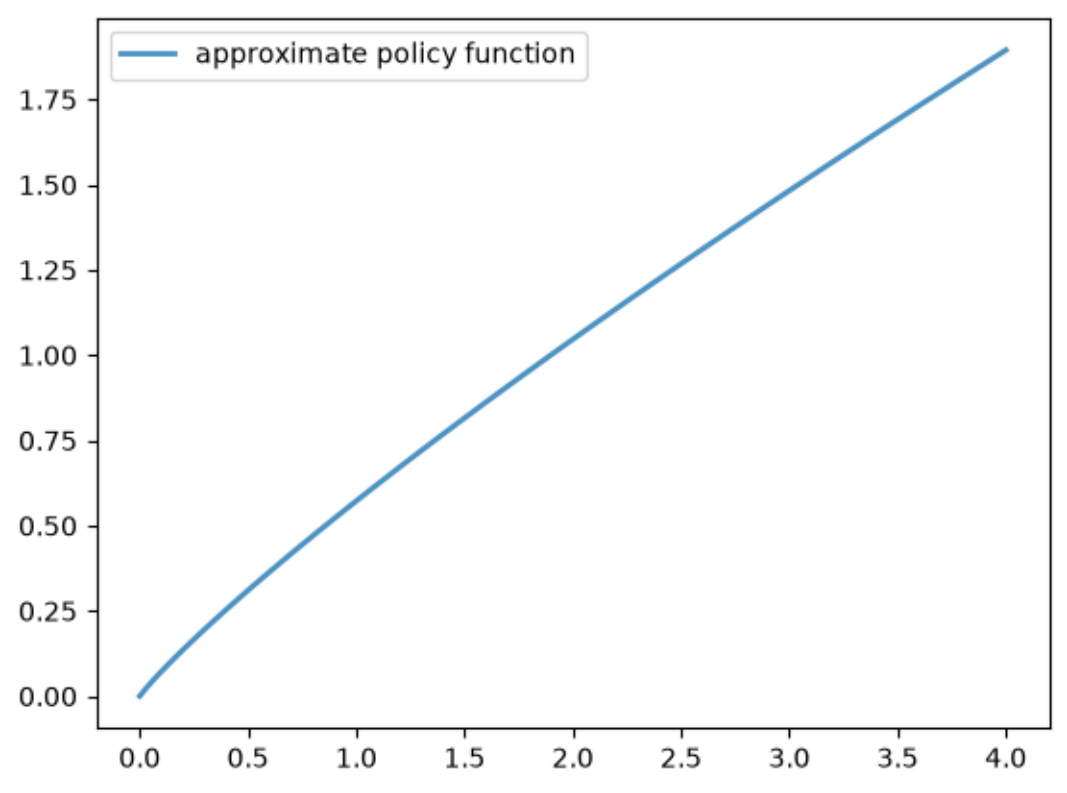
def u_crra(c):
    return c**(1 - γ) / (1 - γ)

def u_prime_crra(c):
    return c**(-γ)

# Use the same production function as before
model_crra = create_model(u=u_crra, f=f, α=α,
                          u_prime=u_prime_crra, f_prime=f_prime)
```

Now we solve and plot the policy:

```
%%time
# Unpack
grid = model_crra.grid



σ_init = np.copy(grid)
σ = solve_model_time_iter(model_crra, σ_init)

fig, ax = plt.subplots()

ax.plot(grid, σ, lw=2,
        alpha=0.8, label='approximate policy function')

ax.legend()
plt.show()
```

```
Iteration 1, error = 1.449604914521836
Iteration 2, error = 0.3966806986253908
Iteration 3, error = 0.14842065541477645
Iteration 4, error = 0.06191571110718308
Iteration 5, error = 0.027010882945130543
Iteration 6, error = 0.012016369353877288

OPTIMAL SAVINGS V: THE ENDOGENOUS GRID METHOD

Contents

- *Optimal Savings V: The Endogenous Grid Method*
  - *Overview*
  - *Key Idea*
  - *Implementation*

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

71.1 Overview

Previously, we solved the optimal savings problem using

1. *value function iteration*
2. *Euler equation based time iteration*

We found time iteration to be significantly more accurate and efficient.

In this lecture, we'll look at a clever twist on time iteration called the **endogenous grid method** (EGM).

EGM is a numerical method for implementing policy iteration invented by Chris Carroll.

The original reference is [Carroll, 2006].

For now we will focus on a clean and simple implementation of EGM that stays close to the underlying mathematics.

Then, in *Optimal Savings VI: EGM with JAX*, we will construct a fully vectorized and parallelized version of EGM based on JAX.

Let's start with some standard imports:

```
import matplotlib.pyplot as plt
import numpy as np
import quantecon as qe
```

71.2 Key Idea

First we remind ourselves of the theory and then we turn to numerical methods.

71.2.1 Theory

We work with the model set out in *Optimal Savings IV: Time Iteration*, following the same terminology and notation.

As we saw, the Coleman-Reffett operator is a nonlinear operator K engineered so that the optimal policy σ^* is a fixed point of K.

It takes as its argument a continuous strictly increasing consumption policy $\sigma \in \Sigma$.

It returns a new function $K\sigma$, where $(K\sigma)(x)$ is the $c \in (0, \infty)$ that solves

$$u'(c) = \beta \int (u' \circ \sigma)(f(x-c)z) f'(x-c) z \phi(dz) \tag{71.1}$$

71.2.2 Exogenous Grid

As discussed in *Optimal Savings IV: Time Iteration*, to implement the method on a computer, we represent a policy function by a set of values on a finite grid.

The function itself is reconstructed from this representation when necessary, using interpolation or some other method.

Our previous strategy in *Optimal Savings IV: Time Iteration* for obtaining a finite representation of an updated consumption policy was to

- fix a grid of income points $\{x_i\}$
- calculate the consumption value c_i corresponding to each x_i using (71.1) and a root-finding routine

Each c_i is then interpreted as the value of the function $K\sigma$ at x_i.

Thus, with the pairs $\{(x_i, c_i)\}$ in hand, we can reconstruct $K\sigma$ via approximation.

Iteration then continues…

71.2.3 Endogenous Grid

The method discussed above requires a root-finding routine to find the c_i corresponding to a given income value x_i.

Root-finding is costly because it typically involves a significant number of function evaluations.

As pointed out by Carroll [Carroll, 2006], we can avoid this step if x_i is chosen endogenously.

The only assumption required is that u' is invertible on $(0, \infty)$.

Let $(u')^{-1}$ be the inverse function of u'.

The idea is this:

- First, we fix an *exogenous* grid $\{s_i\}$ for savings ($s = x - c$).
- Then we obtain c_i via

$$c_i = (u')^{-1} \left\{ \beta \int (u' \circ \sigma)(f(s_i)z) \, f'(s_i) \, z \, \phi(dz) \right\} \tag{71.2}$$

- Finally, for each c_i we set $x_i = c_i + s_i$.

Importantly, each (x_i, c_i) pair constructed in this manner satisfies (71.1).

With the points $\{x_i, c_i\}$ in hand, we can reconstruct $K\sigma$ via approximation as before.

The name EGM comes from the fact that the grid $\{x_i\}$ is determined **endogenously**.

71.3 Implementation

As in *Optimal Savings IV: Time Iteration*, we will start with a simple setting where

- $u(c) = \ln c$,
- the function f has a Cobb-Douglas specification, and
- the shocks are lognormal.

This will allow us to make comparisons with the analytical solutions.

```
def v_star(x, α, β, μ):
    """
    True value function
    """
    c1 = np.log(1 - α * β) / (1 - β)
    c2 = (μ + α * np.log(α * β)) / (1 - α)
    c3 = 1 / (1 - β)
    c4 = 1 / (1 - α * β)
    return c1 + c2 * (c3 - c4) + c4 * np.log(x)

def σ_star(x, α, β):
    """
    True optimal policy
    """
    return (1 - α * β) * x
```

We reuse the `Model` structure from *Optimal Savings IV: Time Iteration*.

```
from typing import NamedTuple, Callable

class Model(NamedTuple):
    u: Callable           # utility function
    f: Callable           # production function
    β: float              # discount factor
    μ: float              # shock location parameter
    ν: float              # shock scale parameter
    s_grid: np.ndarray    # exogenous savings grid
    shocks: np.ndarray    # shock draws
    α: float              # production function parameter
    u_prime: Callable     # derivative of utility
    f_prime: Callable     # derivative of production
    u_prime_inv: Callable # inverse of u_prime

def create_model(
        u: Callable,
        f: Callable,
        β: float = 0.96,
        μ: float = 0.0,
        ν: float = 0.1,
```

(continues on next page)

(continued from previous page)

```
        grid_max: float = 4.0,
        grid_size: int = 120,
        shock_size: int = 250,
        seed: int = 1234,
        α: float = 0.4,
        u_prime: Callable = None,
        f_prime: Callable = None,
        u_prime_inv: Callable = None
    ) -> Model:
    """
    Creates an instance of the optimal savings model.
    """
    # Set up exogenous savings grid
    s_grid = np.linspace(1e-4, grid_max, grid_size)

    # Store shocks (with a seed, so results are reproducible)
    rng = np.random.default_rng(seed)
    shocks = np.exp(μ + ν * rng.standard_normal(shock_size))

    return Model(
        u, f, β, μ, ν, s_grid, shocks, α, u_prime, f_prime, u_prime_inv
    )
```

71.3.1 The Operator

Here's an implementation of K using EGM as described above.

```
def K(
        c_in: np.ndarray,    # Consumption values on the endogenous grid
        x_in: np.ndarray,    # Current endogenous grid
        model: Model         # Model specification
    ):
    """
    An implementation of the Coleman-Reffett operator using EGM.

    """

    # Simplify names
    u, f, β, μ, ν, s_grid, shocks, α, u_prime, f_prime, u_prime_inv = model

    # Linear interpolation of policy on the endogenous grid
    σ = lambda x: np.interp(x, x_in, c_in)

    # Allocate memory for new consumption array
    c_out = np.empty_like(s_grid)

    for i, s in enumerate(s_grid):
        # Approximate marginal utility ∫ u'(σ(f(s, α)z)) f'(s, α) z ϕ(z)dz
        vals = u_prime(σ(f(s, α) * shocks)) * f_prime(s, α) * shocks
        mu = np.mean(vals)
        # Compute consumption
        c_out[i] = u_prime_inv(β * mu)

    # Determine corresponding endogenous grid
    x_out = s_grid + c_out        # x_i = s_i + c_i
```

(continues on next page)

(continued from previous page)

```
    return c_out, x_out
```

Note the lack of any root-finding algorithm.

Note

The routine is still not particularly fast because we are using pure Python loops.

But in the next lecture (*Optimal Savings VI: EGM with JAX*) we will use a fully vectorized and efficient solution.

71.3.2 Testing

First we create an instance.

```
# Define utility and production functions with derivatives
u = lambda c: np.log(c)
u_prime = lambda c: 1 / c
u_prime_inv = lambda x: 1 / x
f = lambda k, α: k**α
f_prime = lambda k, α: α * k**(α - 1)

model = create_model(u=u, f=f, u_prime=u_prime,
                     f_prime=f_prime, u_prime_inv=u_prime_inv)
s_grid = model.s_grid
```

Here's our solver routine:

```
def solve_model_time_iter(
        model: Model,              # Model details
        c_init: np.ndarray,        # initial guess of consumption on EG
        x_init: np.ndarray,        # initial guess of endogenous grid
        tol: float = 1e-5,         # Error tolerance
        max_iter: int = 1000,      # Max number of iterations of K
        verbose: bool = True       # If true print output
    ):
    """
    Solve the model using time iteration with EGM.
    """
    c, x = c_init, x_init
    error = tol + 1
    i = 0

    while error > tol and i < max_iter:
        c_new, x_new = K(c, x, model)
        error = np.max(np.abs(c_new - c))
        c, x = c_new, x_new
        i += 1
        if verbose:
            print(f"Iteration {i}, error = {error}")

    if i == max_iter:
        print("Warning: maximum iterations reached")
```

(continues on next page)

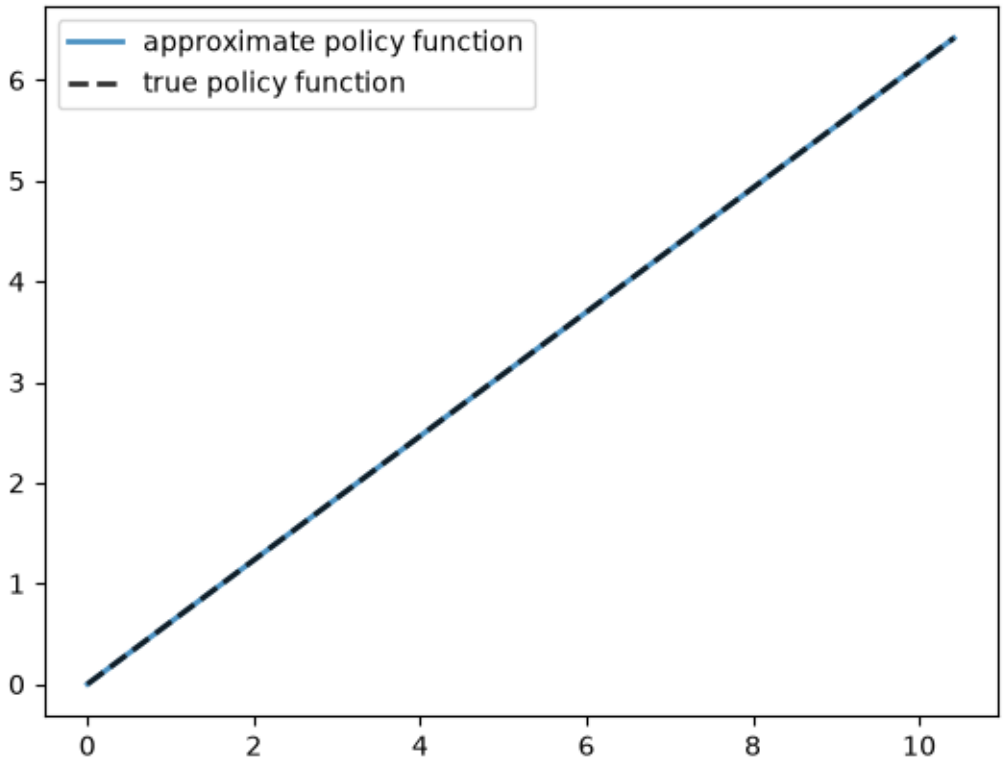
(continued from previous page)

```
    return c, x
```

Let's call it:

```
c_init = np.copy(s_grid)
x_init = s_grid + c_init
c, x = solve_model_time_iter(model, c_init, x_init)
```

```
Iteration 1, error = 1.208333333333333
Iteration 2, error = 0.6834464555052788
Iteration 3, error = 0.3126351338414741
Iteration 4, error = 0.12905177785629984
Iteration 5, error = 0.05099394329538409
Iteration 6, error = 0.01980055511172729
Iteration 7, error = 0.007636088144566955
Iteration 8, error = 0.002937098891578671
Iteration 9, error = 0.0011285611196765188
Iteration 10, error = 0.00043347299641638415
Iteration 11, error = 0.00016646919532892213
Iteration 12, error = 6.392646635156041e-05
Iteration 13, error = 2.454810155327891e-05
Iteration 14, error = 9.426520909627811e-06
```



Here is a plot of the resulting policy, compared with the true policy:

```
fig, ax = plt.subplots()

ax.plot(x, c, lw=2,
        alpha=0.8, label='approximate policy function')

ax.plot(x, σ_star(x, model.α, model.β), 'k--',
        lw=2, alpha=0.8, label='true policy function')

ax.legend()
plt.show()
```

The maximal absolute deviation between the two policies is

```
np.max(np.abs(c - σ_star(x, model.α, model.β)))
```

```
np.float64(2.2564941266622895e-06)
```

Here's the execution time:

```
with qe.Timer():
    c, x = solve_model_time_iter(model, c_init, x_init, verbose=False)
```

```
0.0328 seconds elapsed
```

EGM is faster than time iteration because it avoids numerical root-finding.

Instead, we invert the marginal utility function directly, which is much more efficient.

In *Optimal Savings VI: EGM with JAX*, we will use a fully vectorized and efficient version of EGM that is also parallelized using JAX.

This provides an extremely fast way to solve the optimal consumption problem we have been studying for the last few lectures.

OPTIMAL SAVINGS VI: EGM WITH JAX

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

Contents

- *Optimal Savings VI: EGM with JAX*
  - *Overview*
  - *Implementation*
  - *Exercises*

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon jax
```

72.1 Overview

In this lecture, we'll implement the endogenous grid method (EGM) using JAX.

This lecture builds on *Optimal Savings V: The Endogenous Grid Method*, which introduced EGM using NumPy.

By converting to JAX, we can leverage fast linear algebra, hardware accelerators, and JIT compilation for improved performance.

We'll also use JAX's `vmap` function to fully vectorize the Coleman-Reffett operator.

Let's start with some standard imports:

```
import matplotlib.pyplot as plt
import jax
import jax.numpy as jnp
import quantecon as qe
from typing import NamedTuple
```

72.2 Implementation

For details on the savings problem and the endogenous grid method (EGM), please see *Optimal Savings V: The Endogenous Grid Method*.

Here we focus on the JAX implementation of EGM.

We use the same setting as in *Optimal Savings V: The Endogenous Grid Method*:

- $u(c) = \ln c$,
- production is Cobb-Douglas, and
- the shocks are lognormal.

Here are the analytical solutions for comparison.

```
def v_star(x, α, β, μ):
    """
    True value function
    """
    c1 = jnp.log(1 - α * β) / (1 - β)
    c2 = (μ + α * jnp.log(α * β)) / (1 - α)
    c3 = 1 / (1 - β)
    c4 = 1 / (1 - α * β)
    return c1 + c2 * (c3 - c4) + c4 * jnp.log(x)

def σ_star(x, α, β):
    """
    True optimal policy
    """
    return (1 - α * β) * x
```

The `Model` class stores only the data (grids, shocks, and parameters).

Utility and production functions will be defined globally to work with JAX's JIT compiler.

```
class Model(NamedTuple):
    β: float              # discount factor
    μ: float              # shock location parameter
    s: float              # shock scale parameter
    s_grid: jnp.ndarray   # exogenous savings grid
    shocks: jnp.ndarray   # shock draws
    α: float              # production function parameter

def create_model(
        β: float = 0.96,
        μ: float = 0.0,
        s: float = 0.1,
        grid_max: float = 4.0,
```

(continues on next page)

(continued from previous page)

```
        grid_size: int = 120,
        shock_size: int = 250,
        seed: int = 1234,
        α: float = 0.4
    ) -> Model:
    """
    Creates an instance of the optimal savings model.
    """
    # Set up exogenous savings grid
    s_grid = jnp.linspace(1e-4, grid_max, grid_size)

    # Store shocks (with a seed, so results are reproducible)
    key = jax.random.key(seed)
    shocks = jnp.exp(μ + s * jax.random.normal(key, shape=(shock_size,)))

    return Model(β, μ, s, s_grid, shocks, α)
```

We define utility and production functions globally.

```
# Define utility and production functions with derivatives
u = lambda c: jnp.log(c)
u_prime = lambda c: 1 / c
u_prime_inv = lambda x: 1 / x
f = lambda k, α: k**α
f_prime = lambda k, α: α * k**(α - 1)
```

Here's the Coleman-Reffett operator using EGM.

The key JAX feature here is `vmap`, which vectorizes the computation over the grid points.

```
def K(
        c_in: jnp.ndarray,  # Consumption values on the endogenous grid
        x_in: jnp.ndarray,  # Current endogenous grid
        model: Model        # Model specification
    ):
    """
    The Coleman-Reffett operator using EGM

    """
    β, μ, s, s_grid, shocks, α = model
    σ = lambda x_val: jnp.interp(x_val, x_in, c_in)

    # Define function to compute consumption at a single grid point
    def compute_c(s):
        # Approximate marginal utility ∫ u'(σ(f(s, α)z)) f'(s, α) z ϕ(z)dz
        vals = u_prime(σ(f(s, α) * shocks)) * f_prime(s, α) * shocks
        mu = jnp.mean(vals)
        # Calculate consumption
        return u_prime_inv(β * mu)

    # Vectorize and calculate on all exogenous grid points
    compute_c_vectorized = jax.vmap(compute_c)
    c_out = compute_c_vectorized(s_grid)

    # Determine corresponding endogenous grid
    x_out = s_grid + c_out  # x_i = s_i + c_i
```

(continues on next page)

(continued from previous page)

```
    return c_out, x_out
```

Now we create a model instance.

```
model = create_model()
s_grid = model.s_grid
```

The solver uses JAX's `jax.lax.while_loop` for the iteration and is JIT-compiled for speed.

```
@jax.jit
def solve_model_time_iter(
        model: Model,
        c_init: jnp.ndarray,
        x_init: jnp.ndarray,
        tol: float = 1e-5,
        max_iter: int = 1000
    ):
    """
    Solve the model using time iteration with EGM.
    """

    def condition(loop_state):
        i, c, x, error = loop_state
        return (error > tol) & (i < max_iter)

    def body(loop_state):
        i, c, x, error = loop_state
        c_new, x_new = K(c, x, model)
        error = jnp.max(jnp.abs(c_new - c))
        return i + 1, c_new, x_new, error

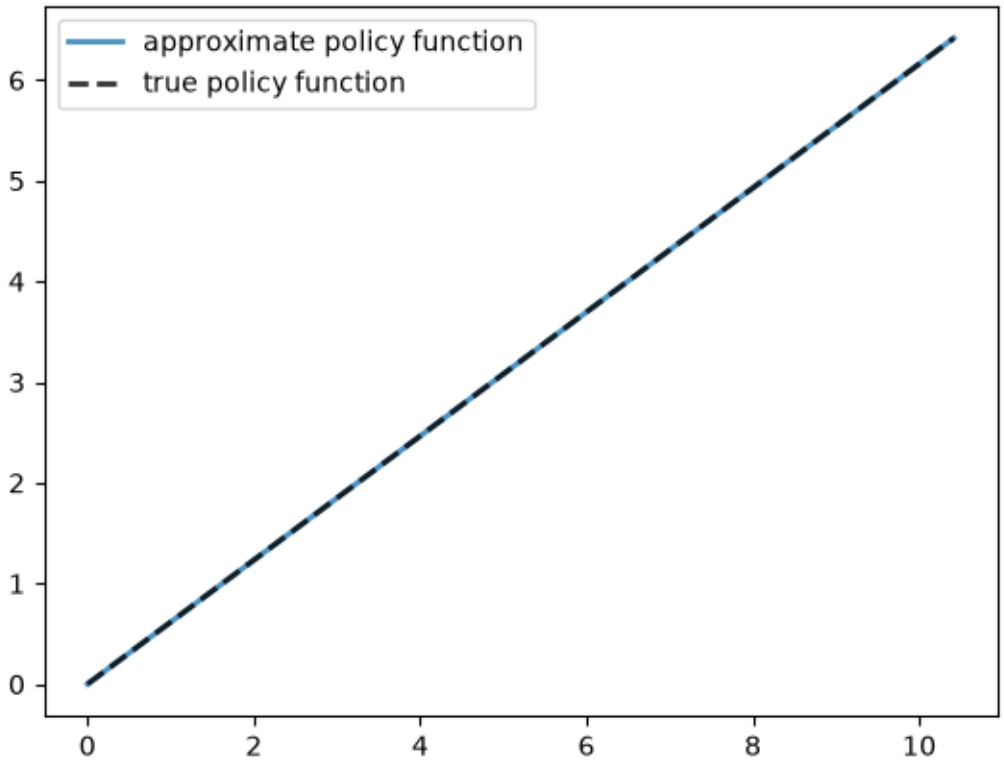
    # Initialize loop state
    initial_state = (0, c_init, x_init, tol + 1)

    # Run the loop
    i, c, x, error = jax.lax.while_loop(condition, body, initial_state)

    return c, x
```

We solve the model starting from an initial guess.

```
c_init = jnp.copy(s_grid)
x_init = s_grid + c_init
c, x = solve_model_time_iter(model, c_init, x_init)
```



Let's plot the resulting policy against the analytical solution.

```
fig, ax = plt.subplots()

ax.plot(x, c, lw=2,
        alpha=0.8, label='approximate policy function')

ax.plot(x, σ_star(x, model.α, model.β), 'k--',
        lw=2, alpha=0.8, label='true policy function')

ax.legend()
plt.show()
```

The fit is very good.

```
max_dev = jnp.max(jnp.abs(c - σ_star(x, model.α, model.β)))
print(f"Maximum absolute deviation: {max_dev:.7}")
```

```
Maximum absolute deviation: 2.861023e-06
```

The JAX implementation is very fast thanks to JIT compilation and vectorization.

```
with qe.Timer(precision=8):
    c, x = solve_model_time_iter(model, c_init, x_init)
    jax.block_until_ready(c)
```

```
0.00296974 seconds elapsed
```

This speed comes from:

- JIT compilation of the entire solver
- Vectorization via `vmap` in the Coleman-Reffett operator
- Use of `jax.lax.while_loop` instead of a Python loop
- Efficient JAX array operations throughout

72.3 Exercises

Exercise 72.3.1

Solve the optimal savings problem with CRRA utility

$$u(c) = \frac{c^{1-\gamma} - 1}{1-\gamma}$$

Compare the optimal policies for values of γ approaching 1 from above (e.g., 1.05, 1.1, 1.2).

Show that as $\gamma \to 1$, the optimal policy converges to the policy obtained with log utility ($\gamma = 1$).

Hint: Use values of γ close to 1 to ensure the endogenous grids have similar coverage and make visual comparison easier.

Solution

We need to create a version of the Coleman-Reffett operator and solver that work with CRRA utility.

The key is to parameterize the utility functions by γ.

```
def u_crra(c, γ):
    return (c**(1 - γ) - 1) / (1 - γ)

def u_prime_crra(c, γ):
    return c**(-γ)

def u_prime_inv_crra(x, γ):
    return x**(-1/γ)
```

Now we create a version of the Coleman-Reffett operator that takes γ as a parameter.

```
def K_crra(
        c_in: jnp.ndarray,  # Consumption values on the endogenous grid
        x_in: jnp.ndarray,  # Current endogenous grid
        model: Model,       # Model specification
        γ: float            # CRRA parameter
    ):
    """
    The Coleman-Reffett operator using EGM with CRRA utility
    """
    # Simplify names
    β, α = model.β, model.α
    s_grid, shocks = model.s_grid, model.shocks

    # Linear interpolation of policy using endogenous grid
    σ = lambda x_val: jnp.interp(x_val, x_in, c_in)

    # Define function to compute consumption at a single grid point
    def compute_c(s):
        vals = u_prime_crra(σ(f(s, α) * shocks), γ) * f_prime(s, α) * shocks
        return u_prime_inv_crra(β * jnp.mean(vals), γ)

    # Vectorize over grid using vmap
    compute_c_vectorized = jax.vmap(compute_c)
    c_out = compute_c_vectorized(s_grid)

    # Determine corresponding endogenous grid
    x_out = s_grid + c_out  # x_i = s_i + c_i

    return c_out, x_out
```

We also need a solver that uses this operator.

```
@jax.jit
def solve_model_crra(model: Model,
                     c_init: jnp.ndarray,
                     x_init: jnp.ndarray,
                     γ: float,
                     tol: float = 1e-5,
                     max_iter: int = 1000):
    """
    Solve the model using time iteration with EGM and CRRA utility.
    """

    def condition(loop_state):
        i, c, x, error = loop_state
        return (error > tol) & (i < max_iter)

    def body(loop_state):
        i, c, x, error = loop_state
        c_new, x_new = K_crra(c, x, model, γ)
        error = jnp.max(jnp.abs(c_new - c))
        return i + 1, c_new, x_new, error

    # Initialize loop state
    initial_state = (0, c_init, x_init, tol + 1)

    # Run the loop
    i, c, x, error = jax.lax.while_loop(condition, body, initial_state)

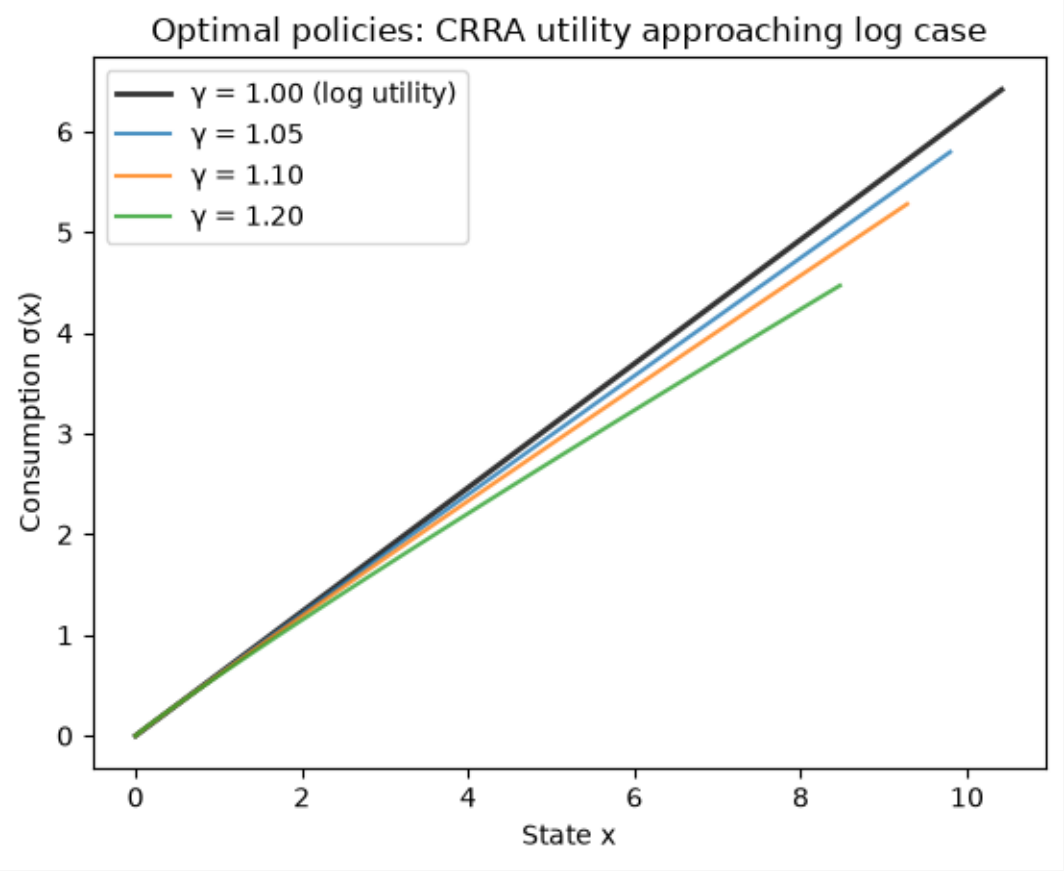
    return c, x
```

Now we solve for $\gamma = 1$ (log utility) and values approaching 1 from above.

```
γ_values = [1.0, 1.05, 1.1, 1.2]
policies = {}
endogenous_grids = {}

model_crra = create_model()

for γ in γ_values:
    c_init = jnp.copy(model_crra.s_grid)
    x_init = model_crra.s_grid + c_init
    c_gamma, x_gamma = solve_model_crra(model_crra, c_init, x_init, γ)
    jax.block_until_ready(c_gamma)
    policies[γ] = c_gamma
    endogenous_grids[γ] = x_gamma
    print(f"Solved for γ = {γ}")
```



```
Solved for γ = 1.0
Solved for γ = 1.05
Solved for γ = 1.1
Solved for γ = 1.2
```

Plot the policies on their endogenous grids.

```
fig, ax = plt.subplots()

for γ in γ_values:
    x = endogenous_grids[γ]
    if γ == 1.0:
        ax.plot(x, policies[γ], 'k-', linewidth=2,
                label=f'γ = {γ:.2f} (log utility)', alpha=0.8)
    else:
        ax.plot(x, policies[γ], label=f'γ = {γ:.2f}', alpha=0.8)

ax.set_xlabel('State x')
ax.set_ylabel('Consumption σ(x)')
ax.legend()
ax.set_title('Optimal policies: CRRA utility approaching log case')
plt.show()
```

Note that the plots for $\gamma > 1$ do not cover the entire x-axis range shown.

This is because the endogenous grid $x = s + \sigma(s)$ depends on the consumption policy, which varies with γ.

Let's check the maximum deviation between the log utility case ($\gamma = 1.0$) and values approaching from above.

```
for γ in [1.05, 1.1, 1.2]:
    max_diff = jnp.max(jnp.abs(policies[1.0] - policies[γ]))
    print(f"Max difference between γ=1.0 and γ={γ}: {max_diff:.6}")
```

```
Max difference between γ=1.0 and γ=1.05: 0.6192
Max difference between γ=1.0 and γ=1.1: 1.1362
Max difference between γ=1.0 and γ=1.2: 1.94592
```

As expected, the differences decrease as γ approaches 1 from above, confirming convergence.

Part X

Household Problems

CHAPTER

SEVENTYTHREE

THE INCOME FLUCTUATION PROBLEM I: DISCRETIZATION AND VFI

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

73.1 Overview

In this lecture, we study an optimal savings problem for an infinitely lived consumer—the "common ancestor" described in [Ljungqvist and Sargent, 2018], section 1.3.

This savings problem is often called an **income fluctuation problem** or a **household problem**.

It is an essential sub-problem for many representative macroeconomic models

- [Aiyagari, 1994]
- [Huggett, 1993]
- etc.

It is related to the decision problem in *Optimal Savings III: Stochastic Returns* but differs in significant ways.

For example,

1. The choice problem for the agent includes an additive income term that leads to an occasionally binding constraint.
2. Shocks affecting the budget constraint are correlated, forcing us to track an extra state variable.

We will begin by working with a relatively basic version of the model and solving it via old-fashioned discretization + value function iteration.

Although this approach is not the fastest or the most efficient, it is very robust and flexible.

For example, if we suddenly decided to add Epstein–Zin preferences, or modify ordinary conditional expectations to quantiles, the technique would continue to work well.

> **Note**
>
> The same is not true of some other methods we will deploy, such as the endogenous grid method.
>
> This is a general rule of computation and analysis — while we can often come up with faster algorithms by exploiting structure, these new algorithms are typically less robust.
>
> They are less robust precisely because they exploit more structure — which implies that they are, inevitably, more vulnerable to change.

In addition to Anaconda, this lecture will need the following libraries:

```
!pip install quantecon jax
```

We will use the following imports:

```
import quantecon as qe
import jax
import jax.numpy as jnp
import matplotlib.pyplot as plt
from typing import NamedTuple
from time import time
```

We'll use 64 bit floats to gain extra precision.

```
jax.config.update("jax_enable_x64", True)
```

73.2 Set Up

We study a household that chooses a state-contingent consumption plan $\{c_t\}_{t \geq 0}$ to maximize

$$\mathbb{E} \sum_{t=0}^{\infty} \beta^t u(c_t)$$

subject to

$$a_{t+1} + c_t \leq R a_t + y_t$$

Here

- c_t is consumption and $c_t \geq 0$,
- a_t is assets and $a_t \geq 0$,
- $R = 1 + r$ is a gross rate of return, and
- $(y_t)_{t \geq 0}$ is labor income, taking values in some finite set Y.

We assume below that labor income dynamics follow a discretized AR(1) process.

We set $\mathsf{S} := \mathbb{R}_+ \times \mathsf{Y}$, which represents the state space.

The **value function** $V \colon \mathsf{S} \to \mathbb{R}$ is defined by

$$V(a, y) := \max \, \mathbb{E} \left\{ \sum_{t=0}^{\infty} \beta^t u(c_t) \right\} \tag{73.1}$$

where the maximization is over all feasible consumption sequences given $(a_0, y_0) = (a, y)$.

The Bellman equation is

$$v(a, y) = \max_{0 \leq a' \leq Ra+y} \left\{ u(Ra + y - a') + \beta \sum_{y'} v(a', y') Q(y, y') \right\}$$

where

$$u(c) = \frac{c^{1-\gamma}}{1-\gamma}$$

In the code we use the function

$$B((a, y), a', v) = u(Ra + y - a') + \beta \sum_{y'} v(a', y') Q(y, y').$$

the encapsulate the right hand side of the Bellman equation.

73.3 Code

The following code defines a `NamedTuple` to store the model parameters and grids.

```
class Model(NamedTuple):
    β: float              # Discount factor
    R: float              # Gross interest rate
    γ: float              # CRRA parameter
    a_grid: jnp.ndarray   # Asset grid
    y_grid: jnp.ndarray   # Income grid
    Q: jnp.ndarray        # Markov matrix for income

def create_consumption_model(
        R=1.01,                    # Gross interest rate
        β=0.98,                    # Discount factor
        γ=2,                       # CRRA parameter
        a_min=0.01,                # Min assets
        a_max=10.0,                # Max assets
        a_size=150,                # Grid size
        ρ=0.9, ν=0.1, y_size=100   # Income parameters
    ):
    """
    Creates an instance of the consumption-savings model.

    """
    a_grid = jnp.linspace(a_min, a_max, a_size)
    mc = qe.tauchen(n=y_size, rho=ρ, sigma=ν)
    y_grid, Q = jnp.exp(mc.state_values), jax.device_put(mc.P)
    return Model(β, R, γ, a_grid, y_grid, Q)
```

Now we define the right hand side of the Bellman equation.

We'll use a vectorized coding style reminiscent of Matlab and NumPy (avoiding all loops).

Your are invited to explore an alternative style based around `jax.vmap` in the Exercises.

```
@jax.jit
def B(v, model):
    """
    A vectorized version of the right-hand side of the Bellman equation
    (before maximization), which is a 3D array representing

        B(a, y, a') = u(Ra + y - a') + β Σ_y' v(a', y') Q(y, y')

    for all (a, y, a').
    """

    # Unpack
    β, R, γ, a_grid, y_grid, Q = model
    a_size, y_size = len(a_grid), len(y_grid)

    # Compute current rewards r(a, y, ap) as array r[i, j, ip]
    a  = jnp.reshape(a_grid, (a_size, 1, 1))    # a[i]   ->  a[i, j, ip]
    y  = jnp.reshape(y_grid, (1, y_size, 1))    # z[j]   ->  z[i, j, ip]
    ap = jnp.reshape(a_grid, (1, 1, a_size))    # ap[ip] -> ap[i, j, ip]
    c = R * a + y - ap

    # Calculate continuation rewards at all combinations of (a, y, ap)
    v = jnp.reshape(v, (1, 1, a_size, y_size))  # v[ip, jp] -> v[i, j, ip, jp]
    Q = jnp.reshape(Q, (1, y_size, 1, y_size))  # Q[j, jp]  -> Q[i, j, ip, jp]
    EV = jnp.sum(v * Q, axis=3)                 # sum over last index jp

    # Compute the right-hand side of the Bellman equation
    return jnp.where(c > 0, c**(1-γ)/(1-γ) + β * EV, -jnp.inf)
```

Some readers might be concerned that we are creating high dimensional arrays, leading to inefficiency.

Could they be avoided by more careful vectorization?

In fact this is not necessary: this function will be JIT-compiled by JAX, and the JIT compiler will optimize compiled code to minimize memory use.

The Bellman operator T can be implemented by

```
@jax.jit
def T(v, model):
    "The Bellman operator."
    return jnp.max(B(v, model), axis=2)
```

The next function computes a v-greedy policy given v (i.e., the policy that maximizes the right-hand side of the Bellman equation.)

```
@jax.jit
def get_greedy(v, model):
    "Computes a v-greedy policy, returned as a set of indices."
    return jnp.argmax(B(v, model), axis=2)
```

73.3.1 Value function iteration

Now we define a solver that implements VFI.

First we write a simple version using a standard Python loop.

```
def value_function_iteration_python(model, tol=1e-5, max_iter=10_000):
    """
    Implements VFI using successive approximation with a Python loop.
    """
    v = jnp.zeros((len(model.a_grid), len(model.y_grid)))
    error = tol + 1
    k = 0

    while error > tol and k < max_iter:
        v_new = T(v, model)
        error = jnp.max(jnp.abs(v_new - v))
        v = v_new
        k += 1

    return v, get_greedy(v, model)
```

Next we write a version that uses `jax.lax.while_loop`.

```
@jax.jit
def value_function_iteration(model, tol=1e-5, max_iter=10_000):
    """
    Implements VFI using successive approximation.
    """
    def body_fun(k_v_err):
        k, v, error = k_v_err
        v_new = T(v, model)
        error = jnp.max(jnp.abs(v_new - v))
        return k + 1, v_new, error

    def cond_fun(k_v_err):
        k, v, error = k_v_err
        return jnp.logical_and(error > tol, k < max_iter)

    v_init = jnp.zeros((len(model.a_grid), len(model.y_grid)))
    k, v_star, error = jax.lax.while_loop(cond_fun, body_fun,
                                          (1, v_init, tol + 1))
    return v_star, get_greedy(v_star, model)
```

73.3.2 Timing

Let's create an instance and compare the two implementations.

```
model = create_consumption_model()
```

First let's time the Python version.

```
print("Starting VFI using Python loop.")
start = time()
v_star_python, σ_star_python = value_function_iteration_python(model)
python_time = time() - start
print(f"VFI completed in {python_time} seconds.")
```

```
Starting VFI using Python loop.
VFI completed in 2.4494223594665527 seconds.
```

Now let's time the `jax.lax.while_loop` version.

```
print("Starting VFI using jax.lax.while_loop.")
start = time()
v_star_jax, σ_star_jax = value_function_iteration(model)
v_star_jax.block_until_ready()
jax_with_compile = time() - start
print(f"VFI completed in {jax_with_compile} seconds.")
```

```
Starting VFI using jax.lax.while_loop.
VFI completed in 1.6163322925567627 seconds.
```

Let's run it again to eliminate compile time.

```
start = time()
v_star_jax, σ_star_jax = value_function_iteration(model)
v_star_jax.block_until_ready()
jax_without_compile = time() - start
print(f"VFI completed in {jax_without_compile} seconds.")
```

```
VFI completed in 1.385864019393921 seconds.
```

Let's check that the two implementations produce the same result.

```
print(f"Values match: {jnp.allclose(v_star_python, v_star_jax)}")
print(f"Policies match: {jnp.allclose(σ_star_python, σ_star_jax)}")
```

```
Values match: True
Policies match: True
```

Here's the speedup from using `jax.lax.while_loop`.

```
print(f"Relative speed = {python_time / jax_without_compile:.2f}")
```

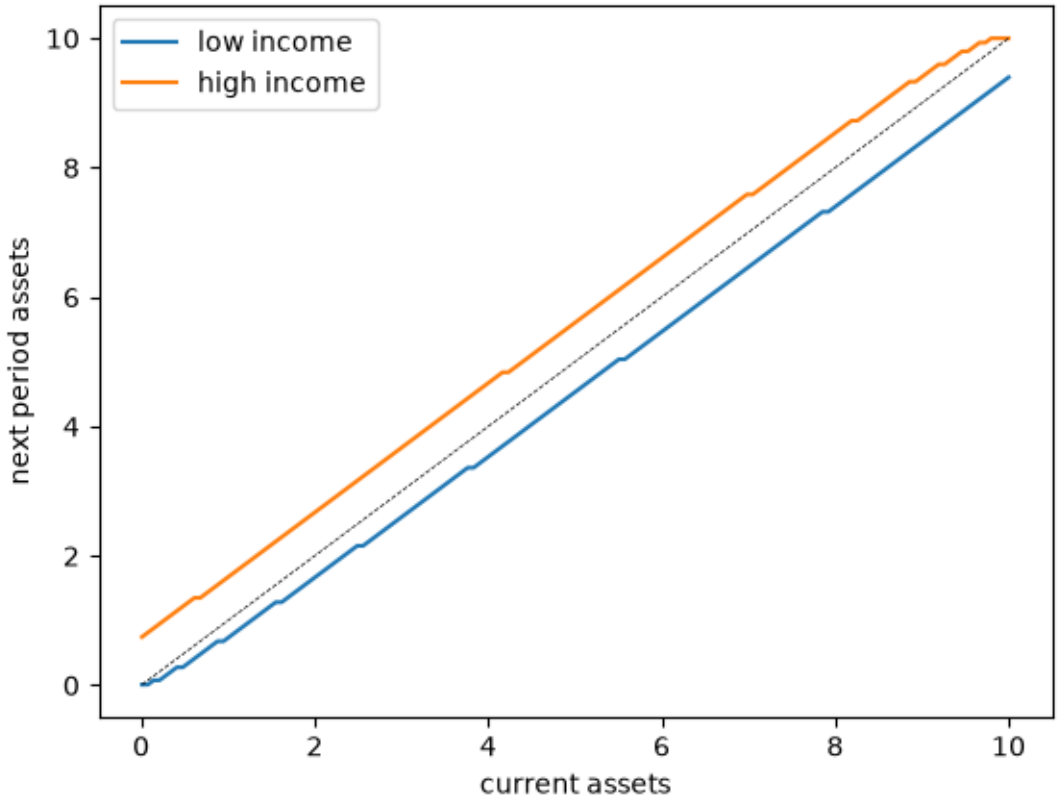
```
Relative speed = 1.77
```

73.3.3 Asset Dynamics

To understand long-run behavior, let's examine the asset accumulation dynamics under the optimal policy.

The following 45-degree diagram shows how assets evolve over time:

```
fig, ax = plt.subplots()



# Plot asset accumulation for first and last income states
for j, label in zip([0, -1], ['low income', 'high income']):
    # Get next-period assets for each current asset level
    a_next = model.a_grid[σ_star_jax[:, j]]
    ax.plot(model.a_grid, a_next, label=label)

# Add 45-degree line
```

(continues on next page)

(continued from previous page)

```
ax.plot(model.a_grid, model.a_grid, 'k--', linewidth=0.5)
ax.set(xlabel='current assets', ylabel='next period assets')
ax.legend()
plt.show()
```

The plot shows the asset accumulation rule for each income state.

The dotted line is the 45-degree line, representing points where $a_{t+1} = a_t$.

We see that:

- For low income levels, assets tend to decrease (points below the 45-degree line)
- For high income levels, assets tend to increase at low asset levels
- The dynamics suggest convergence to a stationary distribution

73.4 Exercises

Exercise 73.4.1

In this exercise, we explore an alternative approach to implementing value function iteration using `jax.vmap`.

For this simple optimal savings problem, direct vectorization is relatively easy.

In particular, it's straightforward to express the right hand side of the Bellman equation as an array that stores evaluations of the function at every state and control.

However, for more complex models, direct vectorization can be much harder.

For this reason, it helps to have another approach to fast JAX implementations up our sleeves.

Your task is to implement a version that:

1. writes the right hand side of the Bellman operator as a function of individual states and controls, and
2. applies `jax.vmap` on the outside to achieve a parallelized solution.

Specifically:

1. Rewrite `B` to take indices `(i, j, ip)` corresponding to `(a, y, a')` and compute the Bellman equation for those specific indices.
2. Use `jax.vmap` successively to vectorize over all indices (use staged vmap as shown in earlier examples).
3. Implement `T_vmap` and `get_greedy_vmap` functions using the vectorized `B`.
4. Implement `value_iteration_vmap` using `jax.lax.while_loop`.
5. Test that your implementation produces the same results as the direct vectorization approach.
6. Compare the execution times of both approaches.

Solution

Here's one solution.

First let's rewrite `B` to work with individual indices:

```
def B(v, model, i, j, ip):
    """
    The right-hand side of the Bellman equation before maximization, which takes
    the form

        B(a, y, a') = u(Ra + y - a') + β Σ_y' v(a', y') Q(y, y')

    The indices are (i, j, ip) -> (a, y, a').
    """
    β, R, γ, a_grid, y_grid, Q = model
    a, y, ap  = a_grid[i], y_grid[j], a_grid[ip]
    c = R * a + y - ap
    EV = jnp.sum(v[ip, :] * Q[j, :])
    return jnp.where(c > 0, c**(1-γ)/(1-γ) + β * EV, -jnp.inf)
```

Now we successively apply `vmap` to simulate nested loops.

```
B_1    = jax.vmap(B,   in_axes=(None, None, None, None, 0))
B_2    = jax.vmap(B_1, in_axes=(None, None, None, 0,    None))
B_vmap = jax.vmap(B_2, in_axes=(None, None, 0,    None, None))
```

Here's the Bellman operator and the `get_greedy` functions for the `vmap` case.

```
@jax.jit
def T_vmap(v, model):
    "The Bellman operator."
    a_indices = jnp.arange(len(model.a_grid))
    y_indices = jnp.arange(len(model.y_grid))
    B_values = B_vmap(v, model, a_indices, y_indices, a_indices)
    return jnp.max(B_values, axis=-1)

@jax.jit
def get_greedy_vmap(v, model):
    "Computes a v-greedy policy, returned as a set of indices."
    a_indices = jnp.arange(len(model.a_grid))
    y_indices = jnp.arange(len(model.y_grid))
    B_values = B_vmap(v, model, a_indices, y_indices, a_indices)
    return jnp.argmax(B_values, axis=-1)
```

Here's the iteration routine.

```
def value_iteration_vmap(model, tol=1e-5, max_iter=10_000):
    """
    Implements VFI using vmap and successive approximation.
    """
    def body_fun(k_v_err):
        k, v, error = k_v_err
        v_new = T_vmap(v, model)
        error = jnp.max(jnp.abs(v_new - v))
        return k + 1, v_new, error

    def cond_fun(k_v_err):
        k, v, error = k_v_err
        return jnp.logical_and(error > tol, k < max_iter)

    v_init = jnp.zeros((len(model.a_grid), len(model.y_grid)))
    k, v_star, error = jax.lax.while_loop(cond_fun, body_fun,
                                          (1, v_init, tol + 1))
    return v_star, get_greedy_vmap(v_star, model)
```

Let's see how long it takes to solve the model using the `vmap` method.

```
print("Starting VFI using vmap.")
start = time()
v_star_vmap, σ_star_vmap = value_iteration_vmap(model)
v_star_vmap.block_until_ready()
jax_vmap_with_compile = time() - start
print(f"VFI completed in {jax_vmap_with_compile} seconds.")
```

```
Starting VFI using vmap.
VFI completed in 0.624108076095581 seconds.
```

Let's run it again to get rid of compile time.

```
start = time()
v_star_vmap, σ_star_vmap = value_iteration_vmap(model)
v_star_vmap.block_until_ready()
jax_vmap_without_compile = time() - start
print(f"VFI completed in {jax_vmap_without_compile} seconds.")
```

```
VFI completed in 0.37119102478027344 seconds.
```

We need to make sure that we got the same result.

```
print(jnp.allclose(v_star_vmap, v_star_jax))
print(jnp.allclose(σ_star_vmap, σ_star_jax))
```

```
True
True
```

Here's the comparison with the first JAX implementation (which used direct vectorization).

```
print(f"Relative speed = {jax_without_compile / jax_vmap_without_compile}")
```

```
Relative speed = 3.733560153331518
```

The execution times for the two JAX versions are relatively similar.

However, as emphasized above, having a second method up our sleeves (i.e, the `vmap` approach) will be helpful when confronting dynamic programs with more sophisticated Bellman equations.

CHAPTER

SEVENTYFOUR

THE INCOME FLUCTUATION PROBLEM II: OPTIMISTIC POLICY ITERATION

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

74.1 Overview

In *The Income Fluctuation Problem I: Discretization and VFI* we studied the income fluctuation problem and solved it using value function iteration (VFI).

In this lecture we'll solve the same problem using **optimistic policy iteration** (OPI), which is very general, typically faster than VFI and only slightly more complex.

OPI combines elements of both value function iteration and policy iteration.

A detailed discussion of the algorithm can be found in DP1.

Here our aim is to implement OPI and test whether or not it yields significant speed improvements over standard VFI for the income fluctuation problem.

In addition to Anaconda, this lecture will need the following libraries:

```
!pip install quantecon jax
```

We will use the following imports:

```
import quantecon as qe
import jax
import jax.numpy as jnp
import matplotlib.pyplot as plt
from typing import NamedTuple
from time import time
```

74.2 Model and Primitives

The model and parameters are the same as in *The Income Fluctuation Problem I: Discretization and VFI*.

We repeat the key elements here for convenience.

The household's problem is to maximize

$$\mathbb{E} \sum_{t=0}^{\infty} \beta^t u(c_t)$$

subject to

$$a_{t+1} + c_t \leq R a_t + y_t$$

where $u(c) = c^{1-\gamma}/(1-\gamma)$.

Here's the model structure:

```
class Model(NamedTuple):
    β: float              # Discount factor
    R: float              # Gross interest rate
    γ: float              # CRRA parameter
    a_grid: jnp.ndarray   # Asset grid
    y_grid: jnp.ndarray   # Income grid
    Q: jnp.ndarray        # Markov matrix for income

def create_consumption_model(
        R=1.01,                    # Gross interest rate
        β=0.98,                    # Discount factor
        γ=2,                       # CRRA parameter
        a_min=0.01,                # Min assets
        a_max=10.0,                # Max assets
        a_size=150,                # Grid size
        ρ=0.9, ν=0.1, y_size=100   # Income parameters
    ):
    """
    Creates an instance of the consumption-savings model.

    """
    a_grid = jnp.linspace(a_min, a_max, a_size)
    mc = qe.tauchen(n=y_size, rho=ρ, sigma=ν)
    y_grid, Q = jnp.exp(mc.state_values), jax.device_put(mc.P)
    return Model(β, R, γ, a_grid, y_grid, Q)
```

74.3 Operators and Policies

We repeat some functions from *The Income Fluctuation Problem I: Discretization and VFI*.

Here is the right hand side of the Bellman equation:

```
def B(v, model, i, j, ip):
    """
    The right-hand side of the Bellman equation before maximization, which takes
    the form
```

(continues on next page)

(continued from previous page)

```
        B(a, y, a') = u(Ra + y - a') + β Σ_y' v(a', y') Q(y, y')

    The indices are (i, j, ip) -> (a, y, a').
    """
    β, R, γ, a_grid, y_grid, Q = model
    a, y, ap  = a_grid[i], y_grid[j], a_grid[ip]
    c = R * a + y - ap
    EV = jnp.sum(v[ip, :] * Q[j, :])
    return jnp.where(c > 0, c**(1-γ)/(1-γ) + β * EV, -jnp.inf)
```

Now we successively apply `vmap` to vectorize over all indices:

```
B_1    = jax.vmap(B,   in_axes=(None, None, None, None, 0))
B_2    = jax.vmap(B_1, in_axes=(None, None, None, 0,    None))
B_vmap = jax.vmap(B_2, in_axes=(None, None, 0,    None, None))
```

Here's the Bellman operator:

```
def T(v, model):
    "The Bellman operator."
    a_indices = jnp.arange(len(model.a_grid))
    y_indices = jnp.arange(len(model.y_grid))
    B_values = B_vmap(v, model, a_indices, y_indices, a_indices)
    return jnp.max(B_values, axis=-1)
```

Here's the function that computes a v-greedy policy:

```
def get_greedy(v, model):
    "Computes a v-greedy policy, returned as a set of indices."
    a_indices = jnp.arange(len(model.a_grid))
    y_indices = jnp.arange(len(model.y_grid))
    B_values = B_vmap(v, model, a_indices, y_indices, a_indices)
    return jnp.argmax(B_values, axis=-1)
```

Now we define the policy operator T_σ, which is the Bellman operator with policy σ fixed.

For a given policy σ, the policy operator is defined by

$$(T_\sigma v)(a, y) = u(Ra + y - \sigma(a, y)) + \beta \sum_{y'} v(\sigma(a, y), y') Q(y, y')$$

```
def T_σ(v, σ, model, i, j):
    """
    The σ-policy operator for indices (i, j) -> (a, y).
    """
    β, R, γ, a_grid, y_grid, Q = model

    # Get values at current state
    a, y = a_grid[i], y_grid[j]
    # Get policy choice
    ap = a_grid[σ[i, j]]

    # Compute current reward
    c = R * a + y - ap
    r = jnp.where(c > 0, c**(1-γ)/(1-γ), -jnp.inf)
```

(continues on next page)

(continued from previous page)

```
    # Compute expected value
    EV = jnp.sum(v[σ[i, j], :] * Q[j, :])

    return r + β * EV
```

Apply vmap to vectorize:

```
T_σ_1    = jax.vmap(T_σ,   in_axes=(None, None, None, None, 0))
T_σ_vmap = jax.vmap(T_σ_1, in_axes=(None, None, None, 0,    None))

def T_σ_vec(v, σ, model):
    """Vectorized version of T_σ."""
    a_size, y_size = len(model.a_grid), len(model.y_grid)
    a_indices = jnp.arange(a_size)
    y_indices = jnp.arange(y_size)
    return T_σ_vmap(v, σ, model, a_indices, y_indices)
```

Now we need a function to apply the policy operator m times:

```
def iterate_policy_operator(σ, v, m, model):
    """
    Apply the policy operator T_σ exactly m times to v.
    """
    def update(i, v):
        return T_σ_vec(v, σ, model)

    v = jax.lax.fori_loop(0, m, update, v)
    return v
```

74.4 Value Function Iteration

For comparison, here's VFI from *The Income Fluctuation Problem I: Discretization and VFI*:

```
@jax.jit
def value_function_iteration(model, tol=1e-5, max_iter=10_000):
    """
    Implements VFI using successive approximation.
    """
    def body_fun(k_v_err):
        k, v, error = k_v_err
        v_new = T(v, model)
        error = jnp.max(jnp.abs(v_new - v))
        return k + 1, v_new, error

    def cond_fun(k_v_err):
        k, v, error = k_v_err
        return jnp.logical_and(error > tol, k < max_iter)

    v_init = jnp.zeros((len(model.a_grid), len(model.y_grid)))
    k, v_star, error = jax.lax.while_loop(cond_fun, body_fun,
                                          (1, v_init, tol + 1))
    return v_star, get_greedy(v_star, model)
```

74.5 Optimistic Policy Iteration

Now we implement OPI.

The algorithm alternates between

1. Performing m policy operator iterations to update the value function
2. Computing a new greedy policy based on the updated value function

```
@jax.jit
def optimistic_policy_iteration(model, m=10, tol=1e-5, max_iter=10_000):
    """
    Implements optimistic policy iteration with step size m.

    Parameters:
    -----------
    model : Model
        The consumption-savings model
    m : int
        Number of policy operator iterations per step
    tol : float
        Tolerance for convergence
    max_iter : int
        Maximum number of iterations
    """
    v_init = jnp.zeros((len(model.a_grid), len(model.y_grid)))

    def condition_function(inputs):
        i, v, error = inputs
        return jnp.logical_and(error > tol, i < max_iter)

    def update(inputs):
        i, v, error = inputs
        last_v = v
        σ = get_greedy(v, model)
        v = iterate_policy_operator(σ, v, m, model)
        error = jnp.max(jnp.abs(v - last_v))
        i += 1
        return i, v, error

    num_iter, v, error = jax.lax.while_loop(condition_function,
                                            update,
                                            (0, v_init, tol + 1))

    return v, get_greedy(v, model)
```

74.6 Timing Comparison

Let's create a model and compare the performance of VFI and OPI.

```
model = create_consumption_model()
```

First, let's time VFI:

```
print("Starting VFI.")
start = time()
v_star_vfi, σ_star_vfi = value_function_iteration(model)
v_star_vfi.block_until_ready()
vfi_time_with_compile = time() - start
print(f"VFI completed in {vfi_time_with_compile:.2f} seconds.")
```

```
Starting VFI.
VFI completed in 0.39 seconds.
```

Run it again to eliminate compile time:

```
start = time()
v_star_vfi, σ_star_vfi = value_function_iteration(model)
v_star_vfi.block_until_ready()
vfi_time = time() - start
print(f"VFI completed in {vfi_time:.2f} seconds.")
```

```
VFI completed in 0.09 seconds.
```

Now let's time OPI with different values of m:

```
print("Starting OPI with m=50.")
start = time()
v_star_opi, σ_star_opi = optimistic_policy_iteration(model, m=50)
v_star_opi.block_until_ready()
opi_time_with_compile = time() - start
print(f"OPI completed in {opi_time_with_compile:.2f} seconds.")
```

```
Starting OPI with m=50.
OPI completed in 0.35 seconds.
```

Run it again:

```
start = time()
v_star_opi, σ_star_opi = optimistic_policy_iteration(model, m=50)
v_star_opi.block_until_ready()
opi_time = time() - start
print(f"OPI completed in {opi_time:.2f} seconds.")
```

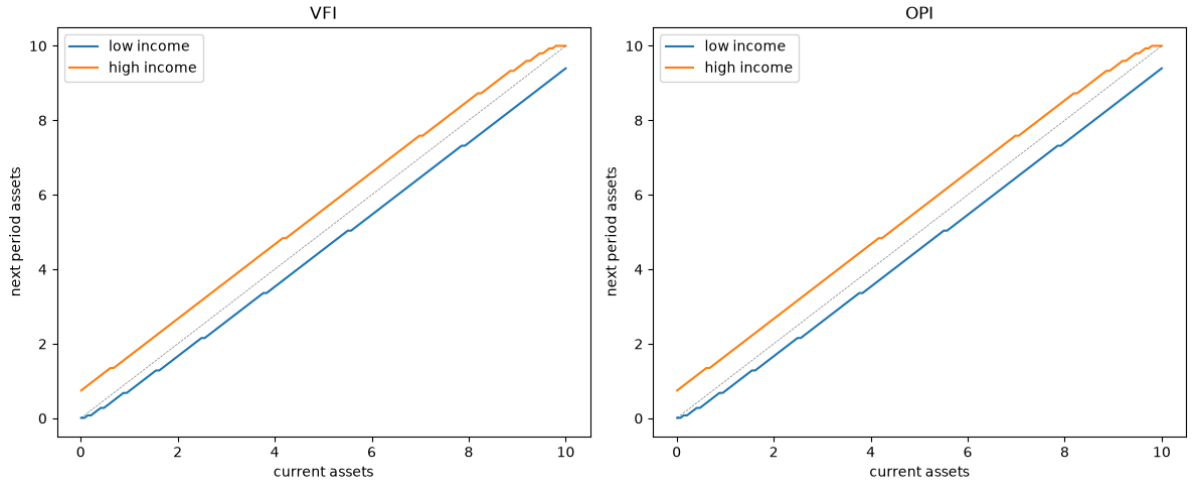
```
OPI completed in 0.04 seconds.
```

Check that we get the same result:

```
print(f"Values match: {jnp.allclose(v_star_vfi, v_star_opi)}")
```

```
Values match: True
```

The value functions match, confirming both algorithms converge to the same solution.



Let's visually compare the asset dynamics under both policies:

```
fig, axes = plt.subplots(1, 2, figsize=(12, 5))

# VFI policy
for j, label in zip([0, -1], ['low income', 'high income']):
    a_next_vfi = model.a_grid[σ_star_vfi[:, j]]
    axes[0].plot(model.a_grid, a_next_vfi, label=label)
axes[0].plot(model.a_grid, model.a_grid, 'k--', linewidth=0.5, alpha=0.5)
axes[0].set(xlabel='current assets', ylabel='next period assets', title='VFI')
axes[0].legend()

# OPI policy
for j, label in zip([0, -1], ['low income', 'high income']):
    a_next_opi = model.a_grid[σ_star_opi[:, j]]
    axes[1].plot(model.a_grid, a_next_opi, label=label)
axes[1].plot(model.a_grid, model.a_grid, 'k--', linewidth=0.5, alpha=0.5)
axes[1].set(xlabel='current assets', ylabel='next period assets', title='OPI')
axes[1].legend()

plt.tight_layout()
plt.show()
```

The policies are visually indistinguishable, confirming both methods produce the same solution.

Here's the speedup:

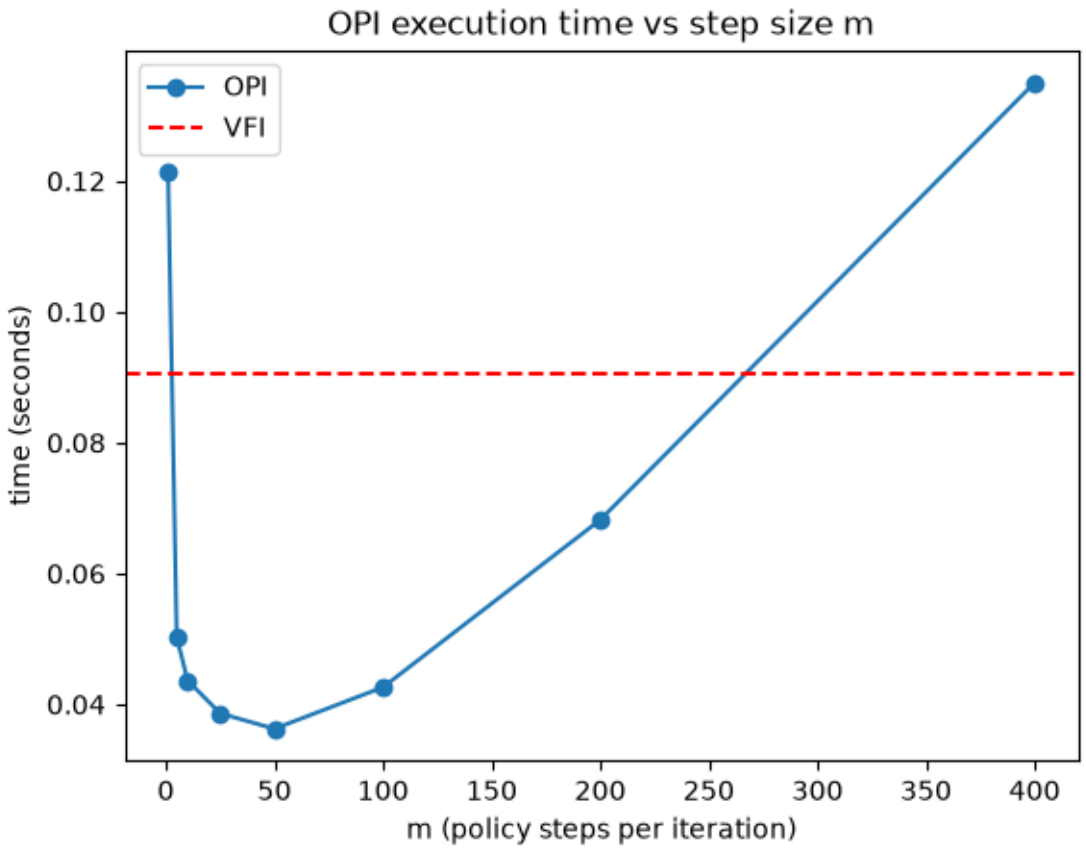
```
print(f"Speedup factor: {vfi_time / opi_time:.2f}")
```

```
Speedup factor: 2.40
```

Let's try different values of m to see how it affects performance:

```
m_vals = [1, 5, 10, 25, 50, 100, 200, 400]
opi_times = []
```

(continues on next page)



(continued from previous page)

```
for m in m_vals:
    start = time()
    v_star, σ_star = optimistic_policy_iteration(model, m=m)
    v_star.block_until_ready()
    elapsed = time() - start
    opi_times.append(elapsed)
    print(f"OPI with m={m:3d} completed in {elapsed:.2f} seconds.")
```

```
OPI with m=  1 completed in 0.12 seconds.
OPI with m=  5 completed in 0.05 seconds.
OPI with m= 10 completed in 0.04 seconds.
OPI with m= 25 completed in 0.04 seconds.
OPI with m= 50 completed in 0.04 seconds.
OPI with m=100 completed in 0.04 seconds.
OPI with m=200 completed in 0.07 seconds.
OPI with m=400 completed in 0.14 seconds.
```

Plot the results:

```
fig, ax = plt.subplots()
ax.plot(m_vals, opi_times, 'o-', label='OPI')
ax.axhline(vfi_time, linestyle='--', color='red', label='VFI')
ax.set_xlabel('m (policy steps per iteration)')
ax.set_ylabel('time (seconds)')
ax.legend()
ax.set_title('OPI execution time vs step size m')
plt.show()
```

Here's a summary of the results

- OPI outperforms VFI for a large range of m values.
- For very large m, OPI performance begins to degrade as we spend too much time iterating the policy operator.

74.7 Exercises

Exercise 74.7.1

The speed gains achieved by OPI are quite robust to parameter changes.

Confirm this by experimenting with different parameter values for the income process (ρ and ν).

Measure how they affect the relative performance of VFI vs OPI.

Try:

- $\rho \in \{0.8, 0.9, 0.95\}$
- $\nu \in \{0.05, 0.1, 0.2\}$

For each combination, compute the speedup factor (VFI time / OPI time) and report your findings.

Solution

Here's one solution:

```
ρ_vals = [0.8, 0.9, 0.95]
ν_vals = [0.05, 0.1, 0.2]

results = []

for ρ in ρ_vals:
    for ν in ν_vals:
        print(f"\nTesting ρ={ρ}, ν={ν}")

        # Create model
        model = create_consumption_model(ρ=ρ, ν=ν)

        # Time VFI
        start = time()
        v_vfi, σ_vfi = value_function_iteration(model)
        v_vfi.block_until_ready()
        vfi_t = time() - start

        # Time OPI
        start = time()
        v_opi, σ_opi = optimistic_policy_iteration(model, m=10)
        v_opi.block_until_ready()
        opi_t = time() - start

        speedup = vfi_t / opi_t
        results.append((ρ, ν, speedup))
        print(f"  VFI: {vfi_t:.2f}s, OPI: {opi_t:.2f}s, Speedup: {speedup:.2f}x")

# Print summary
print("\nSummary of speedup factors:")
for ρ, ν, speedup in results:
    print(f"ρ={ρ}, ν={ν}: {speedup:.2f}x")
```

```
Testing ρ=0.8, ν=0.05
  VFI: 0.06s, OPI: 0.03s, Speedup: 1.66x

Testing ρ=0.8, ν=0.1
  VFI: 0.06s, OPI: 0.03s, Speedup: 1.77x

Testing ρ=0.8, ν=0.2
  VFI: 0.06s, OPI: 0.03s, Speedup: 1.76x

Testing ρ=0.9, ν=0.05
  VFI: 0.06s, OPI: 0.03s, Speedup: 1.75x

Testing ρ=0.9, ν=0.1
  VFI: 0.06s, OPI: 0.03s, Speedup: 1.71x

Testing ρ=0.9, ν=0.2
  VFI: 0.06s, OPI: 0.03s, Speedup: 1.77x

Testing ρ=0.95, ν=0.05
  VFI: 0.06s, OPI: 0.04s, Speedup: 1.66x

Testing ρ=0.95, ν=0.1
  VFI: 0.06s, OPI: 0.03s, Speedup: 1.73x

Testing ρ=0.95, ν=0.2
  VFI: 0.07s, OPI: 0.04s, Speedup: 1.86x

Summary of speedup factors:
ρ=0.8, ν=0.05: 1.66x
```

CHAPTER

SEVENTYFIVE

THE INCOME FLUCTUATION PROBLEM III: THE ENDOGENOUS GRID METHOD

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

Contents

- *The Income Fluctuation Problem III: The Endogenous Grid Method*
  - *Overview*
  - *The Household Problem*
  - *Computation*
  - *NumPy Implementation*
  - *JAX Implementation*
  - *Simulation*

75.1 Overview

In this lecture we continue examining a version of the IFP from

- *The Income Fluctuation Problem I: Discretization and VFI* and
- *The Income Fluctuation Problem II: Optimistic Policy Iteration*.

We will make two changes.

1. Change the timing to one that is more efficient for our set up.
2. Use the endogenous grid method (EGM) to solve the model.

We use EGM because we know it to be fast and accurate from *Optimal Savings VI: EGM with JAX*.

The primary source for the technical details discussed below is [Ma *et al.*, 2020].

Other references include [Deaton, 1991], [Den Haan, 2010], [Kuhn, 2013], [Rabault, 2002], [Reiter, 2009] and [Schechtman and Escudero, 1977].

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon jax
```

We'll also need the following imports:

```
import matplotlib.pyplot as plt
import numpy as np
import numba
from quantecon import MarkovChain
import jax
import jax.numpy as jnp
from typing import NamedTuple
```

75.2 The Household Problem

Let's write down the model and then discuss how to solve it.

75.2.1 Set-Up

A household chooses a state-contingent consumption plan $\{c_t\}_{t \geq 0}$ to maximize

$$\mathbb{E} \sum_{t=0}^{\infty} \beta^t u(c_t)$$

subject to

$$a_{t+1} = R(a_t - c_t) + Y_{t+1} \quad c_t \geq 0, \quad a_t \geq 0 \quad t = 0, 1, \ldots \tag{75.1}$$

Here

- $\beta \in (0, 1)$ is the discount factor
- a_t is asset holdings at time t, with borrowing constraint $a_t \geq 0$
- c_t is consumption
- Y_t is non-capital income (wages, unemployment compensation, etc.)
- $R := 1 + r$, where $r > 0$ is the interest rate on savings

The timing here is as follows:

1. At the start of period t, the household observes current asset holdings a_t.
2. The household chooses current consumption c_t.
3. Savings $s_t := a_t - c_t$ earns interest at rate r.
4. Labor income Y_{t+1} is realized and time shifts to $t + 1$.

Non-capital income Y_t is given by $Y_t = y(Z_t)$, where

- $\{Z_t\}$ is an exogenous state process, and
- y is a function taking values in $\mathbb{R}_+$.

We take $\{Z_t\}$ to be a finite state Markov chain taking values in Z with Markov matrix Π.

Note

In previous lectures we used the more standard household budget constraint $a_{t+1} + c_t \leq Ra_t + Y_t$.

This setup, which is pervasive in quantitative economics, was developed for discretization.

It means that the control variable is also the next period state a_{t+1}, which makes it straightforward to restrict assets to a finite grid.

But fixing the control to be the next period state forces us to include more information in the current state, which expands the size of the state space.

Moreover, aiming for discretization is not always a good idea, since it suffers heavily from the curse of dimensionality.

These ideas will become clearer in the *next lecture*.

We further assume that

1. $\beta R < 1$
2. u is smooth, strictly increasing and strictly concave with $\lim_{c \to 0} u'(c) = \infty$ and $\lim_{c \to \infty} u'(c) = 0$
3. $y(z) = \exp(z)$

The asset space is $\mathbb{R}_+$ and the state is the pair $(a, z) \in \mathsf{S} := \mathbb{R}_+ \times \mathsf{Z}$.

A **feasible consumption path** from $(a, z) \in \mathsf{S}$ is a consumption sequence $\{c_t\}$ such that $\{c_t\}$ and its induced asset path $\{a_t\}$ satisfy

1. $(a_0, z_0) = (a, z)$
2. the feasibility constraints in (75.1), and
3. adaptedness, which means that c_t is a function of random outcomes up to date t but not after.

The meaning of the third point is just that consumption at time t cannot be a function of outcomes are yet to be observed.

In fact, for this problem, consumption can be chosen optimally by taking it to be contingent only on the current state.

Optimality is defined below.

75.2.2 Value Function and Euler Equation

The **value function** $V \colon \mathsf{S} \to \mathbb{R}$ is defined by

$$V(a, z) := \max \mathbb{E} \left\{ \sum_{t=0}^{\infty} \beta^t u(c_t) \right\} \tag{75.2}$$

where the maximization is overall feasible consumption paths from (a, z).

An **optimal consumption path** from (a, z) is a feasible consumption path from (a, z) that maximizes (73.1).

To pin down such paths we can use a version of the Euler equation, which in the present setting is

$$u'(c_t) \geq \beta R \, \mathbb{E}_t u'(c_{t+1}) \tag{75.3}$$

with

$$c_t < a_t \implies u'(c_t) = \beta R \, \mathbb{E}_t u'(c_{t+1}) \tag{75.4}$$

When c_t hits the upper bound a_t, the strict inequality $u'(c_t) > \beta R \, \mathbb{E}_t u'(c_{t+1})$ can occur because c_t cannot increase sufficiently to attain equality.

The case $c_t = 0$ never arises along the optimal path because $u'(0) = \infty$.

75.2.3 Optimality Results

As shown in [Ma *et al.*, 2020],

1. For each $(a, z) \in \mathsf{S}$, a unique optimal consumption path from (a, z) exists
2. This path is the unique feasible path from (a, z) satisfying the Euler equations (75.3)-(75.4) and the transversality condition

$$\lim_{t \to \infty} \beta^t \, \mathbb{E} \left[u'(c_t) a_{t+1} \right] = 0 \tag{75.5}$$

Moreover, there exists an **optimal consumption policy** $\sigma^* \colon \mathsf{S} \to \mathbb{R}_+$ such that the path from (a, z) generated by

$$(a_0, z_0) = (a, z), \quad c_t = \sigma^*(a_t, Z_t) \quad \text{and} \quad a_{t+1} = R(a_t - c_t) + Y_{t+1}$$

satisfies both the Euler equations (75.3)-(75.4) and (75.5), and hence is the unique optimal path from (a, z).

Thus, to solve the optimization problem, we need to compute the policy σ^*.

75.3 Computation

We solve for the optimal consumption policy using time iteration and the endogenous grid method, which were previously discussed in

- *Optimal Savings IV: Time Iteration*
- *Optimal Savings V: The Endogenous Grid Method*

75.3.1 Solution Method

We rewrite (75.4) to make it a statement about functions rather than random variables:

$$(u' \circ \sigma)(a, z) = \beta R \sum_{z'} (u' \circ \sigma)[R(a - \sigma(a, z)) + y(z'), \, z'] \, \Pi(z, z') \tag{75.6}$$

Here

- $(u' \circ \sigma)(s) := u'(\sigma(s))$,
- primes indicate next period states (as well as derivatives), and
- σ is the unknown function.

The equality (75.6) holds at all interior choices, meaning $\sigma(a, z) < a$.

We aim to find a fixed point σ of (75.6).

To do so we use the EGM.

Below we use the relationships $a_t = c_t + s_t$ and $a_{t+1} = R s_t + Y_{t+1}$.

We begin with an exogenous savings grid $s_0 < s_1 < \cdots < s_m$ with $s_0 = 0$.

We fix a current guess of the policy function σ.

For each exogenous savings level s_i with $i \geq 1$ and current state z_j, we set

$$c_{ij} := (u')^{-1} \left[\beta R \sum_{z'} u'[\sigma(Rs_i + y(z'), z')] \, \Pi(z_j, z') \right] \tag{75.7}$$

The Euler equation holds here because $i \geq 1$ implies $s_i > 0$ and hence consumption is interior.

For the boundary case $s_0 = 0$ we set

$$c_{0j} := 0 \quad \text{for all j}$$

We then obtain a corresponding endogenous grid of current assets via

$$a_{ij} := c_{ij} + s_i.$$

Notice that, for each j, we have $a_{0j} = c_{0j} = 0$.

This anchors the interpolation at the correct value at the origin, since, without borrowing, consumption is zero when assets are zero.

Our next guess of the policy function, which we write as $K\sigma$, is the linear interpolation of the interpolation points

$$\{(a_{0j}, c_{0j}), \ldots, (a_{mj}, c_{mj})\}$$

for each j.

(The number of one-dimensional linear interpolations is equal to the size of Z.)

75.4 NumPy Implementation

In this section we'll code up a NumPy version of the code that aims only for clarity, rather than efficiency.

Once we have it working, we'll produce a JAX version that's far more efficient and check that we obtain the same results.

We use the CRRA utility specification

$$u(c) = \frac{c^{1-\gamma}}{1-\gamma}$$

75.4.1 Set Up

Here we build a class called `IFPNumPy` that stores the model primitives.

The exogenous state process $\{Z_t\}$ defaults to a two-state Markov chain with transition matrix Π.

```
class IFPNumPy(NamedTuple):
    R: float                  # Gross interest rate R = 1 + r
    β: float                  # Discount factor
    γ: float                  # Preference parameter
    Π: np.ndarray             # Markov matrix for exogenous shock
    z_grid: np.ndarray        # Markov state values for Z_t
    s: np.ndarray             # Exogenous savings grid
```

(continues on next page)

(continued from previous page)

```
def create_ifp(r=0.01,
               β=0.96,
               γ=1.5,
               Π=((0.6, 0.4),
                  (0.05, 0.95)),
               z_grid=(-10.0, np.log(2.0)),
               savings_grid_max=16,
               savings_grid_size=200):

    s = np.linspace(0, savings_grid_max, savings_grid_size)
    Π, z_grid = np.array(Π), np.array(z_grid)
    R = 1 + r
    assert R * β < 1, "Stability condition violated."
    return IFPNumPy(R, β, γ, Π, z_grid, s)
```

75.4.2 Solver

Here is the operator K that transforms current guess σ into next period guess $K\sigma$.

In practice, it takes in

- a guess of optimal consumption values c_{ij}, stored as `c_vec`
- and a corresponding set of endogenous grid points a^e_{ij}, stored as `a_vec`

These are converted into a consumption policy $a \mapsto \sigma(a, z_j)$ by linear interpolation of (a^e_{ij}, c_{ij}) over i for each j.

Since there are no shocks to integrate out in this version of the model, we can compute (75.7) directly by summing over the finite state space Z.

```
@numba.jit
def K_numpy(
        c_in: np.ndarray,   # Initial guess of σ on grid endogenous grid
        a_in: np.ndarray,   # Initial endogenous grid
        ifp_numpy: IFPNumPy
    ) -> np.ndarray:
    """
    The Euler equation operator for the IFP model using the
    Endogenous Grid Method.

    This operator implements one iteration of the EGM algorithm to
    update the consumption policy function.

    """
    R, β, γ, Π, z_grid, s = ifp_numpy
    n_a, n_z = len(s), len(z_grid)
    c_out = np.zeros_like(c_in)
    u_prime = lambda c: c**(-γ)
    u_prime_inv = lambda c: c**(-1/γ)
    y = lambda z: np.exp(z)

    for i in range(1, n_a):  # Start from 1 for positive savings levels
        for j in range(n_z):

            # Compute Σ_z' u'(σ(R s_i + y(z'), z')) Π[z_j, z']
```

(continues on next page)

(continued from previous page)

```
            expectation = 0.0
            for k in range(n_z):
                z_prime = z_grid[k]
                # Calculate next period assets
                next_a = R * s[i] + y(z_prime)
                # Interpolate to get σ(R s_i + y(z'), z')
                next_c = np.interp(next_a, a_in[:, k], c_in[:, k])
                # Weight by transition probability and add to the expectation
                expectation += u_prime(next_c) * Π[j, k]

            # Calculate updated c_{ij} values
            c_out[i, j] = u_prime_inv(β * R * expectation)

    a_out = c_out + s[:, None]
    return c_out, a_out
```

To solve the model we use a simple while loop.

```
def solve_model_numpy(
        ifp_numpy: IFPNumPy,
        c_init: np.ndarray,
        a_init: np.ndarray,
        tol: float = 1e-5,
        max_iter: int = 1_000
    ) -> np.ndarray:
    """
    Solve the model using time iteration with EGM.

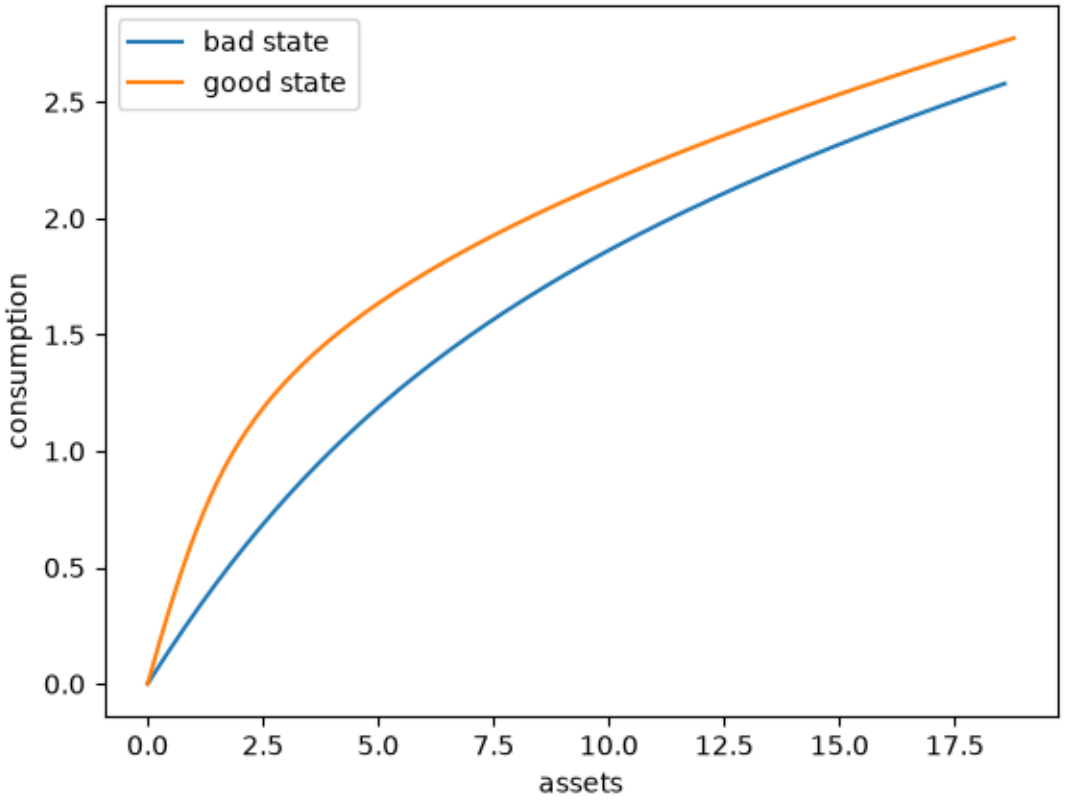
    """
    c_in, a_in = c_init, a_init
    i = 0
    error = tol + 1

    while error > tol and i < max_iter:
        c_out, a_out = K_numpy(c_in, a_in, ifp_numpy)
        error = np.max(np.abs(c_out - c_in))
        i = i + 1
        c_in, a_in = c_out, a_out

    return c_out, a_out
```

Let's road test the EGM code.

```
ifp_numpy = create_ifp()
R, β, γ, Π, z_grid, s = ifp_numpy
# Initial conditions -- agent consumes everything
a_init = s[:, None] * np.ones(len(z_grid))
c_init = a_init
# Solve from these initial conditions
c_vec, a_vec = solve_model_numpy(
    ifp_numpy, c_init, a_init
)
```



Here's a plot of the optimal consumption policy for each z state

```
fig, ax = plt.subplots()
```

(continues on next page)

(continued from previous page)

```
ax.plot(a_vec[:, 0], c_vec[:, 0], label='bad state')
ax.plot(a_vec[:, 1], c_vec[:, 1], label='good state')
ax.set(xlabel='assets', ylabel='consumption')
ax.legend()
plt.show()
```

75.5 JAX Implementation

Now we write a more efficient JAX version, which can run on a GPU.

75.5.1 Set Up

We start with a class called `IFP` that stores the model primitives.

```
class IFP(NamedTuple):
    R: float                  # Gross interest rate R = 1 + r
    β: float                  # Discount factor
    γ: float                  # Preference parameter
    Π: jnp.ndarray            # Markov matrix for exogenous shock
    z_grid: jnp.ndarray       # Markov state values for Z_t
    s: jnp.ndarray            # Exogenous savings grid

def create_ifp(r=0.01,
```

(continues on next page)

(continued from previous page)

```
                β=0.94,
                γ=1.5,
                Π=((0.6, 0.4),
                   (0.05, 0.95)),
                z_grid=(-10.0, jnp.log(2.0)),
                savings_grid_max=16,
                savings_grid_size=200):

    s = jnp.linspace(0, savings_grid_max, savings_grid_size)
    Π, z_grid = jnp.array(Π), jnp.array(z_grid)
    R = 1 + r
    assert R * β < 1, "Stability condition violated."
    return IFP(R, β, γ, Π, z_grid, s)
```

75.5.2 Solver

Here is the operator K that transforms current guess σ into next period guess $K\sigma$.

```
def K(
        c_in: jnp.ndarray,
        a_in: jnp.ndarray,
        ifp: IFP
    ) -> jnp.ndarray:
    """
    The Euler equation operator for the IFP model using the
    Endogenous Grid Method.

    This operator implements one iteration of the EGM algorithm to
    update the consumption policy function.

    """
    R, β, γ, Π, z_grid, s = ifp
    n_z = len(z_grid)
    z_indices = jnp.arange(n_z)
    u_prime = lambda c: c**(-γ)
    u_prime_inv = lambda c: c**(-1/γ)
    y = lambda z: jnp.exp(z)

    def compute_c(i, j):
        " Computes consumption for one (i, j) pair where i >= 1. "

        def compute_mu_k(k):
            " Given i, compute marginal utility u'(σ(R s_i + y(z_k), z_k)) "
            next_a = R * s[i] + y(z_grid[k])
            # Interpolate to get σ(R * s_i + y(z_k), z_k)
            next_c = jnp.interp(next_a, a_in[:, k], c_in[:, k])
            # Return u'(σ(R * s_i + y(z_k), z_k))
            return u_prime(next_c)

        # Compute marginal utility u'(σ(R * s_i + y(z_k), z_k)) for all k
        mu_values = jax.vmap(compute_mu_k)(z_indices)
        # Compute expectation Σ_k u'(σ(...)) * Π[j, k]
        expectation = jnp.sum(mu_values * Π[j, :])
        # Invert to get consumption c_{ij} at (s_i, z_j)
        return u_prime_inv(β * R * expectation)
```

(continues on next page)

(continued from previous page)

```
    # vmap over j for each i
    compute_c_i = jax.vmap(compute_c, in_axes=(None, 0))
    # vmap over i
    compute_c = jax.vmap(lambda i: compute_c_i(i, z_indices))
    # Compute consumption for i >= 1
    c_out_interior = compute_c(jnp.arange(1, len(s)))
    # For i = 0, set consumption to 0
    c_out_boundary = jnp.zeros((1, n_z))
    # Concatenate boundary and interior
    c_out = jnp.concatenate([c_out_boundary, c_out_interior], axis=0)
    # Compute endogenous asset grid a_{ij} = c_{ij} + s_i
    a_out = c_out + s[:, None]
    return c_out, a_out
```

Here's a jit-accelerated iterative routine to solve the model using this operator.

```
@jax.jit
def solve_model(
        ifp: IFP,
        c_init: jnp.ndarray,  # Initial guess of σ on grid endogenous grid
        a_init: jnp.ndarray,  # Initial endogenous grid
        tol: float = 1e-5,
        max_iter: int = 1000
    ) -> jnp.ndarray:
    """
    Solve the model using time iteration with EGM.

    """

    def condition(loop_state):
        c_in, a_in, i, error = loop_state
        return (error > tol) & (i < max_iter)

    def body(loop_state):
        c_in, a_in, i, error = loop_state
        c_out, a_out = K(c_in, a_in, ifp)
        error = jnp.max(jnp.abs(c_out - c_in))
        i += 1
        return c_out, a_out, i, error

    i, error = 0, tol + 1
    initial_state = (c_init, a_init, i, error)
    final_loop_state = jax.lax.while_loop(condition, body, initial_state)
    c_out, a_out, i, error = final_loop_state

    return c_out, a_out
```

75.5.3 Test run

Let's road test the EGM code.

```
ifp = create_ifp()
R, β, γ, Π, z_grid, s = ifp
# Set initial conditions where the agent consumes everything
a_init = s[:, None] * jnp.ones(len(z_grid))
c_init = a_init
# Solve starting from these initial conditions
c_vec_jax, a_vec_jax = solve_model(ifp, c_init, a_init)
```

To verify the correctness of our JAX implementation, let's compare it with the NumPy version we developed earlier.

```
# Compare the results
max_c_diff = np.max(np.abs(np.array(c_vec) - c_vec_jax))
max_ae_diff = np.max(np.abs(np.array(a_vec) - a_vec_jax))

print(f"Maximum difference in consumption policy: {max_c_diff:.2e}")
print(f"Maximum difference in asset grid:        {max_ae_diff:.2e}")
```

```
Maximum difference in consumption policy: 4.45e-01
Maximum difference in asset grid:        4.45e-01
```

These numbers confirm that we are computing essentially the same policy using the two approaches.

75.5.4 Timing

Now let's compare the execution time between NumPy and JAX implementations.

```
import time

# Set up initial conditions for NumPy version
s_np = np.array(s)
z_grid_np = np.array(z_grid)
a_init_np = s_np[:, None] * np.ones(len(z_grid_np))
c_init_np = a_init_np.copy()

# Set up initial conditions for JAX version
a_init_jx = s[:, None] * jnp.ones(len(z_grid))
c_init_jx = a_init_jx

# Time NumPy version
start = time.time()
c_vec_np, a_vec_np = solve_model_numpy(ifp_numpy, c_init_np, a_init_np)
numpy_time = time.time() - start

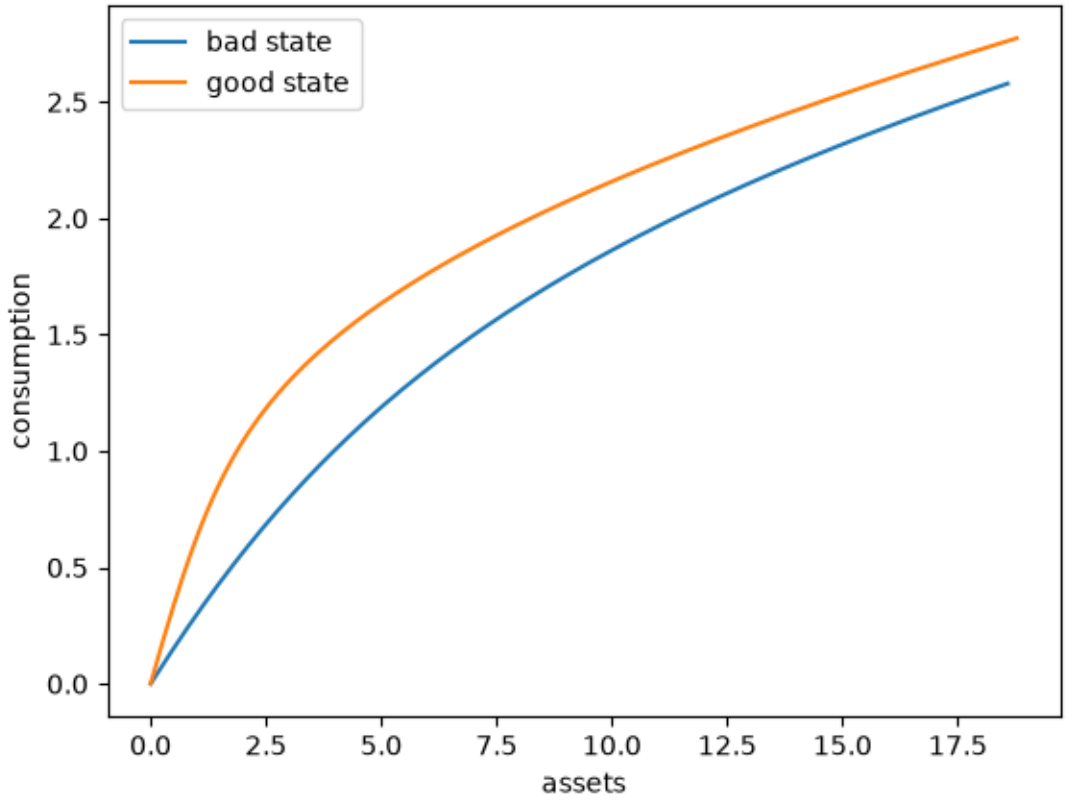
# Time JAX version (with compilation)
start = time.time()
c_vec_jx, a_vec_jx = solve_model(ifp, c_init_jx, a_init_jx)
c_vec_jx.block_until_ready()
jax_time_with_compile = time.time() - start

# Time JAX version (without compilation - second run)
start = time.time()
c_vec_jx, a_vec_jx = solve_model(ifp, c_init_jx, a_init_jx)
```

(continues on next page)

(continued from previous page)

```
c_vec_jx.block_until_ready()
jax_time = time.time() - start



print(f"NumPy time:                 {numpy_time:.4f} seconds")
print(f"JAX time (with compile):    {jax_time_with_compile:.4f} seconds")
print(f"JAX time (without compile): {jax_time:.4f} seconds")
print(f"Speedup (NumPy/JAX):        {numpy_time/jax_time:.2f}x")
```

```
NumPy time:                 0.0206 seconds
JAX time (with compile):    0.0103 seconds
JAX time (without compile): 0.0101 seconds
Speedup (NumPy/JAX):        2.04x
```

The JAX implementation is faster due to JIT compilation and GPU/TPU acceleration (if available).

Here's a plot of the optimal policy for each z state

```
fig, ax = plt.subplots()
ax.plot(a_vec[:, 0], c_vec[:, 0], label='bad state')
ax.plot(a_vec[:, 1], c_vec[:, 1], label='good state')
ax.set(xlabel='assets', ylabel='consumption')
ax.legend()
plt.show()
```

75.5.5 Dynamics

To begin to understand the long run asset levels held by households under the default parameters, let's look at the 45 degree diagram showing the law of motion for assets under the optimal consumption policy.

```
fig, ax = plt.subplots()

y = lambda z: jnp.exp(z)

def y_bar(k):
    """
    Taking z = z_grid[k], compute

            E_z Y' = Σ_{z'} y(z') Π[z, z']

    This is the expectation of Y_{t+1} given Z_t = z.
    """
    # Compute y(z') for all z'
    y_values = jax.vmap(y)(z_grid)
    # Weight by transition probabilities and sum
    return jnp.sum(y_values * Π[k, :])

for k, label in zip((0, 1), ('low income', 'high income')):
    # Interpolate consumption policy on the savings grid
    c_on_grid = jnp.interp(s, a_vec[:, k], c_vec[:, k])
    ax.plot(s, R * (s - c_on_grid) + y_bar(k) , label=label)

ax.plot(s, s, 'k--')
ax.set(xlabel='current assets', ylabel='next period assets')

ax.legend()
plt.show()
```

The unbroken lines show the update function for assets at each z, which is

$$a \mapsto R(a - \sigma^*(a, z)) + \bar{y}(z)$$

where

$$\bar{y}(z) := \sum_{z'} y(z')\Pi(z, z')$$

is the expected labor income conditional on current state z.

The dashed line is the 45 degree line.

The figure suggests that, on average, the dynamics will be stable — assets do not diverge even in the highest state.

This turns out to be true: there is a unique stationary distribution of assets.

- For details see [Ma *et al.*, 2020]

This stationary distribution represents the long run dispersion of assets across households when households have idiosyncratic shocks.

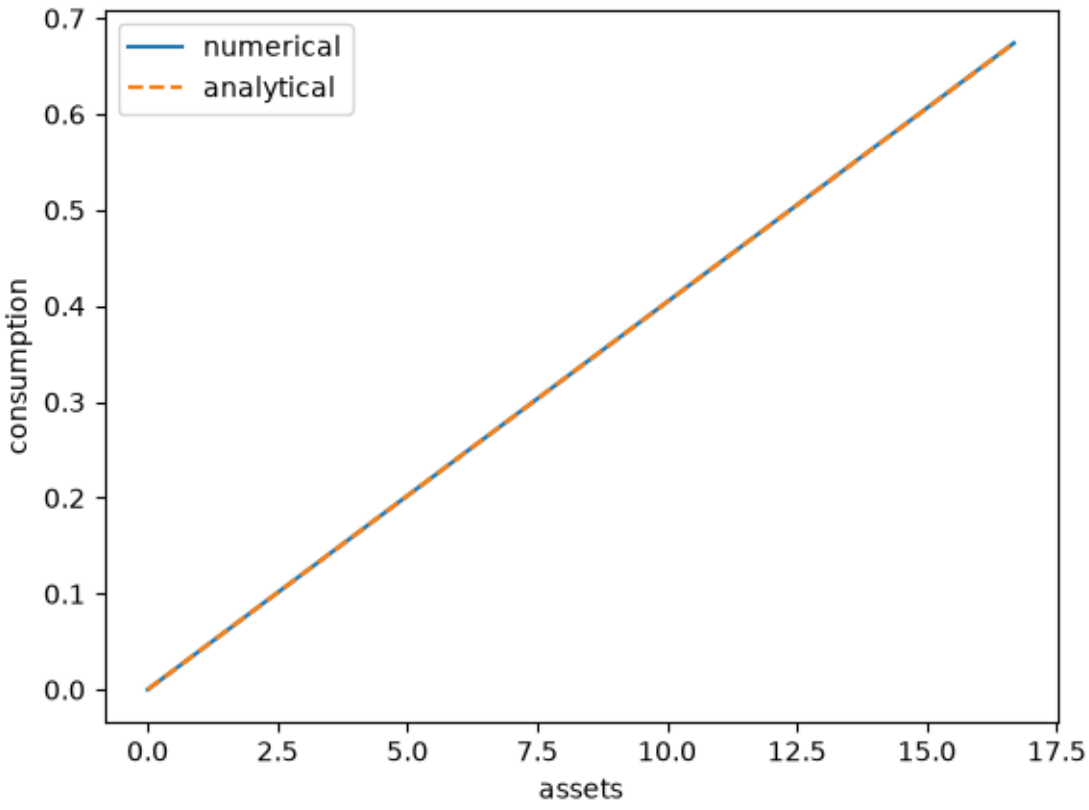
75.5.6 A Sanity Check

One way to check our results is to

- set labor income to zero in each state and
- set the gross interest rate R to unity.

In this case, our income fluctuation problem is just a CRRA cake eating problem.

Then the value function and optimal consumption policy are given by



```
def c_star(x, β, γ):
    return (1 - β ** (1/γ)) * x

def v_star(x, β, γ):
    return (1 - β**(1 / γ))**(-γ) * (x**(1-γ) / (1-γ))
```

Let's see if we match up:

```
ifp_cake_eating = create_ifp(r=0.0, z_grid=(-jnp.inf, -jnp.inf))
R, β, γ, Π, z_grid, s = ifp_cake_eating
a_init = s[:, None] * jnp.ones(len(z_grid))
c_init = a_init
c_vec, a_vec = solve_model(ifp_cake_eating, c_init, a_init)

fig, ax = plt.subplots()
ax.plot(a_vec[:, 0], c_vec[:, 0], label='numerical')
ax.plot(a_vec[:, 0],
        c_star(a_vec[:, 0], ifp_cake_eating.β, ifp_cake_eating.γ),
        '--', label='analytical')
ax.set(xlabel='assets', ylabel='consumption')
ax.legend()
plt.show()
```

This looks pretty good.

75.6 Simulation

Let's return to the default model and study the stationary distribution of assets.

Our plan is to run a large number of households forward for T periods and then histogram the cross-sectional distribution of assets.

Set `num_households=50_000, T=500`.

First we write a function to run a single household forward in time and record the final value of assets.

The function takes a solution pair `c_vec` and `a_vec`, understanding them as representing an optimal policy associated with a given model `ifp`

```
@jax.jit
def simulate_household(
        key, a_0, z_idx_0, c_vec, a_vec, ifp, T
    ):
    """
    Simulates a single household for T periods to approximate the stationary
    distribution of assets.

    - key is the state of the random number generator
    - ifp is an instance of IFP
    - c_vec, a_vec are the optimal consumption policy, endogenous grid for ifp
```

(continues on next page)

(continued from previous page)

```
    """
    R, β, γ, Π, z_grid, s = ifp
    n_z = len(z_grid)

    y = lambda z: jnp.exp(z)
    σ = lambda a, z_idx: jnp.interp(a, a_vec[:, z_idx], c_vec[:, z_idx])

    # Simulate forward T periods
    def update(t, state):
        a, z_idx = state
        # Draw next shock z' from Π[z, z']
        current_key = jax.random.fold_in(key, t)
        z_next_idx = jax.random.choice(current_key, n_z, p=Π[z_idx]).astype(jnp.int32)
        z_next = z_grid[z_next_idx]
        # Update assets: a' = R * (a - c) + Y'
        a_next = R * (a - σ(a, z_idx)) + y(z_next)
        # Return updated state
        return a_next, z_next_idx

    initial_state = a_0, z_idx_0
    final_state = jax.lax.fori_loop(0, T, update, initial_state)
    a_final, _ = final_state
    return a_final
```

Now we write a function to simulate many households in parallel.

```
def compute_asset_stationary(
        c_vec, a_vec, ifp, num_households=50_000, T=500, seed=1234
    ):
    """
    Simulates num_households households for T periods to approximate
    the stationary distribution of assets.

    Returns the final cross-section of asset holdings.

    - ifp is an instance of IFP
    - c_vec, a_vec are the optimal consumption policy and endogenous grid.

    """
    R, β, γ, Π, z_grid, s = ifp
    n_z = len(z_grid)

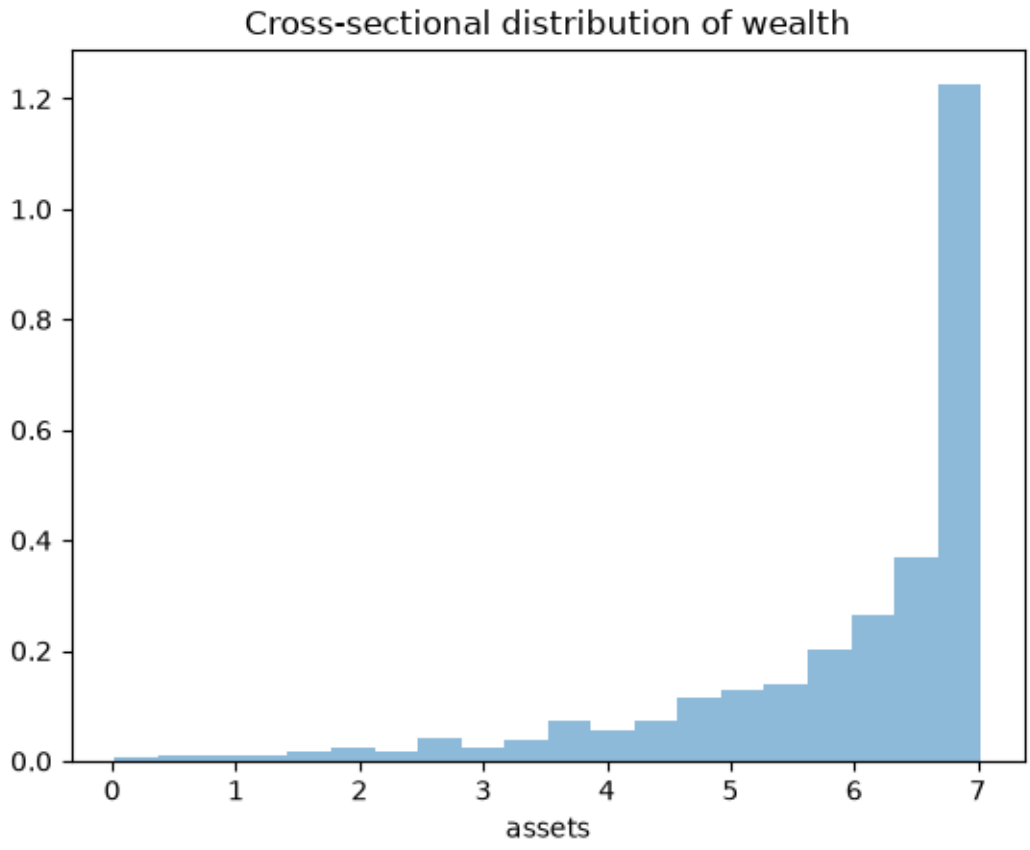
    # Create interpolation function for consumption policy
    # Interpolate on the endogenous grid
    σ = lambda a, z_idx: jnp.interp(a, a_vec[:, z_idx], c_vec[:, z_idx])

    # Start with assets = savings_grid_max / 2
    a_0_vector = jnp.full(num_households, s[-1] / 2)
    # Initialize the exogenous state of each household
    z_idx_0_vector = jnp.zeros(num_households).astype(jnp.int32)

    # Vectorize over many households
    key = jax.random.key(seed)
    keys = jax.random.split(key, num_households)
    # Vectorize simulate_household in (key, a_0, z_idx_0)
    sim_all_households = jax.vmap(
        simulate_household, in_axes=(0, 0, 0, None, None, None, None)
```

(continues on next page)

(continued from previous page)



```
    )
    assets = sim_all_households(keys, a_0_vector, z_idx_0_vector, c_vec, a_vec, ifp,␣
↪T)

    return np.array(assets)
```

Now we call the function, generate the asset distribution and histogram it:

```
ifp = create_ifp()
R, β, γ, Π, z_grid, s = ifp
a_init = s[:, None] * jnp.ones(len(z_grid))
c_init = a_init
c_vec, a_vec = solve_model(ifp, c_init, a_init)
assets = compute_asset_stationary(c_vec, a_vec, ifp)

fig, ax = plt.subplots()
ax.hist(assets, bins=20, alpha=0.5, density=True)
ax.set(xlabel='assets', title="Cross-sectional distribution of wealth")
plt.show()
```

The wealth distribution looks very different to a typical wealth distribution in the data.

For one thing it is left-skewed rather than right-skewed.

In fact there is essentially no right-hand tail, even though real-world wealth distributions have long right-hand tails.

We'll do our best to fix these issues in the next few lectures.

CHAPTER

SEVENTYSIX

THE INCOME FLUCTUATION PROBLEM IV: TRANSIENT INCOME SHOCKS

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

76.1 Overview

In this lecture we continue extend the IFP from *The Income Fluctuation Problem III: The Endogenous Grid Method* by adding transient shocks to the income process.

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon jax
```

We'll also need the following imports:

```
import matplotlib.pyplot as plt
import numpy as np
import numba
from quantecon import MarkovChain
import jax
import jax.numpy as jnp
from typing import NamedTuple
```

76.2 The Household Problem

We briefly outline the model and then discuss how to solve it.

Readers seeking a more extensive discussion of the model and the EGM solution method can review *The Income Fluctuation Problem III: The Endogenous Grid Method*.

76.2.1 Set-Up

A household chooses a state-contingent consumption plan $\{c_t\}_{t \geq 0}$ to maximize

$$\mathbb{E} \sum_{t=0}^{\infty} \beta^t u(c_t)$$

subject to

$$a_{t+1} = R(a_t - c_t) + Y_{t+1} \quad c_t \geq 0, \quad a_t \geq 0 \quad t = 0, 1, \ldots \tag{76.1}$$

The definitions of symbols and the timing are the same as in *The Income Fluctuation Problem III: The Endogenous Grid Method*.

Now, non-capital income Y_t is given by $Y_t = y(Z_t, \eta_t)$, where

- $\{Z_t\}$ is an exogenous state process (persistent component),
- $\{\eta_t\}$ is an IID shock process, and
- y is a function taking values in $\mathbb{R}_+$.

Throughout this lecture, we assume that $\eta_t \sim N(0, 1)$.

We again take $\{Z_t\}$ to be a finite state Markov chain taking values in Z with Markov matrix Π.

The shock process $\{\eta_t\}$ is independent of $\{Z_t\}$ and represents transient income fluctuations.

In addition to previous assumptions, we suppose that $y(z, \eta) = \exp(a_y \eta + z b_y)$ where a_y, b_y are positive constants

The asset space and state space are unchanged, as is the definition of an optimal path.

The functional Euler equation has the form

$$(u' \circ \sigma)(a, z) = \beta R \sum_{z'} \int (u' \circ \sigma)[R(a - \sigma(a, z)) + y(z', \eta'),\, z'] \phi(\eta') d\eta' \, \Pi(z, z') \tag{76.2}$$

Here

- $(u' \circ \sigma)(s) := u'(\sigma(s))$,
- primes indicate next period states (as well as derivatives),
- ϕ is the density of the shock η_t (standard normal), and

- σ is the unknown function.

The equality (76.2) holds at all interior choices, meaning $\sigma(a, z) < a$.

We aim to find a fixed point σ of (76.2).

To do so we use the EGM.

Below we use the relationships $a_t = c_t + s_t$ and $a_{t+1} = Rs_t + Y_{t+1}$.

We begin with an exogenous savings grid $s_0 < s_1 < \cdots < s_m$ with $s_0 = 0$.

We fix a current guess of the policy function σ.

For each exogenous savings level s_i with $i \geq 1$ and current state z_j, we set

$$c_{ij} := (u')^{-1} \left[\beta R \sum_{z'} \int u'[\sigma(Rs_i + y(z', \eta'), z')] \phi(\eta') d\eta' \, \Pi(z_j, z') \right] \tag{76.3}$$

The Euler equation holds here because $i \geq 1$ implies $s_i > 0$ and hence consumption is interior.

For the boundary case $s_0 = 0$ we set

$$c_{0j} := 0 \quad \text{for all j}$$

We then obtain a corresponding endogenous grid of current assets via

$$a_{ij} := c_{ij} + s_i.$$

Our next guess of the policy function, which we write as $K\sigma$, is the linear interpolation of the interpolation points

$$\{(a_{0j}, c_{0j}), \ldots, (a_{mj}, c_{mj})\}$$

for each j.

76.3 NumPy Implementation

In this section we'll code up a NumPy version of the code that aims only for clarity, rather than efficiency.

Once we have it working, we'll produce a JAX version that's far more efficient and check that we obtain the same results.

We use the CRRA utility specification

$$u(c) = \frac{c^{1-\gamma}}{1-\gamma}$$

76.3.1 Set Up

Here we build a class called `IFPNumPy` that stores the model primitives.

The exogenous state process $\{Z_t\}$ defaults to a two-state Markov chain with transition matrix Π.

```
class IFPNumPy(NamedTuple):
    R: float                  # Gross interest rate R = 1 + r
    β: float                  # Discount factor
    γ: float                  # Preference parameter
    Π: np.ndarray             # Markov matrix for exogenous shock
```

(continues on next page)

(continued from previous page)

```
    z_grid: np.ndarray        # Markov state values for Z_t
    s: np.ndarray             # Exogenous savings grid
    a_y: float                # Scale parameter for Y_t
    b_y: float                # Additive parameter for Y_t
    η_draws: np.ndarray       # Draws of innovation η for MC

def create_ifp(r=0.01,
               β=0.96,
               γ=1.5,
               Π=((0.6, 0.4),
                  (0.05, 0.95)),
               z_grid=(-10.0, np.log(2.0)),
               savings_grid_max=16,
               savings_grid_size=50,
               a_y=0.2,
               b_y=0.5,
               shock_draw_size=100,
               seed=1234):

    np.random.seed(seed)
    s = np.linspace(0, savings_grid_max, savings_grid_size)
    Π, z_grid = np.array(Π), np.array(z_grid)
    R = 1 + r
    η_draws = np.random.randn(shock_draw_size)
    assert R * β < 1, "Stability condition violated."
    return IFPNumPy(R, β, γ, Π, z_grid, s, a_y, b_y, η_draws)
```

76.3.2 Solver

Here is the operator K that transforms current guess σ into next period guess $K\sigma$.

In practice, it takes in

- a guess of optimal consumption values c_{ij}, stored as `c_vec`
- and a corresponding set of endogenous grid points a^e_{ij}, stored as `a_vec`

These are converted into a consumption policy $a \mapsto \sigma(a, z_j)$ by linear interpolation of (a^e_{ij}, c_{ij}) over i for each j.

When we compute consumption in (76.3), we will use Monte Carlo over η', so that the expression becomes

$$c_{ij} := (u')^{-1} \left[\beta R \sum_{z'} \frac{1}{m} \sum_{\ell=1}^{m} u'[\sigma(Rs_i + y(z', \eta_\ell), z')] \, \Pi(z_j, z') \right] \tag{76.4}$$

with each η_ℓ being a standard normal draw.

```
@numba.jit
def K_numpy(
        c_in: np.ndarray,    # Initial guess of σ on grid endogenous grid
        a_in: np.ndarray,    # Initial endogenous grid
        ifp_numpy: IFPNumPy
    ) -> np.ndarray:
    """
    The Euler equation operator for the IFP model using the
    Endogenous Grid Method.
```

(continues on next page)

(continued from previous page)

```
    This operator implements one iteration of the EGM algorithm to
    update the consumption policy function.

    """
    R, β, γ, Π, z_grid, s, a_y, b_y, η_draws = ifp_numpy
    n_a = len(s)
    n_z = len(z_grid)

    # Utility functions
    def u_prime(c):
        return c**(-γ)

    def u_prime_inv(c):
        return c**(-1/γ)

    def y(z, η):
        return np.exp(a_y * η + z * b_y)

    c_out = np.zeros_like(c_in)

    for i in range(1, n_a):  # Start from 1 for positive savings levels
        for j in range(n_z):

            # Compute Σ_z' ∫ u'(σ(R s_i + y(z', η'), z')) ψ(η') dη' Π[z_j, z']
            expectation = 0.0
            for k in range(n_z):
                z_prime = z_grid[k]
                # Integrate over η draws (Monte Carlo)
                inner_sum = 0.0
                for η in η_draws:
                    # Calculate next period assets
                    next_a = R * s[i] + y(z_prime, η)
                    # Interpolate to get σ(R s_i + y(z', η), z')
                    next_c = np.interp(next_a, a_in[:, k], c_in[:, k])
                    # Add to the inner sum
                    inner_sum += u_prime(next_c)
                # Average over η draws to approximate the integral
                # ∫ u'(σ(R s_i + y(z', η'), z')) ψ(η') dη' when z' = z_grid[k]
                inner_mean_k = (inner_sum / len(η_draws))
                # Weight by transition probability and add to the expectation
                expectation += inner_mean_k * Π[j, k]

            # Calculate updated c_{ij} values
            c_out[i, j] = u_prime_inv(β * R * expectation)

    a_out = c_out + s[:, None]

    return c_out, a_out
```

To solve the model we use a simple while loop.

```
def solve_model_numpy(
        ifp_numpy: IFPNumPy,
        c_init: np.ndarray,
        a_init: np.ndarray,
        tol: float = 1e-5,
```

(continues on next page)

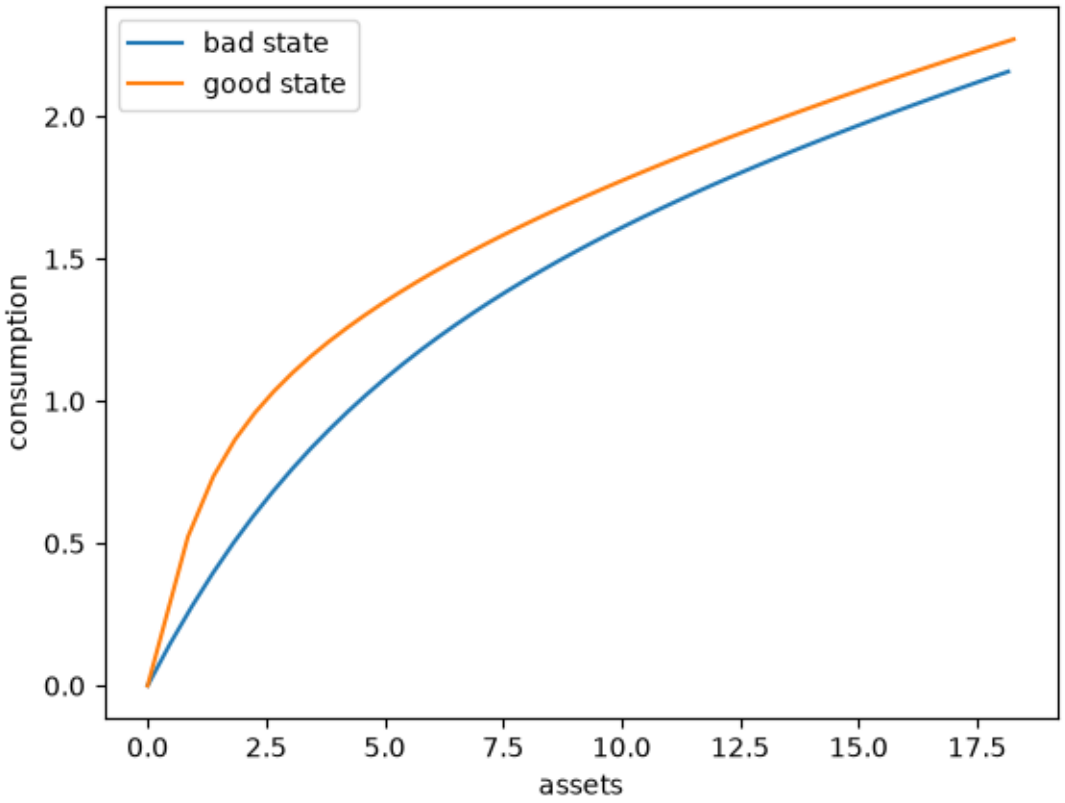
(continued from previous page)

```
        max_iter: int = 1_000
    ) -> np.ndarray:
    """
    Solve the model using time iteration with EGM.

    """
    c_in, a_in = c_init, a_init
    i = 0
    error = tol + 1

    while error > tol and i < max_iter:
        c_out, a_out = K_numpy(c_in, a_in, ifp_numpy)
        error = np.max(np.abs(c_out - c_in))
        i = i + 1
        c_in, a_in = c_out, a_out

    return c_out, a_out
```



Let's road test the EGM code.

```
ifp_numpy = create_ifp()
R, β, γ, Π, z_grid, s, a_y, b_y, η_draws = ifp_numpy
# Initial conditions -- agent consumes everything
a_init = s[:, None] * np.ones(len(z_grid))
c_init = a_init
# Solve from these initial conditions
c_vec, a_vec = solve_model_numpy(
    ifp_numpy, c_init, a_init
)
```

Here's a plot of the optimal consumption policy for each z state

```
fig, ax = plt.subplots()

ax.plot(a_vec[:, 0], c_vec[:, 0], label='bad state')
ax.plot(a_vec[:, 1], c_vec[:, 1], label='good state')
ax.set(xlabel='assets', ylabel='consumption')
ax.legend()
plt.show()
```

76.4 JAX Implementation

Now we write a more efficient JAX version, which can run on a GPU.

76.4.1 Set Up

We start with a class called `IFP` that stores the model primitives.

```
class IFP(NamedTuple):
    R: float                    # Gross interest rate R = 1 + r
    β: float                    # Discount factor
    γ: float                    # Preference parameter
    Π: jnp.ndarray              # Markov matrix for exogenous shock
    z_grid: jnp.ndarray         # Markov state values for Z_t
    s: jnp.ndarray              # Exogenous savings grid
    a_y: float                  # Scale parameter for Y_t
    b_y: float                  # Additive parameter for Y_t
    η_draws: jnp.ndarray        # Draws of innovation η for MC

def create_ifp(r=0.01,
               β=0.94,
               γ=1.5,
               Π=((0.6, 0.4),
                  (0.05, 0.95)),
```

(continues on next page)

(continued from previous page)

```
                z_grid=(-10.0, jnp.log(2.0)),
                savings_grid_max=16,
                savings_grid_size=50,
                a_y=0.2,
                b_y=0.5,
                shock_draw_size=100,
                seed=1234):

    key = jax.random.key(seed)
    s = jnp.linspace(0, savings_grid_max, savings_grid_size)
    Π, z_grid = jnp.array(Π), jnp.array(z_grid)
    R = 1 + r
    η_draws = jax.random.normal(key, (shock_draw_size,))
    assert R * β < 1, "Stability condition violated."
    return IFP(R, β, γ, Π, z_grid, s, a_y, b_y, η_draws)
```

76.4.2 Solver

Here is the operator K that transforms current guess σ into next period guess $K\sigma$.

```
def K(
        c_in: jnp.ndarray,
        a_in: jnp.ndarray,
        ifp: IFP
    ) -> jnp.ndarray:
    """
    The Euler equation operator for the IFP model using the
    Endogenous Grid Method.

    This operator implements one iteration of the EGM algorithm to
    update the consumption policy function.

    """
    R, β, γ, Π, z_grid, s, a_y, b_y, η_draws = ifp
    n_a = len(s)
    n_z = len(z_grid)

    # Utility functions
    def u_prime(c):
        return c**(-γ)

    def u_prime_inv(c):
        return c**(-1/γ)

    def y(z, η):
        return jnp.exp(a_y * η + z * b_y)

    def compute_c(i, j):
        " Compute c_ij when i >= 1 (interior choice). "

        def expected_mu(k):
            " Approximate ∫ u'(σ(R s_i + y(z_k, η'), z_k)) ψ(η') dη' "

            def compute_mu_at_eta(η):
                " Compute u'(σ(R * s_i + y(z_k, η), z_k)) "
```

(continues on next page)

(continued from previous page)

```
                next_a = R * s[i] + y(z_grid[k], η)
                # Interpolate to get σ(R * s_i + y(z_k, η), z_k)
                next_c = jnp.interp(next_a, a_in[:, k], c_in[:, k])
                # Return u'(σ(R * s_i + y(z_k, η), z_k))
                return u_prime(next_c)

            # Average over η draws to approximate the inner integral
            # ∫ u'(σ(R s_i + y(z_k, η'), z_k)) φ(η') dη'
            all_draws = jax.vmap(compute_mu_at_eta)(η_draws)
            return jnp.mean(all_draws)

        # Compute expectation: Σ_k [∫ u'(σ(...)) φ(η) dη] * Π[j, k]
        expectations = jax.vmap(expected_mu)(jnp.arange(n_z))
        expectation = jnp.sum(expectations * Π[j, :])
        # Invert to get consumption c_ij at (s_i, z_j)
        return u_prime_inv(β * R * expectation)

    # Set up index grids for vmap computation of all c_{ij}
    i_grid = jnp.arange(1, n_a)
    j_grid = jnp.arange(n_z)

    # vmap over j for each i
    compute_c_i = jax.vmap(compute_c, in_axes=(None, 0))
    # vmap over i
    compute_c = jax.vmap(lambda i: compute_c_i(i, j_grid))
    # Compute consumption for i >= 1
    c_out_interior = compute_c(i_grid)  # Shape: (n_a-1, n_z)
    # For i = 0, set consumption to 0
    c_out_boundary = jnp.zeros((1, n_z))

    # Concatenate boundary and interior
    c_out = jnp.concatenate([c_out_boundary, c_out_interior], axis=0)

    # Compute endogenous asset grid: a^e_{ij} = c_{ij} + s_i
    a_out = c_out + s[:, None]

    return c_out, a_out
```

Here's a jit-accelerated iterative routine to solve the model using this operator.

```
@jax.jit
def solve_model(
        ifp: IFP,
        c_init: jnp.ndarray,  # Initial guess of σ on grid endogenous grid
        a_init: jnp.ndarray,  # Initial endogenous grid
        tol: float = 1e-5,
        max_iter: int = 1000
    ) -> jnp.ndarray:
    """
    Solve the model using time iteration with EGM.

    """

    def condition(loop_state):
        c_in, a_in, i, error = loop_state
        return (error > tol) & (i < max_iter)
```

(continues on next page)

(continued from previous page)

```
    def body(loop_state):
        c_in, a_in, i, error = loop_state
        c_out, a_out = K(c_in, a_in, ifp)
        error = jnp.max(jnp.abs(c_out - c_in))
        i += 1
        return c_out, a_out, i, error

    i, error = 0, tol + 1
    initial_state = (c_init, a_init, i, error)
    final_loop_state = jax.lax.while_loop(condition, body, initial_state)
    c_out, a_out, i, error = final_loop_state

    return c_out, a_out
```

76.4.3 Test run

Let's road test the EGM code.

```
ifp = create_ifp()
R, β, γ, Π, z_grid, s, a_y, b_y, η_draws = ifp
# Set initial conditions where the agent consumes everything
a_init = s[:, None] * jnp.ones(len(z_grid))
c_init = a_init
# Solve starting from these initial conditions
c_vec_jax, a_vec_jax = solve_model(ifp, c_init, a_init)
```

To verify the correctness of our JAX implementation, let's compare it with the NumPy version we developed earlier.

```
# Compare the results
max_c_diff = np.max(np.abs(np.array(c_vec) - c_vec_jax))
max_ae_diff = np.max(np.abs(np.array(a_vec) - a_vec_jax))

print(f"Maximum difference in consumption policy: {max_c_diff:.2e}")
print(f"Maximum difference in asset grid:        {max_ae_diff:.2e}")
```

```
Maximum difference in consumption policy: 3.94e-01
Maximum difference in asset grid:        3.94e-01
```

These numbers confirm that we are computing essentially the same policy using the two approaches.

(Remaining differences are mainly due to different Monte Carlo integration outcomes over relatively small samples.)

76.4.4 Timing

Now let's compare the execution time between NumPy and JAX implementations.

```
import time

# Set up initial conditions for NumPy version
s_np = np.array(s)
z_grid_np = np.array(z_grid)
a_init_np = s_np[:, None] * np.ones(len(z_grid_np))
c_init_np = a_init_np.copy()
```

(continues on next page)

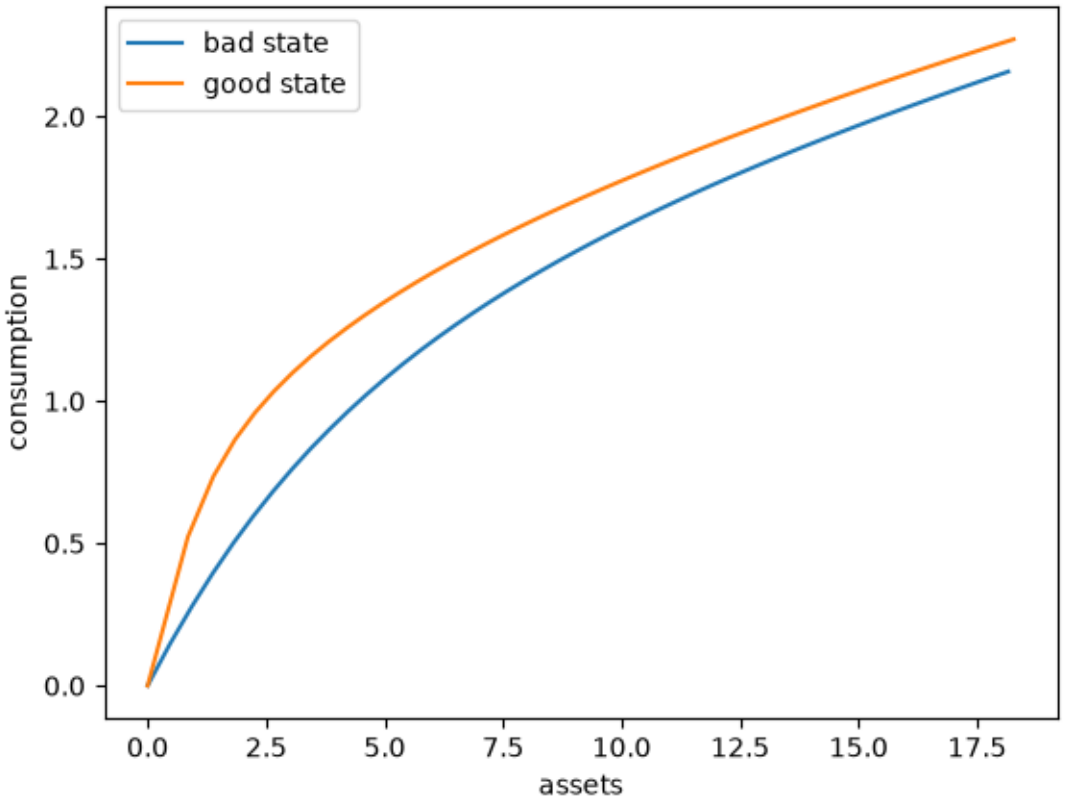
(continued from previous page)

```
# Set up initial conditions for JAX version
a_init_jx = s[:, None] * jnp.ones(len(z_grid))
c_init_jx = a_init_jx

# Time NumPy version
start = time.time()
c_vec_np, a_vec_np = solve_model_numpy(ifp_numpy, c_init_np, a_init_np)
numpy_time = time.time() - start

# Time JAX version (with compilation)
start = time.time()
c_vec_jx, a_vec_jx = solve_model(ifp, c_init_jx, a_init_jx)
c_vec_jx.block_until_ready()
jax_time_with_compile = time.time() - start

# Time JAX version (without compilation - second run)
start = time.time()
c_vec_jx, a_vec_jx = solve_model(ifp, c_init_jx, a_init_jx)
c_vec_jx.block_until_ready()
jax_time = time.time() - start



print(f"NumPy time:                 {numpy_time:.4f} seconds")
print(f"JAX time (with compile):    {jax_time_with_compile:.4f} seconds")
print(f"JAX time (without compile): {jax_time:.4f} seconds")
print(f"Speedup (NumPy/JAX):        {numpy_time/jax_time:.2f}x")
```

```
NumPy time:                 0.3796 seconds
JAX time (with compile):    0.0094 seconds
JAX time (without compile): 0.0092 seconds
Speedup (NumPy/JAX):        41.17x
```

The JAX implementation is significantly faster due to JIT compilation and GPU/TPU acceleration (if available).

Here's a plot of the optimal policy for each z state

```
fig, ax = plt.subplots()
ax.plot(a_vec[:, 0], c_vec[:, 0], label='bad state')
ax.plot(a_vec[:, 1], c_vec[:, 1], label='good state')
ax.set(xlabel='assets', ylabel='consumption')
ax.legend()
plt.show()
```

76.4.5 Dynamics

To begin to understand the long run asset levels held by households under the default parameters, let's look at the 45 degree diagram showing the law of motion for assets under the optimal consumption policy.

```
fig, ax = plt.subplots()

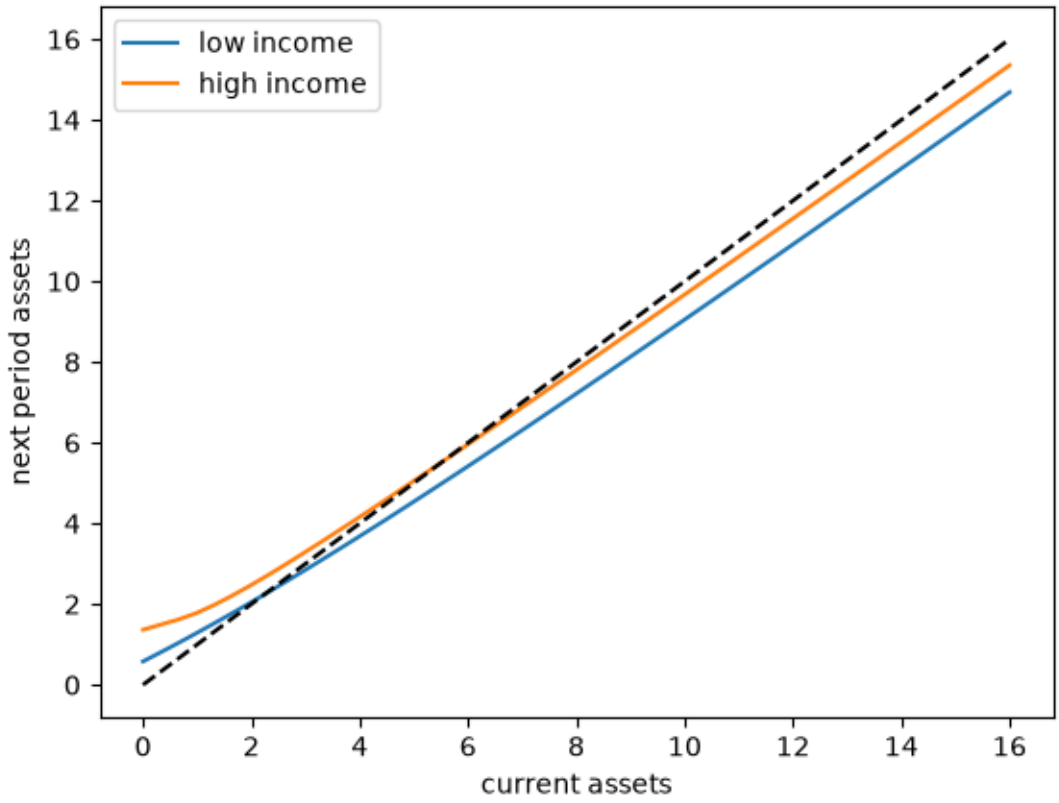
def y(z, η):
    return jnp.exp(a_y * η + z * b_y)

def y_bar(k):
    """
    Taking z = z_grid[k], compute an approximation to

            E_z Y' = Σ_{z'} ∫ y(z', η') ψ(η') dη' Π[z, z']

    This is the expectation of Y_{t+1} given Z_t = z.
    """
    # Approximate ∫ y(z', η') ψ(η') dη' at given z'
    def mean_y_at_z(z_prime):
        return jnp.mean(y(z_prime, η_draws))
    # Evaluate this integral across all z'
    y_means = jax.vmap(mean_y_at_z)(z_grid)
    # Weight by transition probabilities and sum
    return jnp.sum(y_means * Π[k, :])

for k, label in zip((0, 1), ('low income', 'high income')):
```



(continues on next page)

(continued from previous page)

```
    # Interpolate consumption policy on the savings grid
    c_on_grid = jnp.interp(s, a_vec[:, k], c_vec[:, k])
    ax.plot(s, R * (s - c_on_grid) + y_bar(k) , label=label)

ax.plot(s, s, 'k--')
ax.set(xlabel='current assets', ylabel='next period assets')

ax.legend()
plt.show()
```

The unbroken lines show the update function for assets at each z, which is

$$a \mapsto R(a - \sigma^*(a, z)) + \bar{y}(z)$$

where

$$\bar{y}(z) := \sum_{z'} \frac{1}{m} \sum_{\ell=1}^{m} y(z', \eta_\ell) \Pi(z, z')$$

is a Monte Carlo approximation to expected labor income conditional on current state z.

The dashed line is the 45 degree line.

The figure suggests that, on average, the dynamics will be stable — assets do not diverge even in the highest state.

This turns out to be true: there is a unique stationary distribution of assets.

- For details see [Ma *et al.*, 2020]

This stationary distribution represents the long run dispersion of assets across households when households have idiosyncratic shocks.

76.5 Simulation

Let's return to the default model and study the stationary distribution of assets.

Our plan is to run a large number of households forward for T periods and then histogram the cross-sectional distribution of assets.

Set `num_households=50_000, T=500`.

First we write a function to run a single household forward in time and record the final value of assets.

The function takes a solution pair `c_vec` and `a_vec`, understanding them as representing an optimal policy associated with a given model `ifp`

```
@jax.jit
def simulate_household(
        key, a_0, z_idx_0, c_vec, a_vec, ifp, T
    ):
    """
    Simulates a single household for T periods to approximate the stationary
    distribution of assets.

    - key is the state of the random number generator
    - ifp is an instance of IFP
    - c_vec, a_vec are the optimal consumption policy, endogenous grid for ifp

    """
    R, β, γ, Π, z_grid, s, a_y, b_y, η_draws = ifp
    n_z = len(z_grid)

    def y(z, η):
        return jnp.exp(a_y * η + z * b_y)

    # Create interpolation function for consumption policy
    σ = lambda a, z_idx: jnp.interp(a, a_vec[:, z_idx], c_vec[:, z_idx])

    # Simulate forward T periods
    def update(t, state):
        a, z_idx = state
        # Draw next shock z' from Π[z, z']
        current_key = jax.random.fold_in(key, 2*t)
        z_next_idx = jax.random.choice(current_key, n_z, p=Π[z_idx]).astype(jnp.int32)
        z_next = z_grid[z_next_idx]
        # Draw η shock
        η_key = jax.random.fold_in(key, 2*t + 1)
        η = jax.random.normal(η_key)
        # Update assets: a' = R * (a - c) + Y'
        a_next = R * (a - σ(a, z_idx)) + y(z_next, η)
        # Return updated state
        return a_next, z_next_idx

    initial_state = a_0, z_idx_0
    final_state = jax.lax.fori_loop(0, T, update, initial_state)
    a_final, _ = final_state
    return a_final
```

Now we write a function to simulate many households in parallel.

```
def compute_asset_stationary(
        c_vec, a_vec, ifp, num_households=50_000, T=500, seed=1234
    ):
    """
    Simulates num_households households for T periods to approximate
    the stationary distribution of assets.

    Returns the final cross-section of asset holdings.

    - ifp is an instance of IFP
    - c_vec, a_vec are the optimal consumption policy and endogenous grid.

    """
    R, β, γ, Π, z_grid, s, a_y, b_y, η_draws = ifp
    n_z = len(z_grid)

    # Create interpolation function for consumption policy
    # Interpolate on the endogenous grid
    σ = lambda a, z_idx: jnp.interp(a, a_vec[:, z_idx], c_vec[:, z_idx])

    # Start with assets = savings_grid_max / 2
    a_0_vector = jnp.full(num_households, s[-1] / 2)
    # Initialize the exogenous state of each household
    z_idx_0_vector = jnp.zeros(num_households).astype(jnp.int32)

    # Vectorize over many households
    key = jax.random.key(seed)
    keys = jax.random.split(key, num_households)
    # Vectorize simulate_household in (key, a_0, z_idx_0)
    sim_all_households = jax.vmap(
        simulate_household, in_axes=(0, 0, 0, None, None, None, None)
    )
    assets = sim_all_households(keys, a_0_vector, z_idx_0_vector, c_vec, a_vec, ifp,␣
↪T)

    return np.array(assets)
```

Now we call the function, generate the asset distribution and histogram it:

```
ifp = create_ifp()
R, β, γ, Π, z_grid, s, a_y, b_y, η_draws = ifp
a_init = s[:, None] * jnp.ones(len(z_grid))
c_init = a_init
c_vec, a_vec = solve_model(ifp, c_init, a_init)
assets = compute_asset_stationary(c_vec, a_vec, ifp)

fig, ax = plt.subplots()
ax.hist(assets, bins=20, alpha=0.5, density=True)
ax.set(xlabel='assets', title="Cross-sectional distribution of wealth")
plt.show()
```

As was the case in *The Income Fluctuation Problem III: The Endogenous Grid Method*, the wealth distribution looks implausible.

While we have at least gained a nontrivial right tail, we still have a left skew.

76.6 Wealth Inequality

Lets' look at wealth inequality by computing some standard measures of this phenomenon.

We will also examine how inequality varies with the interest rate.

76.6.1 Measuring Inequality

We'll compute two common measures of wealth inequality:

1. **Gini coefficient**: A measure of inequality ranging from 0 (perfect equality) to 1 (perfect inequality)
2. **Top 1% wealth share**: The fraction of total wealth held by the richest 1% of households

Here are functions to compute these measures:

```
def gini_coefficient(x):
    """
    Compute the Gini coefficient for array x.

    """
```

(continues on next page)

(continued from previous page)

```
    x = jnp.asarray(x)
    n = len(x)
    x_sorted = jnp.sort(x)
    # Compute Gini coefficient
    cumsum = jnp.cumsum(x_sorted)
    a = (2 * jnp.sum((jnp.arange(1, n+1)) * x_sorted)) / (n * cumsum[-1])
    return a - (n + 1) / n

def top_share(
        x: jnp.array,    # array of wealth values
        p: float=0.01    # fraction of top households (default 0.01 for top 1%)
    ):
    """
    Compute the share of total wealth held by the top p fraction of households.

    """
    x = jnp.asarray(x)
    x_sorted = jnp.sort(x)
    # Number of households in top p%
    n_top = int(jnp.ceil(len(x) * p))
    # Wealth held by top p%
    wealth_top = jnp.sum(x_sorted[-n_top:])
    # Total wealth
    wealth_total = jnp.sum(x_sorted)
    return wealth_top / wealth_total
```

Let's compute these measures for our baseline simulation:

```
gini = gini_coefficient(assets)
top1 = top_share(assets, p=0.01)

print(f"Gini coefficient: {gini:.4f}")
print(f"Top 1% wealth share: {top1:.4f}")
```

```
Gini coefficient: 0.1428
Top 1% wealth share: 0.0154
```

These numbers are a long way out, at least for a country such as the US!

Recent numbers suggest that

- the Gini coefficient for wealth in the US is around 0.8
- the top 1% wealth share is over 0.3

Of course we have not made much effort to accurately estimate or calibrate our parameters.

But actually the cause is deeper — a model with this structure will always struggle to replicate the observed wealth distribution.

In a *later lecture* we'll see if we can improve on these numbers.

76.6.2 Interest Rate and Inequality

Let's examine how wealth inequality varies with the interest rate r.

We conjecture that higher interest rates will increase wealth inequality, as wealthier households benefit more from returns on their assets.

Let's investigate empirically:

```
# Test over 8 interest rate values
M = 8
r_vals = np.linspace(0, 0.05, M)

gini_vals = []
top1_vals = []

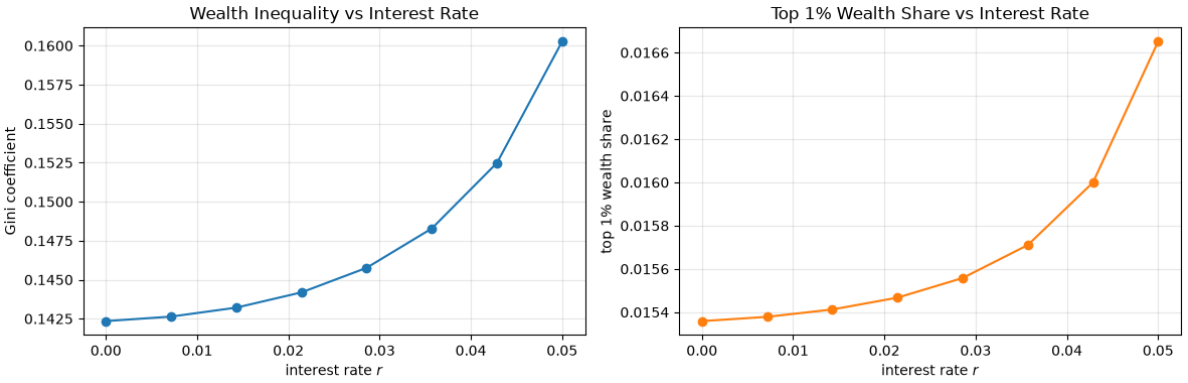
# Solve and simulate for each r
for r in r_vals:
    print(f'Analyzing inequality at r = {r:.4f}')
    ifp = create_ifp(r=r)
    R, β, γ, Π, z_grid, s, a_y, b_y, η_draws = ifp
    a_init = s[:, None] * jnp.ones(len(z_grid))
    c_init = a_init
    c_vec, a_vec = solve_model(ifp, c_init, a_init)
    assets = compute_asset_stationary(
        c_vec, a_vec, ifp, num_households=50_000, T=500
    )
    gini = gini_coefficient(assets)
    top1 = top_share(assets, p=0.01)
    gini_vals.append(gini)
    top1_vals.append(top1)
    # Use last solution as initial conditions for the policy solver
    c_init = c_vec
    a_init = a_vec
```

```
Analyzing inequality at r = 0.0000
Analyzing inequality at r = 0.0071
Analyzing inequality at r = 0.0143
Analyzing inequality at r = 0.0214
Analyzing inequality at r = 0.0286
Analyzing inequality at r = 0.0357
Analyzing inequality at r = 0.0429
Analyzing inequality at r = 0.0500
```

Now let's visualize the results:

```
fig, axes = plt.subplots(1, 2, figsize=(12, 4))

# Plot Gini coefficient vs interest rate
axes[0].plot(r_vals, gini_vals, 'o-')
axes[0].set_xlabel('interest rate $r$')
axes[0].set_ylabel('Gini coefficient')
axes[0].set_title('Wealth Inequality vs Interest Rate')
axes[0].grid(alpha=0.3)



# Plot top 1% share vs interest rate
axes[1].plot(r_vals, top1_vals, 'o-', color='C1')
axes[1].set_xlabel('interest rate $r$')
```

(continues on next page)

(continued from previous page)

```
axes[1].set_ylabel('top 1% wealth share')
axes[1].set_title('Top 1% Wealth Share vs Interest Rate')
axes[1].grid(alpha=0.3)

plt.tight_layout()
plt.show()
```

The results show that these two inequality measures increase with the interest rate.

However the differences are minor and we cannot increase r much more without violating the stability constraint.

Certainly changing the interest rate cannot produce the kinds of numbers that we see in the data.

76.7 Exercises

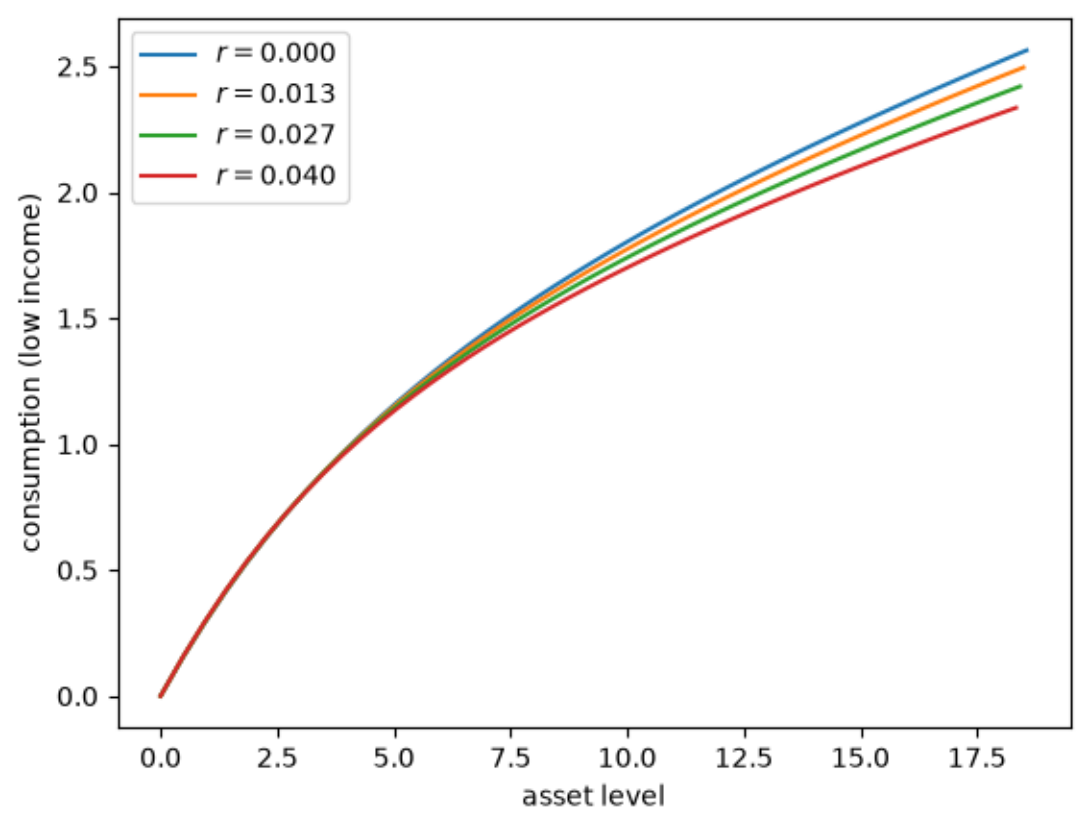
Exercise 76.7.1

Let's consider how the interest rate affects consumption.

- Step `r` through `np.linspace(0, 0.016, 4)`.
- Other than `r`, hold all parameters at their default values.
- Plot consumption against assets for income shock fixed at the smallest value.

Your figure should show that, for this model, higher interest rates suppress consumption (because they encourage more savings).

Solution



Here's one solution:

```
# With β=0.96, we need R*β < 1, so r < 0.0416
r_vals = np.linspace(0, 0.04, 4)

fig, ax = plt.subplots()
for r_val in r_vals:
    ifp = create_ifp(r=r_val)
    R, β, γ, Π, z_grid, s, a_y, b_y, η_draws = ifp
    a_init = s[:, None] * jnp.ones(len(z_grid))
    c_init = a_init
```

```
    c_vec, a_vec = solve_model(ifp, c_init, a_init)
    # Plot policy
    ax.plot(a_vec[:, 0], c_vec[:, 0], label=f'$r = {r_val:.3f}$')
    # Start next round with last solution
    c_init = c_vec
    a_init = a_vec

ax.set(xlabel='asset level', ylabel='consumption (low income)')
ax.legend()
plt.show()
```

Exercise 76.7.2

Following on from Exercises 1, let's look at how savings and aggregate asset holdings vary with the interest rate

Note

[Ljungqvist and Sargent, 2018] section 18.6 can be consulted for more background on the topic treated in this exercise.

For a given parameterization of the model, the mean of the stationary distribution of assets can be interpreted as aggregate capital in an economy with a unit mass of *ex-ante* identical households facing idiosyncratic shocks.

Your task is to investigate how this measure of aggregate capital varies with the interest rate.

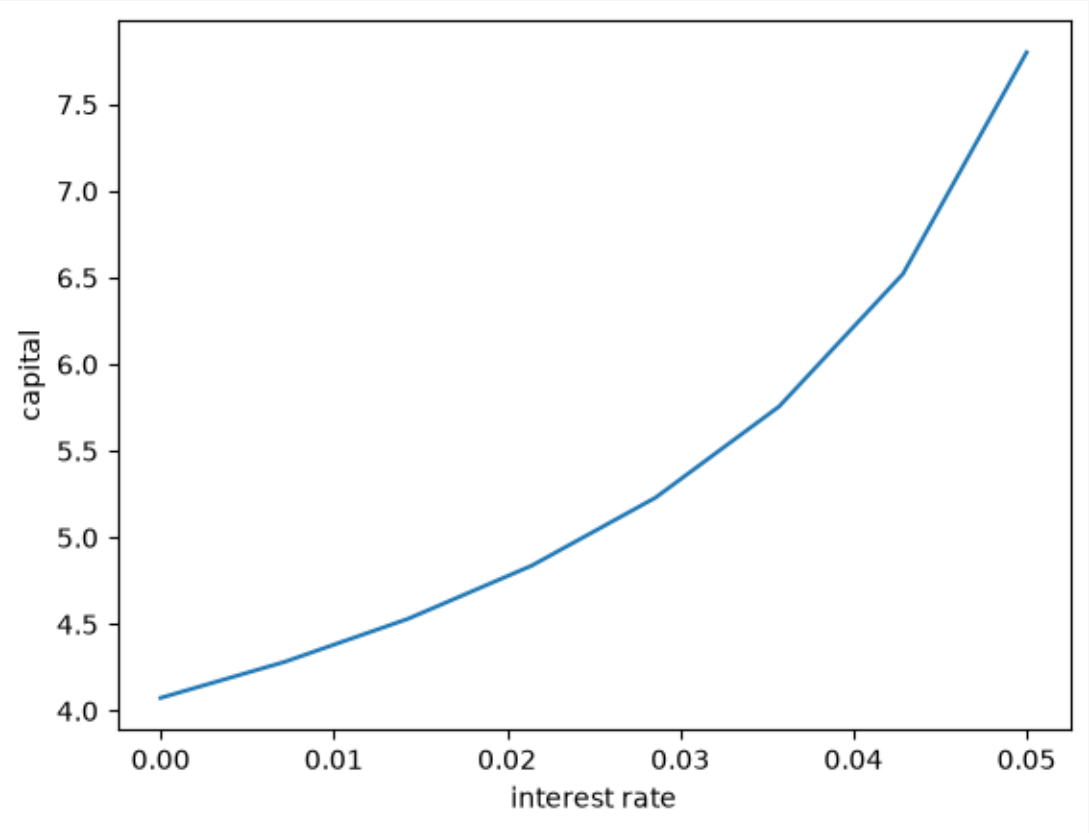
Intuition suggests that a higher interest rate should encourage capital formation — test this.

For the interest rate grid, use

```
M = 8
r_vals = np.linspace(0, 0.05, M)
```

Solution

Here's one solution



```
fig, ax = plt.subplots()

asset_mean = []
for r in r_vals:
    print(f'Solving model at r = {r}')
    ifp = create_ifp(r=r)
    R, β, γ, Π, z_grid, s, a_y, b_y, η_draws = ifp
    a_init = s[:, None] * jnp.ones(len(z_grid))
    c_init = a_init
    c_vec, a_vec = solve_model(ifp, c_init, a_init)
    assets = compute_asset_stationary(
        c_vec, a_vec, ifp, num_households=10_000, T=500
    )
    mean = np.mean(assets)
    asset_mean.append(mean)
    print(f'  Mean assets: {mean:.4f}')
    # Start next round with last solution
    c_init = c_vec
    a_init = a_vec
ax.plot(r_vals, asset_mean)

ax.set(xlabel='interest rate', ylabel='capital')

plt.show()
```

```
Solving model at r = 0.0
  Mean assets: 4.0748
Solving model at r = 0.0071428571428571435
  Mean assets: 4.2822
Solving model at r = 0.014285714285714287
  Mean assets: 4.5313

  Mean assets: 6.5214
Solving model at r = 0.05
  Mean assets: 7.8005
```

As expected, aggregate savings increases with the interest rate.

CHAPTER

SEVENTYSEVEN

THE INCOME FLUCTUATION PROBLEM V: STOCHASTIC RETURNS ON ASSETS

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

Contents

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon jax
```

77.1 Overview

In this lecture, we continue our study of the income fluctuation problem described in *The Income Fluctuation Problem III: The Endogenous Grid Method*.

While the interest rate was previously taken to be fixed, we now allow returns on assets to be state-dependent.

This matches the fact that most households with a positive level of assets face some capital income risk.

It has been argued that modeling capital income risk is essential for understanding the joint distribution of income and wealth (see, e.g., [Benhabib *et al.*, 2015] or [Stachurski and Toda, 2019]).

Theoretical properties of the household savings model presented here are analyzed in detail in [Ma *et al.*, 2020].

In terms of computation, we use a combination of time iteration and the endogenous grid method to solve the model quickly and accurately.

We require the following imports:

```
import matplotlib.pyplot as plt
import numpy as np
import quantecon as qe
import jax
import jax.numpy as jnp
from jax import vmap
from typing import NamedTuple
from functools import partial
```

77.2 The Model

In this section we review the household problem and optimality results.

77.2.1 Set Up

A household chooses a consumption-asset path $\{(c_t, a_t)\}$ to maximize

$$\mathbb{E}\left\{\sum_{t=0}^{\infty} \beta^t u(c_t)\right\} \tag{77.1}$$

subject to

$$a_{t+1} = R_{t+1}(a_t - c_t) + Y_{t+1} \text{ and } 0 \leq c_t \leq a_t, \tag{77.2}$$

with initial condition $(a_0, Z_0) = (a, z)$ treated as given.

The only difference from *The Income Fluctuation Problem IV: Transient Income Shocks* is that $\{R_t\}_{t\geq 1}$, the gross rate of return on wealth, is allowed to be stochastic.

In particular, we assume that

$$R_t = R(Z_t, \zeta_t) \quad \text{and} \quad Y_t = Y(Z_t, \eta_t), \tag{77.3}$$

where

- R and Y are time-invariant nonnegative functions,
- the innovation processes $\{\zeta_t\}$ and $\{\eta_t\}$ are IID and independent of each other, and

- $\{Z_t\}_{t \geq 0}$ is a Markov chain on a finite set Z

Let P represent the Markov matrix for the chain $\{Z_t\}_{t \geq 0}$.

In what follows, $\mathbb{E}_z \hat{X}$ means expectation of next period value $\hat{X}$ given current value $Z = z$.

77.2.2 Assumptions

We need restrictions to ensure that the objective (77.1) is finite and the solution methods described below converge.

We also need to ensure that the present discounted value of wealth does not grow too quickly.

When $\{R_t\}$ was constant we required that $\beta R < 1$.

Since it is now stochastic, we require (see [Ma *et al.*, 2020]) that

$$\beta G_R < 1, \quad \text{where} \quad G_R := \lim_{n \to \infty} \left(\mathbb{E} \prod_{t=1}^{n} R_t \right)^{1/n} \tag{77.4}$$

The value G_R can be thought of as the long run (geometric) average gross rate of return.

To simplify this lecture, we will *assume that the interest rate process is IID*.

In that case, it is clear from the definition of G_R that G_R is just $\mathbb{E} R_t$.

We test the condition $\beta \mathbb{E} R_t < 1$ in the code below.

Finally, we impose some routine technical restrictions on non-financial income.

$$\mathbb{E}\, Y_t < \infty \text{ and } \mathbb{E}\, u'(Y_t) < \infty$$

One relatively simple setting where all these restrictions are satisfied is the IID and CRRA environment of [Benhabib *et al.*, 2015].

77.2.3 Optimality

Let the class of candidate consumption policies $\mathcal{C}$ be defined as in *The Income Fluctuation Problem III: The Endogenous Grid Method*.

In [Ma *et al.*, 2020] it is shown that, under the stated assumptions,

- any $\sigma \in \mathcal{C}$ satisfying the Euler equation is an optimal policy and
- exactly one such policy exists in $\mathcal{C}$.

In the present setting, the Euler equation takes the form

$$(u' \circ \sigma)(a, z) = \max \left\{ \beta\, \mathbb{E}_z\, \hat{R}\, (u' \circ \sigma)[\hat{R}(a - \sigma(a, z)) + \hat{Y},\ \hat{Z}],\ u'(a) \right\} \tag{77.5}$$

(Intuition and derivation are similar to *The Income Fluctuation Problem III: The Endogenous Grid Method*.)

We again solve the Euler equation using time iteration, iterating with a Coleman–Reffett operator K defined to match the Euler equation (77.5).

77.3 Solution Algorithm

77.3.1 A Time Iteration Operator

Our definition of the candidate class $\sigma \in \mathcal{C}$ of consumption policies is the same as in *The Income Fluctuation Problem III: The Endogenous Grid Method*.

For fixed $\sigma \in \mathcal{C}$ and $(a, z) \in \mathbf{S}$, the value $K\sigma(a, z)$ of the function $K\sigma$ at (a, z) is defined as the $\xi \in (0, a]$ that solves

$$u'(\xi) = \max \left\{ \beta \, \mathbb{E}_z \, \hat{R} \, (u' \circ \sigma)[\hat{R}(a - \xi) + \hat{Y}, \, \hat{Z}], \, u'(a) \right\} \tag{77.6}$$

The idea behind K is that, as can be seen from the definitions, $\sigma \in \mathcal{C}$ satisfies the Euler equation if and only if $K\sigma(a, z) = \sigma(a, z)$ for all $(a, z) \in \mathbf{S}$.

This means that fixed points of K in $\mathcal{C}$ and optimal consumption policies exactly coincide (see [Ma *et al.*, 2020] for more details).

77.3.2 Convergence Properties

As before, we pair $\mathcal{C}$ with the distance

$$\rho(c, d) := \sup_{(a,z) \in \mathbf{S}} \left| (u' \circ c) \, (a, z) - (u' \circ d) \, (a, z) \right|,$$

It can be shown that

1. $(\mathcal{C}, \rho)$ is a complete metric space,
2. there exists an integer n such that K^n is a contraction mapping on $(\mathcal{C}, \rho)$, and
3. The unique fixed point of K in $\mathcal{C}$ is the unique optimal policy in $\mathcal{C}$.

We now have a clear path to successfully approximating the optimal policy: choose some $\sigma \in \mathcal{C}$ and then iterate with K until convergence (as measured by the distance ρ).

77.3.3 Using an Endogenous Grid

In the study of that model we found that it was possible to further accelerate time iteration via the *endogenous grid method*.

We will use the same method here.

The methodology is the same as it was for the optimal growth model, with the minor exception that we need to remember that consumption is not always interior.

In particular, optimal consumption can be equal to assets when the level of assets is low.

Finding Optimal Consumption

The endogenous grid method (EGM) calls for us to take a grid of *savings* values s_i, where each such s is interpreted as $s = a - c$.

For the lowest grid point we take $s_0 = 0$.

For the corresponding a_0, c_0 pair we have $a_0 = c_0$.

This happens close to the origin, where assets are low and the household consumes all that it can.

Although there are many solutions, the one we take is $a_0 = c_0 = 0$, which pins down the policy at the origin, aiding interpolation.

For $s > 0$, we have, by definition, $c < a$, and hence consumption is interior.

Hence the max component of (77.5) drops out, and we solve for

$$c_i = (u')^{-1} \left\{ \beta \, \mathbb{E}_z \hat{R} (u' \circ \sigma) \left[\hat{R} s_i + \hat{Y}, \, \hat{Z} \right] \right\} \tag{77.7}$$

at each s_i.

Iterating

Once we have the pairs $\{s_i, c_i\}$, the endogenous asset grid is obtained by $a_i = c_i + s_i$.

Also, we held $z \in \mathsf{Z}$ in the discussion above so we can pair it with a_i.

An approximation of the policy $(a, z) \mapsto \sigma(a, z)$ can be obtained by interpolating $\{a_i, c_i\}$ at each z.

In what follows, we use linear interpolation.

77.4 Implementation

Here's the model as a `NamedTuple`.

```
class IFP(NamedTuple):
    """
    A NamedTuple that stores primitives for the income fluctuation
    problem, using JAX.
    """
    γ: float
    β: float
    P: jnp.ndarray
    a_r: float
    b_r: float
    a_y: float
    b_y: float
    s_grid: jnp.ndarray
    η_draws: jnp.ndarray
    ζ_draws: jnp.ndarray

def create_ifp(
        γ=1.5,                      # Utility parameter
        β=0.96,                     # Discount factor
        P=jnp.array([(0.9, 0.1),    # Default Markov chain for Z
                     (0.1, 0.9)]),
        a_r=0.16,                   # Volatility term in R shock
        b_r=0.0,                    # Mean shift R shock
        a_y=0.2,                    # Volatility term in Y shock
        b_y=0.5,                    # Mean shift Y shock
        shock_draw_size=100,        # For Monte Carlo
        grid_max=100,               # Exogenous grid max
        grid_size=100,              # Exogenous grid size
        seed=1234                   # Random seed
    ):
```

(continues on next page)

(continued from previous page)

```
    """
    Create an instance of IFP with the given parameters.

    """
    # Test stability assuming {R_t} is IID and ln R ~ N(b_r, a_r)
    ER = np.exp(b_r + a_r**2 / 2)
    assert β * ER < 1, "Stability condition failed."

    # Generate random draws using JAX
    key = jax.random.key(seed)
    subkey1, subkey2 = jax.random.split(key)
    η_draws = jax.random.normal(subkey1, (shock_draw_size,))
    ζ_draws = jax.random.normal(subkey2, (shock_draw_size,))
    s_grid = jnp.linspace(0, grid_max, grid_size)

    return IFP(
        γ, β, P, a_r, b_r, a_y, b_y, s_grid, η_draws, ζ_draws
    )

def u_prime(c, γ):
    """Marginal utility"""
    return c**(-γ)

def u_prime_inv(c, γ):
    """Inverse of marginal utility"""
    return c**(-1/γ)

def R(z, ζ, a_r, b_r):
    """Gross return on assets"""
    return jnp.exp(a_r * ζ + b_r)

def Y(z, η, a_y, b_y):
    """Labor income"""
    return jnp.exp(a_y * η + (z * b_y))
```

Here's the Coleman-Reffett operator using JAX:

```
def K(
        c_in: jnp.array,   # c_in[i, z] = consumption at a_in[i, z]
        a_in: jnp.array,   # a_in[i, z] is an asset grid
        ifp: IFP
    ):
    """
    The Coleman--Reffett operator for the income fluctuation problem,
    using the endogenous grid method with JAX.

    """

    # Extract parameters from ifp
    γ, β, P, a_r, b_r, a_y, b_y, s_grid, η_draws, ζ_draws = ifp
    n = len(P)

    def compute_expectation(s, z):
        def inner_expectation(z_hat):
            def compute_term(η, ζ):
                R_hat = R(z_hat, ζ, a_r, b_r)
```

(continues on next page)

(continued from previous page)

```
                Y_hat = Y(z_hat, η, a_y, b_y)
                a_val = R_hat * s + Y_hat
                # Interpolate consumption
                c_interp = jnp.interp(a_val, a_in[:, z_hat], c_in[:, z_hat])
                mu = u_prime(c_interp, γ)
                return R_hat * mu
            # Vectorize over all shock combinations
            η_grid, ζ_grid = jnp.meshgrid(η_draws, ζ_draws, indexing='ij')
            terms = vmap(vmap(compute_term))(η_grid, ζ_grid)
            return P[z, z_hat] * jnp.mean(terms)
        # Sum over z_hat states
        Ez = jnp.sum(vmap(inner_expectation)(jnp.arange(n)))
        return u_prime_inv(β * Ez, γ)

    # Vectorize over s_grid and z
    compute_exp_v1 = vmap(compute_expectation, in_axes=(None, 0))
    compute_exp_v2 = vmap(compute_exp_v1,      in_axes=(0, None))
    c_out = compute_exp_v2(s_grid, jnp.arange(n))
    # Calculate endogenous asset grid
    a_out = s_grid[:, None] + c_out
    # Fix consumption-asset pair at (0, 0)
    c_out = c_out.at[0, :].set(0)
    a_out = a_out.at[0, :].set(0)

    return c_out, a_out
```

The next function solves for an approximation of the optimal consumption policy via time iteration using JAX:

```
@jax.jit
def solve_model(
        ifp: IFP,
        c_init: jnp.ndarray,  # Initial guess of σ on grid endogenous grid
        a_init: jnp.ndarray,  # Initial endogenous grid
        tol: float = 1e-5,
        max_iter: int = 1000
    ) -> jnp.ndarray:
    " Solve the model using time iteration with EGM. "

    def condition(loop_state):
        c_in, a_in, i, error = loop_state
        return (error > tol) & (i < max_iter)

    def body(loop_state):
        c_in, a_in, i, error = loop_state
        c_out, a_out = K(c_in, a_in, ifp)
        error = jnp.max(jnp.abs(c_out - c_in))
        i += 1
        return c_out, a_out, i, error

    i, error = 0, tol + 1
    initial_state = (c_init, a_init, i, error)
    final_loop_state = jax.lax.while_loop(condition, body, initial_state)
    c_out, a_out, i, error = final_loop_state

    return c_out, a_out
```

Now we can create an instance and solve the model using JAX:

```
ifp = create_ifp()
```

Set up the initial condition:

```
# Initial guess of σ = consume all assets
k = len(ifp.s_grid)
n = len(ifp.P)
σ_init = jnp.empty((k, n))
for z in range(n):
    σ_init = σ_init.at[:, z].set(ifp.s_grid)
a_init = σ_init.copy()
```

Let's generate an approximation solution with JAX:

```
σ_star, a_star = solve_model(ifp, σ_init, a_init)
```

Let's try it again with a timer.

```
with qe.Timer(precision=8):
    σ_star, a_star = solve_model(ifp, σ_init, a_init)
    σ_star.block_until_ready()
```

```
0.45814991 seconds elapsed
```

77.5 Simulation

Let's return to the default model and study the stationary distribution of assets.

Our plan is to run a large number of households forward for T periods and then histogram the cross-sectional distribution of assets.

Set `num_households=50_000, T=500`.

First we write a function to run a single household forward in time and record the final value of assets.

The function takes a solution pair `c_vec` and `a_vec`, understanding them as representing an optimal policy associated with a given model `ifp`

```
def simulate_household(
        key, a_0, z_idx_0, c_vec, a_vec, ifp, T
    ):
    """
    Simulates a single household for T periods to approximate the stationary
    distribution of assets.

    - key is the state of the random number generator
    - ifp is an instance of IFP
    - c_vec, a_vec are the optimal consumption policy, endogenous grid for ifp

    """
    # Extract parameters from ifp
    γ, β, P, a_r, b_r, a_y, b_y, s_grid, η_draws, ζ_draws = ifp
    n_z = len(P)

    # Create interpolation function for consumption policy
```

(continues on next page)

(continued from previous page)

```
    σ = lambda a, z_idx: jnp.interp(a, a_vec[:, z_idx], c_vec[:, z_idx])

    # Simulate forward T periods
    def update(t, state):
        a, z_idx = state
        # Draw next shock z' from P[z, z']
        current_key = jax.random.fold_in(key, 3*t)
        z_next_idx = jax.random.choice(current_key, n_z, p=P[z_idx]).astype(jnp.int32)
        # Draw η shock for income
        η_key = jax.random.fold_in(key, 3*t + 1)
        η = jax.random.normal(η_key)
        # Draw ζ shock for return
        ζ_key = jax.random.fold_in(key, 3*t + 2)
        ζ = jax.random.normal(ζ_key)
        # Compute stochastic return
        R_next = R(z_next_idx, ζ, a_r, b_r)
        # Compute income
        Y_next = Y(z_next_idx, η, a_y, b_y)
        # Update assets: a' = R' * (a - c) + Y'
        a_next = R_next * (a - σ(a, z_idx)) + Y_next
        # Return updated state
        return a_next, z_next_idx

    initial_state = a_0, z_idx_0
    final_state = jax.lax.fori_loop(0, T, update, initial_state)
    a_final, _ = final_state
    return a_final
```

Now we write a function to simulate many households in parallel.

```
@partial(jax.jit, static_argnums=(3, 4, 5))
def compute_asset_stationary(
        c_vec, a_vec, ifp, num_households=50_000, T=500, seed=1234
    ):
    """
    Simulates num_households households for T periods to approximate
    the stationary distribution of assets.

    Returns the final cross-section of asset holdings.

    - ifp is an instance of IFP
    - c_vec, a_vec are the optimal consumption policy and endogenous grid.

    """
    # Extract parameters from ifp
    γ, β, P, a_r, b_r, a_y, b_y, s_grid, η_draws, ζ_draws = ifp

    # Start with assets = savings_grid_max / 2
    a_0_vector = jnp.full(num_households, s_grid[-1] / 2)
    # Initialize the exogenous state of each household
    z_idx_0_vector = jnp.zeros(num_households).astype(jnp.int32)

    # Vectorize over many households
    key = jax.random.key(seed)
    keys = jax.random.split(key, num_households)
    # Vectorize simulate_household in (key, a_0, z_idx_0)
    sim_all_households = jax.vmap(
```

(continues on next page)

(continued from previous page)

```
        simulate_household, in_axes=(0, 0, 0, None, None, None, None)
    )
    assets = sim_all_households(keys, a_0_vector, z_idx_0_vector, c_vec, a_vec, ifp,␣
↪T)

    return jnp.array(assets)
```

We'll need some inequality measures for visualization, so let's define them first:

```
def gini_coefficient(x):
    """
    Compute the Gini coefficient for array x.

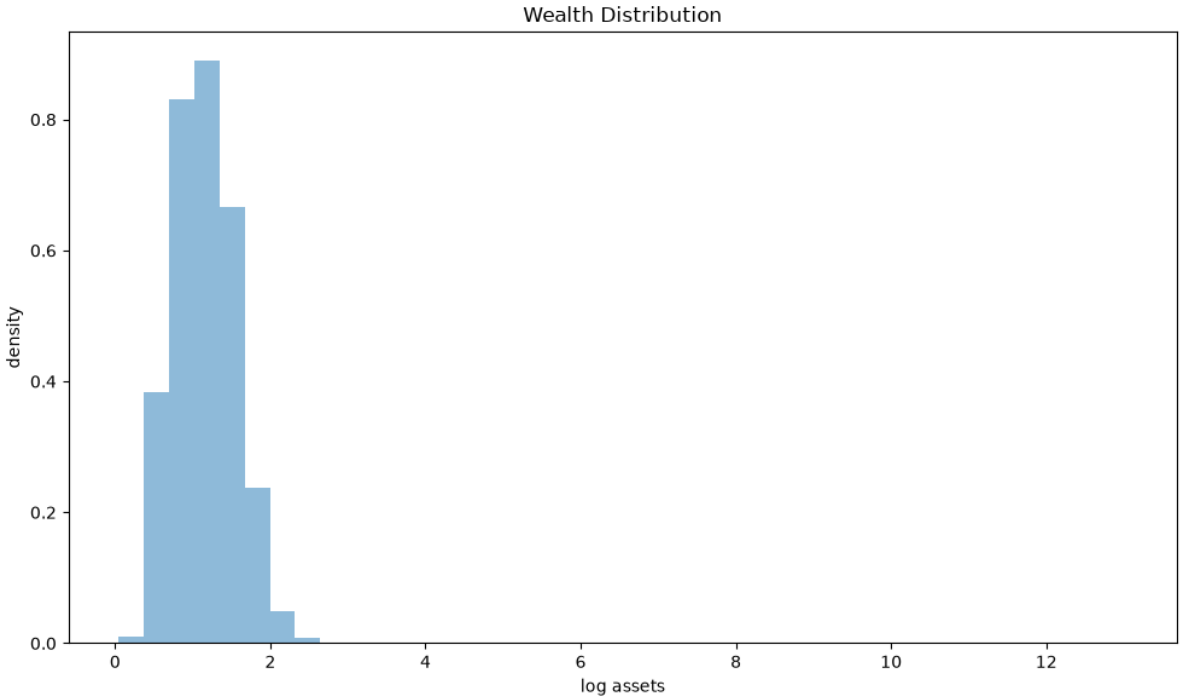
    """
    x = jnp.asarray(x)
    n = len(x)
    x_sorted = jnp.sort(x)
    # Compute Gini coefficient
    cumsum = jnp.cumsum(x_sorted)
    a = (2 * jnp.sum((jnp.arange(1, n+1)) * x_sorted)) / (n * cumsum[-1])
    return a - (n + 1) / n

def top_share(
        x: jnp.array,    # array of wealth values
        p: float=0.01    # fraction of top households (default 0.01 for top 1%)
    ):
    """
    Compute the share of total wealth held by the top p fraction of households.

    """
    x = jnp.asarray(x)
    x_sorted = jnp.sort(x)
    # Number of households in top p%
    n_top = int(jnp.ceil(len(x) * p))
    # Wealth held by top p%
    wealth_top = jnp.sum(x_sorted[-n_top:])
    # Total wealth
    wealth_total = jnp.sum(x_sorted)
    return wealth_top / wealth_total
```

Now we call the function, generate the asset distribution and visualize it:

```
ifp = create_ifp()
# Extract parameters for initialization
s_grid = ifp.s_grid
n_z = len(ifp.P)
a_init = s_grid[:, None] * jnp.ones(n_z)
c_init = a_init
c_vec, a_vec = solve_model(ifp, c_init, a_init)
assets = compute_asset_stationary(c_vec, a_vec, ifp, num_households=200_000)



# Compute Gini coefficient for the plot
gini_plot = gini_coefficient(assets)

# Plot histogram of log wealth
fig, ax = plt.subplots(figsize=(10, 6))
```

(continues on next page)

(continued from previous page)

```
ax.hist(jnp.log(assets), bins=40, alpha=0.5, density=True)
ax.set(xlabel='log assets', ylabel='density', title="Wealth Distribution")
plt.tight_layout()
plt.show()
```

The histogram shows the distribution of log wealth.

Bearing in mind that we are looking at log values, the histogram suggests a long right tail of the distribution.

Below we examine this in more detail.

77.6 Wealth Inequality

Lets' look at wealth inequality by computing some standard measures of this phenomenon.

We will also examine how inequality varies with the interest rate.

77.6.1 Measuring Inequality

Let's print the Gini coefficient and the top 1% wealth share from our simulation:

```
gini = gini_coefficient(assets)
top1 = top_share(assets, p=0.01)

print(f"Gini coefficient: {gini:.4f}")
print(f"Top 1% wealth share: {top1:.4f}")
```

```
Gini coefficient: 0.7847
Top 1% wealth share: 0.7306
```

Recent numbers suggest that

- the Gini coefficient for wealth in the US is around 0.8
- the top 1% wealth share is over 0.3

Our model with stochastic returns generates a Gini coefficient close to the empirical value, demonstrating that capital income risk is an important factor in wealth inequality.

The top 1% wealth share is, however, too large.

Our model needs proper calibration and additional work – we set these tasks aside for now.

77.7 Exercises

Exercise 77.7.1

Plot how the Gini coefficient varies with the volatility of returns on assets.

Specifically, compute the Gini coefficient for values of `a_r` ranging from 0.10 to 0.16 (use at least 5 different values) and plot the results.

What does this tell you about the relationship between capital income risk and wealth inequality?

Solution

We loop over different values of `a_r`, solve the model for each, simulate the wealth distribution, and compute the Gini coefficient.

```
# Range of a_r values to explore
a_r_vals = np.linspace(0.10, 0.16, 5)
gini_vals = []

print("Computing Gini coefficients for different return volatilities...\n")

for a_r in a_r_vals:
    print(f"a_r = {a_r:.3f}...", end=" ")

    # Create model with this a_r value
    ifp_temp = create_ifp(a_r=a_r, grid_max=100)

    # Solve the model
    s_grid_temp = ifp_temp.s_grid
    n_z_temp = len(ifp_temp.P)
    a_init_temp = s_grid_temp[:, None] * jnp.ones(n_z_temp)
    c_init_temp = a_init_temp
    c_vec_temp, a_vec_temp = solve_model(
        ifp_temp, c_init_temp, a_init_temp
    )

    # Simulate households
    assets_temp = compute_asset_stationary(
        c_vec_temp, a_vec_temp, ifp_temp, num_households=200_000
    )

    # Compute Gini coefficient
```

```
    gini_temp = gini_coefficient(assets_temp)
    gini_vals.append(gini_temp)
    print(f"Gini = {gini_temp:.4f}")

# Plot the results
fig, ax = plt.subplots(figsize=(10, 6))
ax.plot(a_r_vals, gini_vals, 'o-', linewidth=2, markersize=8)
ax.set(xlabel='Return volatility (a_r)',
       ylabel='Gini coefficient',
       title='Wealth Inequality vs Return Volatility')
ax.axhline(y=0.8, color='k', linestyle='--', linewidth=1,
           label='Empirical US Gini (~0.8)')
ax.legend()
plt.tight_layout()
plt.show()
```

```
Computing Gini coefficients for different return volatilities...

a_r = 0.100...
Gini = 0.1925
a_r = 0.115...
Gini = 0.1992
a_r = 0.130...
Gini = 0.2225
a_r = 0.145...
Gini = 0.3362
a_r = 0.160...
Gini = 0.7847
```

The plot shows that wealth inequality (measured by the Gini coefficient) increases with return volatility.

This demonstrates that capital income risk is a key driver of wealth inequality.

When returns are more volatile, lucky households who experience sequences of high returns accumulate substantially

more wealth than unlucky households, leading to greater inequality in the wealth distribution.

Exercise 77.7.2

Plot how the Gini coefficient varies with the volatility of labor income.

Specifically, compute the Gini coefficient for values of `a_y` ranging from 0.125 to 0.20 and plot the results. Set `a_r=0.10` for this exercise.

What does this tell you about the relationship between labor income risk and wealth inequality? Can we achieve the same rise in inequality by varying labor income volatility as we can by varying return volatility?

Solution

We loop over different values of `a_y`, solve the model for each, simulate the wealth distribution, and compute the Gini coefficient.

```
# Range of a_y values to explore
a_y_vals = np.linspace(0.125, 0.20, 5)
gini_vals_y = []

print("Computing Gini coefficients for different labor income volatilities...\n")

for a_y in a_y_vals:
    print(f"a_y = {a_y:.3f}...", end=" ")

    # Create model with this a_y value and a_r=0.10
    ifp_temp = create_ifp(a_y=a_y, a_r=0.10, grid_max=100)

    # Solve the model
    s_grid_temp = ifp_temp.s_grid
    n_z_temp = len(ifp_temp.P)
    a_init_temp = s_grid_temp[:, None] * jnp.ones(n_z_temp)
    c_init_temp = a_init_temp
    c_vec_temp, a_vec_temp = solve_model(
        ifp_temp, c_init_temp, a_init_temp
    )

    # Simulate households
    assets_temp = compute_asset_stationary(
        c_vec_temp, a_vec_temp, ifp_temp, num_households=200_000
    )

    # Compute Gini coefficient
    gini_temp = gini_coefficient(assets_temp)
    gini_vals_y.append(gini_temp)
    print(f"Gini = {gini_temp:.4f}")

# Plot the results
fig, ax = plt.subplots(figsize=(10, 6))
ax.plot(a_y_vals, gini_vals_y, 'o-', linewidth=2, markersize=8, color='green')
ax.set(xlabel='Labor income volatility (a_y)',
       ylabel='Gini coefficient',
       title='Wealth Inequality vs Labor Income Volatility')
ax.axhline(y=0.8, color='k', linestyle='--', linewidth=1,
```

```
            label='Empirical US Gini (~0.8)')
ax.legend()
plt.tight_layout()
plt.show()
```

```
Computing Gini coefficients for different labor income volatilities...

a_y = 0.125...
Gini = 0.1787
a_y = 0.144...
Gini = 0.1818
a_y = 0.163...
Gini = 0.1852
a_y = 0.181...
Gini = 0.1887
a_y = 0.200...
Gini = 0.1925
```

The plot shows that wealth inequality increases with labor income volatility, but the effect is much weaker than the effect of return volatility.

Comparing the two exercises:

- When return volatility (`a_r`) varies from 0.10 to 0.16, the Gini coefficient rises dramatically from around 0.20 to 0.79
- When labor income volatility (`a_y`) varies from 0.125 to 0.20, a similar amount in percentage terms, the Gini coefficient increases but by a much smaller amount

This suggests that capital income risk is a more important driver of wealth inequality than labor income risk.

The intuition is that wealth accumulation compounds over time: households who experience favorable returns on their assets can reinvest those returns, leading to exponential growth.

In contrast, labor income shocks, while they affect current consumption and savings, do not have the same compound-

ing effect on wealth accumulation.

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

78.1 Overview

Linear quadratic (LQ) control refers to a class of dynamic optimization problems that have found applications in almost every scientific field.

This lecture provides an introduction to LQ control and its economic applications.

As we will see, LQ systems have a simple structure that makes them an excellent workhorse for a wide variety of economic problems.

Moreover, while the linear-quadratic structure is restrictive, it is in fact far more flexible than it may appear initially.

These themes appear repeatedly below.

Mathematically, LQ control problems are closely related to *the Kalman filter*

- Recursive formulations of linear-quadratic control problems and Kalman filtering problems both involve matrix Riccati equations.
- Classical formulations of linear control and linear filtering problems make use of similar matrix decompositions (see for example Classical Control with Linear Algebra and Classical Prediction and Filtering With Linear Algebra).

In reading what follows, it will be useful to have some familiarity with

- matrix manipulations
- vectors of random variables
- dynamic programming and the Bellman equation (see for example Shortest Paths and *Optimal Savings III: Stochastic Returns*)

For additional reading on LQ control, see, for example,

- [Ljungqvist and Sargent, 2018], chapter 5
- [Hansen and Sargent, 2008], chapter 4
- [Hernandez-Lerma and Lasserre, 1996], section 3.5

In order to focus on computation, we leave longer proofs to these sources (while trying to provide as much intuition as possible).

Let's start with some imports:

```
import matplotlib.pyplot as plt
import numpy as np
from quantecon import LQ
from typing import NamedTuple
```

78.2 Introduction

The "linear" part of LQ is a linear law of motion for the state, while the "quadratic" part refers to preferences.

Let's begin with the former, move on to the latter, and then put them together into an optimization problem.

78.2.1 The law of motion

Let x_t be a vector describing the state of some economic system.

Suppose that x_t follows a linear law of motion given by

$$x_{t+1} = Ax_t + Bu_t + Cw_{t+1}, \qquad t = 0, 1, 2, \ldots \tag{78.1}$$

Here

- u_t is a "control" vector, incorporating choices available to a decision-maker confronting the current state x_t
- $\{w_t\}$ is a sequence of uncorrelated zero mean shocks satisfying $\mathbb{E} w_t w_t^\top = I$, where the right-hand side is the identity matrix

Regarding the dimensions

- x_t is $n \times 1$, A is $n \times n$
- u_t is $k \times 1$, B is $n \times k$
- w_t is $j \times 1$, C is $n \times j$

Example 1

Consider a household budget constraint given by

$$a_{t+1} + c_t = (1 + r)a_t + y_t$$

Here a_t is assets, r is a fixed interest rate, c_t is current consumption, and y_t is current non-financial income.

If we suppose that $\{y_t\}$ is serially uncorrelated and $N(0, \sigma^2)$, then, taking $\{w_t\}$ to be standard normal, we can write the system as

$$a_{t+1} = (1 + r)a_t - c_t + \sigma w_{t+1}$$

This is clearly a special case of (78.1), with assets being the state and consumption being the control.

Example 2

One unrealistic feature of the previous model is that non-financial income has a zero mean and is often negative.

This can easily be overcome by adding a sufficiently large mean.

Hence in this example, we take $y_t = \sigma w_{t+1} + \mu$ for some positive real number μ.

Another alteration that's useful to introduce (we'll see why soon) is to change the control variable from consumption to the deviation of consumption from some "ideal" quantity $\bar{c}$.

(Most parameterizations will be such that $\bar{c}$ is large relative to the amount of consumption that is attainable in each period, and hence the household wants to increase consumption.)

For this reason, we now take our control to be $u_t := c_t - \bar{c}$.

In terms of these variables, the budget constraint $a_{t+1} = (1 + r)a_t - c_t + y_t$ becomes

$$a_{t+1} = (1 + r)a_t - u_t - \bar{c} + \sigma w_{t+1} + \mu \tag{78.2}$$

How can we write this new system in the form of equation (78.1)?

If, as in the previous example, we take a_t as the state, then we run into a problem: the law of motion contains some constant terms on the right-hand side.

This means that we are dealing with an *affine* function, not a linear one (recall *this discussion*).

Fortunately, we can easily circumvent this problem by adding an extra state variable.

In particular, if we write

$$\begin{bmatrix} a_{t+1} \\ 1 \end{bmatrix} = \begin{bmatrix} 1 + r & -\bar{c} + \mu \\ 0 & 1 \end{bmatrix} \begin{bmatrix} a_t \\ 1 \end{bmatrix} + \begin{bmatrix} -1 \\ 0 \end{bmatrix} u_t + \begin{bmatrix} \sigma \\ 0 \end{bmatrix} w_{t+1} \tag{78.3}$$

then the first row is equivalent to (78.2).

Moreover, the model is now linear and can be written in the form of (78.1) by setting

$$x_t := \begin{bmatrix} a_t \\ 1 \end{bmatrix}, \quad A := \begin{bmatrix} 1 + r & -\bar{c} + \mu \\ 0 & 1 \end{bmatrix}, \quad B := \begin{bmatrix} -1 \\ 0 \end{bmatrix}, \quad C := \begin{bmatrix} \sigma \\ 0 \end{bmatrix} \tag{78.4}$$

In effect, we've bought ourselves linearity by adding another state.

78.2.2 Preferences

In the LQ model, the aim is to minimize flow of losses, where time-t loss is given by the quadratic expression

$$x_t^\top R x_t + u_t^\top Q u_t \tag{78.5}$$

The entries in R and Q are chosen to match the specific problem being studied.

Here

- R is assumed to be $n \times n$, symmetric and nonnegative definite.
- Q is assumed to be $k \times k$, symmetric and positive definite.

Note

In fact, for many economic problems, the definiteness conditions on R and Q can be relaxed. It is sufficient that certain submatrices of R and Q be nonnegative definite. See [Hansen and Sargent, 2008] for details.

Note also that this notation is not universal: some authors let Q be the matrix associated with the state and R the matrix associated with the control.

Example 1

A very simple example that satisfies these assumptions is to take R and Q to be identity matrices so that current loss is

$$x_t^\top I x_t + u_t^\top I u_t = \|x_t\|^2 + \|u_t\|^2$$

Thus, for both the state and the control, loss is measured as squared distance from the origin.

(In fact, the general case (78.5) can also be understood in this way, but with R and Q identifying other – non-Euclidean – notions of "distance" from the zero vector.)

Intuitively, we can often think of the state x_t as representing deviation from a target, such as

- deviation of inflation from some target level
- deviation of a firm's capital stock from some desired quantity

The aim is to put the state close to the target, while using controls parsimoniously.

Example 2

In the household problem *studied above*, setting $R = 0$ and $Q = 1$ yields preferences

$$x_t^\top R x_t + u_t^\top Q u_t = u_t^2 = (c_t - \bar{c})^2$$

Under this specification, the household's current loss is the squared deviation of consumption from the ideal level $\bar{c}$.

78.3 Optimality – finite horizon

Let's now be precise about the optimization problem we wish to consider, and look at how to solve it.

78.3.1 The objective

We will begin with the finite horizon case, with terminal time $T \in \mathbb{N}$.

In this case, the aim is to choose a sequence of controls $\{u_0, \dots, u_{T-1}\}$ to minimize the objective

$$\mathbb{E}\left\{\sum_{t=0}^{T-1} \beta^t (x_t^\top R x_t + u_t^\top Q u_t) + \beta^T x_T^\top R_f x_T\right\} \tag{78.6}$$

subject to the law of motion (78.1) and initial state x_0.

The new objects introduced here are β and the matrix R_f.

The scalar β is the discount factor, while $x^\top R_f x$ gives terminal loss associated with state x.

Comments:

- We assume R_f to be $n \times n$, symmetric and nonnegative definite.
- We allow $\beta = 1$, and hence include the undiscounted case.
- x_0 may itself be random, in which case we require it to be independent of the shock sequence $\{w_1, \dots, w_T\}$.

78.3.2 Information

There's one constraint we've neglected to mention so far, which is that the decision-maker who solves this LQ problem knows only the present and the past, not the future.

To clarify this point, consider the sequence of controls $\{u_0, \dots, u_{T-1}\}$.

When choosing these controls, the decision-maker is permitted to take into account the effects of the shocks $\{w_1, \dots, w_T\}$ on the system.

However, it is typically assumed — and will be assumed here — that the time-t control u_t can be made with knowledge of past and present shocks only.

The fancy measure-theoretic way of saying this is that u_t must be measurable with respect to the σ-algebra generated by $x_0, w_1, w_2, \dots, w_t$.

This is in fact equivalent to stating that u_t can be written in the form $u_t = g_t(x_0, w_1, w_2, \dots, w_t)$ for some Borel measurable function g_t.

(Just about every function that's useful for applications is Borel measurable, so, for the purposes of intuition, you can read that last phrase as "for some function g_t")

Now note that x_t will ultimately depend on the realizations of $x_0, w_1, w_2, \dots, w_t$.

In fact, it turns out that x_t summarizes all the information about these historical shocks that the decision-maker needs to set controls optimally.

More precisely, it can be shown that any optimal control u_t can always be written as a function of the current state alone.

Hence in what follows we restrict attention to control policies (i.e., functions) of the form $u_t = g_t(x_t)$.

Actually, the preceding discussion applies to all standard dynamic programming problems.

What's special about the LQ case is that – as we shall soon see — the optimal u_t turns out to be a linear function of x_t.

78.3.3 Solution

To solve the finite horizon LQ problem we can use a dynamic programming strategy based on backward induction that is conceptually similar to the approach adopted in Shortest Paths.

For reasons that will soon become clear, we first introduce the notation $J_T(x) = x^\top R_f x$.

Now consider the problem of the decision-maker in the second to last period.

In particular, let the time be $T-1$, and suppose that the state is x_{T-1}.

The decision-maker must trade-off current and (discounted) final losses, and hence solves

$$\min_u \{x_{T-1}^\top R x_{T-1} + u^\top Q u + \beta \, \mathbb{E} J_T(A x_{T-1} + B u + C w_T)\}$$

We use u instead of u_{T-1} here to simplify notation.

At this stage, it is convenient to define the function

$$J_{T-1}(x) = \min_u \{x^\top R x + u^\top Q u + \beta \, \mathbb{E} J_T(A x + B u + C w_T)\} \tag{78.7}$$

The function J_{T-1} will be called the $T-1$ value function, and $J_{T-1}(x)$ can be thought of as representing total "loss-to-go" from state x at time $T-1$ when the decision-maker behaves optimally.

Now let's step back to $T-2$.

For a decision-maker at $T-2$, the value $J_{T-1}(x)$ plays a role analogous to that played by the terminal loss $J_T(x) = x^\top R_f x$ for the decision-maker at $T-1$.

That is, $J_{T-1}(x)$ summarizes the future loss associated with moving to state x.

The decision-maker chooses her control u to trade off current loss against future loss, where

- the next period state is $x_{T-1} = A x_{T-2} + B u + C w_{T-1}$, and hence depends on the choice of current control.
- the "cost" of landing in state x_{T-1} is $J_{T-1}(x_{T-1})$.

Her problem is therefore

$$\min_u \{x_{T-2}^\top R x_{T-2} + u^\top Q u + \beta \, \mathbb{E} J_{T-1}(A x_{T-2} + B u + C w_{T-1})\}$$

Letting

$$J_{T-2}(x) = \min_u \{x^\top R x + u^\top Q u + \beta \, \mathbb{E} J_{T-1}(A x + B u + C w_{T-1})\}$$

the pattern for backward induction is now clear.

In particular, we define a sequence of value functions $\{J_0, \ldots, J_T\}$ via

$$J_{t-1}(x) = \min_u \{x^\top R x + u^\top Q u + \beta \, \mathbb{E} J_t(A x + B u + C w_t)\} \quad \text{and} \quad J_T(x) = x^\top R_f x$$

The first equality is the Bellman equation from dynamic programming theory specialized to the finite horizon LQ problem.

Now that we have $\{J_0, \ldots, J_T\}$, we can obtain the optimal controls.

As a first step, let's find out what the value functions look like.

It turns out that every J_t has the form $J_t(x) = x^\top P_t x + d_t$ where P_t is a $n \times n$ matrix and d_t is a constant.

We can show this by induction, starting from $P_T := R_f$ and $d_T = 0$.

Using this notation, (78.7) becomes

$$J_{T-1}(x) = \min_u \{x^\top R x + u^\top Q u + \beta \, \mathbb{E} (A x + B u + C w_T)^\top P_T (A x + B u + C w_T)\} \tag{78.8}$$

To obtain the minimizer, we can take the derivative of the r.h.s. with respect to u and set it equal to zero.

Applying the relevant rules of *matrix calculus*, this gives

$$u = -(Q + \beta B^\top P_T B)^{-1} \beta B^\top P_T A x \tag{78.9}$$

Plugging this back into (78.8) and rearranging yields

$$J_{T-1}(x) = x^\top P_{T-1} x + d_{T-1}$$

where

$$P_{T-1} = R - \beta^2 A^\top P_T B (Q + \beta B^\top P_T B)^{-1} B^\top P_T A + \beta A^\top P_T A \tag{78.10}$$

and

$$d_{T-1} := \beta \, \text{trace}(C^\top P_T C) \tag{78.11}$$

(The algebra is a good exercise — we'll leave it up to you.)

If we continue working backwards in this manner, it soon becomes clear that $J_t(x) = x^\top P_t x + d_t$ as claimed, where P_t and d_t satisfy the recursions

$$P_{t-1} = R - \beta^2 A^\top P_t B (Q + \beta B^\top P_t B)^{-1} B^\top P_t A + \beta A^\top P_t A \quad \text{with} \quad P_T = R_f \tag{78.12}$$

and

$$d_{t-1} = \beta (d_t + \text{trace}(C^\top P_t C)) \quad \text{with} \quad d_T = 0 \tag{78.13}$$

Recalling (78.9), the minimizers from these backward steps are

$$u_t = -F_t x_t \quad \text{where} \quad F_t := (Q + \beta B^\top P_{t+1} B)^{-1} \beta B^\top P_{t+1} A \tag{78.14}$$

These are the linear optimal control policies we *discussed above*.

In particular, the sequence of controls given by (78.14) and (78.1) solves our finite horizon LQ problem.

Rephrasing this more precisely, the sequence $\{u_0, \ldots, u_{T-1}\}$ given by

$$u_t = -F_t x_t \quad \text{with} \quad x_{t+1} = (A - BF_t) x_t + C w_{t+1} \tag{78.15}$$

for $t = 0, \ldots, T-1$ attains the minimum of (78.6) subject to our constraints.

78.4 Implementation

We will use code from lqcontrol.py in QuantEcon.py to solve finite and infinite horizon linear quadratic control problems.

In the module, the various updating, simulation and fixed point methods are wrapped in a class called `LQ`, which includes

- Instance data:
  - The required parameters Q, R, A, B and optional parameters C, β, T, R_f, N specifying a given LQ model
    - set T and R_f to `None` in the infinite horizon case
    - set `C = None` (or zero) in the deterministic case
  - the value function and policy data

    * d_t, P_t, F_t in the finite horizon case
    * d, P, F in the infinite horizon case

- Methods:
  - `update_values` — shifts d_t, P_t, F_t to their $t-1$ values via (78.12), (78.13) and (78.14)
  - `stationary_values` — computes P, d, F in the infinite horizon case
  - `compute_sequence` —- simulates the dynamics of x_t, u_t, w_t given x_0 and assuming standard normal shocks

78.4.1 An application

Early Keynesian models assumed that households have a constant marginal propensity to consume from current income.

Data contradicted the constancy of the marginal propensity to consume.

In response, Milton Friedman, Franco Modigliani and others built models based on a consumer's preference for an intertemporally smooth consumption stream.

(See, for example, [Friedman, 1956] or [Modigliani and Brumberg, 1954].)

One property of those models is that households purchase and sell financial assets to make consumption streams smoother than income streams.

The household savings problem *outlined above* captures these ideas.

The optimization problem for the household is to choose a consumption sequence in order to minimize

$$\mathbb{E}\left\{\sum_{t=0}^{T-1}\beta^t(c_t-\bar{c})^2+\beta^T q a_T^2\right\} \tag{78.16}$$

subject to the sequence of budget constraints $a_{t+1}=(1+r)a_t-c_t+y_t,\ t\geq 0$.

Here q is a large positive constant, the role of which is to induce the consumer to target zero debt at the end of her life.

(Without such a constraint, the optimal choice is to choose $c_t=\bar{c}$ in each period, letting assets adjust accordingly.)

As before we set $y_t=\sigma w_{t+1}+\mu$ and $u_t:=c_t-\bar{c}$, after which the constraint can be written as in (78.2).

We saw how this constraint could be manipulated into the LQ formulation $x_{t+1}=Ax_t+Bu_t+Cw_{t+1}$ by setting $x_t=(a_t\ 1)^\top$ and using the definitions in (78.4).

To match with this state and control, the objective function (78.16) can be written in the form of (78.6) by choosing

$$Q:=1,\quad R:=\begin{bmatrix}0&0\\0&0\end{bmatrix},\quad \text{and}\quad R_f:=\begin{bmatrix}q&0\\0&0\end{bmatrix}$$

Now that the problem is expressed in LQ form, we can proceed to the solution by applying (78.12) and (78.14).

After generating shocks $\{w_1,\dots,w_T\}$, the dynamics for assets and consumption can be simulated via (78.15).

The following figure was computed using $r=0.05, \beta=1/(1+r), \bar{c}=2, \mu=1, \sigma=0.25, T=45$ and $q=10^6$.

The shocks $\{w_t\}$ were taken to be IID and standard normal.

simulate_and_plot(model)
```

The top panel shows the time path of consumption c_t and income y_t in the simulation.

As anticipated by the discussion on consumption smoothing, the time path of consumption is much smoother than that for income.

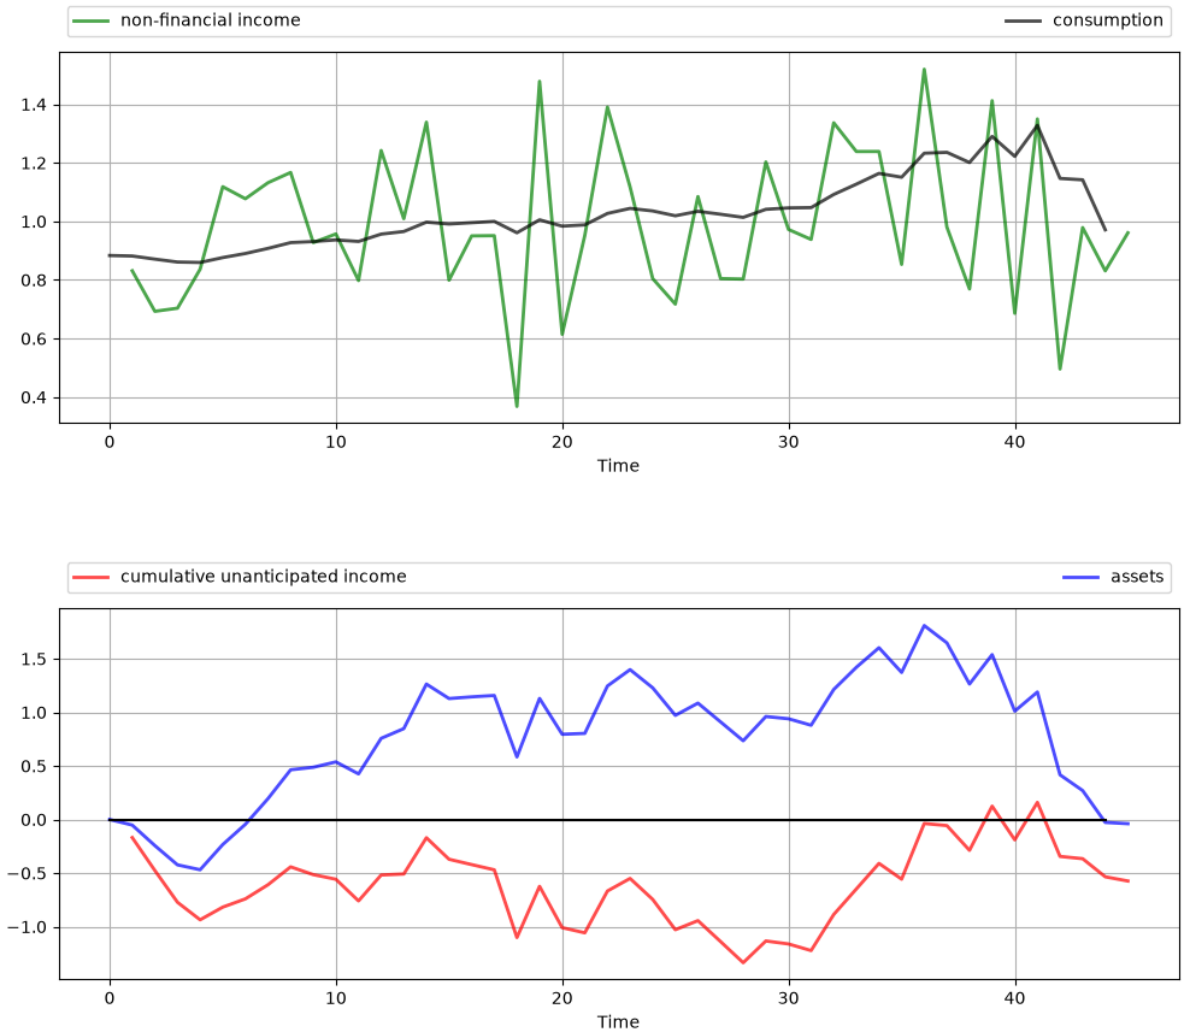
(But note that consumption becomes more irregular towards the end of life, when the zero final asset requirement impinges more on consumption choices.)

The second panel in the figure shows that the time path of assets a_t is closely correlated with cumulative unanticipated income, where the latter is defined as

$$z_t := \sum_{j=0}^{t} \sigma w_t$$

A key message is that unanticipated windfall gains are saved rather than consumed, while unanticipated negative shocks are met by reducing assets.

(Again, this relationship breaks down towards the end of life due to the zero final asset requirement.)



These results are relatively robust to changes in parameters.

For example, let's increase β from $1/(1+r) \approx 0.952$ to 0.96 while keeping other parameters fixed.

This consumer is slightly more patient than the last one, and hence puts relatively more weight on later consumption values.

Since `LQModel` is a `NamedTuple`, we can obtain the new model by copying the old one with a single field changed.

```
simulate_and_plot(model._replace(β=0.96))
```

We now have a slowly rising consumption stream and a hump-shaped build-up of assets in the middle periods to fund rising consumption.

However, the essential features are the same: consumption is smooth relative to income, and assets are strongly positively correlated with cumulative unanticipated income.

78.5 Extensions and comments

Let's now consider a number of standard extensions to the LQ problem treated above.

78.5.1 Time-varying parameters

In some settings, it can be desirable to allow A, B, C, R and Q to depend on t.

For the sake of simplicity, we've chosen not to treat this extension in our implementation given below.

However, the loss of generality is not as large as you might first imagine.

In fact, we can tackle many models with time-varying parameters by suitable choice of state variables.

One illustration is given *below*.

For further examples and a more systematic treatment, see [Hansen and Sargent, 2013], section 2.4.

78.5.2 Adding a cross-product term

In some LQ problems, preferences include a cross-product term $u_t^\top N x_t$, so that the objective function becomes

$$\mathbb{E}\left\{\sum_{t=0}^{T-1}\beta^t(x_t^\top R x_t + u_t^\top Q u_t + 2u_t^\top N x_t) + \beta^T x_T^\top R_f x_T\right\} \tag{78.17}$$

Our results extend to this case in a straightforward way.

The sequence $\{P_t\}$ from (78.12) becomes

$$P_{t-1} = R - (\beta B^\top P_t A + N)^\top (Q + \beta B^\top P_t B)^{-1}(\beta B^\top P_t A + N) + \beta A^\top P_t A \quad \text{with} \quad P_T = R_f \tag{78.18}$$

The policies in (78.14) are modified to

$$u_t = -F_t x_t \quad \text{where} \quad F_t := (Q + \beta B^\top P_{t+1} B)^{-1}(\beta B^\top P_{t+1} A + N) \tag{78.19}$$

The sequence $\{d_t\}$ is unchanged from (78.13).

We leave interested readers to confirm these results (the calculations are long but not overly difficult).

78.5.3 Infinite horizon

Finally, we consider the infinite horizon case, with *cross-product term*, unchanged dynamics and objective function given by

$$\mathbb{E}\left\{\sum_{t=0}^{\infty}\beta^t(x_t^\top R x_t + u_t^\top Q u_t + 2u_t^\top N x_t)\right\} \tag{78.20}$$

In the infinite horizon case, optimal policies can depend on time only if time itself is a component of the state vector x_t.

In other words, there exists a fixed matrix F such that $u_t = -Fx_t$ for all t.

That decision rules are constant over time is intuitive — after all, the decision-maker faces the same infinite horizon at every stage, with only the current state changing.

Not surprisingly, P and d are also constant.

The stationary matrix P is the solution to the discrete-time algebraic Riccati equation.

$$P = R - (\beta B^\top P A + N)^\top (Q + \beta B^\top P B)^{-1}(\beta B^\top P A + N) + \beta A^\top P A \tag{78.21}$$

Equation (78.21) is also called the *LQ Bellman equation*, and the map that sends a given P into the right-hand side of (78.21) is called the *LQ Bellman operator*.

The stationary optimal policy for this model is

$$u = -Fx \quad \text{where} \quad F = (Q + \beta B^\top P B)^{-1}(\beta B^\top P A + N) \tag{78.22}$$

The sequence $\{d_t\}$ from (78.13) is replaced by the constant value

$$d := \text{trace}(C^\top P C)\frac{\beta}{1-\beta} \tag{78.23}$$

The state evolves according to the time-homogeneous process $x_{t+1} = (A - BF)x_t + Cw_{t+1}$.

An example infinite horizon problem is treated *below*.

78.5.4 Certainty equivalence

Linear quadratic control problems of the class discussed above have the property of *certainty equivalence*.

By this, we mean that the optimal policy F is not affected by the parameters in C, which specify the shock process.

This can be confirmed by inspecting (78.22) or (78.19).

It follows that we can ignore uncertainty when solving for optimal behavior, and plug it back in when examining optimal state dynamics.

78.6 Further applications

78.6.1 Application 1: Age-dependent income process

Previously we studied a permanent income model that generated consumption smoothing.

One unrealistic feature of that model is the assumption that the mean of the random income process does not depend on the consumer's age.

A more realistic income profile is one that rises in early working life, peaks towards the middle and maybe declines toward the end of working life and falls more during retirement.

In this section, we will model this rise and fall as a symmetric inverted "U" using a polynomial in age.

As before, the consumer seeks to minimize

$$\mathbb{E}\left\{\sum_{t=0}^{T-1}\beta^t(c_t - \bar{c})^2 + \beta^T q a_T^2\right\} \tag{78.24}$$

subject to $a_{t+1} = (1+r)a_t - c_t + y_t,\ t \geq 0$.

For income we now take $y_t = p(t) + \sigma w_{t+1}$ where $p(t) := m_0 + m_1 t + m_2 t^2$.

(In *the next section* we employ some tricks to implement a more sophisticated model.)

The coefficients m_0, m_1, m_2 are chosen such that $p(0) = 0, p(T/2) = \mu$, and $p(T) = 0$.

You can confirm that the specification $m_0 = 0, m_1 = T\mu/(T/2)^2, m_2 = -\mu/(T/2)^2$ satisfies these constraints.

To put this into an LQ setting, consider the budget constraint, which becomes

$$a_{t+1} = (1+r)a_t - u_t - \bar{c} + m_1 t + m_2 t^2 + \sigma w_{t+1} \tag{78.25}$$

The fact that a_{t+1} is a linear function of $(a_t, 1, t, t^2)$ suggests taking these four variables as the state vector x_t.

Once a good choice of state and control (recall $u_t = c_t - \bar{c}$) has been made, the remaining specifications fall into place relatively easily.

Thus, for the dynamics we set

$$x_t := \begin{bmatrix} a_t \\ 1 \\ t \\ t^2 \end{bmatrix}, \quad A := \begin{bmatrix} 1+r & -\bar{c} & m_1 & m_2 \\ 0 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 1 & 2 & 1 \end{bmatrix}, \quad B := \begin{bmatrix} -1 \\ 0 \\ 0 \\ 0 \end{bmatrix}, \quad C := \begin{bmatrix} \sigma \\ 0 \\ 0 \\ 0 \end{bmatrix} \tag{78.26}$$

If you expand the expression $x_{t+1} = Ax_t + Bu_t + Cw_{t+1}$ using this specification, you will find that assets follow (78.25) as desired and that the other state variables also update appropriately.

To implement preference specification (78.24) we take

$$Q := 1, \quad R := \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \quad \text{and} \quad R_f := \begin{bmatrix} q & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \tag{78.27}$$

The next figure shows a simulation of consumption and assets computed using the `compute_sequence` method of `lqcontrol.py` with initial assets set to zero.

Once again, smooth consumption is a dominant feature of the sample paths.

The asset path exhibits dynamics consistent with standard life cycle theory.

Exercise 78.7.1 gives the full set of parameters used here and asks you to replicate the figure.

78.6.2 Application 2: A permanent income model with retirement

In the *previous application*, we generated income dynamics with an inverted U shape using polynomials and placed them in an LQ framework.

It is arguably the case that this income process still contains unrealistic features.

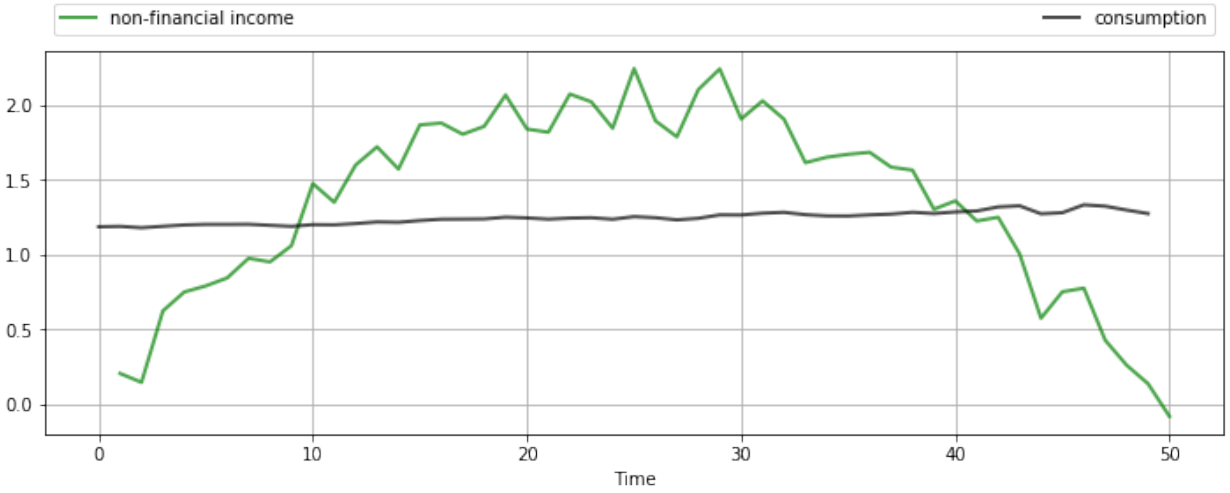
A more common earning profile is where

1. income grows over working life, fluctuating around an increasing trend, with growth flattening off in later years
2. retirement follows, with lower but relatively stable (non-financial) income

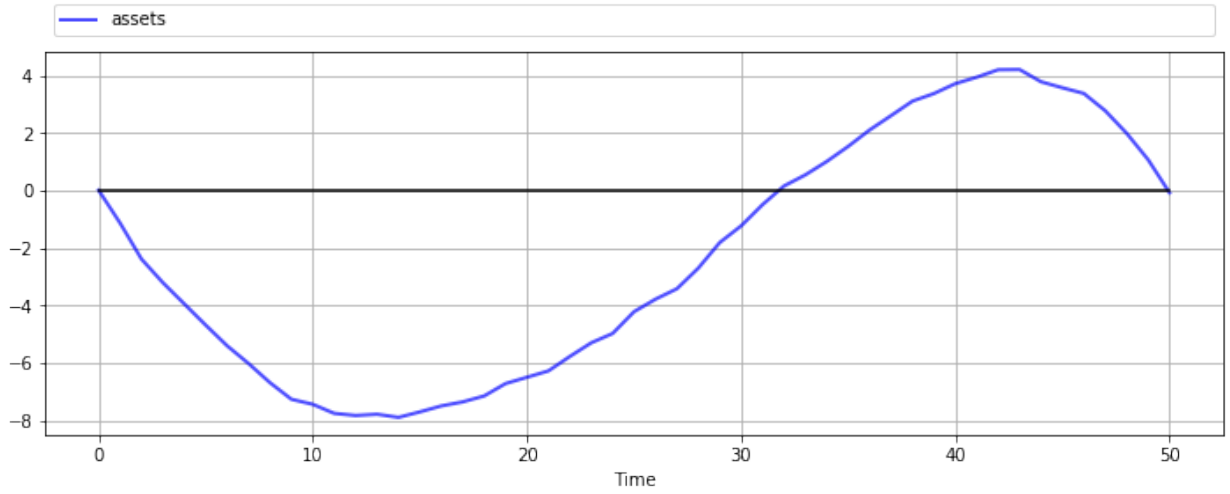
Letting K be the retirement date, we can express these income dynamics by

$$y_t = \begin{cases} p(t) + \sigma w_{t+1} & \text{if } t \leq K \\ s & \text{otherwise} \end{cases} \tag{78.28}$$

Here



- $p(t) := m_1 t + m_2 t^2$ with the coefficients m_1, m_2 chosen such that $p(K) = \mu$ and $p(0) = p(2K) = 0$
- s is retirement income



We suppose that preferences are unchanged and given by (78.16).

The budget constraint is also unchanged and given by $a_{t+1} = (1+r)a_t - c_t + y_t$.

Our aim is to solve this problem and simulate paths using the LQ techniques described in this lecture.

In fact, this is a nontrivial problem, as the kink in the dynamics (78.28) at K makes it very difficult to express the law of motion as a fixed-coefficient linear system.

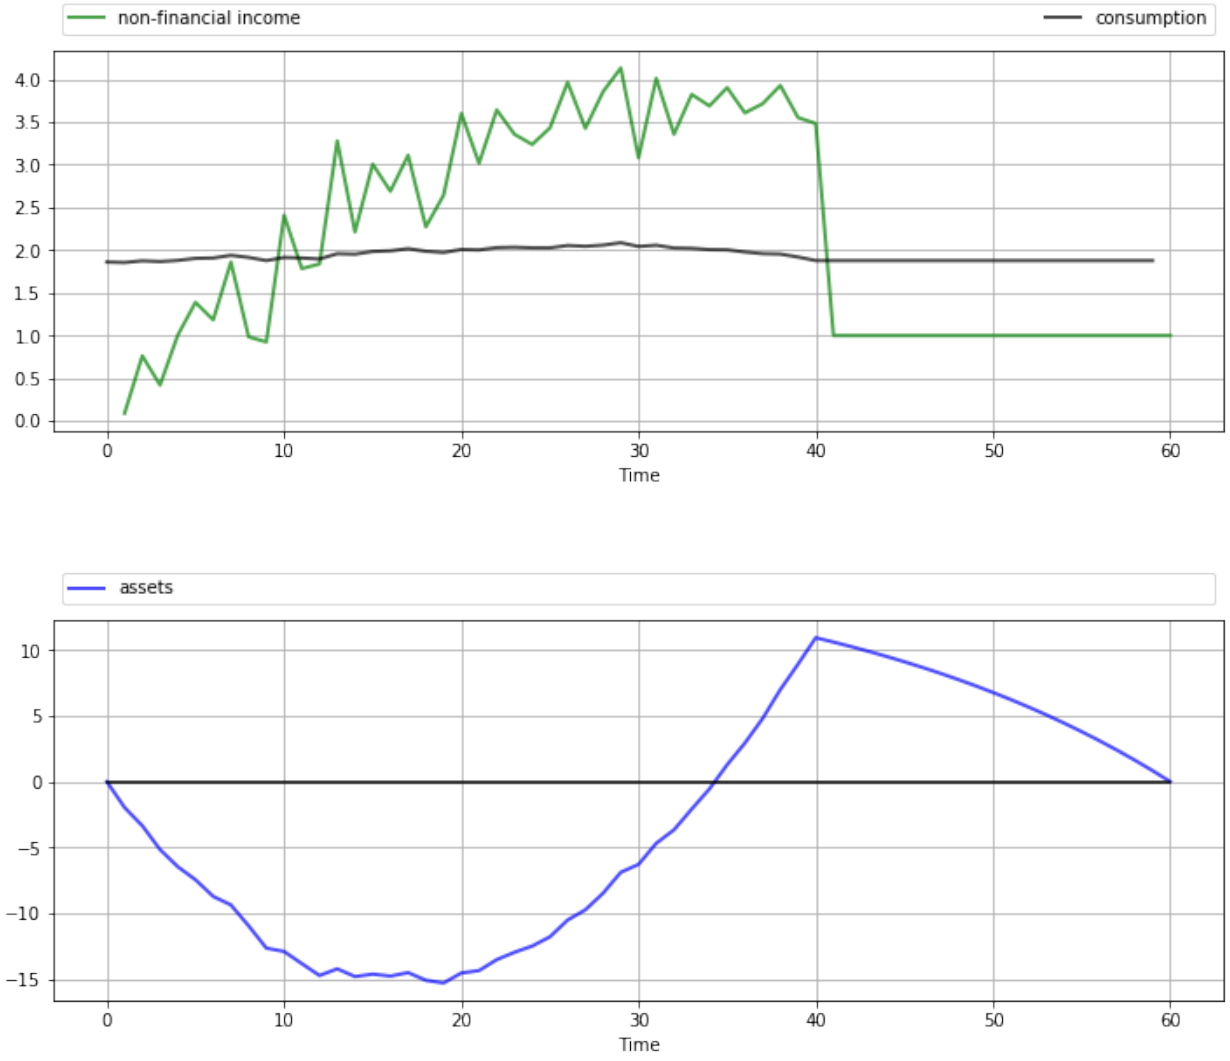
However, we can still use our LQ methods here by suitably linking two-component LQ problems.

These two LQ problems describe the consumer's behavior during her working life (`lq_working`) and retirement (`lq_retired`).

(This is possible because, in the two separate periods of life, the respective income processes [polynomial trend and constant] each fit the LQ framework.)



The basic idea is that although the whole problem is not a single time-invariant LQ problem, it is still a dynamic programming problem, and hence we can use appropriate Bellman equations at every stage.

Based on this logic, we can

1. solve `lq_retired` by the usual backward induction procedure, iterating back to the start of retirement.
2. take the start-of-retirement value function generated by this process, and use it as the terminal condition R_f to feed into the `lq_working` specification.
3. solve `lq_working` by backward induction from this choice of R_f, iterating back to the start of working life.

This process gives the entire life-time sequence of value functions and optimal policies.

The next figure shows one simulation based on this procedure.

The full set of parameters used in the simulation is discussed in Exercise 78.7.2, where you are asked to replicate the figure.

Once again, the dominant feature observable in the simulation is consumption smoothing.

The asset path fits well with standard life cycle theory, with dissaving early in life followed by later saving.

Assets peak at retirement and subsequently decline.

78.6.3 Application 3: Monopoly with adjustment costs

Consider a monopolist facing stochastic inverse demand function

$$p_t = a_0 - a_1 q_t + d_t$$

Here q_t is output, and the demand shock d_t follows

$$d_{t+1} = \rho d_t + \sigma w_{t+1}$$

where $\{w_t\}$ is IID and standard normal.

The monopolist maximizes the expected discounted sum of present and future profits

$$\mathbb{E}\left\{\sum_{t=0}^{\infty} \beta^t \pi_t\right\} \quad \text{where} \quad \pi_t := p_t q_t - c q_t - \gamma (q_{t+1} - q_t)^2 \tag{78.29}$$

Here

- $\gamma (q_{t+1} - q_t)^2$ represents adjustment costs
- c is average cost of production

This can be formulated as an LQ problem and then solved and simulated, but first let's study the problem and try to get some intuition.

One way to start thinking about the problem is to consider what would happen if $\gamma = 0$.

Without adjustment costs there is no intertemporal trade-off, so the monopolist will choose output to maximize current profit in each period.

It's not difficult to show that profit-maximizing output is

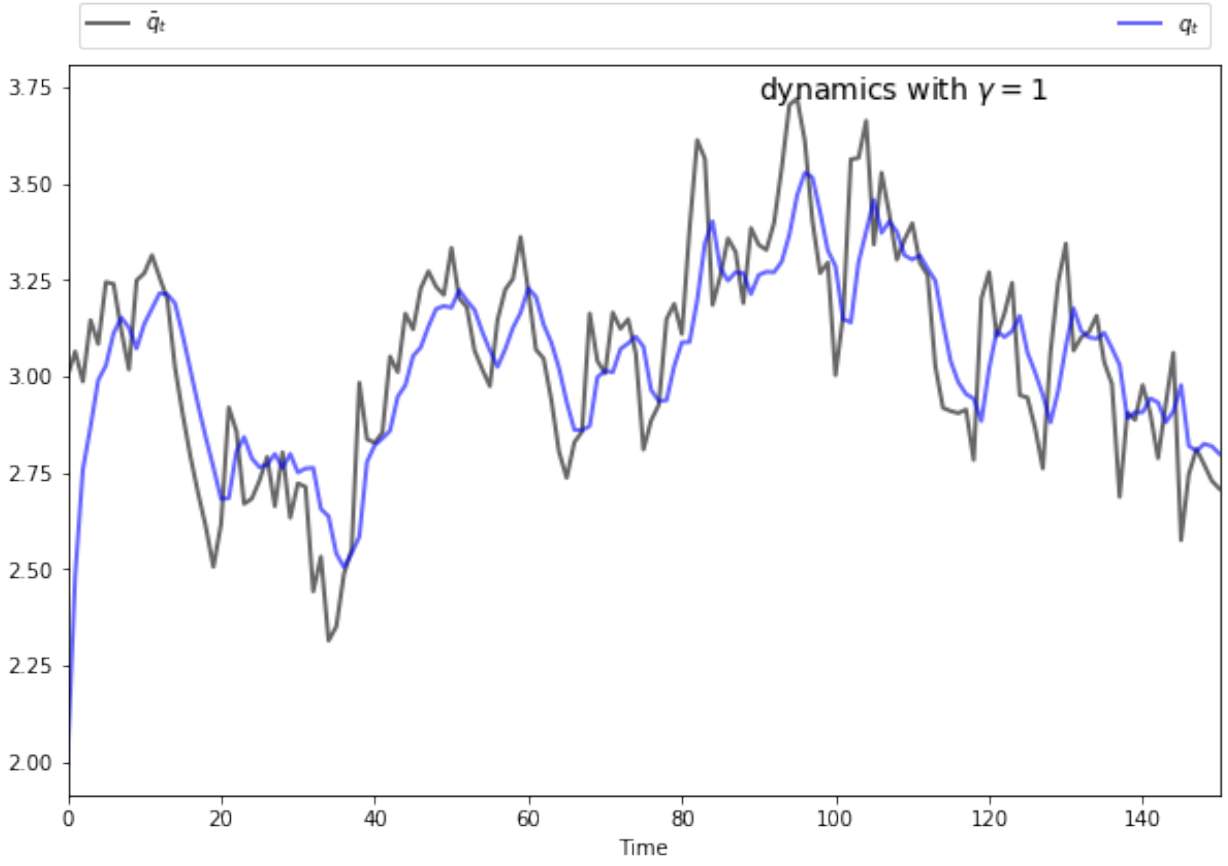
$$\bar{q}_t := \frac{a_0 - c + d_t}{2a_1}$$

In light of this discussion, what we might expect for general γ is that

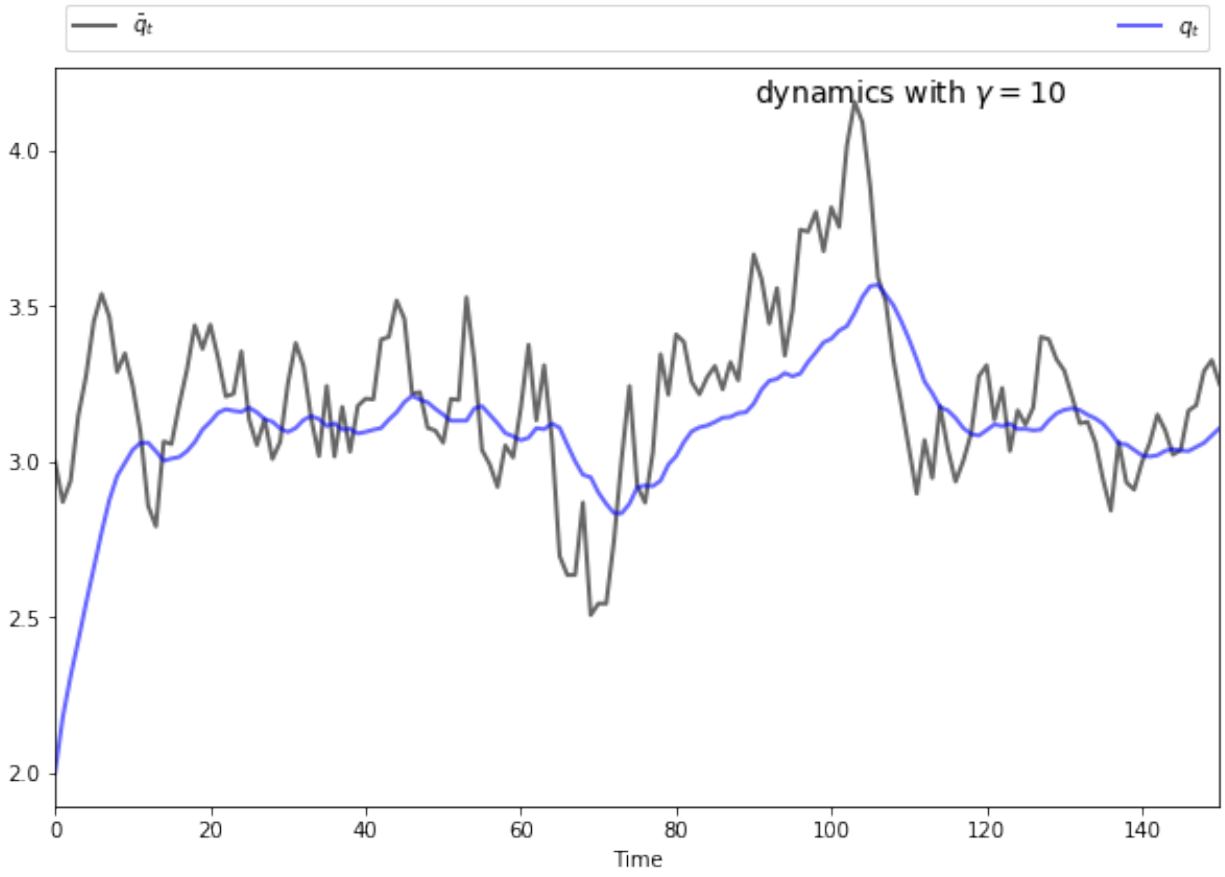
- if γ is close to zero, then q_t will track the time path of $\bar{q}_t$ relatively closely.
- if γ is larger, then q_t will be smoother than $\bar{q}_t$, as the monopolist seeks to avoid adjustment costs.

This intuition turns out to be correct.

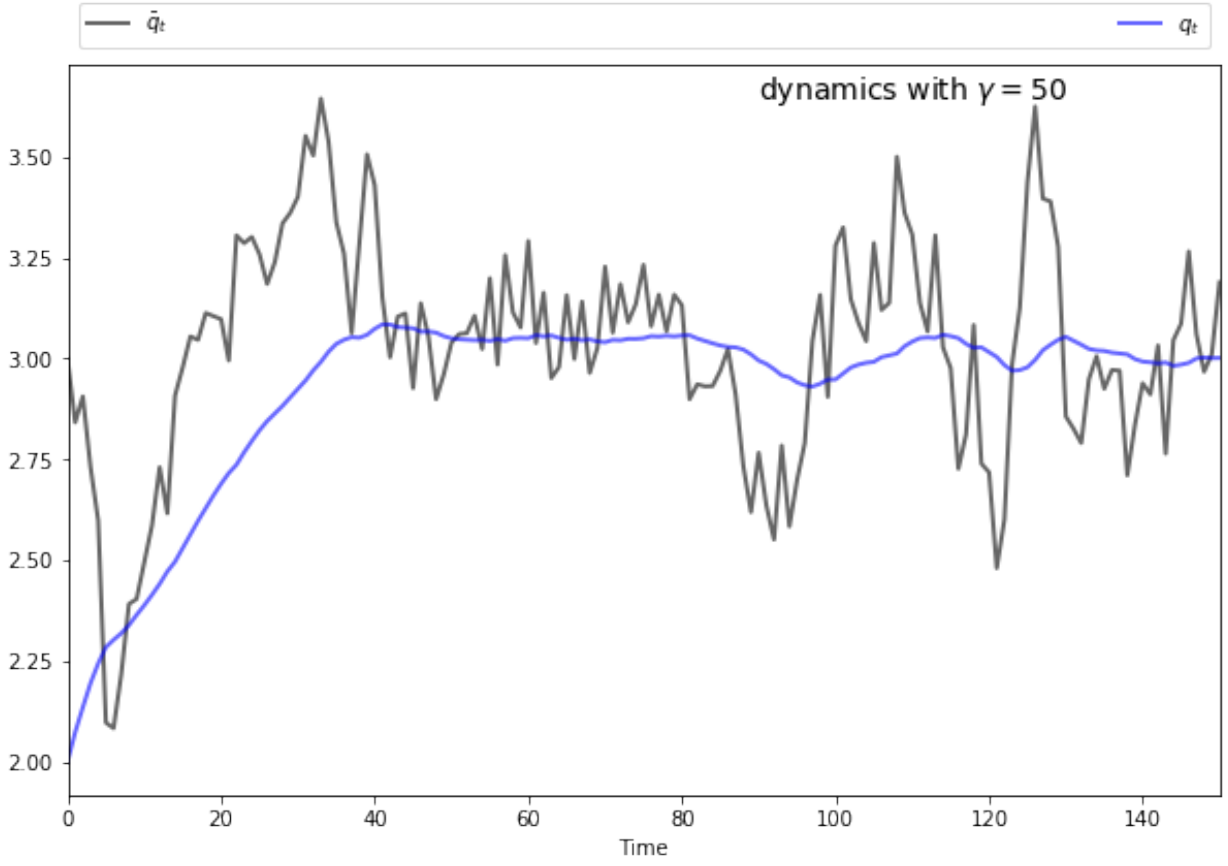
The following figures show simulations produced by solving the corresponding LQ problem.



The only difference in parameters across the figures is the size of γ



To produce these figures we converted the monopolist problem into an LQ problem.



The key to this conversion is to choose the right state — which can be a bit of an art.

Here we take $x_t = (\bar{q}_t \;\; q_t \;\; 1)^\top$, while the control is chosen as $u_t = q_{t+1} - q_t$.

We also manipulated the profit function slightly.

In (78.29), current profits are $\pi_t := p_t q_t - c q_t - \gamma (q_{t+1} - q_t)^2$.

Let's now replace π_t in (78.29) with $\hat{\pi}_t := \pi_t - a_1 \bar{q}_t^2$.

This makes no difference to the solution, since $a_1 \bar{q}_t^2$ does not depend on the controls.

(In fact, we are just adding a constant term to (78.29), and optimizers are not affected by constant terms.)

The reason for making this substitution is that, as you will be able to verify, $\hat{\pi}_t$ reduces to the simple quadratic

$$\hat{\pi}_t = -a_1 (q_t - \bar{q}_t)^2 - \gamma u_t^2$$

After negation to convert to a minimization problem, the objective becomes

$$\min \mathbb{E} \sum_{t=0}^{\infty} \beta^t \left\{ a_1 (q_t - \bar{q}_t)^2 + \gamma u_t^2 \right\} \tag{78.30}$$

It's now relatively straightforward to find R and Q such that (78.30) can be written as (78.20).

Furthermore, the matrices A, B and C from (78.1) can be found by writing down the dynamics of each element of the state.

Exercise 78.7.3 asks you to complete this process, and reproduce the preceding figures.

78.7 Exercises

Exercise 78.7.1

Replicate the figure with polynomial income *shown above*.

The parameters are $r = 0.05, \beta = 1/(1+r), \bar{c} = 1.5, \mu = 2, \sigma = 0.15, T = 50$ and $q = 10^4$.

Solution

Here's one solution.

We use some fancy plot commands to get a certain style – feel free to use simpler ones.

The model is an LQ permanent income / life-cycle model with hump-shaped income

$$y_t = m_1 t + m_2 t^2 + \sigma w_{t+1}$$

where $\{w_t\}$ is IID $N(0,1)$ and the coefficients m_1 and m_2 are chosen so that $p(t) = m_1 t + m_2 t^2$ has an inverted U shape with

- $p(0) = 0, p(T/2) = \mu$, and
- $p(T) = 0$

```
# Model parameters
r = 0.05
β = 1/(1 + r)
T = 50
c_bar = 1.5
σ = 0.15
μ = 2
q = 1e4
```

```
m1 = T * (μ/(T/2)**2)
m2 = -(μ/(T/2)**2)

# Formulate as an LQ problem
Q = 1
R = np.zeros((4, 4))
Rf = np.zeros((4, 4))
Rf[0, 0] = q
A = [[1 + r, -c_bar, m1, m2],
     [0,           1,  0,  0],
     [0,           1,  1,  0],
     [0,           1,  2,  1]]
B = [[-1],
     [ 0],
     [ 0],
     [ 0]]
C = [[σ],
     [0],
     [0],
     [0]]

# Compute solutions and simulate

axes[1].plot(range(T+1), np.zeros(T+1), 'k-')

for ax in axes:
    ax.grid()
    ax.set_xlabel('Time')
    ax.legend(ncol=2, **legend_args)

plt.show()
```

Exercise 78.7.2

Replicate the figure on work and retirement *shown above*.

The parameters are $r = 0.05, \beta = 1/(1+r), \bar{c} = 4, \mu = 4, \sigma = 0.35, K = 40, T = 60, s = 1$ and $q = 10^4$.

To understand the overall procedure, carefully read the section containing that figure.

Hint

First, in order to make our approach work, we must ensure that both LQ problems have the same state variables and control.
As with previous applications, the control can be set to $u_t = c_t - \bar{c}$.
For `lq_working`, x_t, A, B, C can be chosen as in (78.26).

- Recall that m_1, m_2 are chosen so that $p(K) = \mu$ and $p(2K) = 0$.

For `lq_retired`, use the same definition of x_t and u_t, but modify A, B, C to correspond to constant income $y_t = s$.
For `lq_retired`, set preferences as in (78.27).
For `lq_working`, preferences are the same, except that R_f should be replaced by the final value function that emerges from iterating `lq_retired` back to the start of retirement.
With some careful footwork, the simulation can be generated by patching together the simulations from these two separate models.

Solution

This is a permanent income / life-cycle model with polynomial growth in income over working life followed by a fixed retirement income.

The model is solved by combining two LQ programming problems as described in the lecture.

```
# Model parameters
r = 0.05
β = 1/(1 + r)
T = 60
K = 40
c_bar = 4
σ = 0.35
μ = 4
q = 1e4
s = 1
m1 = 2 * μ/K
m2 = -μ/K**2

# Formulate LQ problem 1 (retirement)
Q = 1
R = np.zeros((4, 4))
Rf = np.zeros((4, 4))
Rf[0, 0] = q
A = [[1 + r, s - c_bar, 0, 0],
     [0,               1, 0, 0],
     [0,               1, 1, 0],
     [0,               1, 2, 1]]
B = [[-1],
     [ 0],
     [ 0],
     [ 0]]
C = [[0],
     [0],
     [0],
     [0]]

Exercise 78.7.3

Reproduce the figures from the monopolist application *given above*.

For parameters, use $a_0 = 5, a_1 = 0.5, \sigma = 0.15, \rho = 0.9, \beta = 0.95$ and $c = 2$, while γ varies between 1 and 50 (see figures).

Solution

The first task is to find the matrices A, B, C, Q, R that define the LQ problem.

Recall that $x_t = (\bar{q}_t \;\; q_t \;\; 1)^\top$, while $u_t = q_{t+1} - q_t$.

Letting $m_0 := (a_0 - c)/2a_1$ and $m_1 := 1/2a_1$, we can write $\bar{q}_t = m_0 + m_1 d_t$, and then, with some manipulation

$$\bar{q}_{t+1} = m_0(1-\rho) + \rho\bar{q}_t + m_1\sigma w_{t+1}$$

By our definition of u_t, the dynamics of q_t are $q_{t+1} = q_t + u_t$.

Using these facts you should be able to build the correct A, B, C matrices (and then check them against those found in the solution code below).

Suitable R, Q matrices can be found by inspecting the objective function, which we repeat here for convenience:

$$\min \mathbb{E}\left\{\sum_{t=0}^{\infty} \beta^t a_1(q_t - \bar{q}_t)^2 + \gamma u_t^2\right\}$$

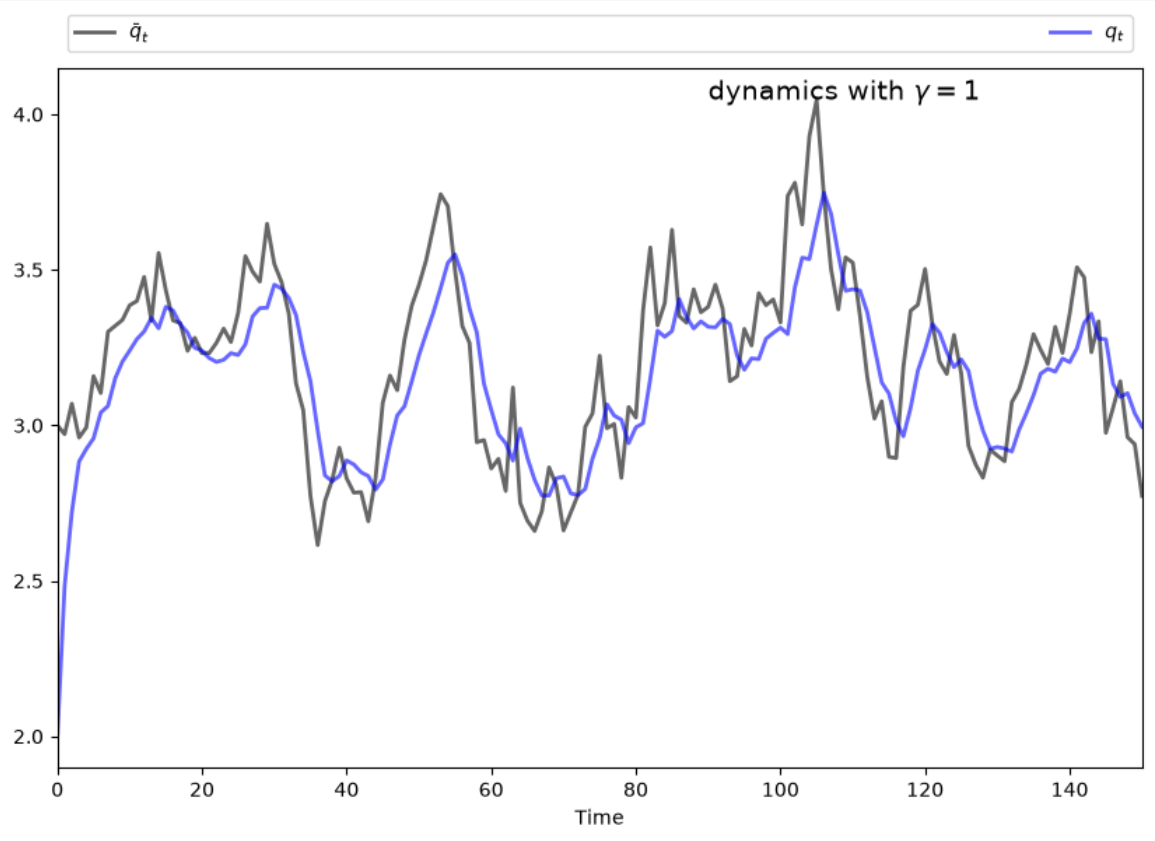
Our solution code is

```
# Model parameters
a0 = 5
a1 = 0.5
σ = 0.15
ρ = 0.9
γ = 1
β = 0.95
c = 2
T = 120

# Useful constants
m0 = (a0-c)/(2 * a1)
m1 = 1/(2 * a1)

# Formulate LQ problem
Q = γ
R = [[ a1, -a1,  0],
     [-a1,  a1,  0],
     [  0,   0,  0]]
A = [[ρ, 0, m0 * (1 - ρ)],
     [0, 1,           0],
     [0, 0,           1]]

B = [[0],
     [1],
     [0]]
C = [[m1 * σ],
     [     0],
     [     0]]



lq = LQ(Q, R, A, B, C=C, beta=β)

# Simulate state / control paths
x0 = (m0, 2, 1)
xp, up, wp = lq.compute_sequence(x0, ts_length=150)
q_bar = xp[0, :]
q = xp[1, :]

# Plot simulation results
fig, ax = plt.subplots(figsize=(10, 6.5))
```

```
# Some fancy plotting stuff -- simplify if you prefer
bbox = (0., 1.01, 1., .101)
legend_args = {'bbox_to_anchor': bbox, 'loc': 3, 'mode': 'expand'}
p_args = {'lw': 2, 'alpha': 0.6}

time = range(len(q))
ax.set(xlabel='Time', xlim=(0, max(time)))
ax.plot(time, q_bar, 'k-', lw=2, alpha=0.6, label=r'$\bar q_t$')
ax.plot(time, q, 'b-', lw=2, alpha=0.6, label='$q_t$')
ax.legend(ncol=2, **legend_args)
s = fr'dynamics with $\gamma = {γ}$'
ax.text(max(time) * 0.6, 1 * q_bar.max(), s, fontsize=14)
plt.show()
```

CHAPTER

SEVENTYNINE

LAGRANGIAN FOR LQ CONTROL

```
!pip install quantecon
```

```
import numpy as np
from quantecon import LQ
from scipy.linalg import schur
```

79.1 Overview

This is a sequel to this lecture *linear quadratic dynamic programming*

It can also be regarded as presenting **invariant subspace** techniques that extend ones that we encountered earlier in this lecture *stability in linear rational expectations models*

We present a Lagrangian formulation of an infinite horizon linear quadratic undiscounted dynamic programming problem.

Such a problem is also sometimes called an optimal linear regulator problem.

A Lagrangian formulation

- carries insights about connections between stability and optimality
- is the basis for fast algorithms for solving Riccati equations
- opens the way to constructing solutions of dynamic systems that don't come directly from an intertemporal optimization problem

A key tool in this lecture is the concept of an $n \times n$ **symplectic** matrix.

A symplectic matrix has eigenvalues that occur in **reciprocal pairs**, meaning that if $\lambda_i \in (-1, 1)$ is an eigenvalue, then so is λ_i^{-1}.

This reciprocal pairs property of the eigenvalues of a matrix is a tell-tale sign that the matrix describes the joint dynamics of a system of equations describing the **states** and **costates** that constitute first-order necessary conditions for solving an undiscounted linear-quadratic infinite-horizon optimization problem.

The symplectic matrix that will interest us describes the first-order dynamics of **state** and **co-state** vectors of an optimally controlled system.

In focusing on eigenvalues and eigenvectors of this matrix, we capitalize on an analysis of **invariant subspaces.**

These invariant subspace formulations of LQ dynamic programming problems provide a bridge between recursive (i.e., dynamic programming) formulations and classical formulations of linear control and linear filtering problems that make use of related matrix decompositions (see for example this lecture and this lecture).

While most of this lecture focuses on undiscounted problems, later sections describe handy ways of transforming discounted problems to undiscounted ones.

The techniques in this lecture will prove useful when we study Stackelberg and Ramsey problem in this lecture.

79.2 Undiscounted LQ DP Problem

The problem is to choose a sequence of controls $\{u_t\}_{t=0}^{\infty}$ to maximize the criterion

$$-\sum_{t=0}^{\infty}\{x_t' R x_t + u_t' Q u_t\}$$

subject to $x_{t+1} = Ax_t + Bu_t$, where x_0 is a given initial state vector.

Here x_t is an $(n \times 1)$ vector of state variables, u_t is a $(k \times 1)$ vector of controls, R is a positive semidefinite symmetric matrix, Q is a positive definite symmetric matrix, A is an $(n \times n)$ matrix, and B is an $(n \times k)$ matrix.

The optimal value function turns out to be quadratic, $V(x) = -x'Px$, where P is a positive semidefinite symmetric matrix.

Using the transition law to eliminate next period's state, the Bellman equation becomes

$$-x'Px = \max_u\{-x'Rx - u'Qu - (Ax + Bu)'P(Ax + Bu)\} \tag{79.1}$$

The first-order necessary conditions for the maximum problem on the right side of equation (79.1) are

Note

We use the following rules for differentiating quadratic and bilinear matrix forms: $\frac{\partial x'Ax}{\partial x} = (A + A')x$; $\frac{\partial y'Bz}{\partial y} = Bz$, $\frac{\partial y'Bz}{\partial z} = B'y$.

$$(Q + B'PB)u = -B'PAx,$$

which implies that an optimal decision rule for u is

$$u = -(Q + B'PB)^{-1}B'PAx$$

or

$$u = -Fx,$$

where

$$F = (Q + B'PB)^{-1}B'PA.$$

Substituting $u = -(Q + B'PB)^{-1}B'PAx$ into the right side of equation (79.1) and rearranging gives

$$P = R + A'PA - A'PB(Q + B'PB)^{-1}B'PA. \tag{79.2}$$

Equation (79.2) is called an **algebraic matrix Riccati** equation.

There are multiple solutions of equation (79.2).

But only one of them is positive definite.

The positive define solution is associated with the maximum of our problem.

It expresses the matrix P as an implicit function of the matrices R, Q, A, B.

Notice that the **gradient of the value function** is

$$\frac{\partial V(x)}{\partial x} = -2Px \tag{79.3}$$

We shall use fact (79.3) later.

79.3 Lagrangian

For the undiscounted optimal linear regulator problem, form the Lagrangian

$$L = -\sum_{t=0}^{\infty}\left\{x_t' R x_t + u_t' Q u_t + 2\mu_{t+1}'[Ax_t + Bu_t - x_{t+1}]\right\} \tag{79.4}$$

where $2\mu_{t+1}$ is a vector of Lagrange multipliers on the time t transition law $x_{t+1} = Ax_t + Bu_t$.

(We put the 2 in front of μ_{t+1} to make things match up nicely with equation (79.3).)

First-order conditions for maximization with respect to $\{u_t, x_{t+1}\}_{t=0}^{\infty}$ are

$$\begin{aligned} 2Qu_t + 2B'\mu_{t+1} &= 0 \ , \ t \geq 0 \\ \mu_t &= Rx_t + A'\mu_{t+1} \ , \ t \geq 1. \end{aligned} \tag{79.5}$$

Define μ_0 to be a vector of shadow prices of x_0 and apply an envelope condition to (79.4) to deduce that

$$\mu_0 = Rx_0 + A'\mu_1,$$

which is a time $t = 0$ counterpart to the second equation of system (79.5).

An important fact is that

$$\mu_{t+1} = Px_{t+1} \tag{79.6}$$

where P is a positive define matrix that solves the algebraic Riccati equation (79.2).

Thus, from equations (79.3) and (79.6), $-2\mu_t$ is the gradient of the value function with respect to x_t.

The Lagrange multiplier vector μ_t is often called the **costate** vector that corresponds to the **state** vector x_t.

It is useful to proceed with the following steps:

- solve the first equation of (79.5) for u_t in terms of μ_{t+1}.
- substitute the result into the law of motion $x_{t+1} = Ax_t + Bu_t$.
- arrange the resulting equation and the second equation of (79.5) into the form

$$L \begin{bmatrix} x_{t+1} \\ \mu_{t+1} \end{bmatrix} = N \begin{bmatrix} x_t \\ \mu_t \end{bmatrix} \ , \ t \geq 0, \tag{79.7}$$

where

$$L = \begin{bmatrix} I & BQ^{-1}B' \\ 0 & A' \end{bmatrix}, \quad N = \begin{bmatrix} A & 0 \\ -R & I \end{bmatrix}.$$

When L is of full rank (i.e., when A is of full rank), we can write system (79.7) as

$$\begin{bmatrix} x_{t+1} \\ \mu_{t+1} \end{bmatrix} = M \begin{bmatrix} x_t \\ \mu_t \end{bmatrix} \tag{79.8}$$

where

$$M \equiv L^{-1}N = \begin{bmatrix} A + BQ^{-1}B'A'^{-1}R & -BQ^{-1}B'A'^{-1} \\ -A'^{-1}R & A'^{-1} \end{bmatrix}. \tag{79.9}$$

79.4 State-Costate Dynamics

We seek to solve the difference equation system (79.8) for a sequence $\{x_t\}_{t=0}^{\infty}$ that satisfies

- an initial condition for x_0
- a terminal condition $\lim_{t\to+\infty} x_t = 0$

This terminal condition reflects our desire for a **stable** solution, one that does not diverge as $t \to \infty$.

We inherit our wish for stability of the $\{x_t\}$ sequence from a desire to maximize

$$-\sum_{t=0}^{\infty}[x_t'Rx_t + u_t'Qu_t],$$

which requires that $x_t'Rx_t$ converge to zero as $t \to +\infty$.

79.5 Reciprocal Pairs Property

To proceed, we study properties of the $(2n \times 2n)$ matrix M defined in (79.9).

It helps to introduce a $(2n \times 2n)$ matrix

$$J = \begin{bmatrix} 0 & -I_n \\ I_n & 0 \end{bmatrix}.$$

The rank of J is $2n$.

Definition: A matrix M is called **symplectic** if

$$MJM' = J. \tag{79.10}$$

Salient properties of symplectic matrices that are readily verified include:

- If M is symplectic, then M^2 is symplectic
- The determinant of a symplectic, then $\det(M) = 1$

It can be verified directly that M in equation (79.9) is symplectic.

It follows from equation (79.10) and from the fact $J^{-1} = J' = -J$ that for any symplectic matrix M,

$$M' = J^{-1}M^{-1}J. \tag{79.11}$$

Equation (79.11) states that M' is related to the inverse of M by a **similarity transformation**.

For square matrices, recall that

- similar matrices share eigenvalues
- eigenvalues of the inverse of a matrix are inverses of eigenvalues of the matrix
- a matrix and its transpose share eigenvalues

It then follows from equation (79.11) that the eigenvalues of M occur in reciprocal pairs: if λ is an eigenvalue of M, so is λ^{-1}.

Write equation (79.8) as

$$y_{t+1} = My_t \tag{79.12}$$

where $y_t = \begin{bmatrix} x_t \\ \mu_t \end{bmatrix}$.

Consider a **triangularization** of M

$$V^{-1}MV = \begin{bmatrix} W_{11} & W_{12} \\ 0 & W_{22} \end{bmatrix} \tag{79.13}$$

where

- each block on the right side is $(n \times n)$
- V is nonsingular
- all eigenvalues of W_{22} exceed 1 in modulus
- all eigenvalues of W_{11} are less than 1 in modulus

79.6 Schur decomposition

The **Schur decomposition** and the **eigenvalue decomposition** are two decompositions of the form (79.13).

Write equation (79.12) as

$$y_{t+1} = VWV^{-1}y_t. \tag{79.14}$$

A solution of equation (79.14) for arbitrary initial condition y_0 is evidently

$$y_t = V \begin{bmatrix} W_{11}^t & W_{12,t} \\ 0 & W_{22}^t \end{bmatrix} V^{-1}y_0 \tag{79.15}$$

where $W_{12,t} = W_{12}$ for $t = 1$ and for $t \geq 2$ obeys the recursion

$$W_{12,t} = W_{11}^{t-1}W_{12,t-1} + W_{12,t-1}W_{22}^{t-1}$$

and where W_{ii}^t is W_{ii} raised to the tth power.

Write equation (79.15) as

$$\begin{bmatrix} y_{1t}^* \\ y_{2t}^* \end{bmatrix} = \begin{bmatrix} W_{11}^t & W_{12,t} \\ 0 & W_{22}^t \end{bmatrix} \begin{bmatrix} y_{10}^* \\ y_{20}^* \end{bmatrix}$$

where $y_t^* = V^{-1}y_t$, and in particular where

$$y_{2t}^* = V^{21}x_t + V^{22}\mu_t, \tag{79.16}$$

and where V^{ij} denotes the (i, j) piece of the partitioned V^{-1} matrix.

Because W_{22} is an unstable matrix, y_t^* will diverge unless $y_{20}^* = 0$.

Let V^{ij} denote the (i, j) piece of the partitioned V^{-1} matrix.

To attain stability, we must impose $y_{20}^* = 0$, which from equation (79.16) implies

$$V^{21}x_0 + V^{22}\mu_0 = 0$$

or

$$\mu_0 = -(V^{22})^{-1}V^{21}x_0.$$

This equation replicates itself over time in the sense that it implies

$$\mu_t = -(V^{22})^{-1} V^{21} x_t.$$

But notice that because $(V^{21}\ V^{22})$ is the second row block of the inverse of V, it follows that

$$(V^{21}\ V^{22}) \quad \begin{bmatrix} V_{11} \\ V_{21} \end{bmatrix} = 0$$

which implies

$$V^{21} V_{11} + V^{22} V_{21} = 0.$$

Therefore,

$$-(V^{22})^{-1} V^{21} = V_{21} V_{11}^{-1}.$$

So we can write

$$\mu_0 = V_{21} V_{11}^{-1} x_0$$

and

$$\mu_t = V_{21} V_{11}^{-1} x_t.$$

However, we know that $\mu_t = P x_t$, where P occurs in the matrix that solves the Riccati equation.

Thus, the preceding argument establishes that

$$P = V_{21} V_{11}^{-1}. \tag{79.17}$$

Remarkably, formula (79.17) provides us with a computationally efficient way of computing the positive definite matrix P that solves the algebraic Riccati equation (79.2) that emerges from dynamic programming.

This same method can be applied to compute the solution of any system of the form (79.8) if a solution exists, even if eigenvalues of M fail to occur in reciprocal pairs.

The method will typically work so long as the eigenvalues of M split half inside and half outside the unit circle.

Systems in which eigenvalues (properly adjusted for discounting) fail to occur in reciprocal pairs arise when the system being solved is an equilibrium of a model in which there are distortions that prevent there being any optimum problem that the equilibrium solves. See [Ljungqvist and Sargent, 2018], ch 12.

79.7 Application

Here we demonstrate the computation with the deterministic permanent-income example from this *LQ Control: Foundations*.

Because that model is discounted, we apply the invariant-subspace method to the equivalent *undiscounted* system obtained from the transformed matrices $\hat{A} = \beta^{1/2} A$ and $\hat{B} = \beta^{1/2} B$.

```
# Model parameters
r = 0.05
β = 1 / (1 + r)
c_bar = 2
μ = 1
```

(continues on next page)

(continued from previous page)

```
# Formulate as an LQ problem
Q = np.array([[1]])
R = np.zeros((2, 2))
A = [[1 + r, -c_bar + μ],
     [0,               1]]
B = [[-1],
     [0]]

# Construct an LQ instance
lq = LQ(Q, R, A, B, beta=β)
```

Given matrices A, B, Q, R, we can then compute L, N, and $M = L^{-1}N$.

```
def construct_LNM(A, B, Q, R):

    n = A.shape[0]

    # construct L and N
    L = np.zeros((2*n, 2*n))
    L[:n, :n] = np.eye(n)
    L[:n, n:] = B @ np.linalg.inv(Q) @ B.T
    L[n:, n:] = A.T

    N = np.zeros((2*n, 2*n))
    N[:n, :n] = A
    N[n:, :n] = -R
    N[n:, n:] = np.eye(n)

    # compute M
    M = np.linalg.inv(L) @ N

    return L, N, M
```

```
A_bar = lq.A * lq.beta ** (1/2)
B_bar = lq.B * lq.beta ** (1/2)

L, N, M = construct_LNM(A_bar, B_bar, lq.Q, lq.R)
```

```
M
```

```
array([[ 1.02469508, -0.97590007, -0.92942864,  0.        ],
       [ 0.        ,  0.97590007,  0.        ,  0.        ],
       [ 0.        ,  0.        ,  0.97590007,  0.        ],
       [ 0.        ,  0.        ,  0.97590007,  1.02469508]])
```

Let's verify that M is symplectic.

```
n = lq.n
J = np.zeros((2*n, 2*n))
J[n:, :n] = np.eye(n)
J[:n, n:] = -np.eye(n)

M @ J @ M.T - J
```

```
array([[-5.15703240e-17,  0.00000000e+00,  0.00000000e+00,
         9.31818882e-18],
       [ 0.00000000e+00,  0.00000000e+00,  0.00000000e+00,
         1.11022302e-16],
       [ 0.00000000e+00,  0.00000000e+00,  0.00000000e+00,
         0.00000000e+00],
       [-9.31818882e-18, -1.11022302e-16,  0.00000000e+00,
         0.00000000e+00]])
```

We can compute the eigenvalues of M using `np.linalg.eigvals`, arranged in ascending order.

```
eigvals = sorted(np.linalg.eigvals(M), key=lambda z: (abs(z), z.real, z.imag))
eigvals
```

```
[np.float64(0.9759000729485331),
 np.float64(0.9759000729485332),
 np.float64(1.0246950765959597),
 np.float64(1.02469507659596)]
```

When we apply Schur decomposition such that $M = VWV^{-1}$, we want

- the upper left block of W, W_{11}, to have all of its eigenvalues less than 1 in modulus, and
- the lower right block W_{22} to have eigenvalues that exceed 1 in modulus.

To get what we want, let's define a sorting function that tells `scipy.schur` to sort the corresponding eigenvalues with modulus smaller than 1 to the upper left.

```
tol = 1e-10

def sort_fun(x):
    "Sort the eigenvalues with modulus smaller than 1 to the top-left."
    return abs(x) < 1 - tol

W, V, stable_dim = schur(M, sort=sort_fun)
stable_dim
```

```
2
```

```
W
```

```
array([[ 9.75900073e-01,  1.06779938e-16,  9.77000404e-01,
        -9.27110864e-01],
       [ 0.00000000e+00,  9.75900073e-01, -2.31777716e-03,
         9.77000404e-01],
       [ 0.00000000e+00,  0.00000000e+00,  1.02469508e+00,
        -2.12887870e-16],
       [ 0.00000000e+00,  0.00000000e+00,  0.00000000e+00,
         1.02469508e+00]])
```

```
V
```

```
array([[ 0.99875234, -0.00236938,  0.04988138,  0.        ],
       [ 0.04993762,  0.0473876 , -0.99762751,  0.        ],
       [ 0.        , -0.04988138, -0.00236938,  0.99875234],
       [ 0.        ,  0.99762751,  0.0473876 ,  0.04993762]])
```

We can check the modulus of eigenvalues of W_{11} and W_{22}.

Since they are both triangular matrices, eigenvalues are the diagonal elements.

```
# W11
np.diag(W[:n, :n])
```

```
array([0.97590007, 0.97590007])
```

```
# W22
np.diag(W[n:, n:])
```

```
array([1.02469508, 1.02469508])
```

The following functions wrap M matrix construction, Schur decomposition, and stability-imposing computation of P.

```
def stable_solution(M, verbose=True):
    """
    Given a system of linear difference equations

        y' = |a b| y
        x' = |c d| x

    which is potentially unstable, find the solution
    by imposing stability.

    Parameter
    ---------
    M : np.ndarray(float)
        The matrix represents the linear difference equations system.
    """
    n = M.shape[0] // 2
    tol = 1e-10

    def sort_fun(x):
        "Sort the eigenvalues with modulus smaller than 1 to the top-left."
        return abs(x) < 1 - tol

    W, V, stable_dim = schur(M, sort=sort_fun)
    if stable_dim != n:
        raise ValueError(
    f"Expected {n} stable eigenvalues inside the unit circle, found {stable_dim}."
    )
    if verbose:
        print('eigenvalues:\n')
        print('    W11: {}'.format(np.diag(W[:n, :n])))
        print('    W22: {}'.format(np.diag(W[n:, n:])))

    # compute V21 V11^{-1} without forming the inverse explicitly
    P = np.linalg.solve(V[:n, :n].T, V[n:, :n].T).T

    return W, V, P

def stationary_P(lq, verbose=True):
    """
    Computes the matrix :math:`P` that represent the value function
```

(continues on next page)

(continued from previous page)

```
        V(x) = x' P x

    in the infinite horizon case. Computation is via imposing stability
    on the solution path and using Schur decomposition.

    Parameters
    ----------
    lq : qe.LQ
        QuantEcon class for analyzing linear quadratic optimal control
        problems of infinite horizon form.

    Returns
    -------
    P : array_like(float)
        P matrix in the value function representation.
    """

    Q = lq.Q
    R = lq.R
    A = lq.A * lq.beta ** (1/2)
    B = lq.B * lq.beta ** (1/2)

    n, k = lq.n, lq.k

    L, N, M = construct_LNM(A, B, Q, R)
    W, V, P = stable_solution(M, verbose=verbose)

    return P
```

```
# compute P
stationary_P(lq)
```

```
eigenvalues:

    W11: [0.97590007 0.97590007]
    W22: [1.02469508 1.02469508]
```

```
array([[ 0.0525, -1.05  ],
       [-1.05  , 21.    ]])
```

Note that the matrix P computed in this way is close to what we get from the routine in quantecon that solves an algebraic Riccati equation by iterating to convergence on a Riccati difference equation.

The small difference comes from computational errors and will decrease as we increase the maximum number of iterations or decrease the tolerance for convergence.

```
lq.stationary_values()
```

```
(array([[ 0.0525, -1.05  ],
        [-1.05  , 21.    ]]),
 array([[-0.05,  1.  ]]),
 np.float64(0.0))
```

Using a Schur decomposition is much more efficient.

```

1.84 ms ± 6.81 µs per loop (mean ± std. dev. of 7 runs, 1,000 loops each)
```

79.8 Other Applications

The preceding approach to imposing stability on a system of potentially unstable linear difference equations is not limited to linear quadratic dynamic optimization problems.

For example, the same method is used in our Stability in Linear Rational Expectations Models lecture.

Let's try to solve the model described in that lecture by applying the `stable_solution` function defined in this lecture above.

```
def construct_H(ρ, λ, δ):
    "contruct matrix H given parameters."

    H = np.empty((2, 2))
    H[0, :] = ρ,δ
    H[1, :] = - (1 - λ) / λ, 1 / λ

    return H

H = construct_H(ρ=.9, λ=.5, δ=0)
```

```
W, V, P = stable_solution(H)
P
```

```
eigenvalues:

    W11: [0.9]
    W22: [2.]
```

```
array([[0.90909091]])
```

79.9 Discounted Problems

79.9.1 Transforming States and Controls to Eliminate Discounting

A pair of useful transformations allows us to convert a discounted problem into an undiscounted one.

Thus, suppose that we have a discounted problem with objective

$$-\sum_{t=0}^{\infty} \beta^t \left\{ x_t' R x_t + u_t' Q u_t \right\}$$

and that the state transition equation is again $x_{t+1} = Ax_t + Bu_t$.

Define the transformed state and control variables

- $\hat{x}_t = \beta^{\frac{t}{2}} x_t$
- $\hat{u}_t = \beta^{\frac{t}{2}} u_t$

and the transformed transition equation matrices

- $\hat{A} = \beta^{\frac{1}{2}} A$
- $\hat{B} = \beta^{\frac{1}{2}} B$

so that the adjusted state and control variables obey the transition law

$$\hat{x}_{t+1} = \hat{A}\hat{x}_t + \hat{B}\hat{u}_t.$$

Then a discounted optimal control problem defined by A, B, R, Q, β having optimal policy characterized by P, F is associated with an equivalent undiscounted problem defined by $\hat{A}, \hat{B}, Q, R$ having optimal policy characterized by $\hat{F}, \hat{P}$ that satisfy the following equations:

$$\hat{F} = (Q + B'\hat{P}B)^{-1}\hat{B}'P\hat{A}$$

and

$$\hat{P} = R + \hat{A}'P\hat{A} - \hat{A}'P\hat{B}(Q + B'\hat{P}\hat{B})^{-1}\hat{B}'P\hat{A}$$

It follows immediately from the definitions of $\hat{A}, \hat{B}$ that $\hat{F} = F$ and $\hat{P} = P$.

By exploiting these transformations, we can solve a discounted problem by solving an associated undiscounted problem.

In particular, we can first transform a discounted LQ problem to an undiscounted one and then solve that discounted optimal regulator problem using the Lagrangian and invariant subspace methods described above.

For example, when $\beta = \frac{1}{1+r}$, we can solve for P with $\hat{A} = \beta^{1/2}A$ and $\hat{B} = \beta^{1/2}B$.

These settings are adopted by default in the function `stationary_P` defined above.

```
stationary_P(lq)
```

```
eigenvalues:

    W11: [0.97590007 0.97590007]
    W22: [1.02469508 1.02469508]
```

```
array([[ 0.0525, -1.05  ],
       [-1.05  , 21.    ]])
```

We can verify that the solution agrees with one that comes from applying the routine `LQ.stationary_values` in the quantecon package.

```
lq.stationary_values()
```

```
(array([[ 0.0525, -1.05  ],
        [-1.05  , 21.    ]]),
 array([[-0.05,  1.  ]]),
 np.float64(0.0))
```

79.9.2 Lagrangian for Discounted Problem

For several purposes, it is useful explicitly briefly to describe a Lagrangian for a discounted problem.

Thus, for the discounted optimal linear regulator problem, form the Lagrangian

$$L = -\sum_{t=0}^{\infty} \beta^t \left\{ x_t' R x_t + u_t' Q u_t + 2\beta \mu_{t+1}' [A x_t + B u_t - x_{t+1}] \right\} \tag{79.18}$$

where $2\mu_{t+1}$ is a vector of Lagrange multipliers on the state vector x_{t+1}.

First-order conditions for maximization with respect to $\{u_t, x_{t+1}\}_{t=0}^{\infty}$ are

$$\begin{aligned} 2Qu_t + 2\beta B'\mu_{t+1} = 0 \ , \ t \geq 0 \\ \mu_t = Rx_t + \beta A' \mu_{t+1} \ , \ t \geq 1. \end{aligned} \tag{79.19}$$

Define $2\mu_0$ to be the vector of shadow prices of x_0 and apply an envelope condition to (79.18) to deduce that

$$\mu_0 = Rx_0 + \beta A' \mu_1,$$

which is a time $t = 0$ counterpart to the second equation of system (79.19).

Proceeding as we did above with the undiscounted system (79.5), we can rearrange the first-order conditions into the system

$$\begin{bmatrix} I & \beta B Q^{-1} B' \\ 0 & \beta A' \end{bmatrix} \begin{bmatrix} x_{t+1} \\ \mu_{t+1} \end{bmatrix} = \begin{bmatrix} A & 0 \\ -R & I \end{bmatrix} \begin{bmatrix} x_t \\ \mu_t \end{bmatrix} \tag{79.20}$$

which in the special case that $\beta = 1$ agrees with equation (79.5), as expected.

By staring at system (79.20), we can infer identities that shed light on the structure of optimal linear regulator problems, some of which will be useful in this lecture when we apply and extend the methods of this lecture to study Stackelberg and Ramsey problems.

First, note that the first block of equation system (79.20) asserts that when $\mu_{t+1} = P x_{t+1}$, then

$$(I + \beta Q^{-1} B' P B P) x_{t+1} = A x_t,$$

which can be rearranged to sbe

$$x_{t+1} = (I + \beta B Q^{-1} B' P)^{-1} A x_t.$$

This expression for the optimal closed loop dynamics of the state must agree with an alternative expression that we had derived with dynamic programming, namely,

$$x_{t+1} = (A - BF) x_t.$$

But using

$$F = \beta (Q + \beta B' P B)^{-1} B' P A \tag{79.21}$$

it follows that

$$A - BF = (I - \beta B (Q + \beta B' P B)^{-1} B' P) A.$$

Thus, our two expressions for the closed loop dynamics agree if and only if

$$(I + \beta B Q^{-1} B' P)^{-1} = (I - \beta B (Q + \beta B' P B)^{-1} B' P). \tag{79.22}$$

Matrix equation (79.22) can be verified by applying a partitioned inverse formula.

Note

Just use the formula $(a-bd^{-1}c)^{-1} = a^{-1}+a^{-1}b(d-ca^{-1}b)^{-1}ca^{-1}$ for appropriate choices of the matrices a, b, c, d.

Next, note that for *any* fixed F for which eigenvalues of $A-BF$ are less than $\frac{1}{\beta}$ in modulus, the value function associated with using this rule forever is $-x_0\tilde{P}x_0$ where $\tilde{P}$ obeys the following matrix equation:

$$\tilde{P} = (R + F'QF) + \beta(A - BF)'P(A - BF). \tag{79.23}$$

Evidently, $\tilde{P} = P$ only when F obeys formula (79.21).

Next, note that the second equation of system (79.20) implies the "forward looking" equation for the Lagrange multiplier

$$\mu_t = Rx_t + \beta A'\mu_{t+1}$$

whose solution is

$$\mu_t = Px_t,$$

where

$$P = R + \beta A'P(A - BF) \tag{79.24}$$

where we must require that F obeys equation (79.21).

Equations (79.23) and (79.24) provide different perspectives on the optimal value function.

CHAPTER

EIGHTY

ELIMINATING CROSS PRODUCTS

80.1 Overview

This lecture describes formulas for eliminating

- cross products between states and control in linear-quadratic dynamic programming problems
- covariances between state and measurement noises in Kalman filtering problems

For a linear-quadratic dynamic programming problem, the idea involves these steps

- transform states and controls in a way that leads to an equivalent problem with no cross-products between transformed states and controls
- solve the transformed problem using standard formulas for problems with no cross-products between states and controls presented in this lecture *Linear Control: Foundations*
- transform the optimal decision rule for the altered problem into the optimal decision rule for the original problem with cross-products between states and controls

80.2 Undiscounted Dynamic Programming Problem

Here is a nonstochastic undiscounted LQ dynamic programming with cross products between states and controls in the objective function.

The problem is defined by the 5-tuple of matrices (A, B, R, Q, H) where R and Q are positive definite symmetric matrices and $A \sim m \times m, B \sim m \times k, Q \sim k \times k, R \sim m \times m$ and $H \sim k \times m$.

The problem is to choose $\{x_{t+1}, u_t\}_{t=0}^{\infty}$ to maximize

$$-\sum_{t=0}^{\infty}(x_t' R x_t + u_t' Q u_t + 2 u_t H x_t)$$

subject to the linear constraints

$$x_{t+1} = A x_t + B u_t, \quad t \geq 0$$

where x_0 is a given initial condition.

The solution to this undiscounted infinite-horizon problem is a time-invariant feedback rule

$$u_t = -F x_t$$

where

$$F = -(Q + B'PB)^{-1}B'PA$$

and $P \sim m \times m$ is a positive definite solution of the algebraic matrix Riccati equation

$$P = R + A'PA - (A'PB + H')(Q + B'PB)^{-1}(B'PA + H).$$

It can be verified that an **equivalent** problem without cross-products between states and controls is defined by a 4-tuple of matrices : (A^*, B, R^*, Q).

That the omitted matrix $H = 0$ indicates that there are no cross products between states and controls in the equivalent problem.

The matrices (A^*, B, R^*, Q) defining the equivalent problem and the value function, policy function matrices P, F^* that solve it are related to the matrices (A, B, R, Q, H) defining the original problem and the value function, policy function matrices P, F that solve the original problem by

$$\begin{aligned}
A^* &= A - BQ^{-1}H, \\
R^* &= R - H'Q^{-1}H, \\
P &= R^* + A^{*'}PA - (A^{*'}PB)(Q + B'PB)^{-1}B'PA^*, \\
F^* &= (Q + B'PB)^{-1}B'PA^*, \\
F &= F^* + Q^{-1}H.
\end{aligned}$$

80.3 Kalman Filter

The **duality** that prevails between a linear-quadratic optimal control and a Kalman filtering problem means that there is an analogous transformation that allows us to transform a Kalman filtering problem with non-zero covariance matrix between between shocks to states and shocks to measurements to an equivalent Kalman filtering problem with zero covariance between shocks to states and measurments.

Let's look at the appropriate transformations.

First, let's recall the Kalman filter with covariance between noises to states and measurements.

The hidden Markov model is

$$\begin{aligned}
x_{t+1} &= Ax_t + Bw_{t+1}, \\
z_{t+1} &= Dx_t + Fw_{t+1},
\end{aligned}$$

where $A \sim m \times m, B \sim m \times p$ and $D \sim k \times m, F \sim k \times p$, and w_{t+1} is the time $t+1$ component of a sequence of i.i.d. $p \times 1$ normally distibuted random vectors with mean vector zero and covariance matrix equal to a $p \times p$ identity matrix.

Thus, x_t is $m \times 1$ and z_t is $k \times 1$.

The Kalman filtering formulas are

$$\begin{aligned}
K(\Sigma_t) &= (A\Sigma_t D' + BF')(D\Sigma_t D' + FF')^{-1}, \\
\Sigma_{t+1} &= A\Sigma_t A' + BB' - (A\Sigma_t D' + BF')(D\Sigma_t D' + FF')^{-1}(D\Sigma_t A' + FB').
\end{aligned}$$

(eq:Kalman102)

Define tranformed matrices

$$\begin{aligned}
A^* &= A - BF'(FF')^{-1}D, \\
B^*B^{*'} &= BB' - BF'(FF')^{-1}FB'.
\end{aligned}$$

80.3.1 Algorithm

A consequence of formulas {eq}`eq:Kalman102} is that we can use the following algorithm to solve Kalman filtering problems that involve non zero covariances between state and signal noises.

First, compute Σ, K^* using the ordinary Kalman filtering formula with $BF' = 0$, i.e., with zero covariance matrix between random shocks to states and random shocks to measurements.

That is, compute K^* and Σ that satisfy

$$
\begin{aligned}
K^* &= (A^*\Sigma D')(D\Sigma D' + FF')^{-1} \\
\Sigma &= A^*\Sigma A^{*'} + B^*B^{*'} - (A^*\Sigma D')(D\Sigma D' + FF')^{-1}(D\Sigma A^{*'}).
\end{aligned}
$$

The Kalman gain for the original problem **with non-zero covariance** between shocks to states and measurements is then

$$
K = K^* + BF'(FF')^{-1},
$$

The state reconstruction covariance matrix Σ for the original problem equals the state reconstrution covariance matrix for the transformed problem.

80.4 Duality table

Here is a handy table to remember how the Kalman filter and dynamic program are related.

Dynamic Program	Kalman Filter
A	A'
B	D'
H	FB'
Q	FF'
R	BB'
F	K'
P	Σ

THE PERMANENT INCOME MODEL

Contents

- *The Permanent Income Model*
  - *Overview*
  - *The Savings Problem*
  - *Alternative Representations*
  - *Two Classic Examples*
  - *Further Reading*
  - *Appendix: The Euler Equation*

81.1 Overview

This lecture describes a rational expectations version of the famous permanent income model of Milton Friedman [Friedman, 1956].

Robert Hall cast Friedman's model within a linear-quadratic setting [Hall, 1978].

Like Hall, we formulate an infinite-horizon linear-quadratic savings problem.

We use the model as a vehicle for illustrating

- alternative formulations of the *state* of a dynamic system
- the idea of *cointegration*
- impulse response functions
- the idea that changes in consumption are useful as predictors of movements in income

Background readings on the linear-quadratic-Gaussian permanent income model are Hall's [Hall, 1978] and chapter 2 of [Ljungqvist and Sargent, 2018].

Let's start with some imports

```
import matplotlib.pyplot as plt
import numpy as np
import random
from numba import jit
```

81.2 The Savings Problem

In this section, we state and solve the savings and consumption problem faced by the consumer.

81.2.1 Preliminaries

We use a class of stochastic processes called martingales.

A discrete-time martingale is a stochastic process (i.e., a sequence of random variables) $\{X_t\}$ with finite mean at each t and satisfying

$$\mathbb{E}_t[X_{t+1}] = X_t, \qquad t = 0, 1, 2, ...$$

Here $\mathbb{E}_t := \mathbb{E}[\cdot \mid \mathcal{F}_t]$ is a conditional mathematical expectation conditional on the time t *information set* $\mathcal{F}_t$.

The latter is just a collection of random variables that the modeler declares to be visible at t.

- When not explicitly defined, it is usually understood that $\mathcal{F}_t = \{X_t, X_{t-1}, ..., X_0\}$.

Martingales have the feature that the history of past outcomes provides no predictive power for changes between current and future outcomes.

For example, the current wealth of a gambler engaged in a "fair game" has this property.

One common class of martingales is the family of *random walks*.

A **random walk** is a stochastic process $\{X_t\}$ that satisfies

$$X_{t+1} = X_t + w_{t+1}$$

for some IID zero mean *innovation* sequence $\{w_t\}$.

Evidently, X_t can also be expressed as

$$X_t = \sum_{j=1}^{t} w_j + X_0$$

Not every martingale arises as a random walk (see, for example, Wald's martingale).

81.2.2 The Decision Problem

A consumer has preferences over consumption streams that are ordered by the utility functional

$$\mathbb{E}_0 \left[\sum_{t=0}^{\infty} \beta^t u(c_t) \right] \tag{81.1}$$

where

- $\mathbb{E}_t$ is the mathematical expectation conditioned on the consumer's time t information
- c_t is time t consumption
- u is a strictly concave one-period utility function
- $\beta \in (0, 1)$ is a discount factor

The consumer maximizes (81.1) by choosing a consumption, borrowing plan $\{c_t, b_{t+1}\}_{t=0}^{\infty}$ subject to the sequence of budget constraints

$$c_t + b_t = \frac{1}{1+r} b_{t+1} + y_t \quad t \geq 0 \tag{81.2}$$

Here

- y_t is an exogenous endowment process.
- $r > 0$ is a time-invariant risk-free net interest rate.
- b_t is one-period risk-free debt maturing at t.

The consumer also faces initial conditions b_0 and y_0, which can be fixed or random.

81.2.3 Assumptions

For the remainder of this lecture, we follow Friedman and Hall in assuming that $(1+r)^{-1} = \beta$.

Regarding the endowment process, we assume it has the *state-space representation*

$$\begin{aligned} z_{t+1} &= A z_t + C w_{t+1} \\ y_t &= U z_t \end{aligned} \tag{81.3}$$

where

- $\{w_t\}$ is an IID vector process with $\mathbb{E} w_t = 0$ and $\mathbb{E} w_t w_t' = I$.
- The *spectral radius* of A satisfies $\rho(A) < \sqrt{1/\beta}$.
- U is a selection vector that pins down y_t as a particular linear combination of components of z_t.

The restriction on $\rho(A)$ prevents income from growing so fast that discounted geometric sums of some quadratic forms to be described below become infinite.

Regarding preferences, we assume the quadratic utility function

$$u(c_t) = -(c_t - \gamma)^2$$

where γ is a bliss level of consumption.

Note

Along with this quadratic utility specification, we allow consumption to be negative. However, by choosing parameters appropriately, we can make the probability that the model generates negative consumption paths over finite time horizons as low as desired.

Finally, we impose the *no Ponzi scheme* condition

$$\mathbb{E}_0 \left[\sum_{t=0}^{\infty} \beta^t b_t^2 \right] < \infty \tag{81.4}$$

This condition rules out an always-borrow scheme that would allow the consumer to enjoy bliss consumption forever.

81.2.4 First-Order Conditions

First-order conditions for maximizing (81.1) subject to (81.2) are

$$\mathbb{E}_t[u'(c_{t+1})] = u'(c_t), \qquad t = 0, 1, \ldots \tag{81.5}$$

These optimality conditions are also known as *Euler equations*.

If you're not sure where they come from, you can find a proof sketch in the *appendix*.

With our quadratic preference specification, (81.5) has the striking implication that consumption follows a martingale:

$$\mathbb{E}_t[c_{t+1}] = c_t \tag{81.6}$$

(In fact, quadratic preferences are *necessary* for this conclusion[1].)

One way to interpret (81.6) is that consumption will change only when "new information" about permanent income is revealed.

These ideas will be clarified below.

81.2.5 The Optimal Decision Rule

Now let's deduce the optimal decision rule[2].

Note

One way to solve the consumer's problem is to apply *dynamic programming* as in *this lecture*. We do this later. But first we use an alternative approach that is revealing and shows the work that dynamic programming does for us behind the scenes.

In doing so, we need to combine

1. the optimality condition (81.6)
2. the period-by-period budget constraint (81.2), and
3. the boundary condition (81.4)

To accomplish this, observe first that (81.4) implies $\lim_{t\to\infty} \beta^{\frac{t}{2}} b_{t+1} = 0$.

Using this restriction on the debt path and solving (81.2) forward yields

$$b_t = \sum_{j=0}^{\infty} \beta^j (y_{t+j} - c_{t+j}) \tag{81.7}$$

Take conditional expectations on both sides of (81.7) and use the martingale property of consumption and the *law of iterated expectations* to deduce

$$b_t = \sum_{j=0}^{\infty} \beta^j \mathbb{E}_t[y_{t+j}] - \frac{c_t}{1-\beta} \tag{81.8}$$

[1] A linear marginal utility is essential for deriving (81.6) from (81.5). Suppose instead that we had imposed the following more standard assumptions on the utility function: $u'(c) > 0, u''(c) < 0, u'''(c) > 0$ and required that $c \geq 0$. The Euler equation remains (81.5). But the fact that $u''' < 0$ implies via Jensen's inequality that $\mathbb{E}_t[u'(c_{t+1})] > u'(\mathbb{E}_t[c_{t+1}])$. This inequality together with (81.5) implies that $\mathbb{E}_t[c_{t+1}] > c_t$ (consumption is said to be a 'submartingale'), so that consumption stochastically diverges to $+\infty$. The consumer's savings also diverge to $+\infty$.

[2] An optimal decision rule is a map from the current state into current actions—in this case, consumption.

Expressed in terms of c_t we get

$$c_t = (1-\beta)\left[\sum_{j=0}^{\infty}\beta^j \mathbb{E}_t[y_{t+j}] - b_t\right] = \frac{r}{1+r}\left[\sum_{j=0}^{\infty}\beta^j \mathbb{E}_t[y_{t+j}] - b_t\right] \tag{81.9}$$

where the last equality uses $(1+r)\beta = 1$.

These last two equations assert that consumption equals *economic income*

- **financial wealth** equals $-b_t$
- **non-financial wealth** equals $\sum_{j=0}^{\infty}\beta^j \mathbb{E}_t[y_{t+j}]$
- **total wealth** equals the sum of financial and non-financial wealth
- a **marginal propensity to consume out of total wealth** equals the interest factor $\frac{r}{1+r}$
- **economic income** equals
  - a constant marginal propensity to consume times the sum of non-financial wealth and financial wealth
  - the amount the consumer can consume while leaving its wealth intact

Responding to the State

The *state* vector confronting the consumer at t is $\begin{bmatrix} b_t & z_t \end{bmatrix}$.

Here

- z_t is an *exogenous* component, unaffected by consumer behavior.
- b_t is an *endogenous* component (since it depends on the decision rule).

Note that z_t contains all variables useful for forecasting the consumer's future endowment.

It is plausible that current decisions c_t and b_{t+1} should be expressible as functions of z_t and b_t.

This is indeed the case.

In fact, from *this discussion*, we see that

$$\sum_{j=0}^{\infty}\beta^j \mathbb{E}_t[y_{t+j}] = \mathbb{E}_t\left[\sum_{j=0}^{\infty}\beta^j y_{t+j}\right] = U(I-\beta A)^{-1} z_t$$

Combining this with (81.9) gives

$$c_t = \frac{r}{1+r}\left[U(I-\beta A)^{-1} z_t - b_t\right] \tag{81.10}$$

Using this equality to eliminate c_t in the budget constraint (81.2) gives

$$\begin{aligned} b_{t+1} &= (1+r)(b_t + c_t - y_t) \\ &= (1+r)b_t + r[U(I-\beta A)^{-1} z_t - b_t] - (1+r)U z_t \\ &= b_t + U[r(I-\beta A)^{-1} - (1+r)I]z_t \\ &= b_t + U(I-\beta A)^{-1}(A-I)z_t \end{aligned}$$

To get from the second last to the last expression in this chain of equalities is not trivial.

A key is to use the fact that $(1+r)\beta = 1$ and $(I-\beta A)^{-1} = \sum_{j=0}^{\infty}\beta^j A^j$.

We've now successfully written c_t and b_{t+1} as functions of b_t and z_t.

A State-Space Representation

We can summarize our dynamics in the form of a linear state-space system governing consumption, debt and income:

$$\begin{aligned} z_{t+1} &= Az_t + Cw_{t+1} \\ b_{t+1} &= b_t + U[(I-\beta A)^{-1}(A-I)]z_t \\ y_t &= Uz_t \\ c_t &= (1-\beta)[U(I-\beta A)^{-1}z_t - b_t] \end{aligned} \tag{81.11}$$

To write this more succinctly, let

$$x_t = \begin{bmatrix} z_t \\ b_t \end{bmatrix}, \quad \tilde{A} = \begin{bmatrix} A & 0 \\ U(I-\beta A)^{-1}(A-I) & 1 \end{bmatrix}, \quad \tilde{C} = \begin{bmatrix} C \\ 0 \end{bmatrix}$$

and

$$\tilde{U} = \begin{bmatrix} U & 0 \\ (1-\beta)U(I-\beta A)^{-1} & -(1-\beta) \end{bmatrix}, \quad \tilde{y}_t = \begin{bmatrix} y_t \\ c_t \end{bmatrix}$$

Then we can express equation (81.11) as

$$\begin{aligned} x_{t+1} &= \tilde{A}x_t + \tilde{C}w_{t+1} \\ \tilde{y}_t &= \tilde{U}x_t \end{aligned} \tag{81.12}$$

We can use the following formulas from *linear state space models* to compute population mean $\mu_t = \mathbb{E}x_t$ and covariance $\Sigma_t := \mathbb{E}[(x_t - \mu_t)(x_t - \mu_t)']$

$$\mu_{t+1} = \tilde{A}\mu_t \quad \text{with} \quad \mu_0 \text{ given} \tag{81.13}$$

$$\Sigma_{t+1} = \tilde{A}\Sigma_t\tilde{A}' + \tilde{C}\tilde{C}' \quad \text{with} \quad \Sigma_0 \text{ given} \tag{81.14}$$

We can then compute the mean and covariance of $\tilde{y}_t$ from

$$\begin{aligned} \mu_{y,t} &= \tilde{U}\mu_t \\ \Sigma_{y,t} &= \tilde{U}\Sigma_t\tilde{U}' \end{aligned} \tag{81.15}$$

A Simple Example with IID Income

To gain some preliminary intuition on the implications of (81.11), let's look at a highly stylized example where income is just IID.

(Later examples will investigate more realistic income streams.)

In particular, let $\{w_t\}_{t=1}^{\infty}$ be IID and scalar standard normal, and let

$$z_t = \begin{bmatrix} z_t^1 \\ 1 \end{bmatrix}, \quad A = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}, \quad U = \begin{bmatrix} 1 & \mu \end{bmatrix}, \quad C = \begin{bmatrix} \sigma \\ 0 \end{bmatrix}$$

Finally, let $b_0 = z_0^1 = 0$.

Under these assumptions, we have $y_t = \mu + \sigma w_t \sim N(\mu, \sigma^2)$.

Further, if you work through the state space representation, you will see that

$$b_t = -\sigma\sum_{j=1}^{t-1} w_j$$

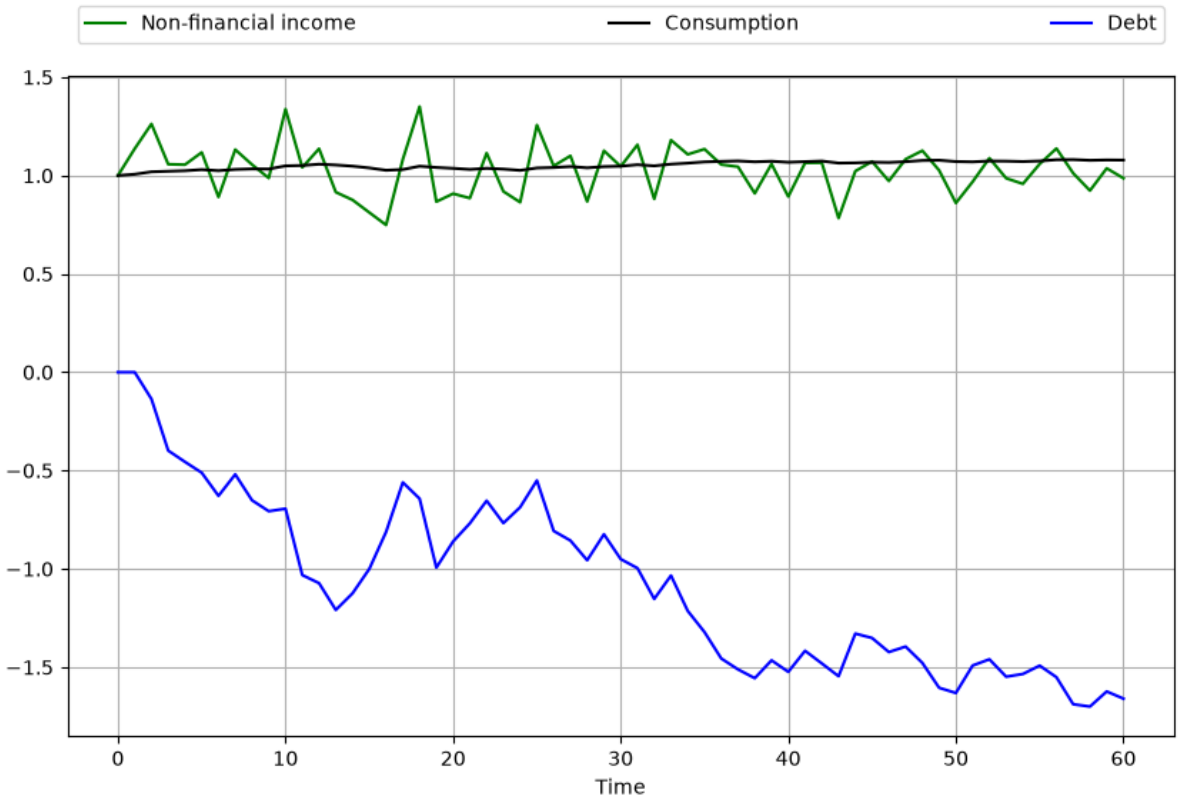
$$c_t = \mu + (1-\beta)\sigma\sum_{j=1}^{t} w_j$$

Thus, income is IID and debt and consumption are both Gaussian random walks.

Defining assets as $-b_t$, we see that assets are just the cumulative sum of unanticipated incomes prior to the present date.

The next figure shows a typical realization with $r = 0.05$, $\mu = 1$, and $\sigma = 0.15$

```
r = 0.05
β = 1 / (1 + r)
σ = 0.15
μ = 1
T = 60



@jit
def time_path(T, rng):
    w = rng.standard_normal(T+1)  # w_0, w_1, ..., w_T
    w[0] = 0
    b = np.zeros(T+1)
    for t in range(1, T+1):
        b[t] = w[1:t].sum()
    b = -σ * b
    c = μ + (1 - β) * (σ * w - b)
    return w, b, c

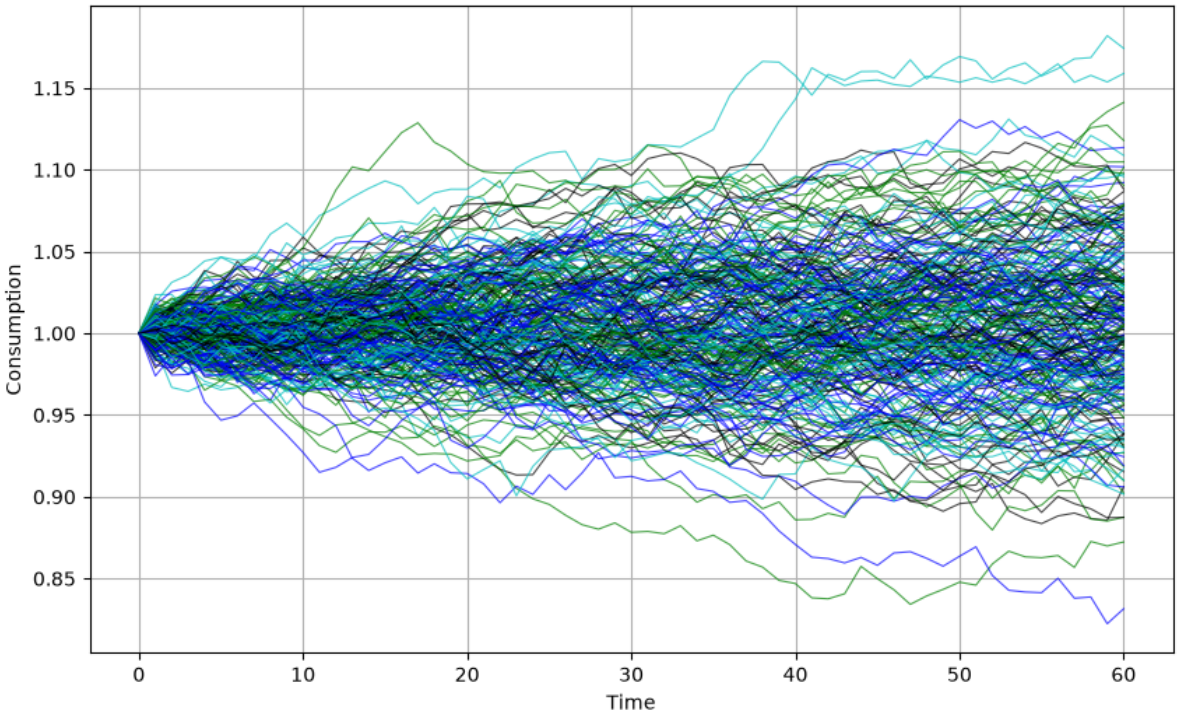
rng = np.random.default_rng()
w, b, c = time_path(T, rng)

fig, ax = plt.subplots(figsize=(10, 6))

ax.plot(μ + σ * w, 'g-', label="Non-financial income")
ax.plot(c, 'k-', label="Consumption")
ax.plot( b, 'b-', label="Debt")
ax.legend(ncol=3, mode='expand', bbox_to_anchor=(0., 1.02, 1., .102))
ax.grid()
ax.set_xlabel('Time')

plt.show()
```

Observe that consumption is considerably smoother than income.



The figure below shows the consumption paths of 250 consumers with independent income streams

```
fig, ax = plt.subplots(figsize=(10, 6))

b_sum = np.zeros(T+1)
for i in range(250):
    w, b, c = time_path(T, rng)   # Generate new time path
    rcolor = random.choice(('c', 'g', 'b', 'k'))
    ax.plot(c, color=rcolor, lw=0.8, alpha=0.7)

ax.grid()
ax.set(xlabel='Time', ylabel='Consumption')

plt.show()
```

81.3 Alternative Representations

In this section, we shed more light on the evolution of savings, debt and consumption by representing their dynamics in several different ways.

81.3.1 Hall's Representation

Hall [Hall, 1978] suggested an insightful way to summarize the implications of LQ permanent income theory.

First, to represent the solution for b_t, shift (81.9) forward one period and eliminate b_{t+1} by using (81.2) to obtain

$$c_{t+1} = (1-\beta)\sum_{j=0}^{\infty}\beta^j \mathbb{E}_{t+1}[y_{t+j+1}] - (1-\beta)\left[\beta^{-1}(c_t + b_t - y_t)\right]$$

If we add and subtract $\beta^{-1}(1-\beta)\sum_{j=0}^{\infty}\beta^j \mathbb{E}_t y_{t+j}$ from the right side of the preceding equation and rearrange, we obtain

$$c_{t+1} - c_t = (1-\beta)\sum_{j=0}^{\infty}\beta^j\left\{\mathbb{E}_{t+1}[y_{t+j+1}] - \mathbb{E}_t[y_{t+j+1}]\right\} \tag{81.16}$$

The right side is the time $t+1$ *innovation to the expected present value* of the endowment process $\{y_t\}$.

We can represent the optimal decision rule for (c_t, b_{t+1}) in the form of (81.16) and (81.8), which we repeat:

$$b_t = \sum_{j=0}^{\infty}\beta^j \mathbb{E}_t[y_{t+j}] - \frac{1}{1-\beta}c_t \tag{81.17}$$

Equation (81.17) asserts that the consumer's debt due at t equals the expected present value of its endowment minus the expected present value of its consumption stream.

A high debt thus indicates a large expected present value of surpluses $y_t - c_t$.

Recalling again our discussion on *forecasting geometric sums*, we have

$$\mathbb{E}_t \sum_{j=0}^{\infty} \beta^j y_{t+j} = U(I - \beta A)^{-1} z_t$$
$$\mathbb{E}_{t+1} \sum_{j=0}^{\infty} \beta^j y_{t+j+1} = U(I - \beta A)^{-1} z_{t+1}$$
$$\mathbb{E}_t \sum_{j=0}^{\infty} \beta^j y_{t+j+1} = U(I - \beta A)^{-1} A z_t$$

Using these formulas together with (81.3) and substituting into (81.16) and (81.17) gives the following representation for the consumer's optimum decision rule:

$$\begin{aligned} c_{t+1} &= c_t + (1-\beta) U(I - \beta A)^{-1} C w_{t+1} \\ b_t &= U(I - \beta A)^{-1} z_t - \frac{1}{1-\beta} c_t \\ y_t &= U z_t \\ z_{t+1} &= A z_t + C w_{t+1} \end{aligned} \tag{81.18}$$

Representation (81.18) makes clear that

- The state can be taken as (c_t, z_t).
  - The endogenous part is c_t and the exogenous part is z_t.
  - Debt b_t has disappeared as a component of the state because it is encoded in c_t.
- Consumption is a random walk with innovation $(1-\beta) U(I - \beta A)^{-1} C w_{t+1}$.
  - This is a more explicit representation of the martingale result in (81.6).

81.3.2 Cointegration

Representation (81.18) reveals that the joint process $\{c_t, b_t\}$ possesses the property that Engle and Granger [Engle and Granger, 1987] called cointegration.

Cointegration is a tool that allows us to apply powerful results from the theory of stationary stochastic processes to (certain transformations of) nonstationary models.

To apply cointegration in the present context, suppose that z_t is asymptotically stationary[3].

Despite this, both c_t and b_t will be non-stationary because they have unit roots (see (81.11) for b_t).

Nevertheless, there is a linear combination of c_t, b_t that *is* asymptotically stationary.

In particular, from the second equality in (81.18) we have

$$(1-\beta) b_t + c_t = (1-\beta) U(I - \beta A)^{-1} z_t \tag{81.19}$$

Hence the linear combination $(1-\beta) b_t + c_t$ is asymptotically stationary.

Accordingly, Granger and Engle would call $\begin{bmatrix} (1-\beta) & 1 \end{bmatrix}$ a **cointegrating vector** for the state.

When applied to the nonstationary vector process $\begin{bmatrix} b_t & c_t \end{bmatrix}'$, it yields a process that is asymptotically stationary.

[3] This would be the case if, for example, the *spectral radius* of A is strictly less than one.

Equation (81.19) can be rearranged to take the form

$$(1-\beta)b_t + c_t = (1-\beta)\mathbb{E}_t \sum_{j=0}^{\infty} \beta^j y_{t+j} \tag{81.20}$$

Equation (81.20) asserts that the *cointegrating residual* on the left side equals the conditional expectation of the geometric sum of future incomes on the right[4].

81.3.3 Cross-Sectional Implications

Consider again (81.18), this time in light of our discussion of distribution dynamics in the *lecture on linear systems*.

The dynamics of c_t are given by

$$c_{t+1} = c_t + (1-\beta)U(I-\beta A)^{-1}Cw_{t+1} \tag{81.21}$$

or

$$c_t = c_0 + \sum_{j=1}^{t} \hat{w}_j \quad \text{for} \quad \hat{w}_{t+1} := (1-\beta)U(I-\beta A)^{-1}Cw_{t+1}$$

The unit root affecting c_t causes the time t variance of c_t to grow linearly with t.

In particular, since $\{\hat{w}_t\}$ is IID, we have

$$\text{Var}[c_t] = \text{Var}[c_0] + t\,\hat{\sigma}^2 \tag{81.22}$$

where

$$\hat{\sigma}^2 := (1-\beta)^2 U(I-\beta A)^{-1}CC'(I-\beta A')^{-1}U'$$

When $\hat{\sigma} > 0$, $\{c_t\}$ has no asymptotic distribution.

Let's consider what this means for a cross-section of ex-ante identical consumers born at time 0.

Let the distribution of c_0 represent the cross-section of initial consumption values.

Equation (81.22) tells us that the variance of c_t increases over time at a rate proportional to t.

A number of different studies have investigated this prediction and found some support for it (see, e.g., [Deaton and Paxson, 1994], [Storesletten *et al.*, 2004]).

81.3.4 Impulse Response Functions

Impulse response functions measure responses to various impulses (i.e., temporary shocks).

The impulse response function of $\{c_t\}$ to the innovation $\{w_t\}$ is a box.

In particular, the response of c_{t+j} to a unit increase in the innovation w_{t+1} is $(1-\beta)U(I-\beta A)^{-1}C$ for all $j \geq 1$.

[4] See [Campbell and Shiller, 1988], [Lettau and Ludvigson, 2001], [Lettau and Ludvigson, 2004] for interesting applications of related ideas.

81.3.5 Moving Average Representation

It's useful to express the innovation to the expected present value of the endowment process in terms of a moving average representation for income y_t.

The endowment process defined by (81.3) has the moving average representation

$$y_{t+1} = d(L)w_{t+1} \tag{81.23}$$

where

- $d(L) = \sum_{j=0}^{\infty} d_j L^j$ for some sequence d_j, where L is the lag operator[5]
- at time t, the consumer has an information set[6] $w^t = [w_t, w_{t-1}, ...]$

Notice that

$$y_{t+j} - \mathbb{E}_t[y_{t+j}] = d_0 w_{t+j} + d_1 w_{t+j-1} + \cdots + d_{j-1} w_{t+1}$$

It follows that

$$\mathbb{E}_{t+1}[y_{t+j}] - \mathbb{E}_t[y_{t+j}] = d_{j-1} w_{t+1} \tag{81.24}$$

Using (81.24) in (81.16) gives

$$c_{t+1} - c_t = (1-\beta)d(\beta)w_{t+1} \tag{81.25}$$

The object $d(\beta)$ is the **present value of the moving average coefficients** in the representation for the endowment process y_t.

81.4 Two Classic Examples

We illustrate some of the preceding ideas with two examples.

In both examples, the endowment follows the process $y_t = z_{1t} + z_{2t}$ where

$$\begin{bmatrix} z_{1t+1} \\ z_{2t+1} \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} z_{1t} \\ z_{2t} \end{bmatrix} + \begin{bmatrix} \sigma_1 & 0 \\ 0 & \sigma_2 \end{bmatrix} \begin{bmatrix} w_{1t+1} \\ w_{2t+1} \end{bmatrix}$$

Here

- w_{t+1} is an IID 2×1 process distributed as $N(0, I)$.
- z_{1t} is a permanent component of y_t.
- z_{2t} is a purely transitory component of y_t.

81.4.1 Example 1

Assume as before that the consumer observes the state z_t at time t.

In view of (81.18) we have

$$c_{t+1} - c_t = \sigma_1 w_{1t+1} + (1-\beta)\sigma_2 w_{2t+1} \tag{81.26}$$

Formula (81.26) shows how an increment $\sigma_1 w_{1t+1}$ to the permanent component of income z_{1t+1} leads to

[5] Representation (81.3) implies that $d(L) = U(I - AL)^{-1}C$.

[6] A moving average representation for a process y_t is said to be **fundamental** if the linear space spanned by y^t is equal to the linear space spanned by w^t. A time-invariant innovations representation, attained via the Kalman filter, is by construction fundamental.

- a permanent one-for-one increase in consumption and
- no increase in savings $-b_{t+1}$

But the purely transitory component of income $\sigma_2 w_{2t+1}$ leads to a permanent increment in consumption by a fraction $1-\beta$ of transitory income.

The remaining fraction β is saved, leading to a permanent increment in $-b_{t+1}$.

Application of the formula for debt in (81.11) to this example shows that

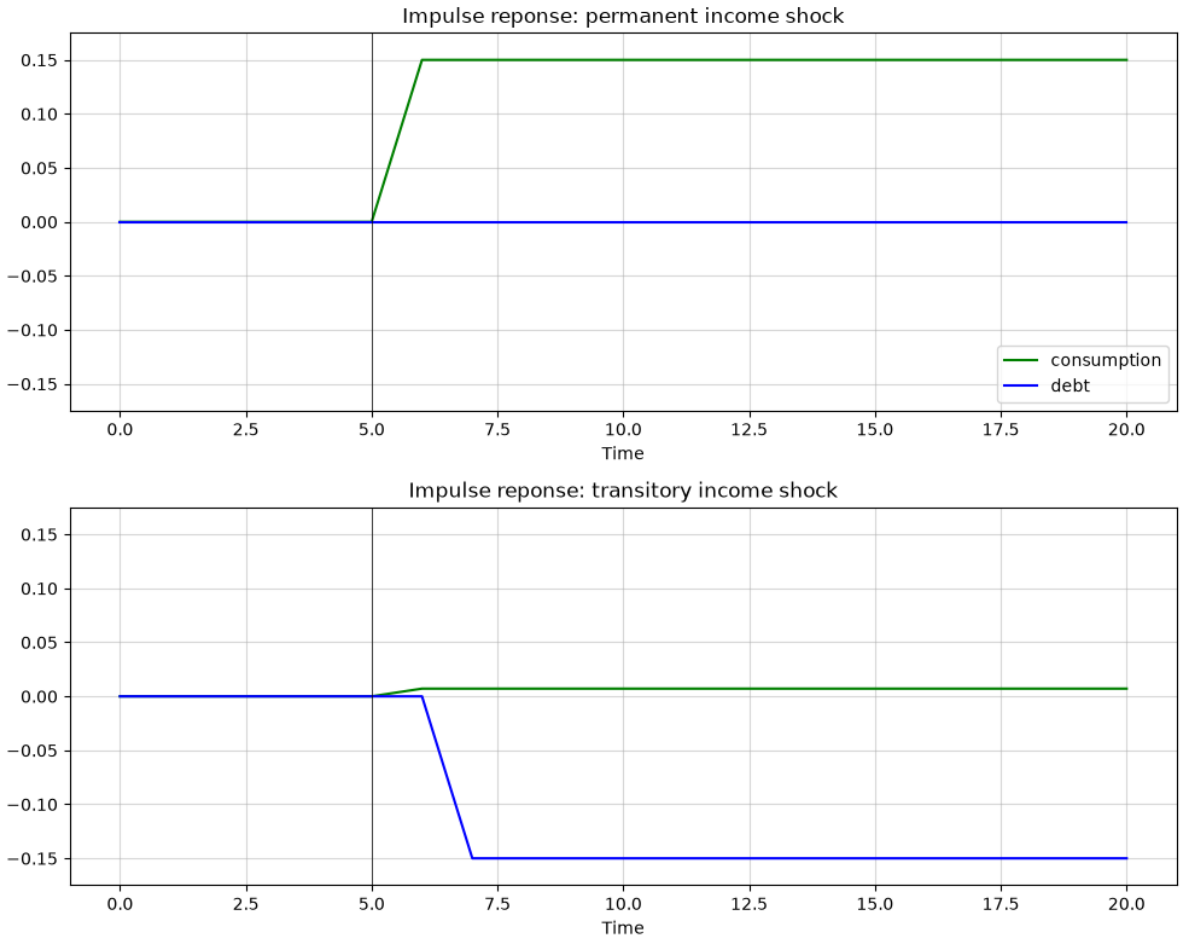
$$b_{t+1} - b_t = -z_{2t} = -\sigma_2 w_{2t} \tag{81.27}$$

This confirms that none of $\sigma_1 w_{1t}$ is saved, while all of $\sigma_2 w_{2t}$ is saved.

The next figure displays impulse-response functions that illustrates these very different reactions to transitory and permanent income shocks.

```
r = 0.05
β = 1 / (1 + r)
S = 5   # Impulse date
σ1 = σ2 = 0.15

@jit
def time_path(T, permanent=False):
    "Time path of consumption and debt given shock sequence"
    w1 = np.zeros(T+1)
    w2 = np.zeros(T+1)
    b = np.zeros(T+1)
    c = np.zeros(T+1)
    if permanent:
        w1[S+1] = 1.0
    else:
        w2[S+1] = 1.0
    for t in range(1, T):
        b[t+1] = b[t] - σ2 * w2[t]
        c[t+1] = c[t] + σ1 * w1[t+1] + (1 - β) * σ2 * w2[t+1]
    return b, c



fig, axes = plt.subplots(2, 1, figsize=(10, 8))
titles = ['permanent', 'transitory']

L = 0.175

for ax, truefalse, title in zip(axes, (True, False), titles):
    b, c = time_path(T=20, permanent=truefalse)
    ax.set_title(f'Impulse reponse: {title} income shock')
    ax.plot(c, 'g-', label="consumption")
    ax.plot(b, 'b-', label="debt")
    ax.plot((S, S), (-L, L), 'k-', lw=0.5)
    ax.grid(alpha=0.5)
    ax.set(xlabel=r'Time', ylim=(-L, L))

axes[0].legend(loc='lower right')

plt.tight_layout()
plt.show()
```

Notice how the permanent income shock provokes no change in assets $-b_{t+1}$ and an immediate permanent change in consumption equal to the permanent increment in non-financial income.

In contrast, notice how most of a transitory income shock is saved and only a small amount is saved.

The box-like impulse responses of consumption to both types of shock reflect the random walk property of the optimal consumption decision.

81.4.2 Example 2

Assume now that at time t the consumer observes y_t, and its history up to t, but not z_t.

Under this assumption, it is appropriate to use an *innovation representation* to form A, C, U in (81.18).

The discussion in sections 2.9.1 and 2.11.3 of [Ljungqvist and Sargent, 2018] shows that the pertinent state space representation for y_t is

$$\begin{bmatrix} y_{t+1} \\ a_{t+1} \end{bmatrix} = \begin{bmatrix} 1 & -(1-K) \\ 0 & 0 \end{bmatrix} \begin{bmatrix} y_t \\ a_t \end{bmatrix} + \begin{bmatrix} 1 \\ 1 \end{bmatrix} a_{t+1}$$

$$y_t = \begin{bmatrix} 1 & 0 \end{bmatrix} \begin{bmatrix} y_t \\ a_t \end{bmatrix}$$

where

- $K :=$ the stationary Kalman gain

- $a_t := y_t - E[y_t \mid y_{t-1}, \ldots, y_0]$

In the same discussion in [Ljungqvist and Sargent, 2018] it is shown that $K \in [0, 1]$ and that K increases as σ_1/σ_2 does.

In other words, K increases as the ratio of the standard deviation of the permanent shock to that of the transitory shock increases.

Please see *first look at the Kalman filter*.

Applying formulas (81.18) implies

$$c_{t+1} - c_t = [1 - \beta(1 - K)]a_{t+1} \tag{81.28}$$

where the endowment process can now be represented in terms of the univariate innovation to y_t as

$$y_{t+1} - y_t = a_{t+1} - (1 - K)a_t \tag{81.29}$$

Equation (81.29) indicates that the consumer regards

- fraction K of an innovation a_{t+1} to y_{t+1} as *permanent*
- fraction $1 - K$ as purely transitory

The consumer permanently increases his consumption by the full amount of his estimate of the permanent part of a_{t+1}, but by only $(1 - \beta)$ times his estimate of the purely transitory part of a_{t+1}.

Therefore, in total, he permanently increments his consumption by a fraction $K + (1 - \beta)(1 - K) = 1 - \beta(1 - K)$ of a_{t+1}.

He saves the remaining fraction $\beta(1 - K)$.

According to equation (81.29), the first difference of income is a first-order moving average.

Equation (81.28) asserts that the first difference of consumption is IID.

Application of formula to this example shows that

$$b_{t+1} - b_t = (K - 1)a_t \tag{81.30}$$

This indicates how the fraction K of the innovation to y_t that is regarded as permanent influences the fraction of the innovation that is saved.

81.5 Further Reading

The model described above significantly changed how economists think about consumption.

While Hall's model does a remarkably good job as a first approximation to consumption data, it's widely believed that it doesn't capture important aspects of some consumption/savings data.

For example, liquidity constraints and precautionary savings appear to be present sometimes.

Further discussion can be found in, e.g., [Hall and Mishkin, 1982], [Parker, 1999], [Deaton, 1991], [Carroll, 2001].

81.6 Appendix: The Euler Equation

Where does the first-order condition (81.5) come from?

Here we'll give a proof for the two-period case, which is representative of the general argument.

The finite horizon equivalent of the no-Ponzi condition is that the agent cannot end her life in debt, so $b_2 = 0$.

From the budget constraint (81.2) we then have

$$c_0 = \frac{b_1}{1+r} - b_0 + y_0 \quad \text{and} \quad c_1 = y_1 - b_1$$

Here b_0 and y_0 are given constants.

Substituting these constraints into our two-period objective $u(c_0) + \beta \mathbb{E}_0[u(c_1)]$ gives

$$\max_{b_1} \left\{ u\left(\frac{b_1}{R} - b_0 + y_0\right) + \beta \, \mathbb{E}_0[u(y_1 - b_1)] \right\}$$

You will be able to verify that the first-order condition is

$$u'(c_0) = \beta R \, \mathbb{E}_0[u'(c_1)]$$

Using $\beta R = 1$ gives (81.5) in the two-period case.

The proof for the general case is similar.

PERMANENT INCOME II: LQ TECHNIQUES

Contents

- *Permanent Income II: LQ Techniques*
  - *Overview*
  - *Setup*
  - *The LQ Approach*
  - *Implementation*
  - *Two Example Economies*

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

82.1 Overview

This lecture continues our analysis of the linear-quadratic (LQ) permanent income model of savings and consumption.

As we saw in our *previous lecture* on this topic, Robert Hall [Hall, 1978] used the LQ permanent income model to restrict and interpret intertemporal comovements of nondurable consumption, nonfinancial income, and financial wealth.

For example, we saw how the model asserts that for any covariance stationary process for nonfinancial income

- consumption is a random walk
- financial wealth has a unit root and is cointegrated with consumption

Other applications use the same LQ framework.

For example, a model isomorphic to the LQ permanent income model has been used by Robert Barro [Barro, 1979] to interpret intertemporal comovements of a government's tax collections, its expenditures net of debt service, and its public debt.

This isomorphism means that in analyzing the LQ permanent income model, we are in effect also analyzing the Barro tax smoothing model.

It is just a matter of appropriately relabeling the variables in Hall's model.

In this lecture, we'll

- show how the solution to the LQ permanent income model can be obtained using LQ control methods.
- represent the model as a linear state space system as in *this lecture*.
- apply QuantEcon's LinearStateSpace class to characterize statistical features of the consumer's optimal consumption and borrowing plans.

We'll then use these characterizations to construct a simple model of cross-section wealth and consumption dynamics in the spirit of Truman Bewley [Bewley, 1986].

(Later we'll study other Bewley models—see *this lecture*.)

The model will prove useful for illustrating concepts such as

- stationarity
- ergodicity
- ensemble moments and cross-section observations

Let's start with some imports:

```
import matplotlib.pyplot as plt
import quantecon as qe
import numpy as np
import scipy.linalg as la
```

82.2 Setup

Let's recall the basic features of the model discussed in the *permanent income model*.

Consumer preferences are ordered by

$$E_0 \sum_{t=0}^{\infty} \beta^t u(c_t) \tag{82.1}$$

where $u(c) = -(c - \gamma)^2$.

The consumer maximizes (82.1) by choosing a consumption, borrowing plan $\{c_t, b_{t+1}\}_{t=0}^{\infty}$ subject to the sequence of budget constraints

$$c_t + b_t = \frac{1}{1+r} b_{t+1} + y_t, \quad t \geq 0 \tag{82.2}$$

and the no-Ponzi condition

$$E_0 \sum_{t=0}^{\infty} \beta^t b_t^2 < \infty \tag{82.3}$$

The interpretation of all variables and parameters are the same as in the *previous lecture*.

We continue to assume that $(1+r)\beta = 1$.

The dynamics of $\{y_t\}$ again follow the linear state space model

$$\begin{aligned} z_{t+1} &= A z_t + C w_{t+1} \\ y_t &= U z_t \end{aligned} \tag{82.4}$$

The restrictions on the shock process and parameters are the same as in our *previous lecture*.

82.2.1 Digression on a Useful Isomorphism

The LQ permanent income model of consumption is mathematically isomorphic with a version of Barro's [Barro, 1979] model of tax smoothing.

In the LQ permanent income model

- the household faces an exogenous process of nonfinancial income
- the household wants to smooth consumption across states and time

In the Barro tax smoothing model

- a government faces an exogenous sequence of government purchases (net of interest payments on its debt)
- a government wants to smooth tax collections across states and time

If we set

- T_t, total tax collections in Barro's model to consumption c_t in the LQ permanent income model.
- G_t, exogenous government expenditures in Barro's model to nonfinancial income y_t in the permanent income model.
- B_t, government risk-free one-period assets falling due in Barro's model to risk-free one-period consumer debt b_t falling due in the LQ permanent income model.
- R, the gross rate of return on risk-free one-period government debt in Barro's model to the gross rate of return $1 + r$ on financial assets in the permanent income model of consumption.

then the two models are mathematically equivalent.

All characterizations of a $\{c_t, y_t, b_t\}$ in the LQ permanent income model automatically apply to a $\{T_t, G_t, B_t\}$ process in the Barro model of tax smoothing.

See consumption and tax smoothing models for further exploitation of an isomorphism between consumption and tax smoothing models.

82.2.2 A Specification of the Nonfinancial Income Process

For the purposes of this lecture, let's assume $\{y_t\}$ is a second-order univariate autoregressive process:

$$y_{t+1} = \alpha + \rho_1 y_t + \rho_2 y_{t-1} + \sigma w_{t+1}$$

We can map this into the linear state space framework in (82.4), as discussed in our lecture on *linear models*.

To do so we take

$$z_t = \begin{bmatrix} 1 \\ y_t \\ y_{t-1} \end{bmatrix}, \quad A = \begin{bmatrix} 1 & 0 & 0 \\ \alpha & \rho_1 & \rho_2 \\ 0 & 1 & 0 \end{bmatrix}, \quad C = \begin{bmatrix} 0 \\ \sigma \\ 0 \end{bmatrix}, \quad \text{and} \quad U = \begin{bmatrix} 0 & 1 & 0 \end{bmatrix}$$

82.3 The LQ Approach

Previously we solved the permanent income model by solving a system of linear expectational difference equations subject to two boundary conditions.

Here we solve the same model using *LQ methods* based on dynamic programming.

After confirming that answers produced by the two methods agree, we apply QuantEcon's LinearStateSpace class to illustrate features of the model.

Why solve a model in two distinct ways?

Because by doing so we gather insights about the structure of the model.

Our earlier approach based on solving a system of expectational difference equations brought to the fore the role of the consumer's expectations about future nonfinancial income.

On the other hand, formulating the model in terms of an LQ dynamic programming problem reminds us that

- finding the state (of a dynamic programming problem) is an art, and
- iterations on a Bellman equation implicitly jointly solve both a forecasting problem and a control problem

82.3.1 The LQ Problem

Recall from our *lecture on LQ theory* that the optimal linear regulator problem is to choose a decision rule for u_t to minimize

$$\mathbb{E} \sum_{t=0}^{\infty} \beta^t \{x_t' R x_t + u_t' Q u_t\},$$

subject to x_0 given and the law of motion

$$x_{t+1} = \tilde{A} x_t + \tilde{B} u_t + \tilde{C} w_{t+1}, \qquad t \geq 0, \tag{82.5}$$

where w_{t+1} is IID with mean vector zero and $\mathbb{E} w_t w_t' = I$.

The tildes in $\tilde{A}, \tilde{B}, \tilde{C}$ are to avoid clashing with notation in (82.4).

The value function for this problem is $v(x) = -x' P x - d$, where

- P is the unique positive semidefinite solution of the *corresponding matrix Riccati equation*.
- The scalar d is given by $d = \beta(1-\beta)^{-1} \text{trace}(P \tilde{C} \tilde{C}')$.

The optimal policy is $u_t = -F x_t$, where $F := \beta(Q + \beta \tilde{B}' P \tilde{B})^{-1} \tilde{B}' P \tilde{A}$.

Under an optimal decision rule F, the state vector x_t evolves according to $x_{t+1} = (\tilde{A} - \tilde{B}F) x_t + \tilde{C} w_{t+1}$.

82.3.2 Mapping into the LQ Framework

To map into the LQ framework, we'll use

$$x_t := \begin{bmatrix} z_t \\ b_t \end{bmatrix} = \begin{bmatrix} 1 \\ y_t \\ y_{t-1} \\ b_t \end{bmatrix}$$

as the state vector and $u_t := c_t - \gamma$ as the control.

With this notation and $U_\gamma := \begin{bmatrix}\gamma & 0 & 0\end{bmatrix}$, we can write the state dynamics as in (82.5) when

$$\tilde{A} := \begin{bmatrix} A & 0 \\ (1+r)(U_\gamma - U) & 1+r \end{bmatrix} \quad \tilde{B} := \begin{bmatrix} 0 \\ 1+r \end{bmatrix} \quad \text{and} \quad \tilde{C} := \begin{bmatrix} C \\ 0 \end{bmatrix} w_{t+1}$$

Please confirm for yourself that, with these definitions, the LQ dynamics (82.5) match the dynamics of z_t and b_t described above.

To map utility into the quadratic form $x_t' R x_t + u_t' Q u_t$ we can set

- $Q := 1$ (remember that we are minimizing) and
- $R :=$ a 4×4 matrix of zeros

However, there is one problem remaining.

We have no direct way to capture the non-recursive restriction (82.3) on the debt sequence $\{b_t\}$ from within the LQ framework.

To try to enforce it, we're going to use a trick: put a small penalty on b_t^2 in the criterion function.

In the present setting, this means adding a small entry $\epsilon > 0$ in the $(4, 4)$ position of R.

That will induce a (hopefully) small approximation error in the decision rule.

We'll check whether it really is small numerically soon.

82.4 Implementation

Let's write some code to solve the model.

One comment before we start is that the bliss level of consumption γ in the utility function has no effect on the optimal decision rule.

We saw this in the previous lecture *permanent income*.

The reason is that it drops out of the Euler equation for consumption.

In what follows we set it equal to unity.

82.4.1 The Exogenous Nonfinancial Income Process

First, we create the objects for the optimal linear regulator

```
# Set parameters
α, β, ρ1, ρ2, σ = 10.0, 0.95, 0.9, 0.0, 1.0

R = 1 / β
A = np.array([[1., 0., 0.],
              [α,  ρ1, ρ2],
              [0., 1., 0.]])
C = np.array([[0.], [σ], [0.]])
G = np.array([[0., 1., 0.]])

# Form LinearStateSpace system and pull off steady state moments
μ_z0 = np.array([[1.0], [0.0], [0.0]])
Σ_z0 = np.zeros((3, 3))
Lz = qe.LinearStateSpace(A, C, G, mu_0=μ_z0, Sigma_0=Σ_z0)
μ_z, μ_y, Σ_z, Σ_y, Σ_yx = Lz.stationary_distributions()
```

(continues on next page)

(continued from previous page)

```
# Mean vector of state for the savings problem
mxo = np.vstack([μ_z, 0.0])

# Create stationary covariance matrix of x -- start everyone off at b=0
a1 = np.zeros((3, 1))
aa = np.hstack([Σ_z, a1])
bb = np.zeros((1, 4))
sxo = np.vstack([aa, bb])

# These choices will initialize the state vector of an individual at zero
# debt and the ergodic distribution of the endowment process. Use these to
# create the Bewley economy.
mxbewley = mxo
sxbewley = sxo
```

The next step is to create the matrices for the LQ system

```
A12 = np.zeros((3,1))
ALQ_l = np.hstack([A, A12])
ALQ_r = np.array([[0, -R, 0, R]])
ALQ = np.vstack([ALQ_l, ALQ_r])

RLQ = np.array([[0., 0., 0., 0.],
                [0., 0., 0., 0.],
                [0., 0., 0., 0.],
                [0., 0., 0., 1e-9]])

QLQ = np.array([1.0])
BLQ = np.array([0., 0., 0., R]).reshape(4,1)
CLQ = np.array([0., σ, 0., 0.]).reshape(4,1)
β_LQ = β
```

Let's print these out and have a look at them

```
print(f"A = \n {ALQ}")
print(f"B = \n {BLQ}")
print(f"R = \n {RLQ}")
print(f"Q = \n {QLQ}")
```

```
A =
 [[ 1.          0.          0.          0.        ]
 [10.          0.9         0.          0.        ]
 [ 0.          1.          0.          0.        ]
 [ 0.         -1.05263158  0.          1.05263158]]
B =
 [[0.        ]
 [0.        ]
 [0.        ]
 [1.05263158]]
R =
 [[0.e+00 0.e+00 0.e+00 0.e+00]
 [0.e+00 0.e+00 0.e+00 0.e+00]
 [0.e+00 0.e+00 0.e+00 0.e+00]
 [0.e+00 0.e+00 0.e+00 1.e-09]]
Q =
 [1.]
```

Now create the appropriate instance of an LQ model

```
lqpi = qe.LQ(QLQ, RLQ, ALQ, BLQ, C=CLQ, beta=β_LQ)
```

We'll save the implied optimal policy function soon compare them with what we get by employing an alternative solution method

```
P, F, d = lqpi.stationary_values()  # Compute value function and decision rule
ABF = ALQ - BLQ @ F  #  Form closed loop system
```

82.4.2 Comparison with the Difference Equation Approach

In our *first lecture* on the infinite horizon permanent income problem we used a different solution method.

The method was based around

- deducing the Euler equations that are the first-order conditions with respect to consumption and savings.
- using the budget constraints and boundary condition to complete a system of expectational linear difference equations.
- solving those equations to obtain the solution.

Expressed in state space notation, the solution took the form

$$
\begin{aligned}
z_{t+1} &= Az_t + Cw_{t+1} \\
b_{t+1} &= b_t + U[(I - \beta A)^{-1}(A - I)]z_t \\
y_t &= Uz_t \\
c_t &= (1 - \beta)[U(I - \beta A)^{-1}z_t - b_t]
\end{aligned}
$$

Now we'll apply the formulas in this system

```
# Use the above formulas to create the optimal policies for b_{t+1} and c_t
b_pol = G @ la.inv(np.eye(3, 3) - β * A) @ (A - np.eye(3, 3))
c_pol = (1 - β) * G @ la.inv(np.eye(3, 3) - β * A)

# Create the A matrix for a LinearStateSpace instance
A_LSS1 = np.vstack([A, b_pol])
A_LSS2 = np.eye(4, 1, -3)
A_LSS = np.hstack([A_LSS1, A_LSS2])

# Create the C matrix for LSS methods
C_LSS = np.vstack([C, np.zeros(1)])

# Create the G matrix for LSS methods
G_LSS1 = np.vstack([G, c_pol])
G_LSS2 = np.vstack([np.zeros(1), -(1 - β)])
G_LSS = np.hstack([G_LSS1, G_LSS2])

# Use the following values to start everyone off at b=0, initial incomes zero
μ_0 = np.array([1., 0., 0., 0.])
Σ_0 = np.zeros((4, 4))
```

`A_LSS` calculated as we have here should equal `ABF` calculated above using the LQ model

```
ABF - A_LSS
```

```
array([[ 0.00000000e+00,  0.00000000e+00,  0.00000000e+00,
         0.00000000e+00],
       [ 0.00000000e+00,  0.00000000e+00,  0.00000000e+00,
         0.00000000e+00],
       [ 0.00000000e+00,  0.00000000e+00,  0.00000000e+00,
         0.00000000e+00],
       [-9.51248364e-06,  9.51247768e-08,  0.00000000e+00,
        -1.99999900e-08]])
```

Now compare pertinent elements of `c_pol` and `F`

```
print(c_pol, "\n", -F)
```

```
[[65.51724138  0.34482759  0.        ]]
 [[ 6.55172323e+01  3.44827677e-01 -0.00000000e+00 -5.00000190e-02]]
```

We have verified that the two methods give the same solution.

Now let's create instances of the LinearStateSpace class and use it to do some interesting experiments.

To do this, we'll use the outcomes from our second method.

82.5 Two Example Economies

In the spirit of Bewley models [Bewley, 1986], we'll generate panels of consumers.

The examples differ only in the initial states with which we endow the consumers.

All other parameter values are kept the same in the two examples

- In the first example, all consumers begin with zero nonfinancial income and zero debt.
  - The consumers are thus *ex-ante* identical.
- In the second example, while all begin with zero debt, we draw their initial income levels from the invariant distribution of financial income.
  - Consumers are *ex-ante* heterogeneous.

In the first example, consumers' nonfinancial income paths display pronounced transients early in the sample

- these will affect outcomes in striking ways

Those transient effects will not be present in the second example.

We use methods affiliated with the LinearStateSpace class to simulate the model.

82.5.1 First Set of Initial Conditions

We generate 25 paths of the exogenous non-financial income process and the associated optimal consumption and debt paths.

In the first set of graphs, darker lines depict a particular sample path, while the lighter lines describe 24 other paths.

A second graph plots a collection of simulations against the population distribution that we extract from the `LinearStateSpace` instance `LSS`.

Comparing sample paths with population distributions at each date t is a useful exercise—see *our discussion* of the laws of large numbers

```
lss = qe.LinearStateSpace(A_LSS, C_LSS, G_LSS, mu_0=μ_0, Sigma_0=Σ_0)
```

82.5.2 Population and Sample Panels

In the code below, we use the LinearStateSpace class to

- compute and plot population quantiles of the distributions of consumption and debt for a population of consumers.
- simulate a group of 25 consumers and plot sample paths on the same graph as the population distribution.

```
def income_consumption_debt_series(A, C, G, μ_0, Σ_0, T=150, npaths=25):
    """
    This function takes initial conditions (μ_0, Σ_0) and uses the
    LinearStateSpace class from QuantEcon to  simulate an economy
    npaths times for T periods. It then uses that information to
    generate some graphs related to the discussion below.
    """
    lss = qe.LinearStateSpace(A, C, G, mu_0=μ_0, Sigma_0=Σ_0)

    # Simulation/Moment Parameters
    moment_generator = lss.moment_sequence()

    # Simulate various paths
    bsim = np.empty((npaths, T))
    csim = np.empty((npaths, T))
    ysim = np.empty((npaths, T))

    for i in range(npaths):
        sims = lss.simulate(T)
        bsim[i, :] = sims[0][-1, :]
        csim[i, :] = sims[1][1, :]
        ysim[i, :] = sims[1][0, :]

    # Get the moments
    cons_mean = np.empty(T)
    cons_var = np.empty(T)
    debt_mean = np.empty(T)
    debt_var = np.empty(T)
    for t in range(T):
        μ_x, μ_y, Σ_x, Σ_y = next(moment_generator)
        cons_mean[t], cons_var[t] = μ_y[1,0], Σ_y[1, 1]
        debt_mean[t], debt_var[t] = μ_x[3,0], Σ_x[3, 3]

    return bsim, csim, ysim, cons_mean, cons_var, debt_mean, debt_var

def consumption_income_debt_figure(bsim, csim, ysim):

    # Get T
    T =  bsim.shape[1]

    # Create the first figure
    fig, ax = plt.subplots(2, 1, figsize=(10, 8))
    xvals = np.arange(T)

    # Plot consumption and income
    ax[0].plot(csim[0, :], label="c", color="b")
```

(continues on next page)

(continued from previous page)

```
    ax[0].plot(ysim[0, :], label="y", color="g")
    ax[0].plot(csim.T, alpha=.1, color="b")
    ax[0].plot(ysim.T, alpha=.1, color="g")
    ax[0].legend(loc=4)
    ax[0].set(title="Nonfinancial Income, Consumption, and Debt",
              xlabel="t", ylabel="y and c")

    # Plot debt
    ax[1].plot(bsim[0, :], label="b", color="r")
    ax[1].plot(bsim.T, alpha=.1, color="r")
    ax[1].legend(loc=4)
    ax[1].set(xlabel="t", ylabel="debt")

    fig.tight_layout()
    return fig

def consumption_debt_fanchart(csim, cons_mean, cons_var,
                              bsim, debt_mean, debt_var):
    # Get T
    T =  bsim.shape[1]

    # Create percentiles of cross-section distributions
    cmean = np.mean(cons_mean)
    c90 = 1.65 * np.sqrt(cons_var)
    c95 = 1.96 * np.sqrt(cons_var)
    c_perc_95p, c_perc_95m = cons_mean + c95, cons_mean - c95
    c_perc_90p, c_perc_90m = cons_mean + c90, cons_mean - c90

    # Create percentiles of cross-section distributions
    dmean = np.mean(debt_mean)
    d90 = 1.65 * np.sqrt(debt_var)
    d95 = 1.96 * np.sqrt(debt_var)
    d_perc_95p, d_perc_95m = debt_mean + d95, debt_mean - d95
    d_perc_90p, d_perc_90m = debt_mean + d90, debt_mean - d90

    # Create second figure
    fig, ax = plt.subplots(2, 1, figsize=(10, 8))
    xvals = np.arange(T)

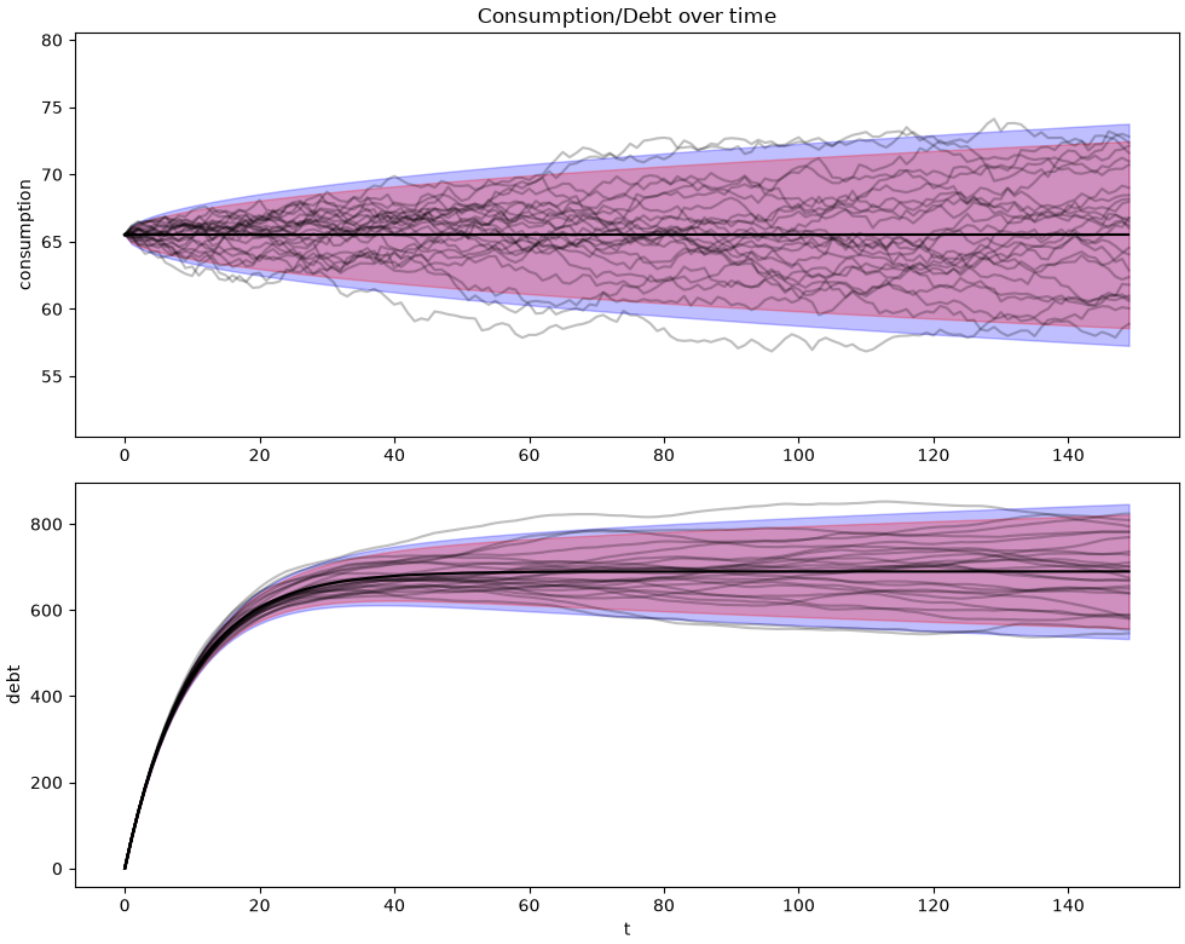
    # Consumption fan
    ax[0].plot(xvals, cons_mean, color="k")
    ax[0].plot(csim.T, color="k", alpha=.25)
    ax[0].fill_between(xvals, c_perc_95m, c_perc_95p, alpha=.25, color="b")
    ax[0].fill_between(xvals, c_perc_90m, c_perc_90p, alpha=.25, color="r")
    ax[0].set(title="Consumption/Debt over time",
              ylim=(cmean-15, cmean+15), ylabel="consumption")

    # Debt fan
    ax[1].plot(xvals, debt_mean, color="k")
    ax[1].plot(bsim.T, color="k", alpha=.25)
    ax[1].fill_between(xvals, d_perc_95m, d_perc_95p, alpha=.25, color="b")
    ax[1].fill_between(xvals, d_perc_90m, d_perc_90p, alpha=.25, color="r")
    ax[1].set(xlabel="t", ylabel="debt")

    fig.tight_layout()
    return fig
```

Now let's create figures with initial conditions of zero for y_0 and b_0

```
out = income_consumption_debt_series(A_LSS, C_LSS, G_LSS, μ_0, Σ_0)
bsim0, csim0, ysim0 = out[:3]
cons_mean0, cons_var0, debt_mean0, debt_var0 = out[3:]



consumption_income_debt_figure(bsim0, csim0, ysim0)

plt.show()
```

```
consumption_debt_fanchart(csim0, cons_mean0, cons_var0,
                          bsim0, debt_mean0, debt_var0)

plt.show()
```

Here is what is going on in the above graphs.

For our simulation, we have set initial conditions $b_0 = y_{-1} = y_{-2} = 0$.

Because $y_{-1} = y_{-2} = 0$, nonfinancial income y_t starts far below its stationary mean $\mu_{y,\infty}$ and rises early in each simulation.

Recall from the *previous lecture* that we can represent the optimal decision rule for consumption in terms of the **cointegrating relationship**

$$(1-\beta)b_t + c_t = (1-\beta)E_t \sum_{j=0}^{\infty} \beta^j y_{t+j} \tag{82.6}$$

So at time 0 we have

$$c_0 = (1-\beta)E_0 \sum_{t=0}^{\infty} \beta^j y_t$$

This tells us that consumption starts at the income that would be paid by an annuity whose value equals the expected discounted value of nonfinancial income at time $t = 0$.

To support that level of consumption, the consumer borrows a lot early and consequently builds up substantial debt.

In fact, he or she incurs so much debt that eventually, in the stochastic steady state, he consumes less each period than his nonfinancial income.

He uses the gap between consumption and nonfinancial income mostly to service the interest payments due on his debt.

Thus, when we look at the panel of debt in the accompanying graph, we see that this is a group of *ex-ante* identical people each of whom starts with zero debt.

All of them accumulate debt in anticipation of rising nonfinancial income.

They expect their nonfinancial income to rise toward the invariant distribution of income, a consequence of our having started them at $y_{-1} = y_{-2} = 0$.

Cointegration Residual

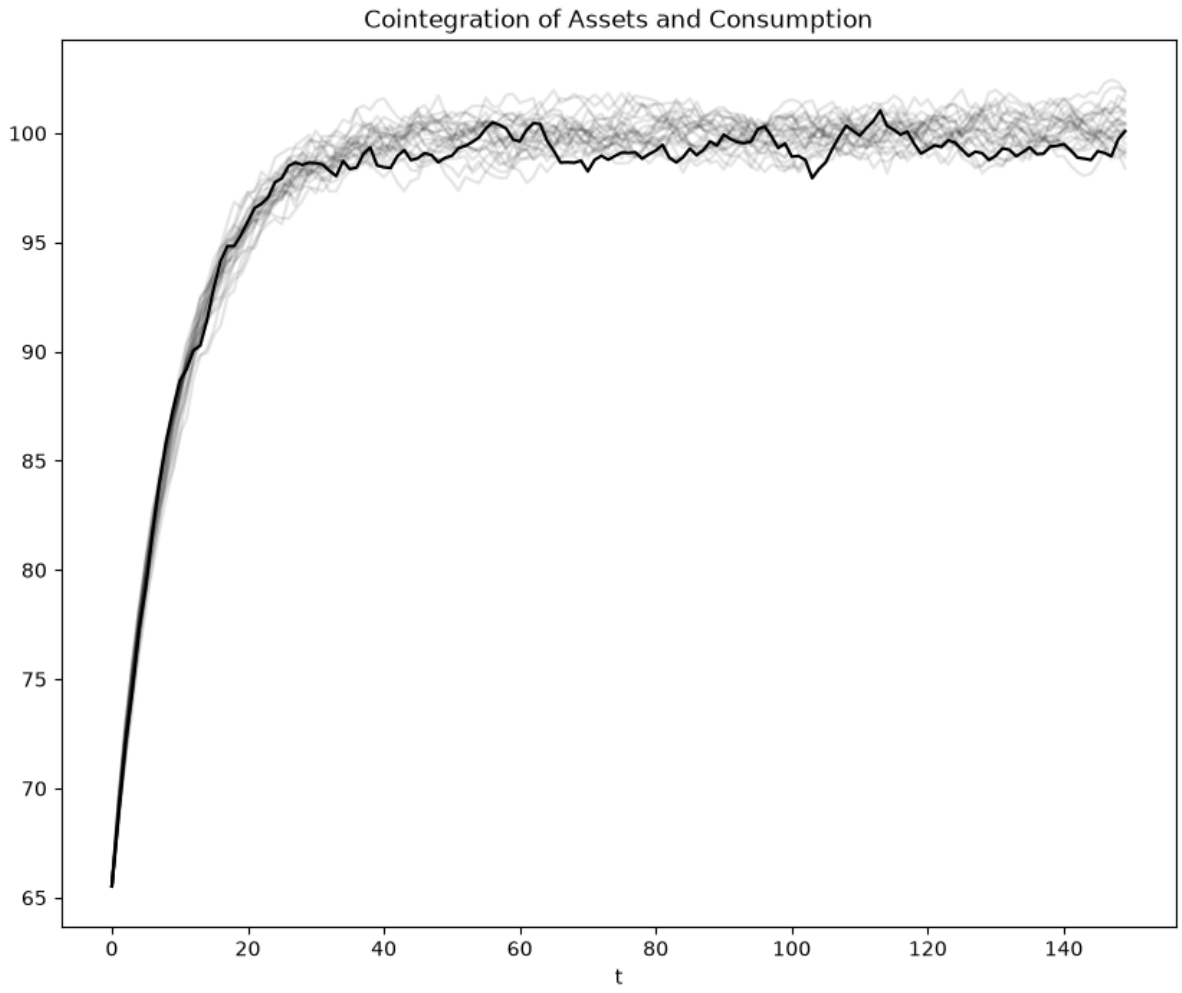
The following figure plots realizations of the left side of (82.6), which, *as discussed in our last lecture*, is called the **cointegrating residual**.

As mentioned above, the right side can be thought of as an annuity payment on the expected present value of future income $E_t \sum_{j=0}^{\infty} \beta^j y_{t+j}$.

Early along a realization, c_t is approximately constant while $(1-\beta)b_t$ and $(1-\beta)E_t \sum_{j=0}^{\infty} \beta^j y_{t+j}$ both rise markedly as the household's present value of income and borrowing rise pretty much together.

This example illustrates the following point: the definition of cointegration implies that the cointegrating residual is *asymptotically* covariance stationary, not *covariance stationary*.

The cointegrating residual for the specification with zero income and zero debt initially has a notable transient component that dominates its behavior early in the sample.



By altering initial conditions, we shall remove this transient in our second example to be presented below

```
def cointegration_figure(bsim, csim):
    """
    Plots the cointegration
    """
    # Create figure
    fig, ax = plt.subplots(figsize=(10, 8))
    ax.plot((1 - β) * bsim[0, :] + csim[0, :], color="k")
    ax.plot((1 - β) * bsim.T + csim.T, color="k", alpha=.1)

    ax.set(title="Cointegration of Assets and Consumption", xlabel="t")

    return fig
```

```
cointegration_figure(bsim0, csim0)
plt.show()
```

82.5.3 A "Borrowers and Lenders" Closed Economy

When we set $y_{-1} = y_{-2} = 0$ and $b_0 = 0$ in the preceding exercise, we make debt "head north" early in the sample.

Average debt in the cross-section rises and approaches the asymptote.

We can regard these as outcomes of a "small open economy" that borrows from abroad at the fixed gross interest rate $R = r + 1$ in anticipation of rising incomes.

So with the economic primitives set as above, the economy converges to a steady state in which there is an excess aggregate supply of risk-free loans at a gross interest rate of R.

This excess supply is filled by "foreigner lenders" willing to make those loans.

We can use virtually the same code to rig a "poor man's Bewley [Bewley, 1986] model" in the following way

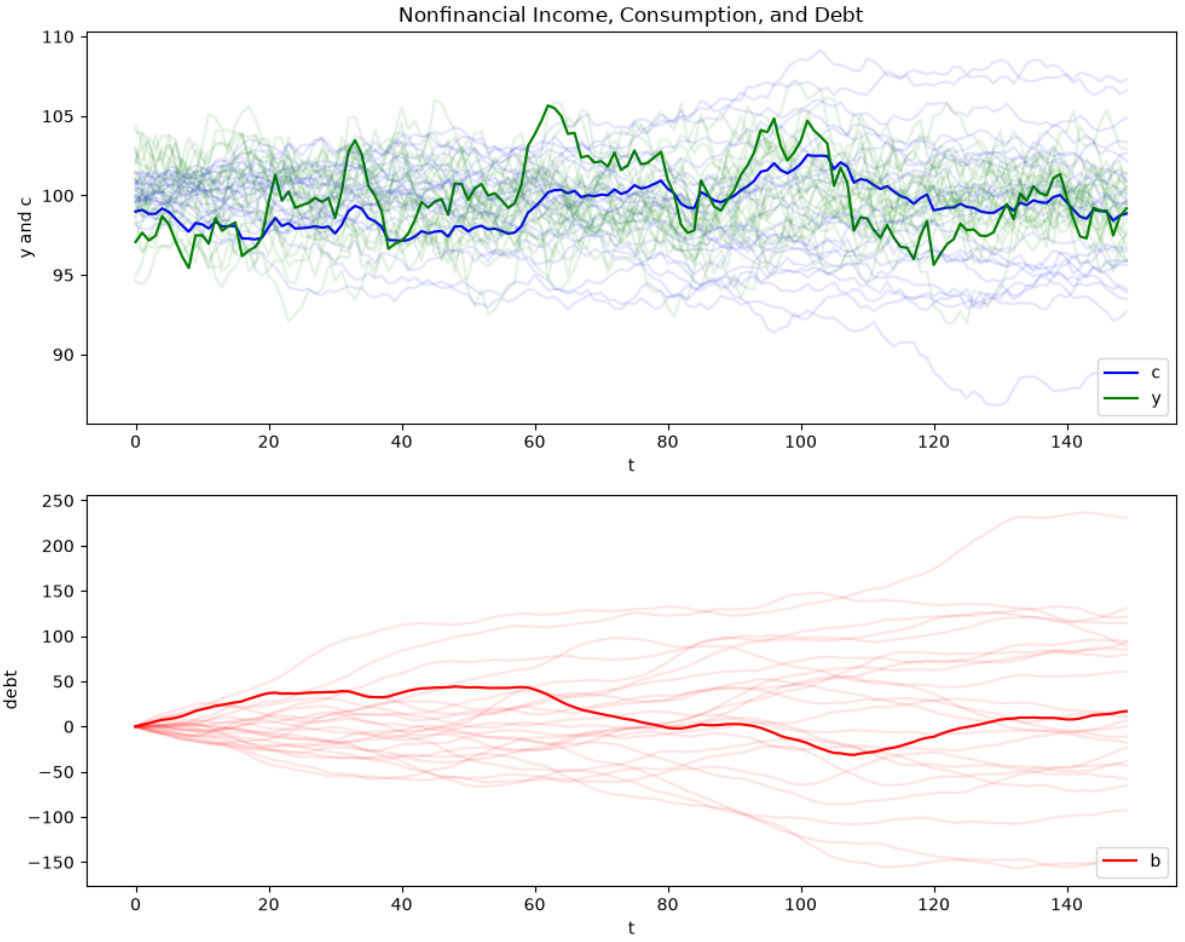
- as before, we start everyone at $b_0 = 0$.
- But instead of starting everyone at $y_{-1} = y_{-2} = 0$, we draw $\begin{bmatrix} y_{-1} \\ y_{-2} \end{bmatrix}$ from the invariant distribution of the $\{y_t\}$ process.

This rigs a closed economy in which people are borrowing and lending with each other at a gross risk-free interest rate of $R = \beta^{-1}$.

Across the group of people being analyzed, risk-free loans are in zero excess supply.

We have arranged primitives so that $R = \beta^{-1}$ clears the market for risk-free loans at zero aggregate excess supply.

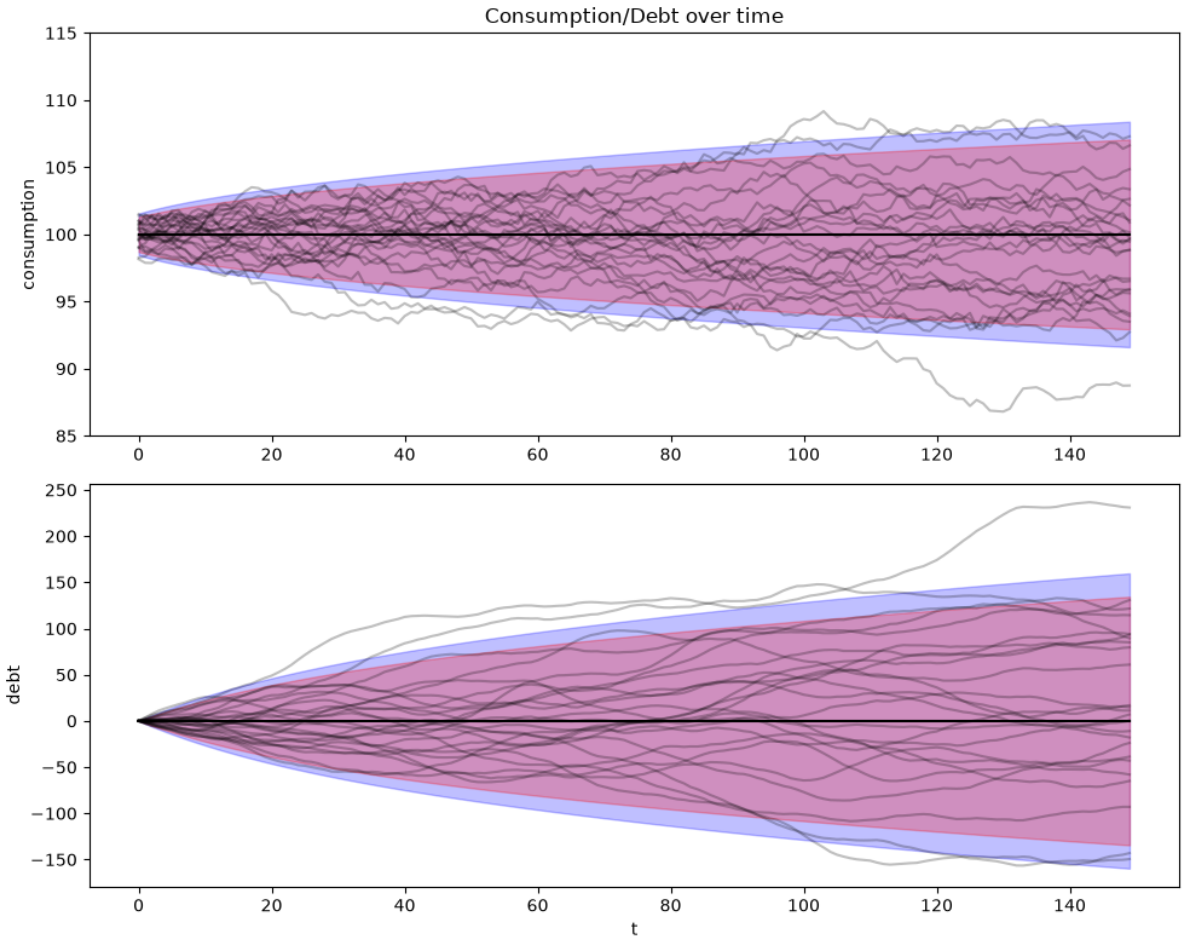
So the risk-free loans are being made from one person to another within our closed set of agents.



There is no need for foreigners to lend to our group.

Let's have a look at the corresponding figures

```
out = income_consumption_debt_series(A_LSS, C_LSS, G_LSS, mxbewley, sxbewley)
bsimb, csimb, ysimb = out[:3]
cons_meanb, cons_varb, debt_meanb, debt_varb = out[3:]



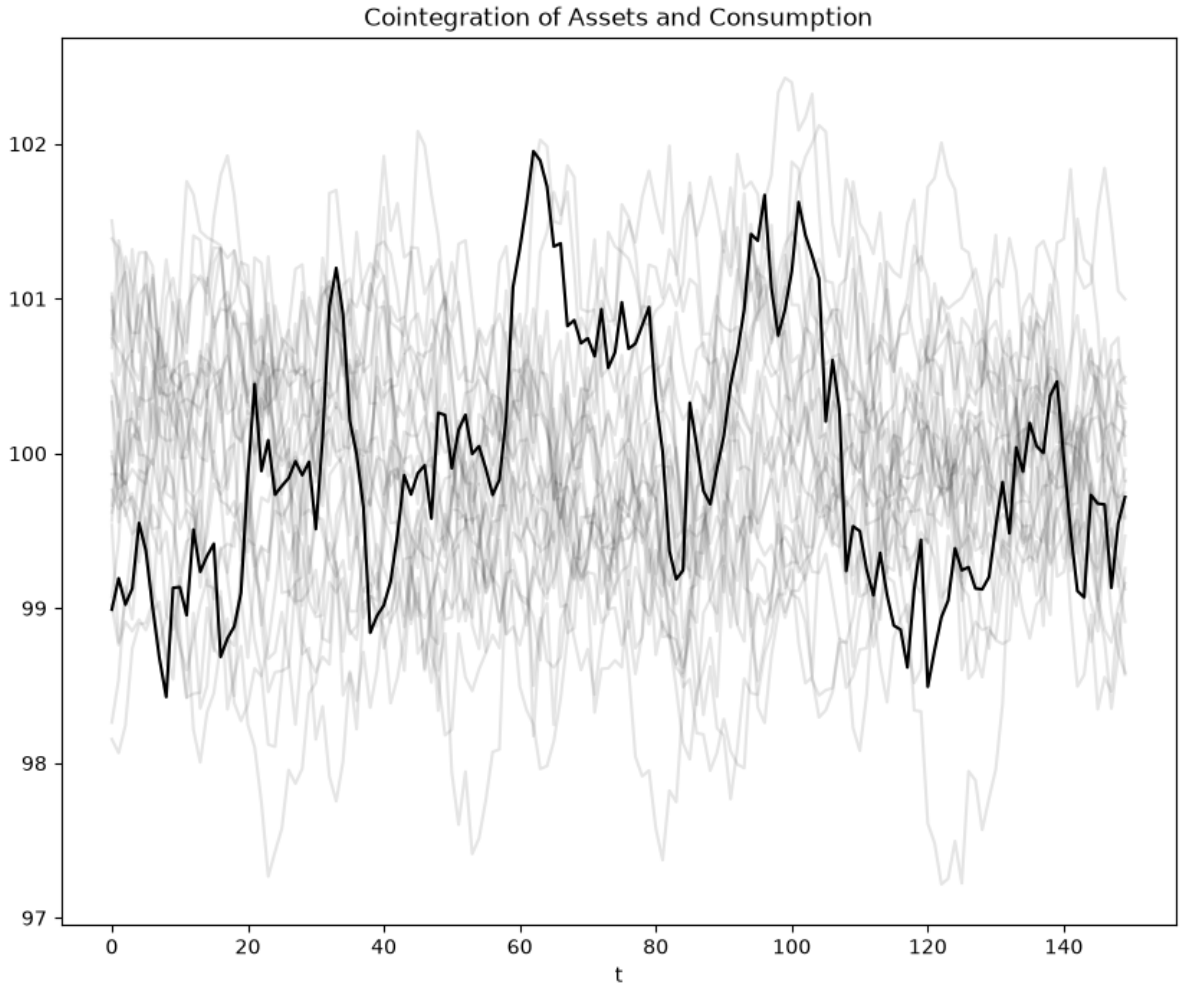
consumption_income_debt_figure(bsimb, csimb, ysimb)

plt.show()
```

```
consumption_debt_fanchart(csimb, cons_meanb, cons_varb,
                          bsimb, debt_meanb, debt_varb)

plt.show()
```

The graphs confirm the following outcomes:



- As before, the consumption distribution spreads out over time.

But now there is some initial dispersion because there is *ex-ante* heterogeneity in the initial draws of $\begin{bmatrix} y_{-1} \\ y_{-2} \end{bmatrix}$.

- As before, the cross-section distribution of debt spreads out over time.
- Unlike before, the average level of debt stays at zero, confirming that this is a closed borrower-and-lender economy.
- Now the cointegrating residual seems stationary, and not just asymptotically stationary.

Let's have a look at the cointegration figure

```
cointegration_figure(bsimb, csimb)
plt.show()
```

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install --upgrade quantecon
```

83.1 Overview

This lecture studies the model of Hansen *et al.* [1999].

The paper asks a simple question with surprising consequences.

What happens to a classic permanent income consumer when, instead of trusting a single probability model of their income, they *fear that their model is misspecified* and want decisions that work well across a *family* of nearby models?

Such a consumer is called a **robust** decision maker.

The central findings are:

- A preference for robustness is hidden inside the quantity implications of the ordinary permanent income model.
- Robustness and risk-sensitivity are two interpretations of the *same* decision rules, with a single parameter σ governing both.

- Concern about *small* amounts of model misspecification can show up as *large* market-based measures of risk aversion.
- The consumption and savings data alone cannot identify the robustness parameter: the model is **observationally equivalent** to a standard permanent income model with a lower discount factor.
- But asset prices, in particular the **market price of risk**, *can* be used to pin robustness down.

We will learn about

- risk-sensitive recursive preferences and the operator $\mathcal{R}_t$
- how a malevolent "second agent" implements a preference for robustness through a two-player zero-sum game
- the link between robustness and **Knightian uncertainty** in the sense of Gilboa and Schmeidler [1989] and Epstein and Wang [1994]
- an **observational equivalence** result that we will reproduce numerically
- how a small worst-case distortion of conditional means translates almost one-for-one into a market price of risk

This lecture builds on ideas in *The Permanent Income Model*, *Permanent Income II: LQ Techniques*, and *LQ Control: Foundations*.

The robustness machinery here is developed at book length in Hansen and Sargent [2008], extended in Anderson *et al.* [2003], and reinterpreted through detection-error probabilities in Barillas *et al.* [2009].

Let's start with some imports.

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.optimize import brentq
from scipy.stats import norm
import quantecon as qe
```

83.2 Risk-sensitive recursive preferences

The theory rests on a recursive linear-quadratic optimization problem with a twist in how continuation utility is aggregated.

The state evolves as

$$x_{t+1} = Ax_t + Bi_t + Cw_{t+1}, \tag{83.1}$$

where i_t is a control vector, x_t is the state vector, and w_{t+1} is an IID Gaussian vector with $\mathbb{E} w_{t+1} = 0$ and $\mathbb{E} w_{t+1} w_{t+1}^\top = I$.

The one-period return is

$$u(i_t, x_t) = -i_t^\top Q i_t - x_t^\top R x_t, \tag{83.2}$$

with Q positive definite and R positive semidefinite.

Following Epstein and Zin [1989], Weil [1989], and Hansen and Sargent [1995], intertemporal preferences are induced by the recursion

$$U_t = u(i_t, x_t) + \beta \, \mathcal{R}_t(U_{t+1}), \tag{83.3}$$

where the **risk-sensitivity operator** is

$$\mathcal{R}_t(U_{t+1}) \equiv \frac{2}{\sigma} \log \mathbb{E}\left[\exp\left(\frac{\sigma U_{t+1}}{2} \right) \Big| J_t \right]. \tag{83.4}$$

Here J_t is the information available at t.

When $\sigma = 0$ we set $\mathcal{R}_t \equiv \mathbb{E}(\cdot \mid J_t)$ and recover the usual von Neumann–Morgenstern, state-additive specification.

When $\sigma \neq 0$ the operator $\mathcal{R}_t$ applies an additional risk adjustment *over and above* the one coming from the curvature of u.

Values of $\sigma < 0$ correspond to *more* aversion to risk than the von Neumann–Morgenstern benchmark, which is the case studied throughout the paper.

Note

The exponential-of-utility form in (83.4) originates in the *risk-sensitive control* literature started by Jacobson [1973] and extended by Whittle [1981] and Whittle [1990].

Hansen *et al.* [1999] give it an economic reinterpretation as a *preference for robustness*.

83.2.1 The operator under Gaussian uncertainty

The operator $\mathcal{R}_t$ has a transparent closed form when continuation utility is Gaussian.

Suppose $U_{t+1} \sim N(\mu, s^2)$ conditional on J_t. Using the Gaussian moment generating function $\mathbb{E}[\exp(aU_{t+1})] = \exp(a\mu + \frac{1}{2}a^2 s^2)$ with $a = \sigma/2$,

$$\mathcal{R}_t(U_{t+1}) = \frac{2}{\sigma} \log \mathbb{E}\left[\exp\left(\frac{\sigma U_{t+1}}{2}\right) \middle| J_t\right] = \frac{2}{\sigma}\left(\frac{\sigma}{2}\mu + \frac{\sigma^2}{8}s^2\right) = \mu + \frac{\sigma}{4}s^2. \tag{83.5}$$

For $\sigma < 0$ this is *below* the conditional mean μ: the decision maker evaluates uncertain prospects *pessimistically*, and the penalty grows with the conditional variance s^2.

This certainty equivalent has a revealing decomposition.

The expectation in (83.4) re-weights outcomes by $\exp(\sigma U_{t+1}/2)$; for a Gaussian this **exponential tilting** produces a new normal density with the *same* variance s^2 but a mean shifted to $\mu + \frac{\sigma}{2}s^2$.

The operator value $\mu + \frac{\sigma}{4}s^2$ lies *halfway* between the original mean μ and this worst-case mean: it equals the worst-case expected utility $\mu + \frac{\sigma}{2}s^2$ *plus* the relative-entropy penalty $-\frac{\sigma}{4}s^2$ that restrains the distortion.

Note

The two coefficients describe different objects.

The **worst-case mean** of U_{t+1} shifts by $\frac{\sigma}{2}s^2$, while the **operator value** (certainty equivalent) shifts by $\frac{\sigma}{4}s^2$.

Both are correct; the smaller shift of $\mathcal{R}_t$ reflects the entropy cost the malevolent player pays for the distortion.

A self-contained derivation of (83.5) is requested in Exercise 83.9.1.

Let's visualize both facts, with the certainty equivalent on the left and the worst-case (tilted) density of continuation utility on the right.

```
μ, s = 0.0, 1.0           # conditional mean and std of continuation utility

def R_operator(μ, s, σ):
    "Risk-sensitive operator for a Gaussian U ~ N(μ, s^2)."
    if σ == 0:
        return μ
```

(continues on next page)

(continued from previous page)

```
    return μ + σ * s**2 / 4

σ_vals = np.linspace(-1.5, 0.0, 200)
R_vals = [R_operator(μ, s, sg) for sg in σ_vals]

fig, axes = plt.subplots(1, 2, figsize=(11, 4))

axes[0].plot(σ_vals, R_vals, lw=2)
axes[0].axhline(μ, color='k', ls='--', lw=1, label=r'$E[U_{t+1}]=\mu$')
axes[0].set_xlabel(r'risk-sensitivity $\sigma$')
axes[0].set_ylabel(r'$\mathcal{R}_t(U_{t+1})$')
axes[0].set_title('certainty equivalent')
axes[0].legend()

# Tilted density
grid = np.linspace(μ - 4*s, μ + 4*s, 400)
axes[1].plot(grid, norm.pdf(grid, μ, s), lw=2,
             label=r'reference $N(\mu, s^2)$')
for σ in [-0.5, -1.0]:
    shift = σ * s**2 / 2      # worst-case mean shift of U_{t+1}
    axes[1].plot(grid, norm.pdf(grid, μ + shift, s), lw=2, ls='--',
                 label=f'worst-case, $\\sigma={σ}$')
    axes[1].axvline(μ + σ * s**2 / 4, color='C3', lw=0.8, ls=':')
axes[1].set_xlabel(r'continuation utility $U_{t+1}$')
axes[1].set_ylabel('density')
axes[1].set_title('worst-case density')
axes[1].legend()
fig.tight_layout()
plt.show()
```

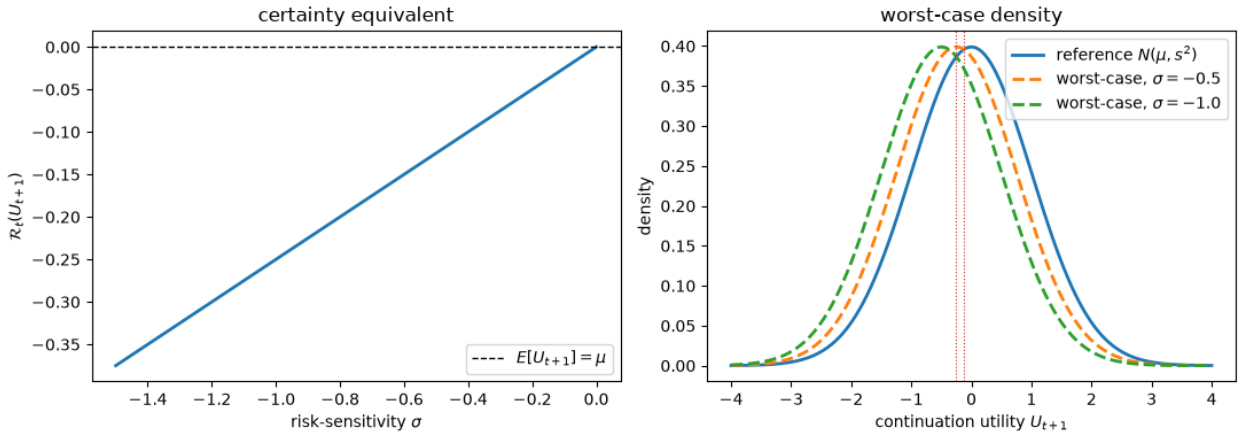

Fig. 83.1: Risk-sensitive operator and worst-case density

The left panel shows the certainty equivalent $\mathcal{R}_t$ sliding below the mean as σ becomes more negative.

The right panel shows the associated worst-case density of continuation utility: a robust agent behaves *as if* U_{t+1} were drawn from a pessimistically re-centered distribution (mean $\mu + \frac{\sigma}{2}s^2$, dashed), while the operator value $\mathcal{R}_t = \mu + \frac{\sigma}{4}s^2$ (dotted) sits halfway between it and the reference mean μ.

83.3 A preference for robustness

The pessimistic tilt in the right panel above is not just an analogy.

Hansen *et al.* [1999] show that the risk-sensitive problem is the value function of a **two-player zero-sum game**.

In this game, one player chooses the control $\{i_t\}$ while a second, malevolent player chooses a distortion $\{v_t\}$ to the conditional mean of the shocks.

The distorted law of motion is

$$x_{t+1} = Ax_t + Bi_t + C(w_{t+1} + v_t). \tag{83.6}$$

The minimizing player would like to push the state in painful directions, but is restrained by a penalty on the size of the distortion.

With $-1/\sigma \geq 0$ acting as a Lagrange multiplier on a constraint that bounds the distortion sequence, the Markov perfect equilibrium has value function

$$\tilde{W}(x) = \inf_v \sup_i \left\{ -i^\top Q i - x^\top R x + \beta \left[-\frac{1}{\sigma} v^\top v + \mathbb{E}\, \tilde{W}(Ax + Bi + C(w + v)) \right] \right\}. \tag{83.7}$$

Because $\sigma < 0$ makes $-1/\sigma > 0$, the term $-\frac{1}{\sigma} v^\top v$ *penalizes* the malevolent player for large distortions.

A smaller $|1/\sigma|$ (more negative σ) means a cheaper distortion budget and hence a larger family of models the agent guards against, reflecting a *stronger* preference for robustness.

This is exactly the max-min expected utility structure of Gilboa and Schmeidler [1989]: the agent's "nominal model" sets $v_t = 0$, but they entertain a whole family of alternatives indexed by $\{v_t\}$ and act against the worst case.

Following Epstein and Wang [1994], the non-uniqueness of the implied probability measures is a form of **Knightian uncertainty**.

The robust and risk-sensitive problems share the same value function matrix Ω and the same decision rule $i_t = -Fx_t$; they differ only in interpretation.

83.4 The permanent income economy

We now specialize to a habit-persistence version of the permanent income model.

A planner orders consumption streams $\{c_t\}$ through a service stream $\{s_t\}$ using the recursion

$$U_t = -(s_t - b_t)^2 + \beta\, \mathcal{R}_t(U_{t+1}), \tag{83.8}$$

where $\{b_t\}$ is an exogenous preference (bliss-point) shock.

Services are produced from consumption via the household technology

$$s_t = (1 + \lambda)c_t - \lambda h_{t-1}, \tag{83.9}$$

$$h_t = \delta_h h_{t-1} + (1 - \delta_h)c_t, \tag{83.10}$$

with $\lambda > 0$ and $\delta_h \in (0, 1)$.

Here h_t is a geometric average of current and past consumption, so (83.9) makes services depend *negatively* on a weighted average of past consumption, which is the **habit persistence**.

There is a linear production technology

$$c_t + i_t = \gamma k_{t-1} + d_t,$$

and capital accumulates as $k_t = \delta_k k_{t-1} + i_t$, where $\{d_t\}$ is an exogenous endowment.

Combining,

$$c_t + k_t = (\delta_k + \gamma) k_{t-1} + d_t, \qquad R \equiv \delta_k + \gamma, \tag{83.11}$$

so R is the gross physical return on capital, which in a decentralized economy equals the gross **risk-free rate**.

The endowment and preference shocks are driven by a common linear state,

$$z_{t+1} = A_{22} z_t + C_2 w_{t+1}, \qquad d_t = U_d z_t, \quad b_t = U_b z_t. \tag{83.12}$$

This whole economy is a special case of the control problem (83.1)–(83.3): stack h_{t-1}, k_{t-1}, and z_t into the state x_t and let the control be $i_t = s_t - b_t$.

83.4.1 The $\sigma = 0$ benchmark and the martingale

To build intuition, set $\sigma = 0$ and impose the permanent income restriction $\beta R = 1$, as in Hall [1978].

The first-order conditions then imply that the marginal utility of consumption services is a **martingale**,

$$\mathbb{E}_t \, \mu_{c,t+1} = \mu_{c,t}, \tag{83.13}$$

and that $\mu_{s,t}$ inherits the representation

$$\mu_{s,t} = \mu_{s,t-1} + v^\top w_t \tag{83.14}$$

for some loading vector v.

Equation (83.13) is the classic statement that, under $\beta R = 1$, consumption responds only to *news*, so it is a random walk.

This is the result that Hall [1978] and Campbell [1987] tested on aggregate U.S. data.

The scalar

$$\theta^2 \equiv v^\top v$$

measures the variance of the innovation to the marginal-utility martingale (83.14).

It will be the one summary statistic of the benchmark economy that we need below.

> **Note**
>
> Under a rational-expectations reading, the benchmark $\sigma = 0$ permanent income model has *no precautionary savings*, as emphasized by Zeldes.
>
> Introducing robustness ($\sigma < 0$) revives a precautionary motive: the consumer guards against worst-case mistakes in the conditional means of shocks.

83.5 Observational equivalence

Here is the paper's first headline result.

Proposition 83.5.1 (Observational Equivalence)

Fix all parameters except β and σ. Suppose $\beta R = 1$. There exists $\underline{\sigma} < 0$ such that the optimal consumption–investment plan for $\sigma = 0$ is *also* optimal for any $\sigma \in (\underline{\sigma}, 0)$, provided the discount factor is lowered to a value $\hat{\beta}(\sigma)$ that varies directly with σ.

In words: as far as the *quantities* $\{c_t, k_t\}$ are concerned, the robust ($\sigma < 0$) permanent income model is indistinguishable from the standard ($\sigma = 0$) one with a smaller discount factor.

Increasing the preference for robustness stimulates a precautionary motive for saving; lowering β makes saving less attractive; along a particular locus the two effects exactly cancel.

The proof is constructive and delivers an explicit locus of observationally equivalent $(\sigma, \hat{\beta})$ pairs. Define

$$\Omega(\beta) = \frac{\beta - 1 + \sigma\theta^2 + \sqrt{(\beta - 1 + \sigma\theta^2)^2 + 4\sigma\theta^2}}{-2\sigma\theta^2}, \tag{83.15}$$

$$\hat{\zeta}(\beta) = 1 + \frac{\theta^2 \sigma\, \Omega(\beta)}{1 - \sigma\theta^2 \Omega(\beta)}. \tag{83.16}$$

The equivalent discount factor $\hat{\beta}$ solves

$$\hat{\beta}\, R\, \hat{\zeta}(\hat{\beta}) = 1. \tag{83.17}$$

The lower bound $\underline{\sigma}$ is the most negative σ for which the square root in (83.15) stays real.

Let's reproduce the locus, a version of Figure 1 in Hansen *et al.* [1999].

```
β_bench = 0.9971          # benchmark discount factor (annual rate ~2.5%)
Rf = 1 / β_bench          # gross risk-free return fixed by β R = 1
θ2 = 0.01                # variance of the marginal-utility innovation, v^T v

def Ω_scalar(β, σ, θ2):
    disc = (β - 1 + σ * θ2)**2 + 4 * σ * θ2
    if disc < 0:
        return np.nan        # below σ-underbar: no real solution
    return (β - 1 + σ * θ2 + np.sqrt(disc)) / (-2 * σ * θ2)

def ζ_hat(β, σ, θ2):
    Ω = Ω_scalar(β, σ, θ2)
    return 1 + (θ2 * σ * Ω) / (1 - σ * θ2 * Ω)

def β_hat(σ, θ2, Rf):
    "Discount factor that makes σ observationally equivalent to σ=0."
    if σ == 0:
        return 1 / Rf
    f = lambda b: b * Rf * ζ_hat(b, σ, θ2) - 1
    return brentq(f, 0.95, 1 / Rf - 1e-12)

σ_vals = np.linspace(-1.2e-4, 0.0, 200)
β_vals = np.array([β_hat(sg, θ2, Rf) for sg in σ_vals])

fig, ax = plt.subplots()
ax.plot(β_vals, σ_vals, lw=2)
ax.set_xlabel(r'discount factor $\hat\beta$')
ax.set_ylabel(r'risk-sensitivity $\sigma$')
ax.axhline(0, color='k', lw=0.8, ls='--')
fig.tight_layout()
plt.show()
```

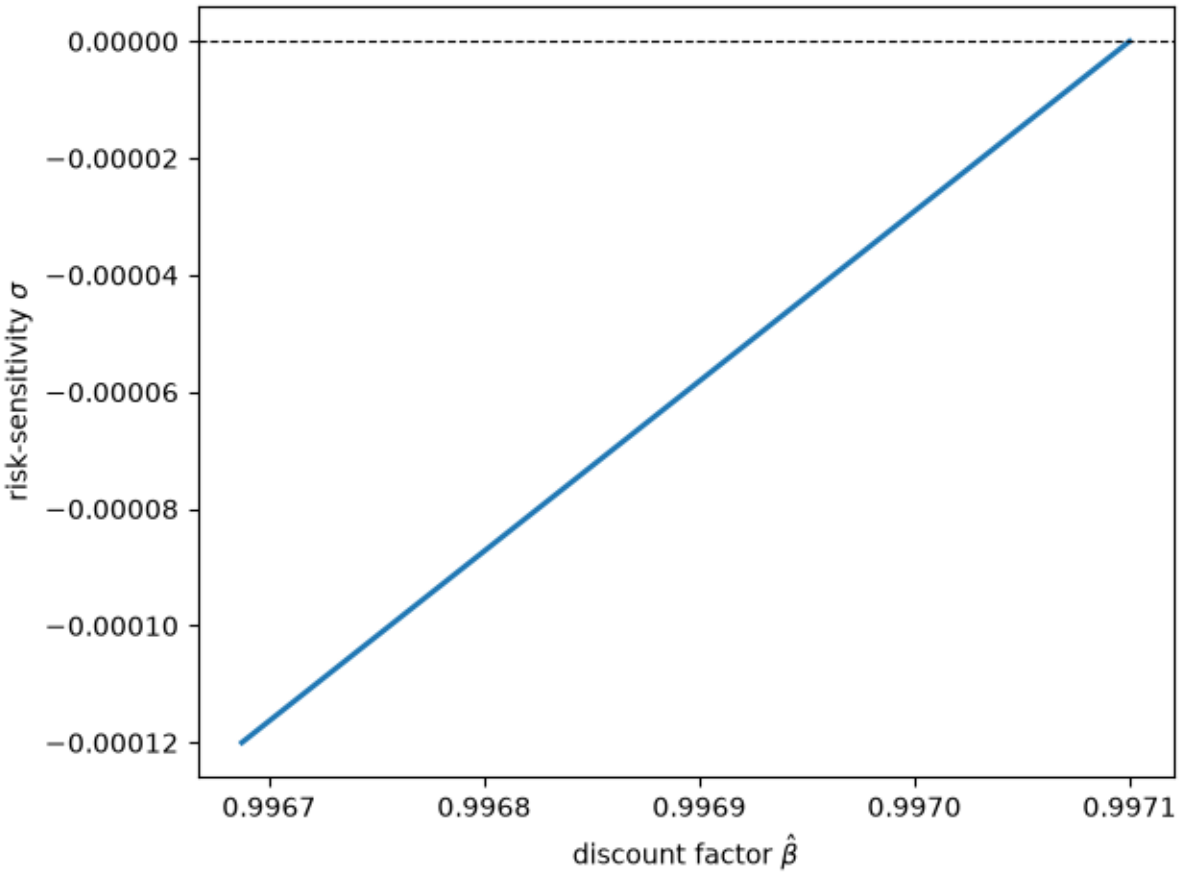

Fig. 83.2: Equivalent $(\sigma, \hat{\beta})$ pairs

Every point on this curve generates *exactly the same* consumption and investment data.

Moving down the curve (more negative σ, i.e. a stronger preference for robustness) requires a *lower* discount factor $\hat{\beta}$ to keep quantities unchanged.

This is why consumption and savings data alone cannot tell us how much the consumer fears model misspecification.

83.6 Estimation

Hansen *et al.* [1999] turns the observational-equivalence result into an empirical strategy.

Because the quantity data cannot pin down σ, the authors first estimate the $\sigma = 0$ version of the model, conditioning the likelihood *only on consumption and investment*, and then use the locus of *Proposition 83.5.1* to trace out the family of $(\sigma, \hat{\beta})$ pairs consistent with those estimates.

Asset prices (the next section) break the tie.

83.6.1 The data and the likelihood

The model is fit to U.S. post-war quarterly data, 1970:I–1996:III.

- *Consumption* is measured as nondurables plus services.
- *Investment* is measured as durables plus gross private investment.

Both series are deflated by the deterministic growth factor 1.0033^t, so the model is fit to *detrended* data.

The likelihood is Gaussian, built recursively (a Kalman filter), with the unobserved part of the initial state estimated using the methods of Hansen and Sargent.

83.6.2 Specification

The preference shock is a constant, $b_t = \mu_b$, fixed at $\mu_b = 32$; recall from the discussion of (83.11) that the *level* of b_t does not affect the decision rules, only prices.

The endowment is the sum of a *persistent* and a *transitory* component, each a second-order autoregression driven by orthogonal shocks,

$$(1 - \phi_1 L)(1 - \phi_2 L)\, d_t^* = c_{d^*}\, w_t^{d^*}, \tag{83.18}$$

$$(1 - \alpha_1 L)(1 - \alpha_2 L)\, \hat{d}_t = c_{\hat{d}}\, w_t^{\hat{d}}, \tag{83.19}$$

with $d_t = \mu_d + d_t^* + \hat{d}_t$.

A likelihood comparison (a gain from AR(1) to AR(2) but not beyond) led the authors to a second-order specification for the transitory component.

The four parameters governing the endogenous dynamics are $(\gamma, \delta_k, \beta, \lambda)$.

The depreciation factor is set to $\delta_k = 0.975$, and the permanent-income restriction $\beta R = 1$ (confirmed by the unrestricted estimates) is imposed with $\beta = 0.9971$, implying a 2.5% annual real interest rate after the growth adjustment.

The maximum-likelihood estimates (with habit persistence) are reproduced below, a version of Table 2 in Hansen *et al.* [1999].

Parameter	Symbol	Estimate
Discount factor	β	0.997
Habit depreciation	δ_h	0.682
Habit weight	λ	2.443
Transitory AR roots	α_1, α_2	0.813, 0.189
Persistent AR roots	ϕ_1, ϕ_2	0.998, 0.704
Endowment mean	μ_d	13.710
Transitory shock scale	$c_{\hat{d}}$	0.155
Persistent shock scale	c_{d^*}	0.108

The single most striking estimate is the autoregressive root $\phi_1 = 0.998$ of the persistent endowment component, a number all but indistinguishable from a unit root.

83.6.3 Impulse responses and the permanent income mechanism

The persistence of a shock is what determines how strongly consumption reacts to it.

Under the permanent income logic (with $\beta R = 1$ and, for transparency, *no* habit), consumption jumps on impact by the **annuity value** of the change in wealth and is a martingale thereafter,

$$\Delta c = \left(1 - \frac{1}{R}\right) \sum_{j \geq 0} R^{-j} \, \psi_j, \tag{83.20}$$

where $\psi_j = \partial d_{t+j} / \partial w_t$ is the endowment's own impulse response.

A near-permanent shock has a large present value and moves consumption a lot; a transitory shock has a small present value and barely moves it.

Let's compute the endowment responses (83.18)–(83.19) and the implied consumption responses.

```
def ar2_irf(r1, r2, c, H):
    "Impulse response of (1 - r1 L)(1 - r2 L) x = c w to a unit w shock."
    ψ = np.zeros(H)
    ψ[0] = c
    if H > 1:
        ψ[1] = (r1 + r2) * ψ[0]
    for j in range(2, H):
        ψ[j] = (r1 + r2) * ψ[j-1] - r1 * r2 * ψ[j-2]
    return ψ

H = 50
disc = Rf**(-np.arange(H))    # Rf = 1/β from the previous cell

ψ_p = ar2_irf(0.998, 0.704, 0.108, H)          # persistent endowment d*
ψ_t = ar2_irf(0.813, 0.189, 0.155, H)          # transitory endowment d_hat

# Flat consumption response
dc_p = (1 - 1/Rf) * np.sum(disc * ψ_p)
dc_t = (1 - 1/Rf) * np.sum(disc * ψ_t)

print(f"persistent shock: consumption responds to "
      f"{100*dc_p/ψ_p[0]:.0f}% of the impact")
print(f"transitory shock: consumption responds to "
      f"{100*dc_t/ψ_t[0]:.0f}% of the impact")
```

(continues on next page)

(continued from previous page)

```
fig, axes = plt.subplots(1, 2, figsize=(11, 4), sharey=True)
for ax, ψ, dc, shock_label in [
        (axes[0], ψ_p, dc_p, 'persistent shock $d^{*}$'),
        (axes[1], ψ_t, dc_t, 'transitory shock $\\hat d$')]:
    ax.plot(ψ, lw=2, label=fr'{shock_label}: endowment response $\psi_j$')
    ax.axhline(dc, color='C3', ls='--', lw=2,
               label=r'consumption response $\Delta c$')
    ax.set_title(shock_label)
    ax.set_xlabel('horizon $j$ (quarters)')
    ax.legend()
axes[0].set_ylabel('response')
fig.tight_layout()
plt.show()
```

```
persistent shock: consumption responds to 41% of the impact
transitory shock: consumption responds to 2% of the impact
```

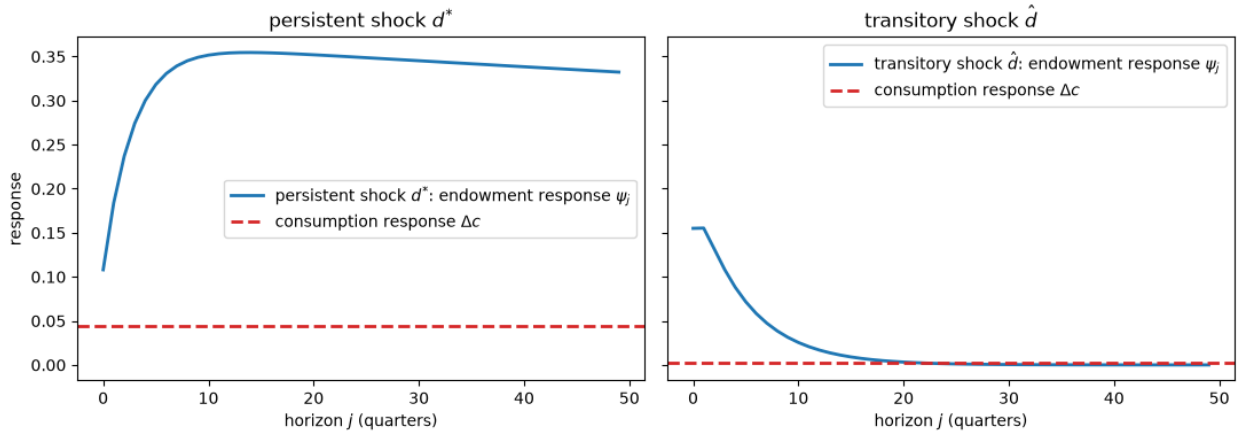

Fig. 83.3: Endowment and consumption impulse responses

The contrast is the heart of the permanent income hypothesis tested by Hall [1978] and Campbell [1987].

Consumption tracks a large fraction of the persistent shock, whose near-unit root makes it almost permanent income, but only a sliver of the transitory shock, the bulk of which is saved and shows up as investment.

Note

With habit persistence ($\lambda > 0$) the consumption responses are no longer flat: they become hump-shaped, because services rather than consumption obey the martingale logic.

The estimated $\lambda = 2.443$ and $\delta_h = 0.682$ imply economically important habit effects, and a likelihood-ratio comparison strongly rejects $\lambda = 0$.

Hansen *et al.* [1999] compare these magnitudes with the habit estimates in the time-nonseparable preference literature.

83.7 Asset pricing and the market price of risk

Hansen *et al.* [1999] shows how the observationally-equivalent pairs that look identical in quantity data have *different* implications for asset prices.

83.7.1 Decentralization

Following Lucas [1978], we regard the robust (or risk-sensitive) planning solution as the allocation of a competitive economy populated by a large number of identical agents who trade securities.

Equilibrium prices are the **shadow prices** that leave each agent content to consume the planner's allocation, treating it as an endowment process.

The equilibrium law of motion for the state is

$$x_{t+1} = A^0 x_t + C w_{t+1}, \tag{83.21}$$

and the value function at the optimum is $U_t^e = x_t^\top \Omega x_t + \rho$.

To support the robust allocation, prices must be computed using the *same* pessimistic, distorted beliefs that rationalize the planner's choices.

This is where risk-sensitivity ($\sigma < 0$) leaves its fingerprint on prices even though, by observational equivalence, it leaves no trace in quantities.

83.7.2 The twisting operator and distorted beliefs

Pricing a claim to next period's *utility* is trivial under the von Neumann–Morgenstern specification but nontrivial under risk-sensitivity.

The key object is the **twisting operator**

$$\mathcal{T}_t U_{t+1} \equiv \frac{\mathbb{E}(V_{t+1} U_{t+1} \mid J_t)}{\mathbb{E}(V_{t+1} \mid J_t)}, \qquad V_{t+1} \equiv \exp\left(\frac{\sigma U_{t+1}^e}{2}\right), \tag{83.22}$$

which re-weights outcomes by the exponential of equilibrium continuation utility.

It satisfies the subgradient inequality

$$\mathcal{R}_t(U_{t+1}) - \mathcal{R}_t(U_{t+1}^e) \leq \mathcal{T}_t U_{t+1} - \mathcal{T}_t U_{t+1}^e, \tag{83.23}$$

so $\mathcal{T}_t$ behaves like a *distorted* conditional expectation, exactly the change of measure used to price derivative claims in Epstein and Wang [1994].

Concretely, $\mathcal{T}_t$ is the ordinary conditional expectation under a **distorted transition law**

$$x_{t+1} = \hat{A} x_t + \hat{C} w_{t+1}, \qquad \hat{C}\hat{C}^\top = C(I - \sigma C^\top \Omega C)^{-1} C^\top, \tag{83.24}$$

with $\hat{A}$ given by (83.30)-style risk corrections.

Because $\sigma < 0$ and Ω is negative semidefinite, $(I - \sigma C^\top \Omega C)^{-1}$ exceeds the identity: the pricing measure assigns a *pessimistically shifted conditional mean and* an *inflated conditional variance* to next period's state.

These two distortions are precisely what generate risk premia.

83.7.3 Multi-period claims and the one-period stochastic discount factor

Prices of streams are built by iterating the operator.

Define $\mathcal{S}_{t,\tau} = \mathcal{T}_t \mathcal{T}_{t+1} \cdots \mathcal{T}_{t+\tau-1}$. The time-$t$ price of a claim to the consumption stream $\{c_{t+\tau}\}$ is then a discounted sum of twisted marginal utilities, and the one-period security with payoff p_{t+1} is priced as

$$q_t = \mathcal{T}_t \left\{ \beta \frac{\mathcal{M}^c_{t+1}}{\mathcal{M}^c_t} \, p_{t+1} \right\} = \mathbb{E}\left(m_{t+1,t} \, p_{t+1} \mid J_t \right), \tag{83.25}$$

where $\mathcal{M}^c_t$ is the marginal utility of consumption and $m_{t+1,t}$ is the one-period **stochastic discount factor** (intertemporal marginal rate of substitution).

Under risk-sensitivity, $m_{t+1,t}$ factors into two pieces,

$$m_{t+1,t} = m^f_{t+1,t} \, m^r_{t+1,t}, \tag{83.26}$$

where

$$m^f_{t+1,t} = \beta \frac{\mathcal{M}^c_{t+1}}{\mathcal{M}^c_t}$$

is the *familiar* intertemporal marginal rate of substitution (the only term present when $\sigma = 0$), and

$$m^r_{t+1,t} = \frac{\exp(\sigma U^e_{t+1}/2)}{\mathbb{E}[\exp(\sigma U^e_{t+1}/2) \mid J_t]} \tag{83.27}$$

is a multiplicative adjustment with conditional mean one.

The factor (83.27) is the source of the extra risk premia.

83.7.4 The market price of risk

Under the *robustness* interpretation, the same multiplicative factor equals a **likelihood ratio** between the worst-case and reference shock densities,

$$m^u_{t+1,t} = \frac{\exp[-(w_{t+1} - \hat{v}_t)^\top (w_{t+1} - \hat{v}_t)/2]}{\exp(-w^\top_{t+1} w_{t+1}/2)}, \tag{83.28}$$

where $\hat{v}_t$ is the worst-case conditional-mean distortion chosen by the malevolent player.

A direct calculation gives

$$\mathbb{E}_t(m^u_{t+1,t}) = 1, \qquad \mathbb{E}_t[(m^u_{t+1,t})^2] = \exp(\hat{v}_t^\top \hat{v}_t),$$

so that, for small distortions,

$$\mathrm{std}_t(m^u_{t+1,t}) = \left[\exp(\hat{v}_t^\top \hat{v}_t) - 1 \right]^{1/2} \approx |\hat{v}_t|. \tag{83.29}$$

The **market price of risk** is the maximal Sharpe ratio attainable, equal to $\mathrm{std}_t(m_{t+1,t})/\mathbb{E}_t(m_{t+1,t})$ along the efficient frontier (the Hansen and Jagannathan [1991] bound).

It is therefore approximately equal to the *magnitude of the worst-case distortion* $|\hat{v}_t|$.

This is the paper's punchline: a conditional-mean misspecification of $x\%$ of a unit-norm direction raises the market price of risk by roughly $x/100$.

A *small*, statistically-hard-to-detect doubt about the model can generate the *large* price of risk seen in the data.

Let's check the key identity (83.29) by Monte Carlo.

```
rng = np.random.default_rng(12345)

def mpr_check(v_hat, n=2_000_000):
    """
    Simulate the worst-case likelihood ratio m^u and compare its
    conditional standard deviation to |v_hat|.
    """
    k = len(v_hat)
    w = rng.standard_normal((n, k))
    # log likelihood ratio of N(v_hat, I) relative to N(0, I)
    log_mu = w @ v_hat - 0.5 * v_hat @ v_hat
    mu = np.exp(log_mu)
    return mu.mean(), mu.std(), np.linalg.norm(v_hat)

print(f"{'|v_hat|':>10}{'E[m^u]':>12}{'std(m^u)':>12}{'approx |v_hat|':>16}")
for scale in [0.05, 0.10, 0.20]:
    v_hat = np.array([scale, 0.0])      # distortion in one direction
    mean, std, norm_v = mpr_check(v_hat)
    print(f"{norm_v:10.3f}{mean:12.4f}{std:12.4f}{norm_v:16.3f}")
```

```
   |v_hat|      E[m^u]    std(m^u)  approx |v_hat|
     0.050      1.0000      0.0500           0.050
     0.100      0.9999      0.1003           0.100
     0.200      0.9997      0.2022           0.200
```

The simulated conditional mean of m^u is one, and its conditional standard deviation tracks $|\hat{v}_t|$ closely, confirming (83.29).

A 10% distortion delivers a market price of risk near 0.10.

83.8 A risk-sensitive regulator

To see the robust decision rules and worst-case shocks concretely, we solve the recursive risk-sensitive control problem (83.1)–(83.3) directly.

Guess a value function $W(x) = x^\top \Omega x + \rho$ with Ω negative semidefinite. The risk-sensitive operator (83.4) acting on this quadratic form introduces the **risk adjustment**

$$\mathcal{D}(\Omega) = \Omega + \sigma \Omega C (I - \sigma C^\top \Omega C)^{-1} C^\top \Omega, \tag{83.30}$$

so that, replacing Ω by $\mathcal{D}(\Omega)$, the Bellman equation becomes an ordinary linear-quadratic one.

Iterating

$$F = (Q - \beta B^\top \mathcal{D} B)^{-1} (N - \beta B^\top \mathcal{D} A),$$

$$\Omega \leftarrow -R - F^\top Q F + (F^\top N + N^\top F) + \beta (A - BF)^\top \mathcal{D} (A - BF),$$

to a fixed point yields the optimal rule $i_t = -F x_t$.

The worst-case mean distortion is then linear in the state, $\hat{v}_t = G x_t$, with

$$G = \sigma (I - \sigma C^\top \Omega C)^{-1} C^\top \Omega (A - BF). \tag{83.31}$$

When $\sigma = 0$ we have $\mathcal{D}(\Omega) = \Omega$ and $G = 0$, recovering the standard regulator.

```
def solve_rslq(A, B, C, Q, R, β, σ, N=None,
               tol=1e-12, max_iter=100_000):
    """
    Solve the recursive risk-sensitive LQ problem

        U_t = -(x^T R x + i^T Q i + 2 i^T N x) + β R_t(U_{t+1})
        x_{t+1} = A x_t + B i_t + C w_{t+1}

    Returns the feedback rule F (i = -F x), the value matrix Ω,
    the closed-loop matrix A - B F, and the worst-case loading G (v = G x).
    """
    A, B, C, Q, R = map(np.atleast_2d, (A, B, C, Q, R))
    n, kw = A.shape[0], C.shape[1]
    if N is None:
        N = np.zeros((B.shape[1], n))
    Ω = -np.eye(n)                # negative-definite start
    Iw = np.eye(kw)
    for it in range(max_iter):
        M = Iw - σ * C.T @ Ω @ C
        D = Ω + σ * Ω @ C @ np.linalg.solve(M, C.T @ Ω)
        F = np.linalg.solve(Q - β * B.T @ D @ B, N - β * B.T @ D @ A)
        Acl = A - B @ F
        Ω_new = (-R - F.T @ Q @ F + (F.T @ N + N.T @ F)
                 + β * Acl.T @ D @ Acl)
        if np.max(np.abs(Ω_new - Ω)) < tol:
            Ω = Ω_new
            break
        Ω = Ω_new
    M = Iw - σ * C.T @ Ω @ C
    G = σ * np.linalg.solve(M, C.T @ Ω @ (A - B @ F))
    return F, Ω, A - B @ F, G
```

We first verify that at $\sigma = 0$ our solver reproduces QuantEcon's ordinary LQ regulator.

```
# Stable regulator
A = np.array([[0.9, 0.0],
              [0.0, 0.8]])
B = np.array([[1.0],
              [0.0]])
C = np.array([[0.3],
              [0.2]])
Q = np.array([[1.0]])
R = np.eye(2)
β = 0.95

# QuantEcon ordinary LQ
lq = qe.LQ(Q, R, A, B, C=C, beta=β)
P, F_qe, d = lq.stationary_values()

# Sigma-zero check
F0, Ω0, Acl0, G0 = solve_rslq(A, B, C, Q, R, β, σ=0.0)

print("QuantEcon LQ feedback rule F :", F_qe.flatten())
print("solve_rslq  feedback rule F  :", F0.flatten())
print("max |difference|             :", np.max(np.abs(F0 - F_qe)))
```

```
QuantEcon LQ feedback rule F : [0.52479699 0.        ]
```

(continues on next page)

(continued from previous page)

```
solve_rslq  feedback rule F  : [0.52479699 0.        ]
max |difference|             : 1.1102230246251565e-16
```

The two agree to machine precision.

Now we crank up the preference for robustness and inspect how the control rule and the worst-case shock respond.

```
σ_vals = [0.0, -0.3, -0.6]

print(f"{'σ':>7}{'F[0]':>10}{'F[1]':>10}{'G[0]':>10}{'G[1]':>10}")
for σ in σ_vals:
    F, Q, Acl, G = solve_rslq(A, B, C, Q, R, β, σ)
    print(f"{σ:7.2f}{F[0,0]:10.4f}{F[0,1]:10.4f}"
          f"{G[0,0]:10.4f}{G[0,1]:10.4f}")
```

```

   0.00    0.5248    0.0000   -0.0000   -0.0000
  -0.30    0.5357    0.0340    0.0532    0.1370
  -0.60    0.5490    0.0803    0.1154    0.3169
```

As σ becomes more negative:

- the feedback gain F grows, since the robust agent reacts *more aggressively* to the state, fearing the worst-case shock will amplify deviations;
- the worst-case loading G moves away from zero, as the malevolent player pushes the shock in the direction that hurts most.

Finally, let's see the worst-case distortion in action by simulating the controlled state under the *reference* model while displaying the conditional mean distortion $\hat{v}_t = Gx_t$ the robust agent is guarding against.

```
def simulate(A, B, C, F, G, T=60, seed=0):
    rng = np.random.default_rng(seed)

axes[1].set_title('mean distortion')
axes[1].legend()
fig.tight_layout()
plt.show()
```

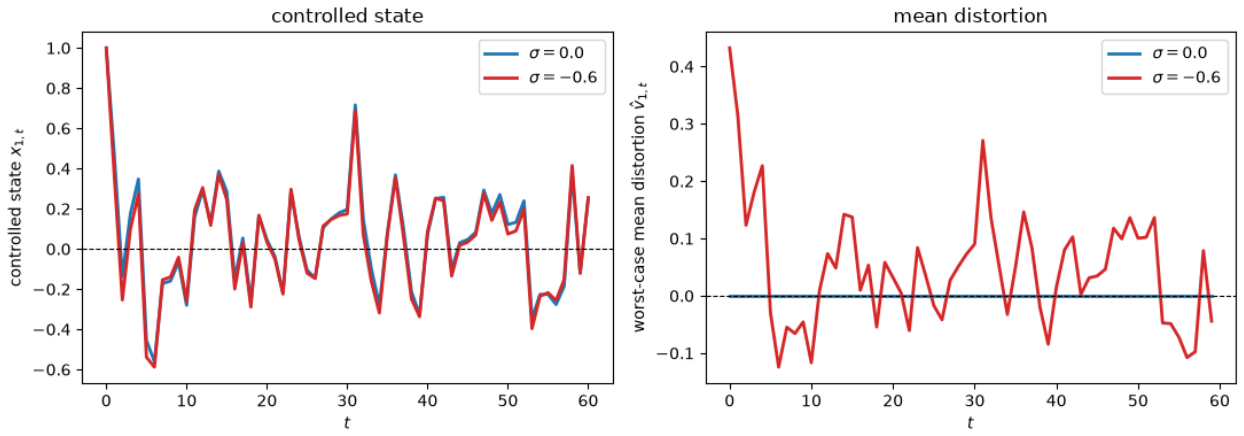

Fig. 83.4: Controlled state and distortion

For $\sigma = 0$ the distortion is identically zero, since the agent fully trusts the model.

For $\sigma < 0$ the robust agent's decisions are shaped by a nonzero worst-case distortion that feeds back on the state, exactly the mechanism that, through (83.29), inflates the market price of risk.

83.9 Exercises

Exercise 83.9.1

The Gaussian formula (83.5) says that for $U_{t+1} \sim N(\mu, s^2)$,

$$\mathcal{R}_t(U_{t+1}) = \mu + \frac{\sigma}{4} s^2.$$

Derive this result directly from the definition (83.4).

Hint: use the moment generating function of a normal random variable, $\mathbb{E}[\exp(aU)] = \exp(a\mu + a^2 s^2/2)$.

Solution

Here is one solution:

Start from the definition with $a = \sigma/2$:

$$\mathcal{R}_t(U_{t+1}) = \frac{2}{\sigma}\log\mathbb{E}\Big[\exp\Big(\frac{\sigma}{2}U_{t+1}\Big)\Big].$$

Since $U_{t+1} \sim N(\mu, s^2)$, the moment generating function gives

$$\mathbb{E}\Big[\exp\Big(\frac{\sigma}{2}U_{t+1}\Big)\Big] = \exp\Big(\frac{\sigma}{2}\mu + \frac{1}{2}\frac{\sigma^2}{4}s^2\Big).$$

Taking logs and multiplying by $2/\sigma$,

$$\mathcal{R}_t(U_{t+1}) = \frac{2}{\sigma}\left(\frac{\sigma}{2}\mu + \frac{\sigma^2}{8}s^2\right) = \mu + \frac{\sigma}{4}s^2.$$

Letting $\sigma \to 0$ recovers $\mathcal{R}_t(U_{t+1}) = \mu = \mathbb{E}_t U_{t+1}$, as expected.

Exercise 83.9.2

The observational-equivalence locus has a left endpoint $\underline{\sigma}$: the most negative σ for which (83.15) has a real solution.

Using the code from the lecture, find $\underline{\sigma}$ numerically for `theta2 = 0.01` and for `theta2 = 0.02`, and explain why a larger θ^2 shrinks the admissible range of σ.

Hint: the square root is real when the discriminant $(\beta - 1 + \sigma\theta^2)^2 + 4\sigma\theta^2 \geq 0$, evaluated at the relevant $\hat{\beta}$.

Solution

Here is one solution:

The boundary $\underline{\sigma}$ is the most negative σ at which a valid $\hat{\beta}$ can still be found.

We scan σ downward and stop when `beta_hat` can no longer return a real solution.

```
def σ_underbar(θ2, Rf, grid=np.linspace(-1e-6, -5e-4, 5000)):
    last_ok = 0.0
    for sg in grid:
        try:
            b = β_hat(sg, θ2, Rf)
            if np.isnan(Ω_scalar(b, sg, θ2)):
                break
            last_ok = sg
        except ValueError:
            break
    return last_ok

for θ2 in [0.01, 0.02]:
    sb = σ_underbar(θ2, Rf)
    print(f"θ2 = {θ2}:  σ_underbar ≈ {sb:.3e}")
```

```
θ2 = 0.01:  σ_underbar ≈ -2.105e-04
θ2 = 0.02:  σ_underbar ≈ -1.052e-04
```

A larger θ^2 means the marginal-utility martingale (83.14) carries a bigger innovation variance, so each unit of $|\sigma|$ generates a larger risk adjustment.

The discriminant in (83.15), which contains the term $4\sigma\theta^2 < 0$, turns negative at a *smaller* $|\sigma|$.

Hence the admissible range $(\underline{\sigma}, 0)$ shrinks as θ^2 grows.

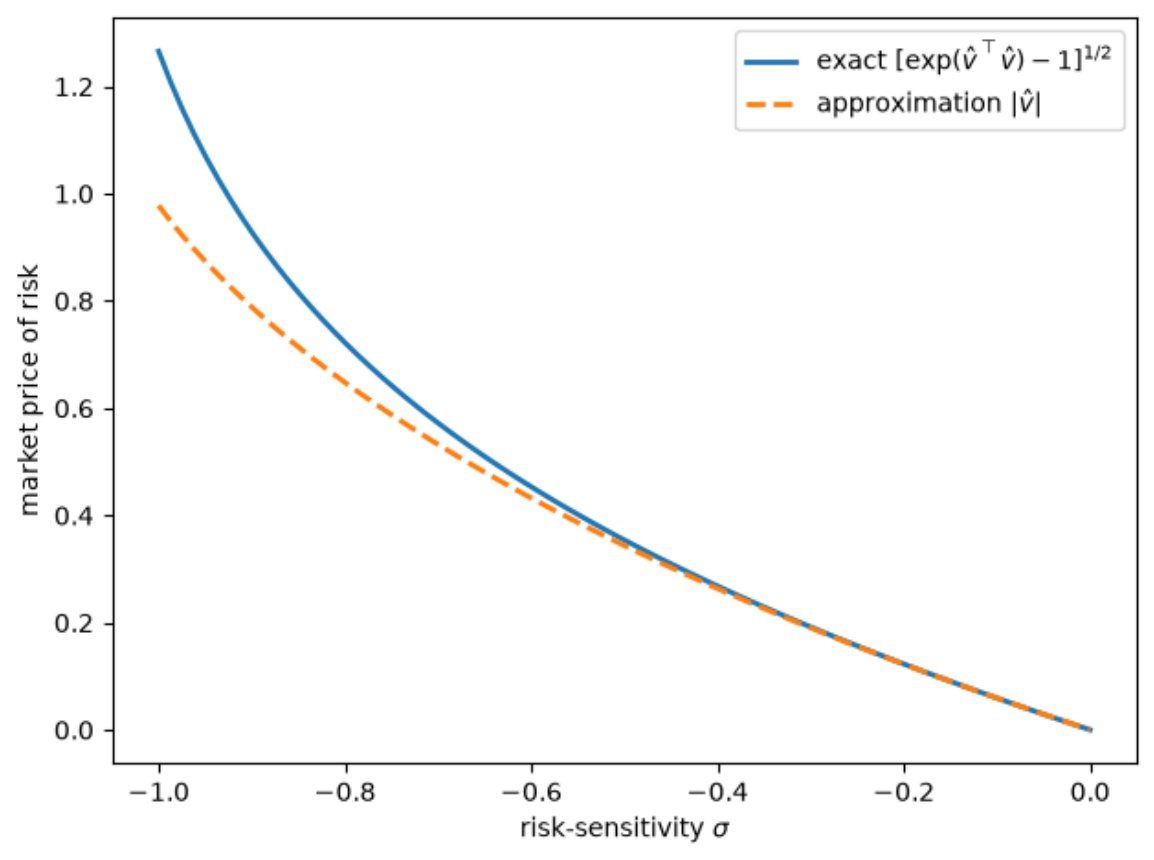
Exercise 83.9.3

The market-price-of-risk approximation (83.29) states that $\text{std}_t(m^u_{t+1,t}) = [\exp(\hat{v}_t^\top \hat{v}_t) - 1]^{1/2} \approx |\hat{v}_t|$.

For the risk-sensitive regulator solved in the lecture (with A, B, C, Q, R, β as given there), compute the *exact* market price of risk $[\exp(\hat{v}_t^\top \hat{v}_t) - 1]^{1/2}$ as a function of σ, evaluated at the state $x = (1, 1)^\top$, and plot it together with the linear approximation $|\hat{v}_t|$.

Comment on the range of σ over which the approximation is accurate.

Solution



Here is one solution:

We solve the regulator for a grid of σ values, evaluate $\hat{v}_t = Gx$ at $x = (1, 1)^\top$, and compare the exact and approximate market prices of risk.

```
x_eval = np.array([1.0, 1.0])
σ_grid = np.linspace(-1.0, 0.0, 80)

exact, approx = [], []
for σ in σ_grid:
    F, Ω, Acl, G = solve_rslq(A, B, C, Q, R, β, σ)
    v_hat = (G @ x_eval).flatten()
    nv2 = v_hat @ v_hat
    exact.append(np.sqrt(np.exp(nv2) - 1))
    approx.append(np.sqrt(nv2))            # |v_hat|

fig, ax = plt.subplots()
ax.plot(σ_grid, exact, lw=2,
        label=r'exact $[\exp(\hat v^\top \hat v)-1]^{1/2}$')
ax.plot(σ_grid, approx, lw=2, ls='--', label=r'approximation $|\hat v|$')
ax.set_xlabel(r'risk-sensitivity $\sigma$')
ax.set_ylabel('market price of risk')
ax.legend()
fig.tight_layout()
plt.show()
```

The two curves are nearly indistinguishable for small $|\hat{v}_t|$ (i.e. σ close to zero) because $\exp(z) - 1 \approx z$ when z is small.

They separate only when the preference for robustness, and hence the worst-case distortion, becomes large.

This is precisely the regime Hansen *et al.* [1999] emphasize: *small*, hard-to-detect distortions map almost linearly into the market price of risk.

83.10 Related lectures

This lecture connects to several others in the QuantEcon collection.

The underlying consumption-smoothing economics is developed in *The Permanent Income Model* and *Permanent Income II: LQ Techniques*, and the linear-quadratic control machinery is laid out in *LQ Control: Foundations*.

The reinterpretation of the market price of risk as a *price of model uncertainty*, calibrated through detection-error probabilities, is the subject of Barillas *et al.* [2009]; the broader semigroup treatment of robustness, pricing, and model detection is in Anderson *et al.* [2003].

Both build directly on Hansen *et al.* [1999].

```

84.1 Overview

Simon [1956] and Theil [1957] established a celebrated *certainty equivalence* (CE) property for linear-quadratic (LQ) dynamic programming problems.

Their result justifies a convenient two-step algorithm:

1. **Optimize** under perfect foresight (treat future exogenous variables as known).
2. **Forecast** – substitute optimal forecasts for the unknown future values.

The striking insight is that these two steps are completely separable.

The decision rule that emerges from step 1 is *identical* to the decision rule for the original stochastic problem once optimal forecasts are substituted in step 2.

The decision rule does not depend on the variance of the shocks, but the *level* of the optimal value function *does*.

After describing the structure of the certainty equivalence property in detail, this lecture describes its role in rational expectations modeling.

We do so by drawing heavily on the introduction to Lucas and Sargent [1981].

In addition to learning the certainty equivalence principle, this lecture describes troubles with pre-rational expectations econometric policy evaluation procedures described by Lucas [1976].

Note

That volume collected early papers on rational expectations modeling and econometrics.

84.2 A central problem of empirical economics

To set the stage, Lucas and Sargent [1981] stated the central question for empirical economics that had been posed by Leonid Hurwicz ([Hurwicz, 1962]):

- Given observations on an agent's behavior in a particular economic environment, what can we infer about how that behavior *would have differed* had the environment been altered?

Note

Hurwicz formulates a notion of 'causality' as a context-specific concept that he casts in terms of a well posed decision problem.

This is the problem of policy-invariant structural inference in the following setting.

- Observations emerged under one environment or 'regime'
- We want to predict behavior under another 'regime'
- Unless we understand *why* agents behaved as they did in the historical regime, i.e., their purposes, we can't predict their behavior under the constraints they face in the new regime.

To confront the problem that Hurwicz had posed, Lucas and Sargent [1981] formulated the following decision framework.

84.3 A formal setup

Consider a single decision maker whose situation at date t is fully described by two state variables (x_t, z_t).

The environment $z_t \in S_1$ is selected by "nature" and evolves exogenously according to

$$z_{t+1} = f(z_t, \epsilon_{t+1}), \tag{84.1}$$

where the innovations $\{\epsilon_t\}$ are IID draws from a fixed CDF $\Phi(\cdot) : \mathcal{E} \to [0, 1]$.

The function $f : S_1 \times \mathcal{E} \to S_1$ is called the **decision maker's environment**.

The endogenous state $x_t \in S_2$ is under partial control of the agent.

Each period the agent selects an action $u_t \in U$.

A fixed technology $g : S_1 \times S_2 \times U \to S_2$ governs the transition

$$x_{t+1} = g(z_t,\, x_t,\, u_t). \tag{84.2}$$

The decision rule $h : S_1 \times S_2 \to U$ maps the agent's current situation into an action:

$$u_t = h(z_t,\, x_t). \tag{84.3}$$

The econometrician observes (some or all of) the process $\{z_t, x_t, u_t\}$, the joint motion of which is determined by (84.1), (84.2), and (84.3).

84.4 Estimated rules are not enough

Suppose we have estimated f, g, and h from a long time series generated under a fixed environment f_0.

This gives us $h_0 = T(f_0)$, where T is the (unknown) functional mapping environments into optimal decision rules.

But this single estimate, however precise, *reveals nothing* about how $T(f)$ varies with f.

Policy evaluation requires knowledge of the entire map $f \mapsto T(f)$.

Under an environment change $f_0 \to f_1$, agents will in general revise their decision rules $h_0 \to h_1 = T(f_1)$, rendering the estimated rule h_0 invalid for forecasting behavior under f_1.

Lucas [1976] and the introduction to Lucas and Sargent [1981] conclude that the only nonexperimental path forward is to recover the **return function** V from which h is derived as the solution to an optimization problem, and then re-solve that problem under the counterfactual environment f_1.

84.5 An optimization problem

Assume the agent selects h to maximize the expected discounted sum of current-period returns $V : S_1 \times S_2 \times U \to \mathbb{R}$:

$$E_0\left\{\sum_{t=0}^{\infty} \beta^t\, V(z_t,\, x_t,\, u_t)\right\}, \qquad 0 < \beta < 1, \tag{84.4}$$

given initial conditions (z_0, x_0), the environment f, and the technology g.

Here $E_0\{\cdot\}$ denotes expectation conditional on (z_0, x_0) with respect to the distribution of $\{z_1, z_2, \ldots\}$ induced by (84.1).

In principle, knowledge of V (together with g and f) allows one to compute $h = T(f)$ theoretically and hence to trace out $T(f)$ for any counterfactual f.

The essential question is whether V can itself be recovered from observations on $\{f, g, h\}$.

> **Note**
>
> The decision rule is in general a functional $h = T(f, g, V)$. The dependence on g and V is suppressed in the main text but made explicit when needed.

84.6 A linear-quadratic DP problem and certainty equivalence

Progress beyond the level of generality of the previous section requires restricting the primitives.

A productive restriction, exploited in the papers collected in Lucas and Sargent [1981], imposes *quadratic* V and *linear* g, which forces h to be linear.

As part of its computational tractability, this specialization delivers a striking structural result:

- the **certainty equivalence** theorem of Simon [1956] and Theil [1957].

84.6.1 Decomposition of h

Under quadratic V and linear g, the optimal decision rule h decomposes into two components applied in sequence.

Step 1 – Forecasting. Define the infinite sequence of optimal point forecasts of all current and future states of nature:

$$\tilde{z}_t \;=\; (z_t,\;\; {}_{t+1}z_t^e,\;\; {}_{t+2}z_t^e,\;\ldots) \;\in\; S_1^\infty, \tag{84.5}$$

where ${}_{t+j}z_t^e$ denotes the least-mean-squared-error forecast of z_{t+j} formed at time t.

The optimal forecast sequence is a (generally nonlinear) function of the current state:

$$\tilde{z}_t = h_2(z_t). \tag{84.6}$$

The function $h_2 : S_1 \to S_1^\infty$ depends entirely on the environment (f, Φ) and is obtained as the solution to a **pure forecasting problem**, with no reference to preferences or technology.

Step 2 – Optimization. Given the forecast sequence $\tilde{z}_t$, the optimal action is a **linear** function of $\tilde{z}_t$ and x_t:

$$u_t = h_1(\tilde{z}_t,\, x_t). \tag{84.7}$$

The function $h_1 : S_1^\infty \times S_2 \to U$ depends entirely on preferences (V) and technology (g) but **not** on the stochastic environment (f, Φ).

The ultimate decision rule is therefore the **composite**:

$$\boxed{h(z_t, x_t) \;=\; h_1[h_2(z_t),\; x_t].} \tag{84.8}$$

84.6.2 The separation principle

(84.8) embodies a clean **separation** of the two sources of dependence in h:

Component	Depends on	Independent of
h_1 (optimization)	V, g	f, Φ
h_2 (forecasting)	f, Φ	V, g

Since policy analysis concerns changes in f, and since h_1 is invariant to f, the policy analyst need only re-solve the forecasting problem $h_2 = S(f)$ under the new environment, keeping h_1 fixed.

The relationship of original interest, $h = T(f)$, then follows directly from (84.8).

84.6.3 Certainty equivalence and perfect foresight

The name "certainty equivalence" reflects a further implication of the LQ structure: the function h_1 can be derived as if the agent **knew the future path** $z_{t+1}, z_{t+2}, \ldots$ **with certainty** – i.e., by solving the deterministic problem in which $\tilde{z}_t$ is treated as the realized path rather than a forecast.

Randomness of the environment affects actions only through the forecast $\tilde{z}_t$; conditional on $\tilde{z}_t$, the optimization problem is deterministic.

This means the LQ problem decouples into:

- **Dynamic optimization under perfect foresight** – solve for h_1 from (V, g) by treating $\tilde{z}_t$ as known, yielding a standard deterministic LQ regulator problem independent of the environment (f, Φ).
- **Optimal linear prediction** – solve for $h_2 = S(f)$ from (f, Φ) using least-squares forecasting theory, which reduces to a standard Kalman/Wiener prediction formula when f is itself linear.

84.6.4 Cross-equation restrictions

A hallmark of the rational expectations hypothesis as it appears in this framework is that it ties together what would otherwise be free parameters in different equations.

The requirement that $\tilde{z}_t = h_2(z_t) = S(f)(z_t)$ – i.e., that agents' forecasts be *optimal* with respect to the *actual* law of motion f – imposes **cross-equation restrictions** between the parameters of the forecasting rule h_2 and the parameters of the environment f.

These restrictions, rather than any conditions on distributed lags within a single equation, are the operative empirical content of rational expectations.

Note

This is the message of Lucas [1976] and Sargent [1981].

The following code verifies the CE principle numerically.

We consider a simple scalar LQ problem:

$$y_{t+1} = a\, y_t + b\, u_t + \sigma\, \varepsilon_{t+1}, \qquad r(y_t, u_t) = -(q\, y_t^2 + r\, u_t^2)$$

and vary the noise standard deviation σ across a wide range.

The CE theorem predicts that:

- the **policy gain** F (the coefficient in $u_t = -F y_t$) is independent of σ, and
- the **value constant** d (the additive term in $V(y) = -y^\top P y - d$) grows with σ.

```
a, b_coeff = 0.9, 1.0
q, r = 1.0, 1.0
β = 0.95

A = np.array([[a]])
B = np.array([[b_coeff]])
R_mat = np.array([[q]])          # state cost
Q_mat = np.array([[r]])          # control cost

σ_vals = np.linspace(0.0, 3.0, 80)
```

(continues on next page)

(continued from previous page)

```
F_vals, d_vals = [], []

for σ in σ_vals:
    C = np.array([[σ]])
    lq = LQ(Q_mat, R_mat, A, B, C=C, beta=β)
    P, F, d = lq.stationary_values()
    F_vals.append(float(F[0, 0]))
    d_vals.append(float(d))

fig, axes = plt.subplots(1, 2, figsize=(12, 4))

axes[0].plot(σ_vals, F_vals, lw=2)
axes[0].set_xlabel('noise level $\\sigma$')
axes[0].set_ylabel('policy gain $F$')
axes[0].set_title('policy gain')
axes[0].set_ylim(0, 2 * max(F_vals) + 0.1)

axes[1].plot(σ_vals, d_vals, lw=2, color='C1')
axes[1].set_xlabel('noise level $\\sigma$')
axes[1].set_ylabel('value constant $d$')
axes[1].set_title('value constant')
fig.tight_layout()
plt.show()
```

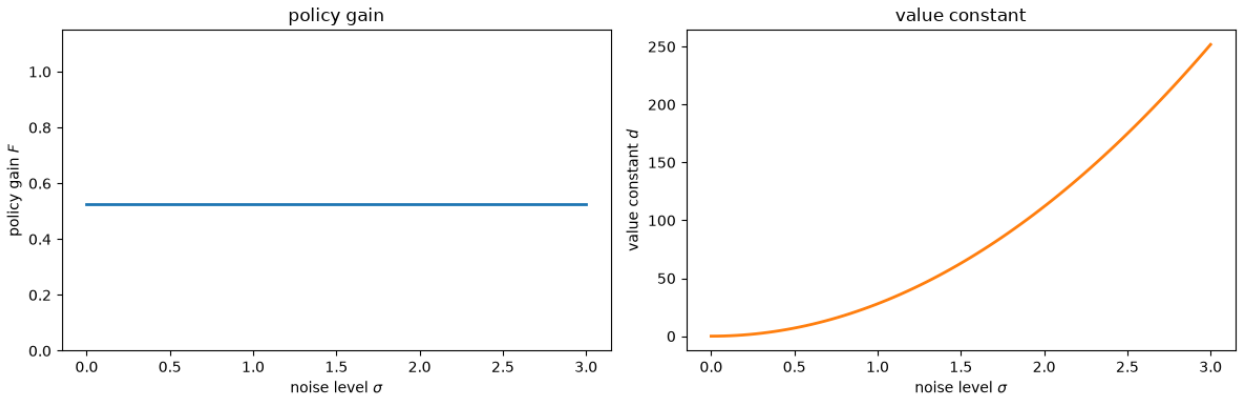

Fig. 84.1: CE: policy does not depend on noise

As the plot confirms, F (the policy gain) is *flat* across all noise levels, while the value constant d increases monotonically with σ.

This is the CE principle in action: uncertainty changes the value of the problem but not the optimal decision rule.

84.7 A trouble with ad hoc expectations

Prior practice, exemplified by the adaptive expectations mechanisms of Friedman [1956] and Cagan [1956], directly postulated a particular form of (84.6):

$$\theta_t^e = \lambda \sum_{i=0}^{\infty} (1-\lambda)^i \, \theta_{t-i}, \qquad 0 < \lambda < 1, \tag{84.9}$$

treating the coefficient λ as a free parameter to be estimated from data, with no reference to the underlying environment f.

The deficiency is not that (84.9) is a distributed lag – linear forecasting rules are perfectly acceptable simplifications.

The deficiency is that the **coefficients** of the distributed lag are left unrestricted by theory.

The mapping $h_2 = S(f)$ shows that optimal forecasting coefficients are *determined* by f: when f changes, h_2 changes, and so does h.

An estimated λ calibrated under f_0 is therefore non-structural and will give incorrect predictions whenever f is altered.

This is the econometric content of the critique delivered by Muth [1960].

Rational expectations equates the subjective distribution that agents use in forming $\tilde{z}_t$ to the objective distribution f that actually generates the data, thereby closing the model and eliminating free parameters in h_2.

84.8 Exercises

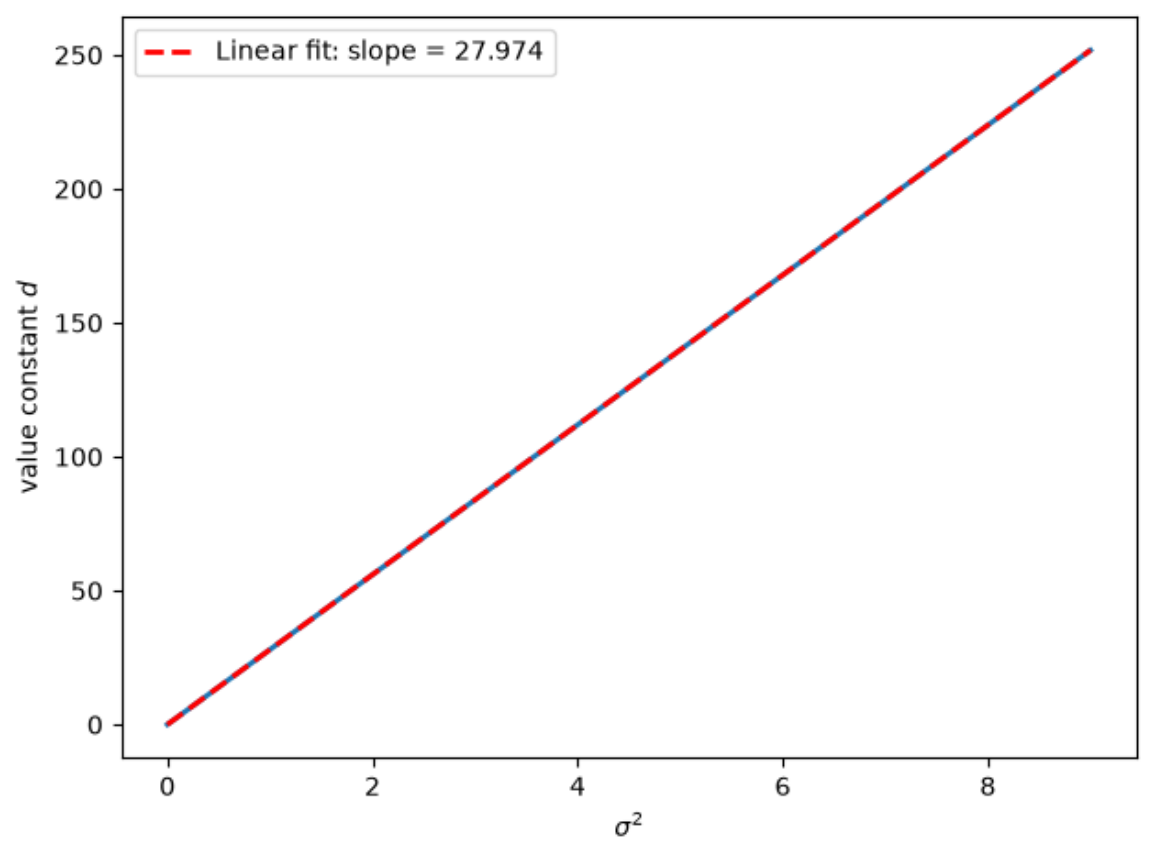
Exercise 84.8.1

Using the scalar LQ setup in the code cell above (with $a = 0.9$, $b = 1$, $q = r = 1$, $\beta = 0.95$), verify numerically that the value constant d satisfies $d \propto \sigma^2$.

Hint: From the CE analysis, the value constant satisfies $d = \frac{\beta}{1-\beta} \operatorname{tr}(C^\top P C)$, and since $C = \sigma$ in the scalar case, this gives $d = \frac{\beta}{1-\beta} P \, \sigma^2$.

Confirm that a plot of d against σ^2 is linear and compute the theoretical slope $\frac{\beta}{1-\beta} P$.

Solution



```
σ_sq_vals = σ_vals ** 2

fig, ax = plt.subplots()
ax.plot(σ_sq_vals, d_vals, lw=2)
ax.set_xlabel('$\\sigma^2$')
ax.set_ylabel('value constant $d$')

coeffs = np.polyfit(σ_sq_vals, d_vals, 1)
ax.plot(σ_sq_vals, np.polyval(coeffs, σ_sq_vals),
        'r--', lw=2, label=f'Linear fit: slope = {coeffs[0]:.3f}')
ax.legend()
fig.tight_layout()
plt.show()

P_scalar = float(LQ(Q_mat, R_mat, A, B, C=np.zeros((1, 1)),
```

```
                    beta=β).stationary_values()[0].item())
theoretical_slope = β / (1 - β) * P_scalar
print(f"Empirical slope:    {coeffs[0]:.4f}")
print(f"Theoretical slope β/(1-β)*P = {theoretical_slope:.4f}")
```

```
Empirical slope:    27.9740
Theoretical slope β/(1-β)*P = 27.9740
```

The slope is indeed $\frac{\beta}{1-\beta}P$, confirming the analytic formula.

The value matrix P is determined entirely by preferences and technology, not by the noise level – a direct consequence of the certainty equivalence principle.

84.9 Concluding remarks

This sequel *certainty equivalence and model uncertainty* describes how to extend the certainty equivalence principle to a linear-quadratic setting in which a decision maker distrusts the transition dynamics specified in his baseline model.

85.1 Overview

This is a sequel to *this lecture on certainty equivalence* that established an important *certainty equivalence* (CE) property for linear-quadratic (LQ) dynamic programming problems.

The property justifies a two-step algorithm for computing optimal decision rules:

1. *Optimize* under perfect foresight (treat future exogenous variables as known).
2. *Forecast* – substitute optimal forecasts for the unknown future values.

This lecture extends the certainty equivalence property in two directions motivated by [Hansen and Sargent, 2004]:

- *Model uncertainty and robustness.* What happens when the decision maker does not trust his model? A remarkable version of CE survives, but now the "forecasting" step uses a *distorted* probability distribution that the decision maker deliberately tilts against himself in order to achieve robustness.
- *Risk-sensitive preferences.* A mathematically equivalent reformulation interprets the same decision rules through recursive risk-sensitive preferences.

  The robustness parameter θ and the risk-sensitivity parameter σ are linked by $\theta = -\sigma^{-1}$.

We illustrate all three settings – ordinary CE, robust CE, and the permanent income application – with Python code using `quantecon`.

85.1.1 Model features

- Linear transition laws and quadratic objectives (LQ framework).
- Ordinary CE: optimal policy independent of noise variance.
- Robust CE: distorted forecasts replace baseline model forecasts; policy function depends on θ.
- Permanent income application: Hall's martingale, precautionary savings under robustness, and observational equivalence between robustness and patience.

This lecture draws on [Hansen and Sargent, 2004] and [Hansen and Sargent, 2008].

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

We use the following imports:

```
import numpy as np
import matplotlib.pyplot as plt
from quantecon import LQ, RBLQ
```

85.2 Recap: ordinary certainty equivalence

The *companion lecture* established the CE property in detail.

Here we collect only the elements needed for the robustness extension below.

The state vector $y_t = \begin{bmatrix} x_t \\ z_t \end{bmatrix}$ has an exogenous component z_t with transition law

$$z_{t+1} = f(z_t,\, \epsilon_{t+1}) \tag{85.1}$$

and an endogenous component x_t obeying

$$x_{t+1} = g(x_t,\, z_t,\, u_t). \tag{85.2}$$

Under the LQ assumption (quadratic return $r(y,u) = -y^\top Q y - u^\top R u$, linear f and g, Gaussian shocks), the optimal decision rule h decomposes as $u_t = h_1(x_t,\, h_2 \cdot z_t)$ where h_1 solves a nonstochastic control problem and h_2 solves an optimal forecasting problem.

The optimal value function is $V(y_0) = -y_0^\top P\, y_0 - p$ where, writing $z_{t+1} = f_1 z_t + f_2 \epsilon_{t+1}$:

- P is the fixed point of an operator $T(P; r, g, f_1)$ that does *not* involve the volatility matrix f_2, so neither P nor the decision rule h depends on the noise loadings.
- The constant $p = \beta/(1-\beta)\,\mathrm{tr}(f_2^\top P f_2)$ grows with volatility.

Uncertainty lowers the value (larger p) but does not alter behaviour.

The following code sets up a scalar LQ problem and confirms that the policy gain F is invariant to the noise level σ while d grows with it.

```
a, b_coeff = 0.9, 1.0
q, r = 1.0, 1.0
β = 0.95

A = np.array([[a]])
```

(continues on next page)

(continued from previous page)

```
B = np.array([[b_coeff]])
Q_mat = np.array([[q]])          # state cost
R_mat = np.array([[r]])          # control cost

σ_vals = np.linspace(0.0, 3.0, 80)
F_vals, d_vals = [], []

for σ in σ_vals:
    C = np.array([[σ]])
    lq = LQ(R_mat, Q_mat, A, B, C=C, beta=β)
    P, F, d = lq.stationary_values()
    F_vals.append(float(F[0, 0]))
    d_vals.append(float(d))

fig, axes = plt.subplots(1, 2, figsize=(12, 4))

axes[0].plot(σ_vals, F_vals, lw=2)
axes[0].set_xlabel('noise level $\\sigma$')
axes[0].set_ylabel('policy gain $F$')
axes[0].set_ylim(0, 2 * max(F_vals) + 0.1)

axes[1].plot(σ_vals, d_vals, lw=2, color='darkorange')
axes[1].set_xlabel('noise level $\\sigma$')
axes[1].set_ylabel('value constant $d$')

plt.tight_layout()
plt.show()
```

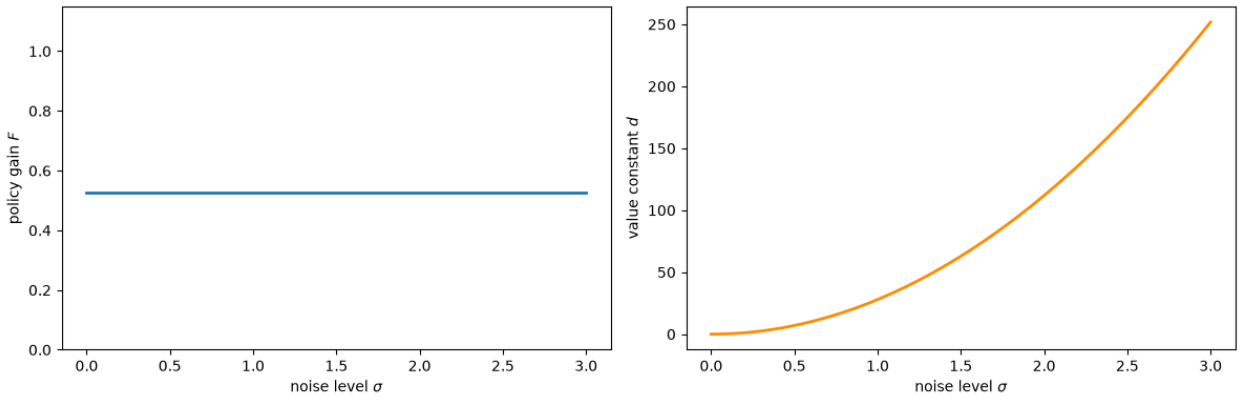

Fig. 85.1: CE principle – policy vs. value

85.3 Model uncertainty and robustness

85.3.1 Setup and the multiplier problem

The decision maker in Simon and Theil's setting knows his model exactly – he has no doubt about the transition law (85.1).

Now suppose he suspects that the true data-generating process is

$$z_{t+1} = f(z_t,\ \epsilon_{t+1} + w_{t+1}) \tag{85.3}$$

where $w_{t+1} = \omega_t(x^t, z^t)$ is a misspecification term chosen by an adversarial "nature."

The decision maker believes his approximating model is a good approximation in the sense that

$$\hat{\mathbb{E}}\left[\sum_{t=0}^{\infty} \beta^t\, w_{t+1}^\top w_{t+1} \,\Big|\, y_0\right] \le \eta_0, \tag{85.4}$$

where η_0 parametrises the tolerated misspecification budget and $\hat{\mathbb{E}}$ is the expectation under the distorted law (85.3).

To construct a *robust* decision rule the decision maker solves the **multiplier problem** – a two-player zero-sum dynamic game:

$$\min_{\{w_{t+1}\}} \max_{\{u_t\}} \hat{\mathbb{E}}\left[\sum_{t=0}^{\infty} \beta^t \Big\{ r(y_t, u_t) + \theta\beta\, w_{t+1}^\top w_{t+1} \Big\} \,\Big|\, y_0\right] \tag{85.5}$$

where $\theta > 0$ penalises large distortions.

A larger θ shrinks the feasible misspecification set; as $\theta \to \infty$ the problem reduces to ordinary LQ.

The Markov perfect equilibrium of (85.5) delivers a *robust* rule $u_t = h(x_t, z_t)$ together with a worst-case distortion process $w_{t+1} = W(x_t, z_t)$.

85.3.2 Stackelberg timing and the modified CE

The Markov perfect equilibrium *conceals* a form of CE.

To reveal it, Hansen and Sargent [2001] impose a **Stackelberg timing protocol**: at time 0, the *minimising* player commits once and for all to a plan $\{w_{t+1}\}$, after which the *maximising* player chooses u_t sequentially.

This makes the minimiser the Stackelberg leader.

To describe the leader's committed plan, introduce "big-letter" state variables (X_t, Z_t) (same dimensions as (x_t, z_t)) that encode the leader's pre-committed strategy:

$$\begin{aligned} w_{t+1} &= W(X_t, Z_t), \\ X_{t+1} &= g(X_t, Z_t,\ h(X_t, Z_t)), \\ Z_{t+1} &= f(Z_t,\ W(X_t, Z_t) + \epsilon_{t+1}). \end{aligned} \tag{85.6}$$

Summarised with $Y_t = \begin{bmatrix} X_t \\ Z_t \end{bmatrix}$:

$$Y_{t+1} = MY_t + N\epsilon_{t+1}, \qquad w_{t+1} = W(Y_t). \tag{85.7}$$

The maximising player then faces an *ordinary* dynamic programming problem subject to his own dynamics (85.2), the distorted z-law (85.3), and the exogenous process (85.7).

His optimal rule takes the form

$$u_t = \tilde{H}(x_t, z_t, Y_t). \tag{85.8}$$

Başar and Bernhard [2008] and Hansen and Sargent [2008] establish that at equilibrium (with "big K = little k" imposed) this collapses to

$$\tilde{H}(X_t, Z_t, Y_t) = h(Y_t), \tag{85.9}$$

the *same* rule as the Markov perfect equilibrium of (85.5).

85.3.3 Modified separation principle

The Stackelberg timing permits an Euler-equation approach.

The two-step algorithm becomes:

The first step is unchanged: solve the same nonstochastic control problem as before, with $\mathbf{z}_t = (z_t, z_{t+1}, ...)$ treated as known, giving $u_t = h_1(x_t, \mathbf{z}_t)$.

The second step is modified: form forecasts using the *distorted* law of motion (85.7). By the linearity and Gaussianity of the system,

$$\hat{\mathbb{E}}[\mathbf{z}_t \mid z^t, Y^t] = \hat{h}_2 \begin{bmatrix} z_t \\ Y_t \end{bmatrix} \tag{85.10}$$

where $\hat{\mathbb{E}}$ uses the distorted model.

Substituting (85.10) into h_1 and imposing $Y_t = y_t$ gives the robust rule

$$u_t = h_1\big(x_t,\ \hat{h}_2 \cdot y_t\big) = h(x_t, z_t). \tag{85.11}$$

This is the modified CE: *step 1 is identical to the non-robust case*; only step 2 changes, using distorted rather than rational forecasts.

In contrast to ordinary CE, the robust policy *does* change as θ varies.

As $\theta \to \infty$ (no robustness) the robust policy converges to the standard LQ policy.

```
σ_fixed = 1.0
C_fixed = np.array([[σ_fixed]])

lq_std = LQ(R_mat, Q_mat, A, B, C=C_fixed, beta=β)
P_std, F_std_arr, d_std = lq_std.stationary_values()
F_standard = float(F_std_arr[0, 0])
P_standard = float(P_std[0, 0])

θ_vals = np.linspace(2.0, 30.0, 120)   # restrict attention to a numerically stable␣
↪range
F_rob_vals, P_rob_vals = [], []

for θ in θ_vals:
    rblq = RBLQ(R_mat, Q_mat, A, B, C_fixed, β, θ)
    F_rob, K_rob, P_rob = rblq.robust_rule()
    F_rob_vals.append(float(F_rob[0, 0]))
    P_rob_vals.append(float(P_rob[0, 0]))

fig, axes = plt.subplots(1, 2, figsize=(12, 4))
```

(continues on next page)

(continued from previous page)

```
axes[0].plot(θ_vals, F_rob_vals, lw=2, label='Robust $F(\\theta)$')
axes[0].axhline(F_standard, color='r', linestyle='--', lw=2,
                label=f'Standard LQ ($F = {F_standard:.3f}$)')
axes[0].set_xlabel('robustness parameter $\\theta$')
axes[0].set_ylabel('policy gain $F$')
axes[0].legend()

axes[1].plot(θ_vals, P_rob_vals, lw=2, color='purple',
             label='Robust $P(\\theta)$')
axes[1].axhline(P_standard, color='r', linestyle='--', lw=2,
                label=f'Standard LQ ($P = {P_standard:.3f}$)')
axes[1].set_xlabel('robustness parameter $\\theta$')
axes[1].set_ylabel('value matrix $P$')
axes[1].legend()

plt.tight_layout()
plt.show()
```

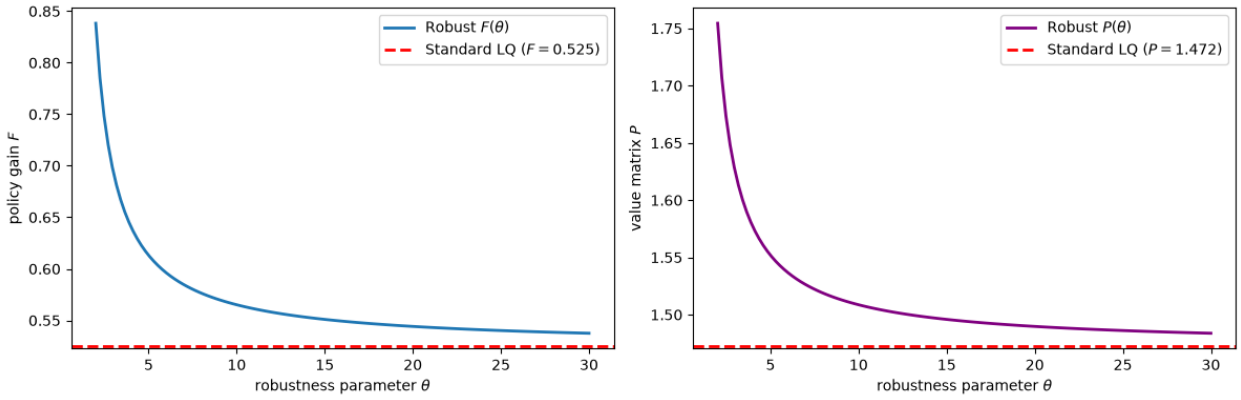

Fig. 85.2: Robust policy varies with θ

Observe that for small θ (strong preference for robustness) both F and P deviate substantially from their non-robust counterparts, converging to the standard values as $\theta \to \infty$.

This contrasts sharply with ordinary CE: under robustness, *both the policy gain and the value matrix depend on the robustness parameter θ and the noise-loading matrix C*.

85.4 Value function under robustness

Under a preference for robustness, the optimised value of (85.5) is again quadratic,

$$V(y_0) = -y_0^\top P\, y_0 - p, \tag{85.12}$$

but now *both P and p* depend on the volatility parameter f_2.

Specifically, P is the fixed point of the composite operator $T \circ \mathcal{D}$ where T is the same Bellman operator as in the non-robust case and $\mathcal{D}$ is the **distortion operator**:

$$\mathcal{D}(P) = \mathcal{D}(P;\, f_2,\, \theta). \tag{85.13}$$

Given the fixed point $P = T(\mathcal{D}(P))$, the constant is

$$p = p(P;\, f_2,\, \beta,\, \theta). \tag{85.14}$$

Despite P now depending on f_2, a form of CE still prevails: the same decision rule (85.11) also emerges from the *nonstochastic* game that maximises (85.5) subject to (85.2) and

$$z_{t+1} = f(z_t,\, w_{t+1}), \tag{85.15}$$

i.e., setting $\epsilon_{t+1} \equiv 0$.

The presence of randomness lowers the value (the constant p) but does not change the decision rule.

85.5 Risk-sensitive preferences

Building on Jacobson [1973] and Whittle [1990], Hansen and Sargent [2004] showed that the same decision rules can be reinterpreted through **risk-sensitive preferences**.

Suppose the decision maker *fully trusts* his model

$$y_{t+1} = A\, y_t + B\, u_t + C\, \epsilon_{t+1} \tag{85.16}$$

but evaluates stochastic processes according to the recursion

$$U_t = r(y_t, u_t) + \beta\, \mathcal{R}_t(U_{t+1}) \tag{85.17}$$

where the *risk-adjusted* continuation operator is

$$\mathcal{R}_t(U_{t+1}) = \frac{2}{\sigma} \log \mathbb{E}\left[\exp\left(\frac{\sigma U_{t+1}}{2}\right) \,\middle|\, y^t\right], \qquad \sigma \leq 0. \tag{85.18}$$

When $\sigma = 0$, L'Hôpital's rule recovers the standard expectation operator.

When $\sigma < 0$, $\mathcal{R}_t$ penalises right-tail risk in the continuation utility U_{t+1}.

For a candidate quadratic continuation value $U^e_{t+1} = -y^\top_{t+1} \Omega\, y_{t+1} - \rho$, let $\hat{y}_{t+1} \equiv A y_t + B u_t$ denote the conditional mean of y_{t+1}.

Evaluating $\mathcal{R}_t$ via the log-moment-generating function of the Gaussian distribution yields

$$\mathcal{R}_t U^e_{t+1} = -\hat{y}^\top_{t+1} \mathcal{D}(\Omega)\, \hat{y}_{t+1} - \hat{\rho} \tag{85.19}$$

where $\mathcal{D}$ is the *same* distortion operator as in (85.13) with $\theta = -\sigma^{-1}$, and $\hat{\rho}$ is the corresponding scalar adjustment term.

Consequently, the risk-sensitive Bellman equation has the *same* fixed point P as the robust control problem, and therefore the *same decision rule* $u_t = -F y_t$.

> **Key equivalence:** robust control with parameter θ and risk-sensitive control with parameter $\sigma = -\theta^{-1}$ produce identical decision rules.

85.6 Application: permanent income model

We now illustrate all of the above in a concrete linear-quadratic permanent income model.

85.6.1 Model setup

A consumer receives an exogenous endowment process $\{z_t\}$ and allocates it between consumption c_t and savings x_t to maximise

$$-\mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t (c_t - b)^2, \qquad \beta \in (0,1) \tag{85.20}$$

where b is a bliss level of consumption.

Defining the **marginal utility of consumption** $\mu_{ct} \equiv b - c_t$ (the control), the budget constraint and endowment process are

$$x_{t+1} = R\, x_t + z_t - b + \mu_{ct} \tag{85.21}$$

$$z_{t+1} = \mu_d(1-\rho) + \rho\, z_t + c_d(\epsilon_{t+1} + w_{t+1}) \tag{85.22}$$

where $R > 1$ is the gross return on savings, $|\rho| < 1$, and w_{t+1} is an optional shock-mean distortion representing model misspecification.

After absorbing the constants $-b$ and $\mu_d(1-\rho)$ by augmenting the state vector, or equivalently by working with deviations from steady state, setting $w_{t+1} \equiv 0$ and taking $Q = 0$ (return depends only on the control μ_{ct}) and $R_{\text{ctrl}} = 1$ puts this in the standard LQ form

$$y_t = \begin{bmatrix} x_t \\ z_t \end{bmatrix}, \quad A = \begin{bmatrix} R & 1 \\ 0 & \rho \end{bmatrix}, \quad B = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad C = \begin{bmatrix} 0 \\ c_d \end{bmatrix}. \tag{85.23}$$

In the numerical code below we add a negligible `1e-8 * I` regularisation to the state-cost matrix to keep the Riccati computation well conditioned in Hall's unit-root case $\beta R = 1$.

We calibrate to parameters estimated by Hansen *et al.* [1999] from post-WWII U.S. data:

```
β_hat = 0.9971
R_rate = 1.0 / β_hat          # β*R = 1 (Hall's case)
ρ     = 0.9992
c_d   = 5.5819
σ_rs  = -2e-7                  # σ_hat < 0
θ_pi  = -1.0 / σ_rs           # θ = -1/σ_hat

A_pi = np.array([[R_rate, 1.0],
                 [0.0,    ρ]])
B_pi = np.array([[1.0],
                 [0.0]])
C_pi = np.array([[0.0],
                 [c_d]])
Q_pi = 1e-8 * np.eye(2)       # regularise for β*R = 1
R_pi = np.array([[1.0]])
```

85.6.2 Without robustness: Hall's martingale

Setting $\sigma = 0$ (no preference for robustness), the consumer's Euler equation is

$$\mathbb{E}_t[\mu_{c,t+1}] = (\beta R)^{-1} \mu_{ct}. \tag{85.24}$$

With $\beta R = 1$ (Hall's case), this is $\mathbb{E}_t[\mu_{c,t+1}] = \mu_{ct}$, i.e., the **marginal utility of consumption is a martingale** – equivalently, consumption follows a random walk.

The optimal policy is $\mu_{ct} = -F y_t$ where, from the solved-forward Euler equation, $F = [(R-1),\ (R-1)/(R-\rho)]$.

The resulting closed-loop projection onto the one-dimensional direction of μ_{ct} gives the scalar AR(1) representation

$$\mu_{c,t+1} = \varphi\, \mu_{ct} + \nu\, \epsilon_{t+1}. \tag{85.25}$$

```
F_pi     = np.array([[(R_rate - 1.0), (R_rate - 1.0) / (R_rate - ρ)]])
A_cl_std = A_pi - B_pi @ F_pi

ψ_std = 1.0 / (β_hat * R_rate)
ν_std = (R_rate - 1.0) * c_d / (R_rate - ρ)

print(f"ψ = {ψ_std:.6f}, ν = {ν_std:.4f}")
```

```
ψ = 1.000000, ν = 4.3777
```

85.6.3 With robustness: precautionary savings

Under a preference for robustness ($\sigma < 0$, $\theta < \infty$), the consumer uses distorted forecasts $\hat{\mathbb{E}}_t[\cdot]$ evaluated under the worst-case model.

The consumption rule takes the certainty-equivalent form

$$\mu_{ct} = -(1 - R^{-2}\beta^{-1})\left(R\, x_t + \hat{\mathbb{E}}_t\left[\sum_{j=0}^{\infty} R^{-j}(z_{t+j} - b)\right]\right) \tag{85.26}$$

where h_1 – the first step of the CE algorithm – is *identical* to the non-robust case.

Only the expectations operator changes.

The resulting AR(1) dynamics for μ_{ct} become:

$$\mu_{c,t+1} = \tilde{\varphi}\, \mu_{ct} + \tilde{\nu}\, \epsilon_{t+1} \tag{85.27}$$

with $\tilde{\varphi} < 1$, implying $\mathbb{E}_t[c_{t+1}] > c_t$ under the approximating model – a form of **precautionary saving**.

The observational equivalence formula (85.28) (derived below) immediately gives the robust AR(1) coefficient: $\tilde{\varphi} = 1/(\tilde{\beta} R)$ where $\tilde{\beta} = \tilde{\beta}(\sigma)$.

The innovation scale $\tilde{\nu}$ follows from the robust permanent income formula with the distorted persistence; Hansen *et al.* [1999] report $\tilde{\nu} \approx 8.0473$ for their calibration.

```
def beta_tilde(σ, β_hat_val, α_sq_val):

85.6.4 Observational equivalence: robustness acts like patience

A key insight of Hansen and Sargent [2001] is that, in the permanent income model, a preference for robustness ($\sigma < 0$) is *observationally equivalent* to an increase in the discount factor from $\hat{\beta}$ to a larger value $\tilde{\beta}(\sigma)$, with σ set back to zero.

The equivalence locus is given by

$$\tilde{\beta}(\sigma) = \frac{\hat{\beta}(1+\hat{\beta})}{2(1+\sigma\alpha^2)}\left[1 + \sqrt{1 - \frac{4\hat{\beta}(1+\sigma\alpha^2)}{(1+\hat{\beta})^2}}\right] \tag{85.28}$$

where $\alpha^2 = \tilde{\nu}^2$ is the squared innovation loading in the robust AR(1) representation (85.27).

```
σ_range = np.linspace(-3e-7, 0.0, 200)
bt_vals = [beta_tilde(s, β_hat, α_sq) for s in σ_range]
bt_check = beta_tilde(σ_rs, β_hat, α_sq)

fig, ax = plt.subplots(figsize=(9, 5))
```

(continues on next page)

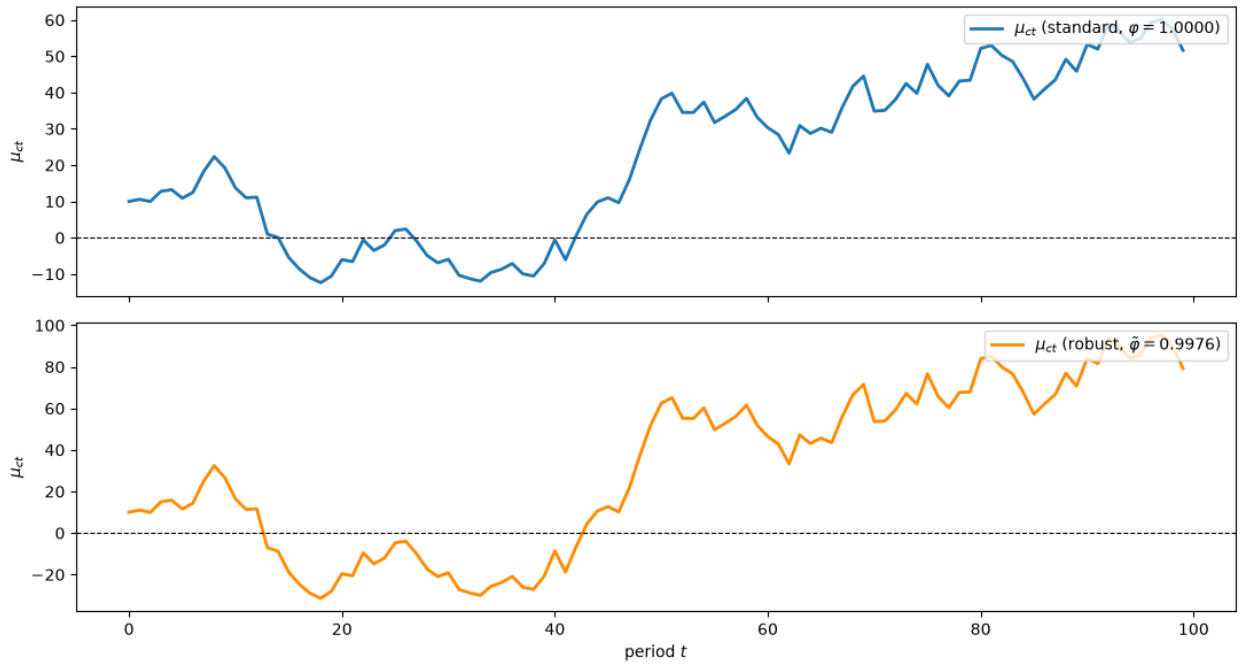

Fig. 85.3: Standard vs robust consumption paths

(continued from previous page)

```
ax.plot(-σ_range * 1e7, bt_vals, lw=2, color='steelblue',
        label='$\\tilde{\\beta}(\\sigma)$')
ax.axhline(β_hat, color='r', linestyle='--', lw=2,
           label=f'$\\hat{{\\beta}} = {β_hat}$')
ax.scatter([-σ_rs * 1e7], [bt_check], zorder=5, color='darkorange', s=80,
           label=f'$(\\hat{{\\sigma}},\\, \\tilde{{\\beta}}) '
                 f'= ({σ_rs:.0e},\\, {bt_check:.4f})$')
ax.set_xlabel('risk sensitivity $-\\sigma$ ($\\times 10^{-7}$)')
ax.set_ylabel('observationally equivalent discount factor $\\tilde{\\beta}$')
ax.legend()
plt.tight_layout()
plt.show()
```

The plot confirms the paper's key finding: *activating a preference for robustness is observationally equivalent – for consumption and saving behaviour – to increasing the discount factor*.

However, Hansen *et al.* [1999] show that the two parametrisations do *not* imply the same asset prices.

This happens because a preference for robustness generates different state-prices through the $\mathcal{D}(P)$ matrix that enters the stochastic discount factor.

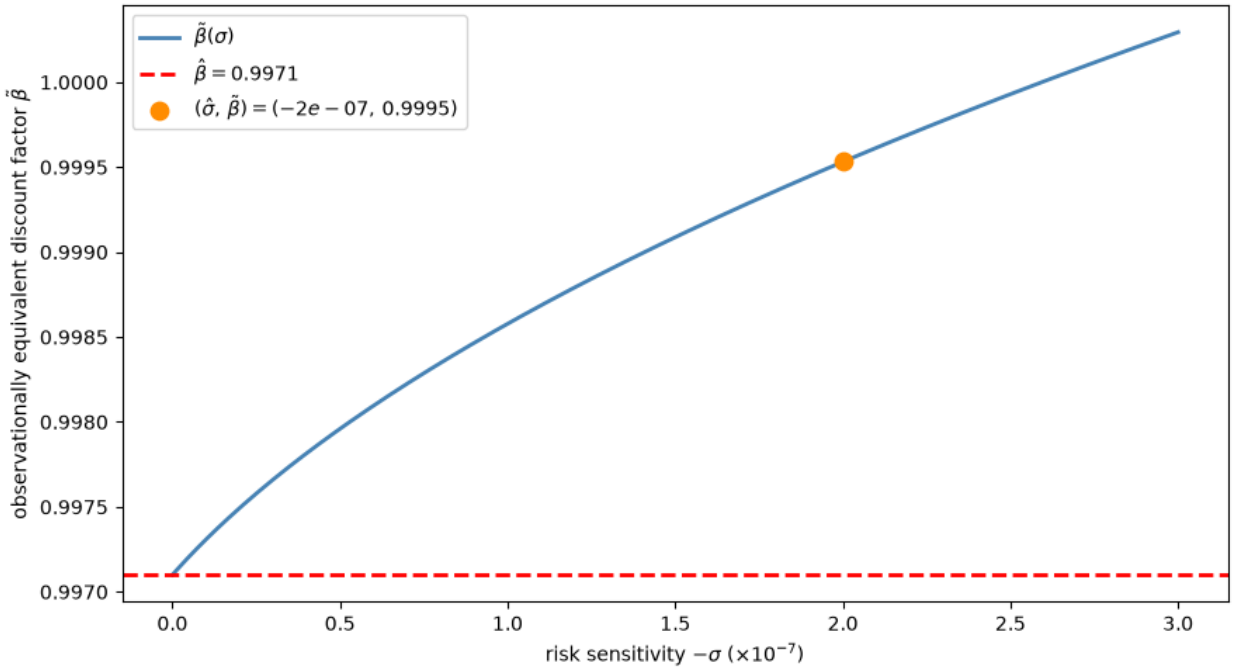

Fig. 85.4: Observational equivalence locus

85.7 Summary

The table below condenses the main results:

Setting	Policy depends on noise?	Forecasts used	CE survives?
Simon–Theil (ordinary LQ)	No	Rational	Yes
Robust control (multiplier)	Yes (P changes with f_2 and θ)	Distorted (worst-case)	Yes (modified)
Risk-sensitive preferences	Yes (same as robust)	Distorted (same)	Yes (same)

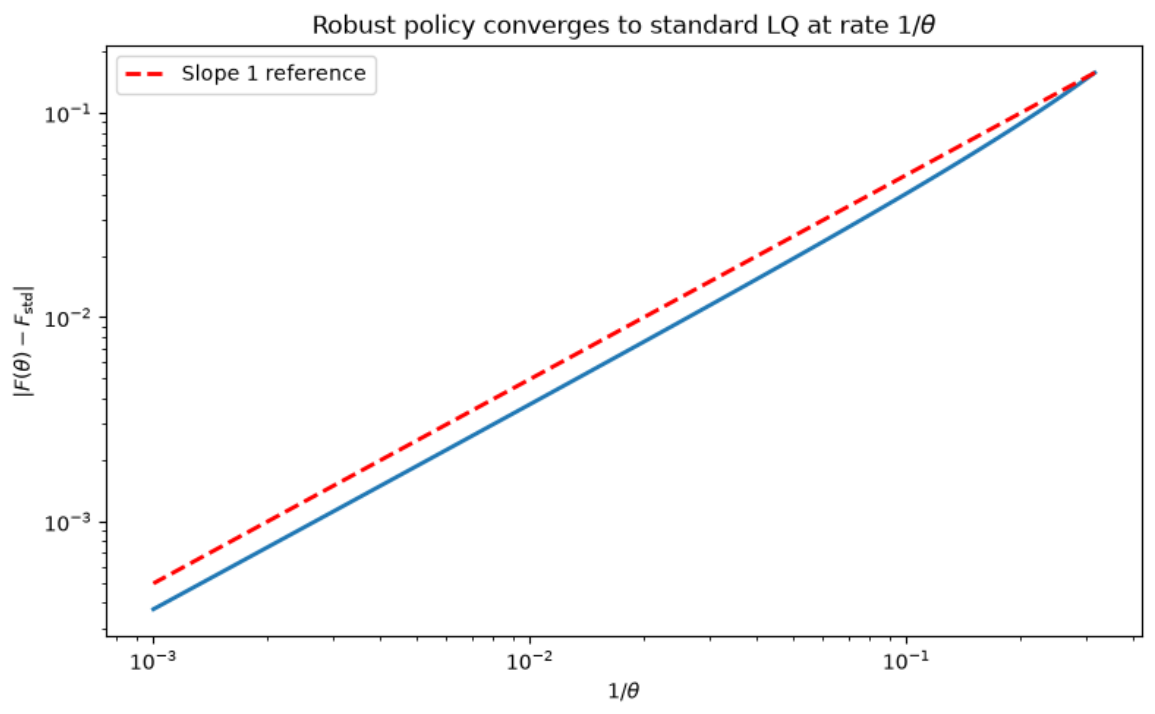
In all three cases, the decision maker can be described as following a two-step procedure: first solve a nonstochastic control problem, then form beliefs.

The difference is in which beliefs are formed in the second step.

85.8 Exercises

Exercise 85.8.1

Show numerically that as $\theta \to \infty$ the robust policy $F(\theta)$ converges to the standard LQ policy F_{std} and that the rate of convergence is of order $1/\theta$. Plot $|F(\theta) - F_{\text{std}}|$ against $1/\theta$ on a log–log scale.



Solution

```
θ_large = np.logspace(0.5, 3.0, 100)
gap_vals = []

for θ in θ_large:
    rblq = RBLQ(R_mat, Q_mat, A, B, C_fixed, β, θ)
    F_r, _, _ = rblq.robust_rule()
    gap_vals.append(abs(float(F_r[0, 0]) - F_standard))

fig, ax = plt.subplots(figsize=(8, 5))
ax.loglog(1.0 / θ_large, gap_vals, lw=2)
ax.set_xlabel('$1/\\theta$')
ax.set_ylabel('$|F(\\theta) - F_{\\mathrm{std}}|$')
ax.set_title('Robust policy converges to standard LQ at rate $1/\\theta$')

x_ref = 1.0 / θ_large
ax.loglog(x_ref, x_ref * gap_vals[0] / x_ref[0],
          'r--', lw=2, label='Slope 1 reference')
ax.legend()
plt.tight_layout()
plt.show()
```

The log–log plot reveals an approximately linear relationship, confirming $O(1/\theta)$ convergence.

Exercise 85.8.2

Pick three values $\sigma_i < 0$ and verify numerically that the robust permanent income model with $(\sigma_i, \hat{\beta})$ produces the same policy matrix F as a suitably chosen non-robust model with $(0, \tilde{\beta}_i)$.

To find $\tilde{\beta}_i$, extract the AR(1) coefficient φ_i for μ_{ct} from the robust closed-loop dynamics and set $\tilde{\beta}_i = 1/(\varphi_i R)$.

Show that $\tilde{\beta}_i > \hat{\beta}$ in every case, confirming that robustness acts like increased patience.

Solution

For each σ_i we solve the robust problem with `RBLQ` and extract the AR(1) coefficient φ for μ_{ct} from the closed-loop dynamics $A_{\text{cl}} = A - BF_{\text{rob}}$.

If F is a left eigenvector of A_{cl} with eigenvalue φ, then $\mu_{ct} = -Fy_t$ satisfies $\mu_{c,t+1} = \varphi\,\mu_{ct} + \nu\,\epsilon_{t+1}$.

Setting $\tilde{\beta} = 1/(\varphi R)$ and solving a standard (non-robust) LQ problem with discount factor $\tilde{\beta}$ should reproduce F.

```
σ_trio = np.array([-5e-8, -1e-7, -2e-7])

for s in σ_trio:
    # Robust model: (σ, β_hat)
    θ_val = -1.0 / s
    rblq = RBLQ(R_pi, Q_pi, A_pi, B_pi, C_pi, β_hat, θ_val)
    F_rob, K_rob, P_rob = rblq.robust_rule()

    # Extract ψ from closed-loop under the approximating model
    A_cl = A_pi - B_pi @ F_rob
    ψ_rob = float((F_rob @ A_cl)[0, 1] / F_rob[0, 1])

    # Implied discount factor
    bt = 1.0 / (ψ_rob * R_rate)

    # Non-robust model with β_tilde
    lq_nr = LQ(R_pi, Q_pi, A_pi, B_pi, C=C_pi, beta=bt)
    P_nr, F_nr, d_nr = lq_nr.stationary_values()

    print(f"σ = {s:.1e},  θ = {θ_val:.1e},  β = {bt:.6f} (> β = {β_hat})")
    print(f"  ψ_rob = {ψ_rob:.8f}")
    print(f"  F_robust  = [{F_rob[0,0]:.6f}, {F_rob[0,1]:.6f}]")
    print(f"  F_non-rob = [{F_nr[0,0]:.6f}, {F_nr[0,1]:.6f}]")
    print(f"  |F_rob - F_nr| = {np.max(np.abs(F_rob - F_nr)):.2e}")
    print(f"  K (worst-case distortion): [{K_rob[0,0]:.2e}, {K_rob[0,1]:.2e}]")
    print()
```

```
σ = -5.0e-08,  θ = 2.0e+07,  β = 0.997472 (> β = 0.9971)
  ψ_rob = 0.99962721
  F_robust  = [0.003284, 0.884886]
  F_non-rob = [0.003284, 0.884894]
  |F_rob - F_nr| = 8.14e-06
  K (worst-case distortion): [2.48e-07, 6.68e-05]

σ = -1.0e-07,  θ = 1.0e+07,  β = 0.997953 (> β = 0.9971)
  ψ_rob = 0.99914484
  F_robust  = [0.003766, 1.014865]
  F_non-rob = [0.003766, 1.014863]
  |F_rob - F_nr| = 2.05e-06
  K (worst-case distortion): [5.68e-07, 1.53e-04]

σ = -2.0e-07,  θ = 5.0e+06,  β = 0.999522 (> β = 0.9971)
  ψ_rob = 0.99757687
  F_robust  = [0.005332, 1.437585]
  F_non-rob = [0.005333, 1.437465]
  |F_rob - F_nr| = 1.20e-04
  K (worst-case distortion): [1.01e-06, 2.72e-04]
```

The policy matrices F match to high precision, confirming observational equivalence for consumption and saving decisions.

In every case $\tilde{\beta} > \hat{\beta}$: a preference for robustness makes the agent behave as if he were more patient.

The non-zero worst-case distortion K in the robust model has no analogue in the non-robust model.

As Hansen *et al.* [1999] show, this is why the two parametrisations imply different asset prices even though saving plans coincide.

THE LQ PERMANENT INCOME MODEL

Contents

- *The LQ Permanent Income Model*
  - *Overview*
  - *The standard LQ permanent income model*
  - *Exercises*

86.1 Overview

This lecture studies consumption smoothing in a linear-quadratic (LQ) permanent income model.

It presents a rational-expectations version of the permanent income theories of Friedman [1956] and Hall [1978].

Throughout, we set $\beta R = 1$, so that the baseline consumer's subjective discount factor equals the bond price.

The model is useful for studying

- impulse response functions
- alternative state-space representations of the optimal decision rule
- cointegration of consumption and assets

We derive the consumer's optimal consumption function, present two state-space representations of the optimal decision rule, and illustrate them with two classic examples.

This is the first of four lectures on the LQ permanent income model.

The two sequels build directly on the tools developed here.

- *Consumption Smoothing with Incomplete and Complete Markets* studies the cross-section behavior of consumption and embeds the single consumer in closed economies with incomplete and complete markets.
- *Robust Consumption Smoothing and Precautionary Savings* studies a consumer who distrusts his model of income and engages in precautionary savings.
- *A Robust LQ Bewley Model* combines the two, building a Bewley economy whose consumers differ in how much they distrust their income model.

Let's begin with some imports.

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.linalg import solve, inv, solve_discrete_lyapunov
from scipy.stats import norm
```

86.2 The standard LQ permanent income model

86.2.1 Setup

A consumer has preferences over consumption streams ordered by

$$\mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t u(c_t) \tag{86.1}$$

where $\mathbb{E}_t$ is a mathematical expectation conditioned on the consumer's time-t information, c_t is time-t consumption, $u(c)$ is a strictly concave one-period utility function, and $\beta \in (0,1)$ is a discount factor.

The consumer maximizes (86.1) by choosing a plan $\{c_t, b_{t+1}\}_{t=0}^{\infty}$ subject to the sequence of budget constraints

$$c_t + b_t = R^{-1} b_{t+1} + y_t, \quad t \geq 0 \tag{86.2}$$

where $\{y_t\}$ is an exogenous stationary endowment process, R is a constant gross risk-free interest rate, b_t is a one-period risk-free bond maturing at t, and b_0 is a given initial condition.

Note

For $t \geq 1$, b_t is chosen at time $t-1$.

The bond $b_t > 0$ represents debt owed by the consumer at the start of period t.

We assume $R^{-1} = \beta$.

The endowment or non-financial income process has the state-space representation

$$\begin{aligned} z_{t+1} &= \check{A} z_t + \check{C} w_{t+1} \\ y_t &= \check{G} z_t \end{aligned} \tag{86.3}$$

where w_{t+1} is IID with mean zero and identity covariance matrix, $\check{A}$ is a stable matrix (eigenvalues strictly less than one in modulus), and $\check{G}$ is a row vector.

The state confronting the household at t is $\begin{bmatrix} b_t & z_t^\top \end{bmatrix}^\top$, where b_t is its one-period debt due at the start of period t and z_t contains all variables useful for forecasting its future endowment.

To make the problem linear-quadratic, we adopt the **quadratic utility function**

$$u(c_t) = -\tfrac{1}{2}(c_t - \gamma)^2$$

where $\gamma > 0$ is a bliss level of consumption.

We allow c_t to be negative (a producer rather than a consumer).

We impose a **transversality condition**

$$\mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t b_t^2 < +\infty, \tag{86.4}$$

which rules out Ponzi schemes.

86.2.2 Euler equation and certainty equivalence

With quadratic utility, the first-order conditions for the consumer's problem imply that

$$\mathbb{E}_t c_{t+1} = c_t \tag{86.5}$$

Note

Equation (86.5) says that consumption is a martingale.

This is the key implication of the LQ permanent income model.

It contrasts with models that have convex marginal utility ($u''' > 0$), where consumption is instead a submartingale.

Because the consumer maximizes a quadratic objective subject to a linear transition equation, the problem satisfies a **certainty-equivalence** property.

This implies that we can find the optimal plan by

- first solving the problem while pretending to have perfect foresight; this lets us express c_t as a function of b_t and the continuation sequence $\{y_{t+j}\}_{j=0}^{\infty}$
- then simply replace $\{y_{t+j}\}_{j=0}^{\infty}$ with $\{\mathbb{E}_t y_{t+j}\}_{j=0}^{\infty}$.

86.2.3 The optimal consumption function

Solving the budget constraint (86.2) forward, imposing the transversality condition, and taking conditional expectations gives

$$b_t = \sum_{j=0}^{\infty} \beta^j \mathbb{E}_t y_{t+j} - \frac{1}{1-\beta} c_t \tag{86.6}$$

Rearranging yields the **consumption function**

$$c_t = (1-\beta)\left[\sum_{j=0}^{\infty} \beta^j \mathbb{E}_t y_{t+j} - b_t\right] \tag{86.7}$$

Equivalently, with net interest rate r defined by $\beta = 1/(1+r)$,

$$c_t = \frac{r}{1+r}\left[\sum_{j=0}^{\infty} \beta^j \mathbb{E}_t y_{t+j} - b_t\right] \tag{86.8}$$

Evidently, consumption at t equals $r/(1+r)$ times total wealth, where total wealth is the sum of human wealth $\sum_{j=0}^{\infty} \beta^j \mathbb{E}_t y_{t+j}$ and financial wealth $-b_t$.

Using state-space representation (86.3) to evaluate the geometric sum of expected future endowments,

$$\sum_{j=0}^{\infty} \beta^j \mathbb{E}_t y_{t+j} = \check{G}(I - \beta \check{A})^{-1} z_t, \tag{86.9}$$

we obtain

$$c_t = (1-\beta)\left[\check{G}(I - \beta \check{A})^{-1} z_t - b_t\right] \tag{86.10}$$

This expresses c_t as a function of the state $[b_t,\ z_t^\top]^\top$ that confronts the household.

86.2.4 Representation 1: state (b_t, z_t)

Combining the endowment law of motion with the optimal debt dynamics (derived by substituting (86.10) into (86.2)) gives the following representation:

$$\begin{aligned} z_{t+1} &= \check{A}\, z_t + \check{C}\, w_{t+1} \\ b_{t+1} &= b_t + \check{G}[(I - \beta\check{A})^{-1}(\check{A} - I)]z_t \\ y_t &= \check{G}\, z_t \\ c_t &= (1-\beta)\left[\check{G}(I - \beta\check{A})^{-1} z_t - b_t\right] \end{aligned} \tag{86.11}$$

In this representation the **exogenous** state is z_t and the **endogenous** state is b_t.

We turn now to an alternative representation.

86.2.5 Representation 2: state (c_t, z_t)

Hall [1978] showed that the LQ permanent income model implies a representation in which the state consists of current consumption c_t and the exogenous endowment state z_t.

In this representation, b_t becomes an outcome rather than a state variable.

Shifting (86.7) forward, eliminating b_{t+1} via (86.2), and rearranging yields

$$c_{t+1} - c_t = (1-\beta)\sum_{j=0}^{\infty} \beta^j (\mathbb{E}_{t+1} y_{t+j+1} - \mathbb{E}_t y_{t+j+1}) \tag{86.12}$$

The right-hand side is $(1-\beta)$ times the time-$(t+1)$ **innovation** to the expected present value of the endowment stream.

Suppose the endowment has the (Wold) moving-average representation

$$y_{t+1} = d(L)\, w_{t+1}, \qquad d(L) = \sum_{j=0}^{\infty} d_j L^j \tag{86.13}$$

where $d(L) = \check{G}(I - \check{A}L)^{-1}\check{C}$.

Then

$$\mathbb{E}_{t+1} y_{t+j} - \mathbb{E}_t y_{t+j} = d_{j-1}\, w_{t+1} \tag{86.14}$$

Substituting (86.14) into (86.12) gives the key result

$$c_{t+1} - c_t = (1-\beta)\, d(\beta)\, w_{t+1}. \tag{86.15}$$

Here, $d(\beta) = \check{G}(I - \beta\check{A})^{-1}\check{C}$ is the **present value of the (Wold) moving-average coefficients**.

Thus, consumption is a **random walk** with innovation $(1-\beta)d(\beta)w_{t+1}$.

Combining (86.15) and (86.6) gives

$$\begin{aligned} c_{t+1} &= c_t + (1-\beta)\,\check{G}(I - \beta\check{A})^{-1}\check{C}\, w_{t+1} \\ b_t &= \check{G}(I - \beta\check{A})^{-1} z_t - \frac{1}{1-\beta}\, c_t \\ y_t &= \check{G}\, z_t \\ z_{t+1} &= \check{A}\, z_t + \check{C}\, w_{t+1} \end{aligned} \tag{86.16}$$

This representation reveals several important features of the optimal decision rule:

1. **State**: The state consists of the endogenous component c_t and the exogenous component z_t, with financial assets b_t encoded in c_t rather than carried as a separate state.
2. **Random walk**: Consumption is a random walk with innovation $(1-\beta)d(\beta)w_{t+1}$, which confirms that the Euler equation (86.5) is built into the solution and implies that consumption has no asymptotic stationary distribution.
3. **Box impulse response**: For all $j \geq 1$, the response of c_{t+j} to the innovation w_{t+1} is the constant $(1-\beta)d(\beta)$, giving a "box-shaped" impulse response.
4. **Cointegration**: Both c_t and b_t are nonstationary (unit-root processes), but the linear combination $(1-\beta)b_t + c_t$ is stationary.

   From (86.6),

$$(1-\beta)b_t + c_t = (1-\beta)\mathbb{E}_t \sum_{j=0}^{\infty} \beta^j y_{t+j} \tag{86.17}$$

The left side is the cointegrating residual.

86.2.6 Debt dynamics

Subtracting (86.16) (equation for b_t) at time t from the same equation at time $t+1$ and substituting gives

$$b_{t+1} - b_t = \check{G}(I - \beta\check{A})^{-1}(\check{A} - I)\, z_t \tag{86.18}$$

This shows that b_{t+1} is **predetermined** at time t as a function of z_t alone.

Solving backward from any t, b_t depends on the entire history $z^{t-1} = [z_{t-1}, \ldots, z_0]$ and the initial condition b_0.

Such **history dependence** is a hallmark of a consumption plan in various incomplete-markets economies.

86.2.7 Two classic examples

We illustrate formulas (86.16) with two examples.

In both, the endowment is $y_t = z_{1t} + z_{2t}$, where

$$\begin{pmatrix} z_{1,t+1} \\ z_{2,t+1} \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} z_{1t} \\ z_{2t} \end{pmatrix} + \begin{pmatrix} \sigma_1 & 0 \\ 0 & \sigma_2 \end{pmatrix} \begin{pmatrix} w_{1,t+1} \\ w_{2,t+1} \end{pmatrix} \tag{86.19}$$

Here z_{1t} is a **permanent** component of y_t and z_{2t} is a **purely transitory** component.

In the full-information example, the consumer observes the state z_t at time t, so he can reconstruct w_{t+1} from z_{t+1} and z_t.

Applying (86.16):

$$c_{t+1} - c_t = \sigma_1 w_{1,t+1} + (1-\beta)\,\sigma_2\, w_{2,t+1} \tag{86.20}$$

A unit increment to the permanent component z_{1t} raises consumption *one-for-one* permanently and causes **zero net saving**.

A unit increment to the purely transitory component raises consumption by only the fraction $(1-\beta)$ permanently, while the remaining fraction β is saved.

From (86.18):

$$b_{t+1} - b_t = -z_{2t} = -\sigma_2 w_{2t} \tag{86.21}$$

confirming that none of the permanent shock is saved, while all of the transitory shock is saved.

In the incomplete-information (Muth model) example, the consumer observes y_t and its history, but not z_{1t} and z_{2t} separately.

The appropriate approach uses an **innovations representation** derived by the Kalman filter.

At the Kalman filter steady state, the **Kalman gain** $K \in [0, 1]$ satisfies

$$K = \frac{\Sigma}{\Sigma + \sigma_2^2}, \qquad \Sigma = \frac{\sigma_1^2 + \sqrt{\sigma_1^4 + 4\sigma_1^2\sigma_2^2}}{2} \tag{86.22}$$

where K increases with the ratio σ_1^2/σ_2^2 (the variance of the permanent shock relative to the transitory shock).

The innovations representation expresses the endowment as an ARMA(1,1) in its own innovation $a_t = y_t - \mathbb{E}[y_t \mid y^{t-1}]$ (the one-step-ahead forecast error):

$$y_{t+1} = y_t - (1 - K)\, a_t + a_{t+1} \tag{86.23}$$

Here the coefficient $-(1 - K)$ on the lagged innovation reflects that only the fraction K of last period's surprise was treated as permanent; the remainder mean-reverts.

The scalar a_t is IID with variance $\Sigma + \sigma_2^2$.

Applying (86.16) to this innovation representation:

$$c_{t+1} - c_t = [1 - \beta(1 - K)]\, a_{t+1} \tag{86.24}$$

The consumer regards a fraction K of the innovation a_{t+1} as permanent and fraction $1 - K$ as transitory.

He permanently increments consumption by $K + (1 - \beta)(1 - K) = 1 - \beta(1 - K)$ of a_{t+1} and saves the remaining fraction $\beta(1 - K)$.

The first difference of income obeys a first-order moving average:

$$y_{t+1} - y_t = a_{t+1} - (1 - K)\, a_t \tag{86.25}$$

By contrast, the first difference of consumption is IID by (86.24).

86.2.8 Implementation

```
# Parameters
β = 0.95       # discount factor (so R = 1/β)
σ1 = 0.15      # std of permanent shock
σ2 = 0.30      # std of transitory shock

# Example 1: full information
A_check = np.array([[1.0, 0.0],
                    [0.0, 0.0]])
C_check = np.array([[σ1, 0.0],
                    [0.0, σ2]])
G_check = np.array([[1.0, 1.0]])

# Key matrix M = G(I - βA)^{-1}
IbA = np.eye(2) - β * A_check
M = G_check @ inv(IbA)   # shape (1, 2)

# Consumption impulse responses
h = (1 - β) * M @ C_check          # shape (1, 2)

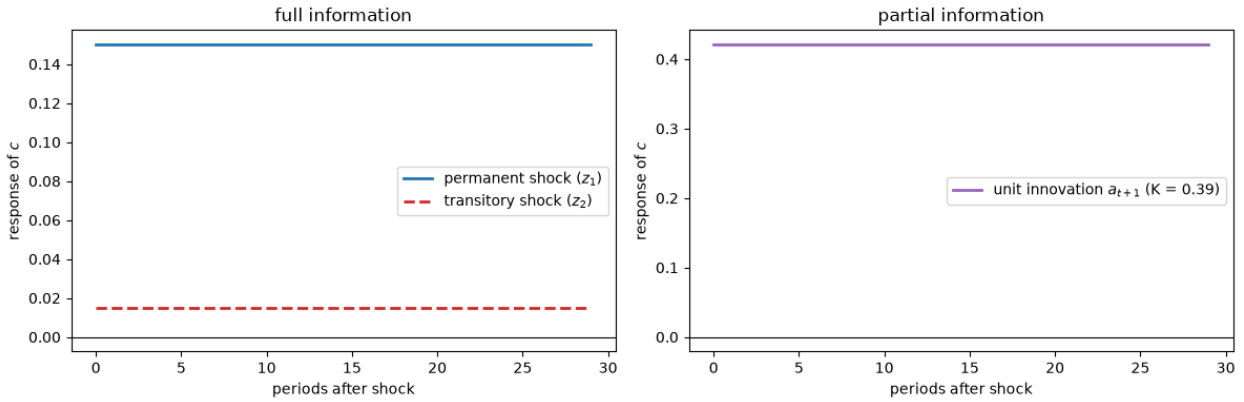

Fig. 86.1: Consumption impulse responses

Note

The impulse responses have the "box" shape characteristic of the LQ permanent income model: once a shock occurs, consumption shifts permanently to a new level and stays there.

The two representations and examples developed here are the foundation for the two sequel lectures.

Consumption Smoothing with Incomplete and Complete Markets uses the (c_t, z_t) representation (86.16) to study how the cross-section distribution of consumption evolves in closed economies with incomplete and complete markets.

Robust Consumption Smoothing and Precautionary Savings studies a consumer who distrusts the endowment process (86.3) and engages in precautionary savings.

A Robust LQ Bewley Model puts such consumers into a Bewley economy and shows that their concerns about misspecification leave no trace in quantity data.

86.3 Exercises

Exercise 86.3.1

This exercise verifies the response of consumption and debt to permanent and transitory shocks in the full-information two-factor model.

Consider the model of (86.19) with the calibration used above.

Suppose the economy starts at $z_0 = 0$ and $b_0 = 0$ and is hit by a single shock at $t = 1$: either a unit permanent shock $w_1 = (1, 0)^\top$ or a unit transitory shock $w_1 = (0, 1)^\top$, with no further shocks thereafter.

1. Using representation (86.11), compute and plot the paths of consumption c_t and debt b_t following each shock.

2. Confirm that the permanent shock raises consumption permanently by σ_1 and induces no saving, while the transitory shock raises consumption permanently by $(1-\beta)\sigma_2$ and is otherwise saved.

Solution

Here is one solution:

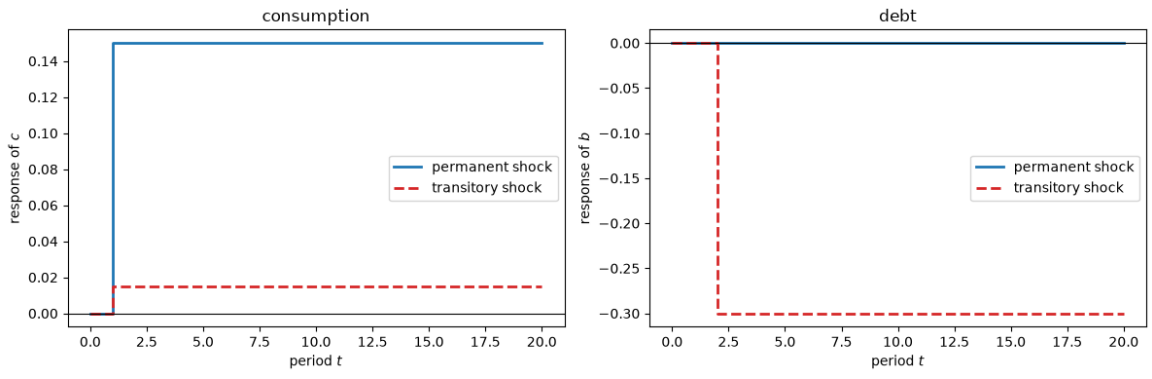
We iterate representation (86.11) forward with a single shock at $t = 1$.

```
def impulse_response(shock, T=20):
    """Paths of c and b after a single shock at t=1 (z_0 = b_0 = 0)."""
    I2 = np.eye(2)
    b_coef = M @ (A_check - I2)       # coefficient on z_t in the b law

    z = np.zeros((T + 1, 2))
    b = np.zeros(T + 1)

    z[1] = C_check @ shock            # shock realized at t = 1
    for t in range(1, T):
        z[t + 1] = A_check @ z[t]
    for t in range(T):
        b[t + 1] = b[t] + (b_coef @ z[t]).item()

    c = np.array([((1 - β) * (M @ z[t] - b[t])).item() for t in range(T + 1)])
    return c, b



c_perm, b_perm = impulse_response(np.array([1.0, 0.0]))
c_tran, b_tran = impulse_response(np.array([0.0, 1.0]))

fig, axes = plt.subplots(1, 2, figsize=(12, 4))

axes[0].step(range(len(c_perm)), c_perm, where='post',
             label='permanent shock', color='C0', lw=2)
axes[0].step(range(len(c_tran)), c_tran, where='post',
             label='transitory shock', color='C3', linestyle='--', lw=2)
axes[0].axhline(0, color='k', lw=0.8)
axes[0].set_xlabel('period $t$')
axes[0].set_ylabel('response of $c$')
axes[0].set_title('consumption')
axes[0].legend()

axes[1].step(range(len(b_perm)), b_perm, where='post',
             label='permanent shock', color='C0', lw=2)
axes[1].step(range(len(b_tran)), b_tran, where='post',
             label='transitory shock', color='C3', linestyle='--', lw=2)
axes[1].axhline(0, color='k', lw=0.8)
axes[1].set_xlabel('period $t$')
axes[1].set_ylabel('response of $b$')
axes[1].set_title('debt')
axes[1].legend()
fig.tight_layout()
plt.show()

print(f"permanent shock:  Δc = {c_perm[-1]:.4f}  (theory σ1 = {σ1:.4f}),"
      f"  Δb = {b_perm[-1]:.4f}")
print(f"transitory shock: Δc = {c_tran[-1]:.4f}  "
      f"(theory (1-β)σ2 = {(1-β)*σ2:.4f}),  Δb = {b_tran[-1]:.4f}")
```

```
permanent shock:  Δc = 0.1500  (theory σ1 = 0.1500),  Δb = 0.0000
transitory shock: Δc = 0.0150  (theory (1-β)σ2 = 0.0150),  Δb = -0.3000
```

The permanent shock lifts consumption by σ_1 and leaves debt at zero: the shock is fully capitalised, so there is no net saving.

The transitory shock lifts consumption by only $(1-\beta)\sigma_2$; the consumer saves the remainder, so debt falls to $-\sigma_2$ (assets accumulate).

Exercise 86.3.2

This exercise illustrates the **cointegration** of consumption and debt described in (86.17).

The cointegration result requires a *stationary* endowment, so we replace the two-factor process with a scalar AR(1),

$$z_{t+1} = \rho z_t + \sigma_\varepsilon w_{t+1}, \qquad y_t = z_t,$$

with $\rho = 0.7$ and $\sigma_\varepsilon = 0.5$.

1. Simulate a long path of c_t and b_t using representation (86.11).
2. Verify that c_t and b_t each inherit a unit root (they wander), while the cointegrating residual $(1-\beta)b_t + c_t$ is stationary and equals $(1-\beta)\check{G}(I-\beta\check{A})^{-1}z_t$.

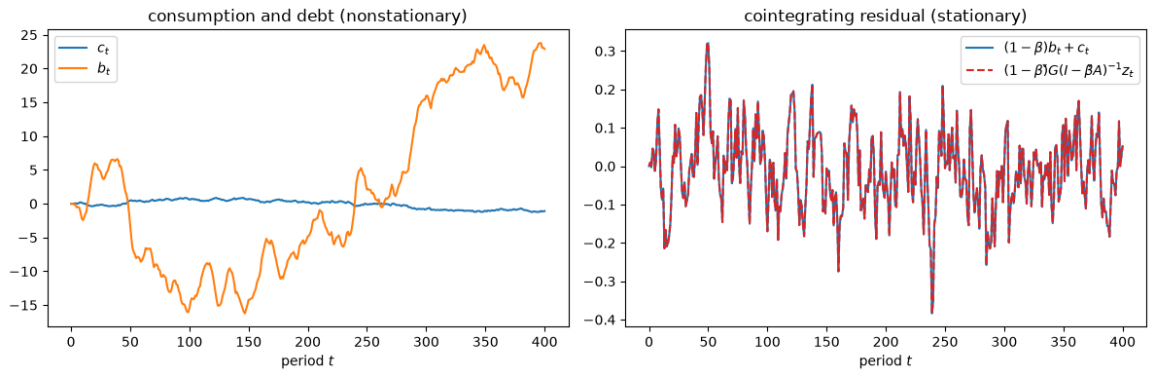
Solution

Here is one solution:

```
ρ, σε = 0.7, 0.5
A_ar = np.array([[ρ]])
C_ar = np.array([[σε]])
G_ar = np.array([[1.0]])

M_ar = G_ar @ inv(np.eye(1) - β * A_ar)      # G(I - βA)^{-1}
b_coef_ar = M_ar @ (A_ar - np.eye(1))        # coefficient on z_t in b law

rng = np.random.default_rng(0)
T = 400
z = np.zeros((T + 1, 1))
b = np.zeros(T + 1)
for t in range(T):
    z[t + 1] = A_ar @ z[t] + C_ar @ rng.standard_normal(1)
```



```
    b[t + 1] = b[t] + (b_coef_ar @ z[t]).item()

c = np.array([((1 - β) * (M_ar @ z[t] - b[t])).item() for t in range(T + 1)])
residual = (1 - β) * b + c
theory = np.array([((1 - β) * (M_ar @ z[t])).item() for t in range(T + 1)])

fig, axes = plt.subplots(1, 2, figsize=(12, 4))
axes[0].plot(c, label='$c_t$', lw=1.5)
axes[0].plot(b, label='$b_t$', lw=1.5)
axes[0].set_xlabel('period $t$')
axes[0].set_title('consumption and debt (nonstationary)')
axes[0].legend()

axes[1].plot(residual, label=r'$(1-\beta)b_t + c_t$', lw=1.5, color='C0')
axes[1].plot(theory, label=r'$(1-\beta)\check{G}(I-\beta\check{A})^{-1}z_t$',
             lw=1.5, linestyle='--', color='C3')
axes[1].set_xlabel('period $t$')
axes[1].set_title('cointegrating residual (stationary)')
axes[1].legend()
fig.tight_layout()
plt.show()

print(f"max |residual - theory| = {np.max(np.abs(residual - theory)):.2e}")
```

```
max |residual - theory| = 2.36e-16
```

Both c_t and b_t inherit the unit root that the random-walk consumption rule builds into the solution, so they drift without settling down.

Their linear combination $(1-\beta)b_t + c_t$ coincides with $(1-\beta)\check{G}(I-\beta\check{A})^{-1}z_t$ (up to floating-point error), which is a stationary function of the stationary state z_t.

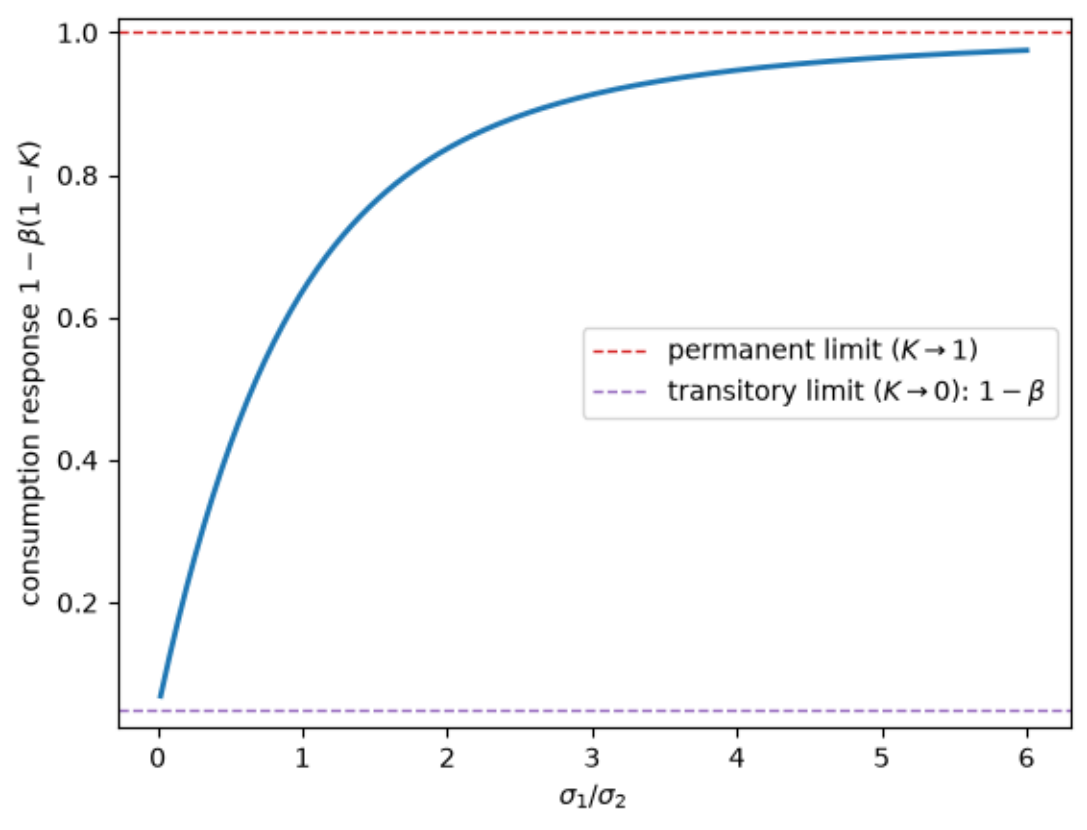
Exercise 86.3.3

This exercise explores how the consumer's information problem shapes his response to income surprises in the Muth model.

Recall from (86.24) that the permanent consumption response to a unit income innovation a_{t+1} is $1-\beta(1-K)$, where the Kalman gain K in (86.22) depends on the ratio σ_1/σ_2.

1. Plot the response $1-\beta(1-K)$ as a function of the ratio σ_1/σ_2, holding σ_2 fixed.
2. Explain the two limiting cases $\sigma_1/\sigma_2 \to 0$ and $\sigma_1/\sigma_2 \to \infty$, and relate them to the two shocks of the full-

information model.



Solution

Here is one solution:

```
ratios = np.linspace(0.02, 6.0, 300)
σ2_fixed = 0.30

responses = []
for r in ratios:
    s1 = r * σ2_fixed
    Σ = (s1**2 + np.sqrt(s1**4 + 4 * s1**2 * σ2_fixed**2)) / 2
    K = Σ / (Σ + σ2_fixed**2)
    responses.append(1 - β * (1 - K))

fig, ax = plt.subplots()
ax.plot(ratios, responses, lw=2, color='C0')
ax.axhline(1.0, color='C3', linestyle='--', lw=1,
           label=r'permanent limit ($K\to1$)')
ax.axhline(1 - β, color='C4', linestyle='--', lw=1,
           label=r'transitory limit ($K\to0$): $1-\beta$')
ax.set_xlabel(r'$\sigma_1/\sigma_2$')
ax.set_ylabel(r'consumption response $1-\beta(1-K)$')
ax.legend()
plt.show()
```

As $\sigma_1/\sigma_2 \to 0$ the endowment is dominated by transitory noise, so $K \to 0$: the consumer treats each innovation as transitory and raises consumption by only $1-\beta$, exactly as for the purely transitory shock in the full-information model.

As $\sigma_1/\sigma_2 \to \infty$ the endowment is dominated by permanent shocks, so $K \to 1$: the consumer treats each innovation as permanent and raises consumption one-for-one, exactly as for the permanent shock.

For intermediate ratios the consumer optimally splits each surprise, capitalising the fraction K he attributes to the permanent component and saving the rest.

87.1 Overview

This lecture studies how the cross-section distribution of consumption evolves when many consumers each solve the LQ permanent income problem.

It is the second of four lectures on the LQ permanent income model and builds directly on *The LQ Permanent Income Model*.

We first show that the unit root in individual consumption causes the cross-section variance of consumption to grow linearly with time.

We then embed the individual consumer in a **closed economy** with a continuum of consumers, following Bewley [1977], and show how the gross interest rate $R = \beta^{-1}$ emerges as an equilibrium outcome.

Finally, we replace the single risk-free bond with a complete set of Arrow securities and show how complete markets deliver a time-invariant cross-section distribution of consumption.

The third lecture, *Robust Consumption Smoothing and Precautionary Savings*, relaxes the assumption that the consumer fully trusts his income model.

The fourth, *A Robust LQ Bewley Model*, returns to the Bewley economy of this lecture and populates it with consumers who differ in how much they trust that model.

Let's begin with some imports.

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.linalg import inv
```

87.2 A brief review

We recall the essentials from *The LQ Permanent Income Model*.

A consumer with quadratic utility, discount factor β, and access to a risk-free bond with gross return $R = \beta^{-1}$ faces the endowment process

$$\begin{aligned} z_{t+1} &= \check{A}\, z_t + \check{C}\, w_{t+1} \\ y_t &= \check{G}\, z_t \end{aligned} \tag{87.1}$$

where w_{t+1} is IID with mean zero and identity covariance matrix.

The optimal consumption function expresses consumption as $r/(1+r) = (1-\beta)$ times total wealth,

$$c_t = (1-\beta)\left[\check{G}(I - \beta\check{A})^{-1} z_t - b_t\right] \tag{87.2}$$

The model has a state-space representation in which the state is current consumption c_t and the exogenous endowment state z_t:

$$\begin{aligned} c_{t+1} &= c_t + (1-\beta)\,\check{G}(I - \beta\check{A})^{-1}\check{C}\, w_{t+1} \\ b_t &= \check{G}(I - \beta\check{A})^{-1} z_t - \frac{1}{1-\beta}\, c_t \\ y_t &= \check{G}\, z_t \\ z_{t+1} &= \check{A}\, z_t + \check{C}\, w_{t+1} \end{aligned} \tag{87.3}$$

Consumption is a **random walk**: its first difference is the IID innovation $h\, w_{t+1}$, where $h = (1-\beta)\,\check{G}(I - \beta\check{A})^{-1}\check{C}$.

Throughout we use the two-factor endowment $y_t = z_{1t} + z_{2t}$ from *The LQ Permanent Income Model*, with z_{1t} a permanent component and z_{2t} a purely transitory component, so that $\check{A} = \mathrm{diag}(1, 0)$ and $\check{C} = \mathrm{diag}(\sigma_1, \sigma_2)$.

The following cell reproduces the calibration and the key matrices.

```
# Parameters
β = 0.95        # discount factor (so R = 1/β)
σ1 = 0.15       # std of permanent shock
σ2 = 0.30       # std of transitory shock

# Two-factor endowment
A_check = np.array([[1.0, 0.0],
                    [0.0, 0.0]])
C_check = np.array([[σ1, 0.0],
                    [0.0, σ2]])
G_check = np.array([[1.0, 1.0]])

# Key matrix M = G(I - βA)^{-1}
IbA = np.eye(2) - β * A_check
M = G_check @ inv(IbA)    # shape (1, 2)
```

87.3 Spreading consumption cross sections

The unit root in consumption (representation (87.3)) causes a **cross-section variance** of consumption to grow linearly with time.

Consider a continuum of *ex ante* identical households born at $t = 0$.

All households i share the same preferences.

They all face a stochastic process for non-financial income of the same form

$$y_t^i = g(w_t^i, w_{t-1}^i, \ldots, w_0^i; z_0^i), \tag{87.4}$$

While all consumers face the same g process, they have different, statistically independent realizations of the **idiosyncratic** shock sequences $\{w_t^i\}_{t=0}^{\infty}$.

Let all households start from the same initial conditions $c_0^i = c_0$ and z_0^i.

From (87.3), household i's consumption follows

$$c_{t+1}^i = c_t^i + h\, w_{t+1}^i, \qquad h = (1-\beta)\,\check{G}(I - \beta\check{A})^{-1}\check{C}$$

Since $\{w_t^i\}$ realizations are independent across agents,

$$\mathbb{E}_0(c_t^i - c_0^i)^2 = t\, hh^\top \tag{87.5}$$

In the two-factor model, h is a 1×2 row vector so $hh^\top$ is a positive scalar equal to $\sigma_1^2 + (1-\beta)^2\sigma_2^2$.

The cross-section variance of consumption grows like t.

```
# Simulate cross-section spreading
rng = np.random.default_rng(42)
N = 5000        # number of agents
T_sim = 80          # number of periods

h_vec = (1 - β) * (M @ C_check)    # shape (1, 2), then flatten
h_vec = h_vec.flatten()             # h = [h1, h2]

c = np.zeros((N, T_sim + 1))        # consumption paths
# initialise all agents at c_0 = 0 (demeaned)
for t in range(T_sim):
    eps = rng.standard_normal((N, 2))     # N draws of 2D shock
    dc = eps @ h_vec                # shape (N,)
    c[:, t+1] = c[:, t] + dc

# Cross-section variance at each date
var_c = np.var(c, axis=0)
theory = np.arange(T_sim + 1) * np.dot(h_vec, h_vec)

fig, ax = plt.subplots()
ax.plot(var_c, label='simulated cross-section variance', lw=2)
ax.plot(theory, label=r'theoretical: $t \cdot h h^\top$',
        linestyle='--', color='C3', lw=2)
ax.set_xlabel('period $t$')
ax.set_ylabel('cross-section variance of $c$')
ax.legend()
plt.show()
```

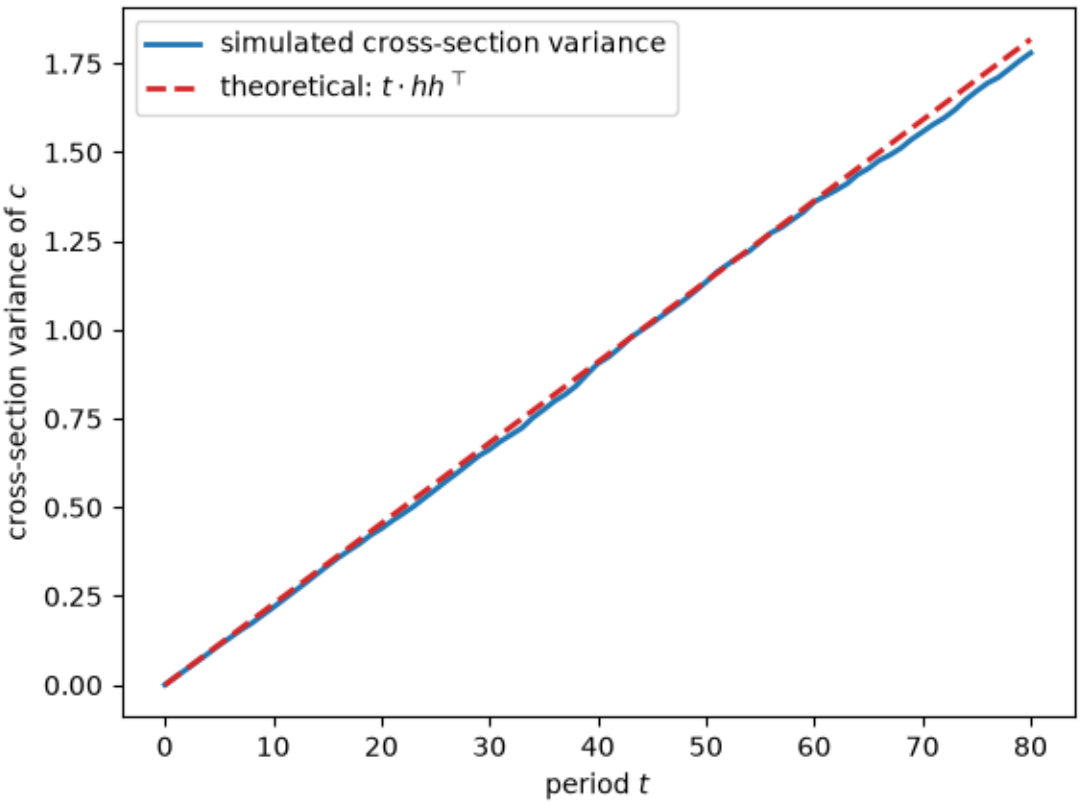

Fig. 87.1: Spreading consumption cross sections

87.4 A borrowers and lenders economy

Up to now we have set $R = \beta^{-1}$ and taken it as determined outside the model ("small open economy").

Following ideas of Bewley [1977], we can construct a **closed economy** in which $R = \beta^{-1}$ is an **equilibrium outcome**.

A continuum of measure one of consumers, indexed by $i \in [0, 1]$, trade a risk-free one-period bond with price β.

All consumers have the same preferences and the same stochastic income process (87.4), but face **idiosyncratic** non-financial income shock process realizations.

Initial bond positions are zero: $b_0^i = 0$ for all i.

Initial endowment states z_0^i are independent draws from a common initial distribution.

Because the permanent component z_{1t} has a unit root, process (87.1) has no stationary distribution, so in the simulation below we draw the permanent component $z_{10}^i \sim N(0, 1)$ and draw the transitory component $z_{20}^i \sim N(0, \sigma_2^2)$ from its stationary distribution.

From (87.2), with $b_0^i = 0$, agent i's time-0 consumption is

$$c_0^i = (1 - \beta)\, \check{G}(I - \beta \check{A})^{-1} z_0^i \tag{87.6}$$

For $t \geq 1$, from (87.3):

$$c_{t+1}^i = c_t^i + h\, w_{t+1}^i, \qquad h = (1 - \beta)\, \check{G}(I - \beta \check{A})^{-1} \check{C} \tag{87.7}$$

Let Y denote the stationary mean of the cross-section average of non-financial income.

Integrating (87.6) over all agents:

$$\int_0^1 c_0^i \, di = (1 - \beta) \sum_{j=0}^{\infty} \beta^j \mathbb{E}_0 \int_0^1 y_j^i \, di = Y \tag{87.8}$$

because the continuum of idiosyncratic shocks averages to zero.

For future periods, integrating (87.7):

$$\int_0^1 c_{t+1}^i \, di = \int_0^1 c_t^i \, di + h \underbrace{\int_0^1 w_{t+1}^i \, di}_{=0} = Y$$

The goods market clears at every date at *constant* aggregate consumption equal to Y.

The bond market clears at zero net supply each period.

Thus $R = \beta^{-1}$ is an equilibrium outcome.

While the cross-section mean of consumption is constant, the cross-section *variance* grows without bound according to (87.5).

Initial differences in endowment draws z_0^i create permanent differences in consumption levels.

```
# Verify Bewley market clearing via simulation
# Online mean and variance avoid storing all paths.
rng = np.random.default_rng(0)
N_bew = 10000    # number of agents
T_bew = 60

# Draw initial states for the simulation.
```

(continues on next page)

(continued from previous page)

```
z0_i = rng.standard_normal((N_bew, 2)) * np.array([1.0, σ2])
c0_i = ((1 - β) * (M @ z0_i.T)).flatten()   # shape (N_bew,)

# Propagate consumption across agents.
mean_c = np.zeros(T_bew + 1)
var_c2 = np.zeros(T_bew + 1)
mean_c[0] = c0_i.mean()
var_c2[0] = c0_i.var()

c_now = c0_i.copy()
for t in range(T_bew):
    eps = rng.standard_normal((N_bew, 2))
    c_now = c_now + eps @ h_vec
    mean_c[t + 1] = c_now.mean()
    var_c2[t + 1] = c_now.var()

# Reuse initial consumption below.
c_bew_t0 = c0_i

fig, axes = plt.subplots(1, 2, figsize=(12, 4))

axes[0].plot(mean_c, lw=2, color='C0')
axes[0].axhline(mean_c[0], linestyle='--', color='C3', label='initial mean')
axes[0].set_xlabel('period $t$')
axes[0].set_ylabel('mean consumption')
axes[0].set_title('mean')
axes[0].legend()

axes[1].plot(var_c2, lw=2, color='C0', label='simulated variance')

axes[1].set_ylabel('variance of consumption')
axes[1].set_title('variance')
axes[1].legend()
fig.tight_layout()
plt.show()
```

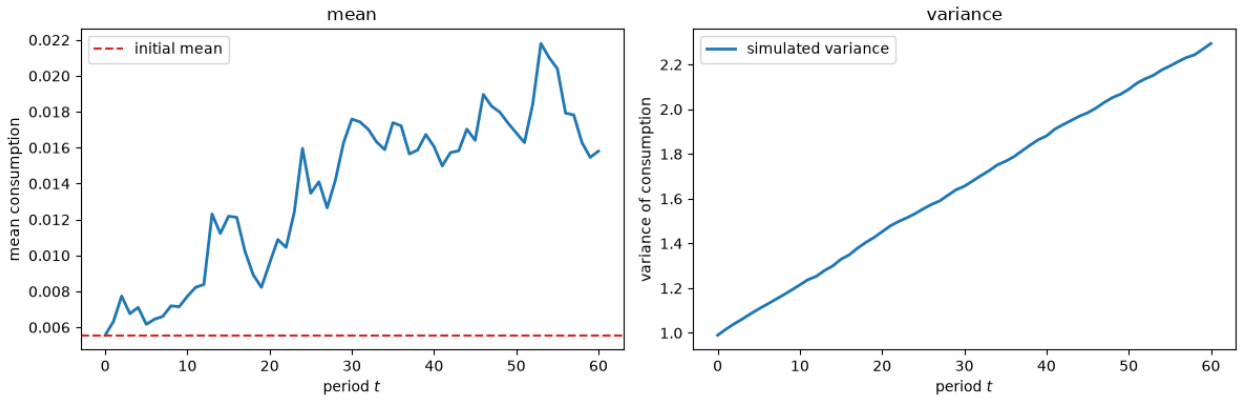

Fig. 87.2: Bewley economy cross-section moments

Because each consumer dislikes variation of consumption over time, each consumer would prefer a completely smoothed stream $c_t^i = c_0^i$ for all t.

Such an allocation is feasible because the cross-section average of income is constant.

The next section describes a complete-markets allocation that supports this outcome.

87.5 Consumption smoothing with complete markets

We replace the single bond with a **complete set of Arrow securities**.

The budget constraint becomes

$$c_t + b_{t-1}(z_t) = \int q(z_{t+1}|z_t)\, b_t(z_{t+1})\, dz_{t+1} + y_t \tag{87.9}$$

where $q(z_{t+1}|z_t)$ is the pricing kernel for one-period state-contingent claims and $b_t(z_{t+1})$ is the household's portfolio of Arrow securities chosen at t.

We guess (and verify) that the equilibrium pricing kernel is

$$q(z_{t+1}|z_t) = \beta\, \phi(z_{t+1}|z_t) \tag{87.10}$$

where $\phi(z_{t+1}|z_t)$ is the transition density of z.

This kernel prices a one-period risk-free bond at β, so $R = \beta^{-1}$, consistent with the incomplete-markets equilibrium.

We conjecture that the equilibrium delivers each consumer i a *constant* consumption level:

$$c_t^i = \bar{c}^i = c_0^i, \quad \forall\, t \geq 0 \tag{87.11}$$

where $c_0^i = (1-\beta)\, \check{G}(I - \beta \check{A})^{-1} z_0^i$ is the consumer's time-0 consumption in the incomplete-markets economy.

The state-contingent debt that supports constant consumption is

$$b_{t-1}(z_t) = \check{G}(I - \beta \check{A})^{-1} z_t - \frac{1}{1-\beta}\, \bar{c}^i \;\equiv\; b(z_t, \bar{c}^i) \tag{87.12}$$

Note that indebtedness depends only on the current Markov state z_t, *not* on the history of earlier states.

This absence of history dependence reflects the **complete risk sharing** attained under complete markets.

Substituting the pricing kernel (87.10) and the portfolio conjecture (87.12) into the budget constraint (87.9) and using the law of iterated expectations confirms that the budget constraint simplifies to $c_t = \bar{c}^i$ in every state and period.

Under complete markets, the cross-section distribution of consumption is **time-invariant**.

Consumer i's rank in the consumption distribution is fixed forever.

A lucky initial draw z_0^i manifests itself as perpetually high consumption $\bar{c}^i$ and lower indebtedness $b(z_t^i, \bar{c}^i)$ across all future states.

This outcome contrasts with what happens in the incomplete-markets Bewley economy, where the cross-section variance of consumption grows without bound.

```
# Complete and incomplete consumption distributions
rng = np.random.default_rng(1)
N_cm = 5000
T_cm = 50

# Initial consumption draws (same as Bewley economy)
c0_cm = c_bew_t0[:N_cm]
```

(continues on next page)

(continued from previous page)

```
# Incomplete markets: consumption evolves (random walk)
c_inc = np.zeros((N_cm, T_cm + 1))
c_inc[:, 0] = c0_cm
for t in range(T_cm):
    eps = rng.standard_normal((N_cm, 2))
    c_inc[:, t+1] = c_inc[:, t] + eps @ h_vec

# Complete markets: consumption stays constant
c_comp = np.tile(c0_cm[:, np.newaxis], T_cm + 1)

fig, axes = plt.subplots(1, 2, figsize=(12, 4))

for t_plot, color in zip([0, 10, 30, 50], ['C0', 'C1', 'C3', 'C4']):
    axes[0].hist(c_inc[:, t_plot], bins=60, alpha=0.4,
                 label=f't = {t_plot}', color=color, density=True)
axes[0].set_xlabel('$c$')
axes[0].set_ylabel('density, incomplete markets')
axes[0].set_title('incomplete markets')
axes[0].legend(fontsize=9)

for t_plot, color in zip([0, 10, 30, 50], ['C0', 'C1', 'C3', 'C4']):
    axes[1].hist(c_comp[:, t_plot], bins=60, alpha=0.4,
                 label=f't = {t_plot}', color=color, density=True)
axes[1].set_xlabel('$c$')
axes[1].set_ylabel('density, complete markets')
axes[1].set_title('complete markets')
axes[1].legend(fontsize=9)
fig.tight_layout()
plt.show()
```

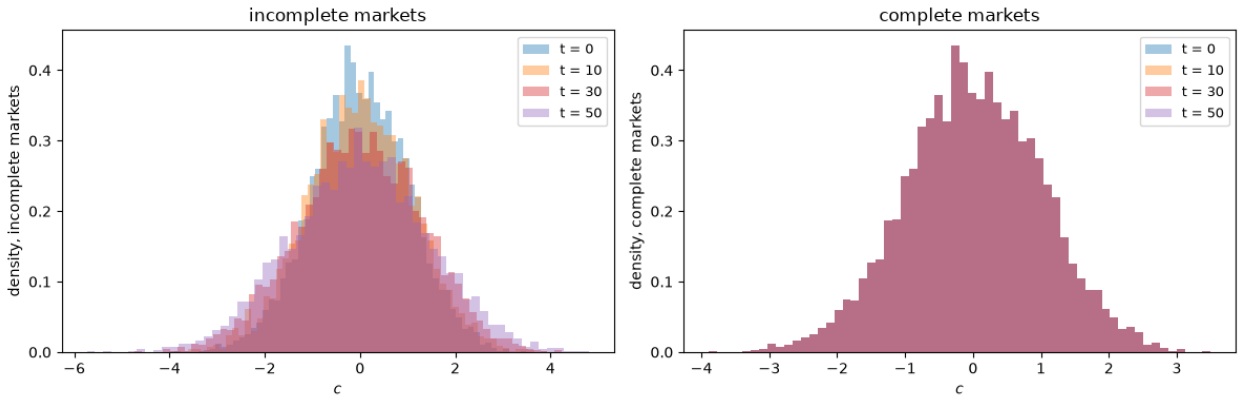

Fig. 87.3: Cross section distributions with incomplete and complete markets

Note

Under **complete markets** the histogram stays the same across all t (distributions coincide perfectly), while under **incomplete markets** distributions spread out over time.

So far the consumer fully trusts his stochastic income model.

In *Robust Consumption Smoothing and Precautionary Savings* we relax that assumption and let the consumer seek decision rules that are robust to plausible misspecifications.

A Robust LQ Bewley Model then returns to the Bewley economy studied here and shows that a cross-section of consumers with different concerns about misspecification can reproduce exactly the equilibrium of this lecture.

The optimal robust rule takes the same form as the rule above, but under a distorted model of the income process that looks more persistent than the approximating one.

87.6 Exercises

Exercise 87.6.1

This exercise studies how patience governs the speed at which the cross-section of consumption spreads out.

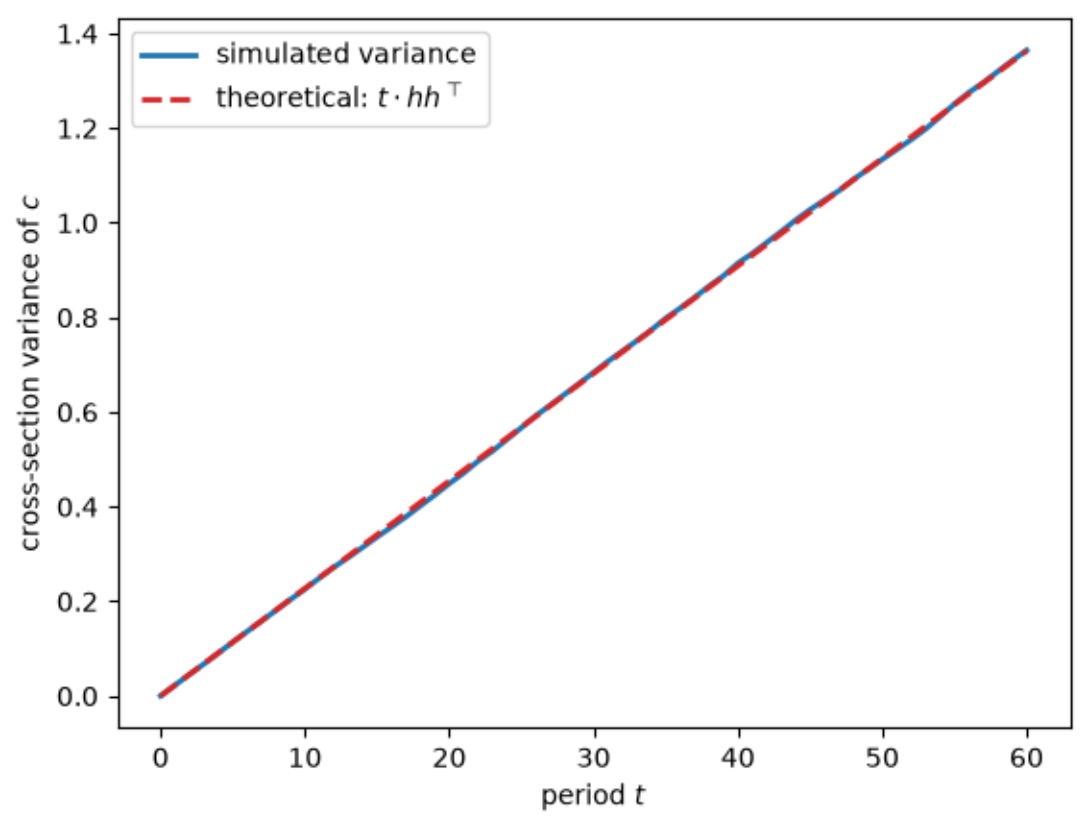
From (87.5), the cross-section variance of consumption grows by $hh^\top = \sigma_1^2 + (1-\beta)^2\sigma_2^2$ per period.

1. Compute this per-period growth rate for $\beta \in \{0.90, 0.95, 0.99\}$ and report the permanent and transitory contributions separately.
2. Confirm by simulation that the cross-section variance grows linearly at the predicted rate for $\beta = 0.95$.
3. Explain why increasing β slows the spreading due to transitory shocks but leaves the contribution of permanent shocks unchanged.

Solution

Here is one solution:

```
for b in (0.90, 0.95, 0.99):
    perm = σ1**2
    tran = (1 - b)**2 * σ2**2
    print(f"β = {b}:  growth = {perm + tran:.5f}  "
          f"(permanent {perm:.5f}, transitory {tran:.5f})")
```



```
β = 0.9:  growth = 0.02340  (permanent 0.02250, transitory 0.00090)
β = 0.95:  growth = 0.02272  (permanent 0.02250, transitory 0.00023)
β = 0.99:  growth = 0.02251  (permanent 0.02250, transitory 0.00001)
```

```
rng = np.random.default_rng(7)
N, T_sim = 20000, 60
hh = float(h_vec @ h_vec)

c = np.zeros((N, T_sim + 1))
for t in range(T_sim):
    c[:, t + 1] = c[:, t] + rng.standard_normal((N, 2)) @ h_vec

var_c = c.var(axis=0)
theory = np.arange(T_sim + 1) * hh

fig, ax = plt.subplots()
ax.plot(var_c, lw=2, label='simulated variance')
ax.plot(theory, lw=2, linestyle='--', color='C3',
        label=r'theoretical: $t\cdot h h^\top$')
ax.set_xlabel('period $t$')
ax.set_ylabel('cross-section variance of $c$')
ax.legend()
plt.show()
```

The permanent contribution σ_1^2 does not depend on β because a permanent shock is capitalised one-for-one into consumption regardless of patience.

The transitory contribution $(1-\beta)^2\sigma_2^2$ shrinks as $\beta \to 1$ because a more patient consumer smooths a transitory shock over a longer horizon, moving consumption by only the small annuity value $(1-\beta)$.

Exercise 87.6.2

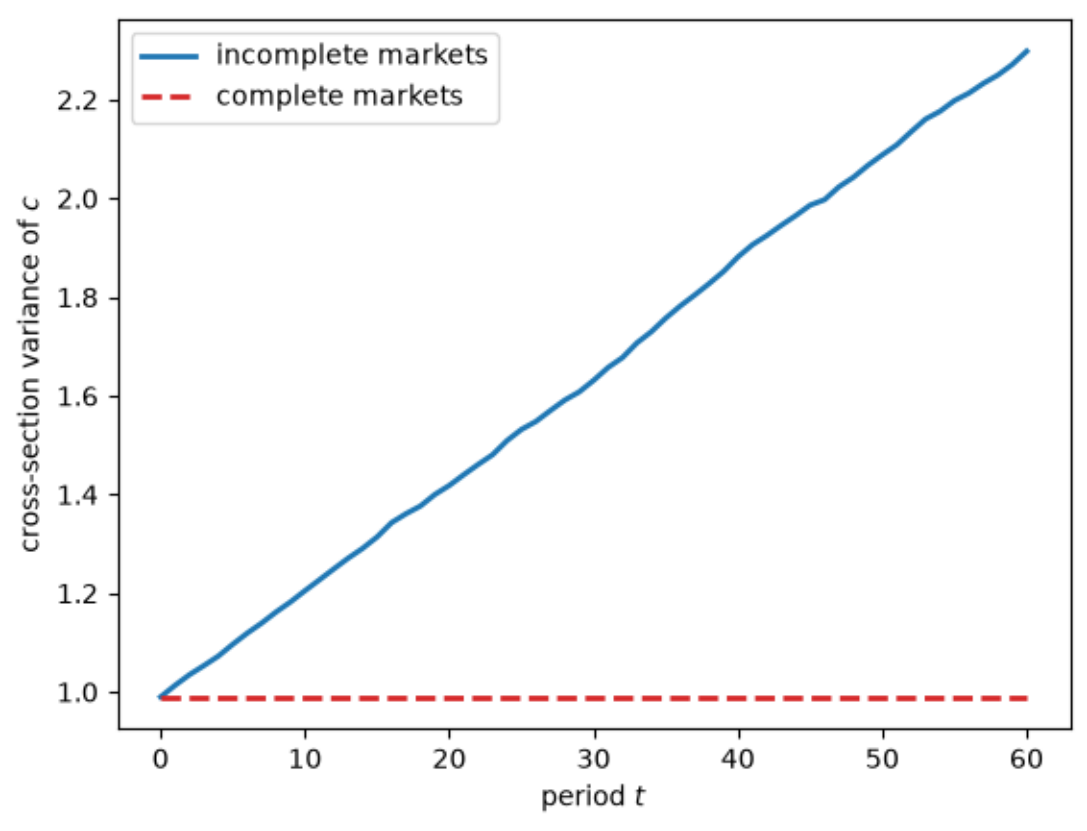
This exercise contrasts the cross-section variance of consumption under incomplete and complete markets.

Start all consumers from the initial consumption draws `c_bew_t0` computed above.

1. Compute the cross-section variance at each date $t = 0, 1, \ldots, 60$ under incomplete markets (consumption is a random walk) and under complete markets (consumption is constant).
2. Plot the two variance paths on the same axes and comment on the difference.

Solution

Here is one solution:



```
rng = np.random.default_rng(11)
T = 60
c0 = c_bew_t0

# Incomplete markets: random-walk consumption
```

```
c_inc = np.zeros((len(c0), T + 1))
c_inc[:, 0] = c0
for t in range(T):
    c_inc[:, t + 1] = c_inc[:, t] + rng.standard_normal((len(c0), 2)) @ h_vec

var_inc = c_inc.var(axis=0)
var_comp = np.full(T + 1, c0.var())   # complete markets: constant consumption

fig, ax = plt.subplots()
ax.plot(var_inc, lw=2, label='incomplete markets')
ax.plot(var_comp, lw=2, linestyle='--', color='C3', label='complete markets')
ax.set_xlabel('period $t$')
ax.set_ylabel('cross-section variance of $c$')
ax.legend()
plt.show()
```

Under incomplete markets the variance rises linearly without bound: each consumer accumulates an independent random walk of consumption innovations.

Under complete markets the variance is flat: each consumer locks in a constant consumption level $\bar{c}^i$, so the cross-section distribution never changes.

Exercise 87.6.3

This exercise shows how complete markets freeze each consumer's *rank* in the consumption distribution.

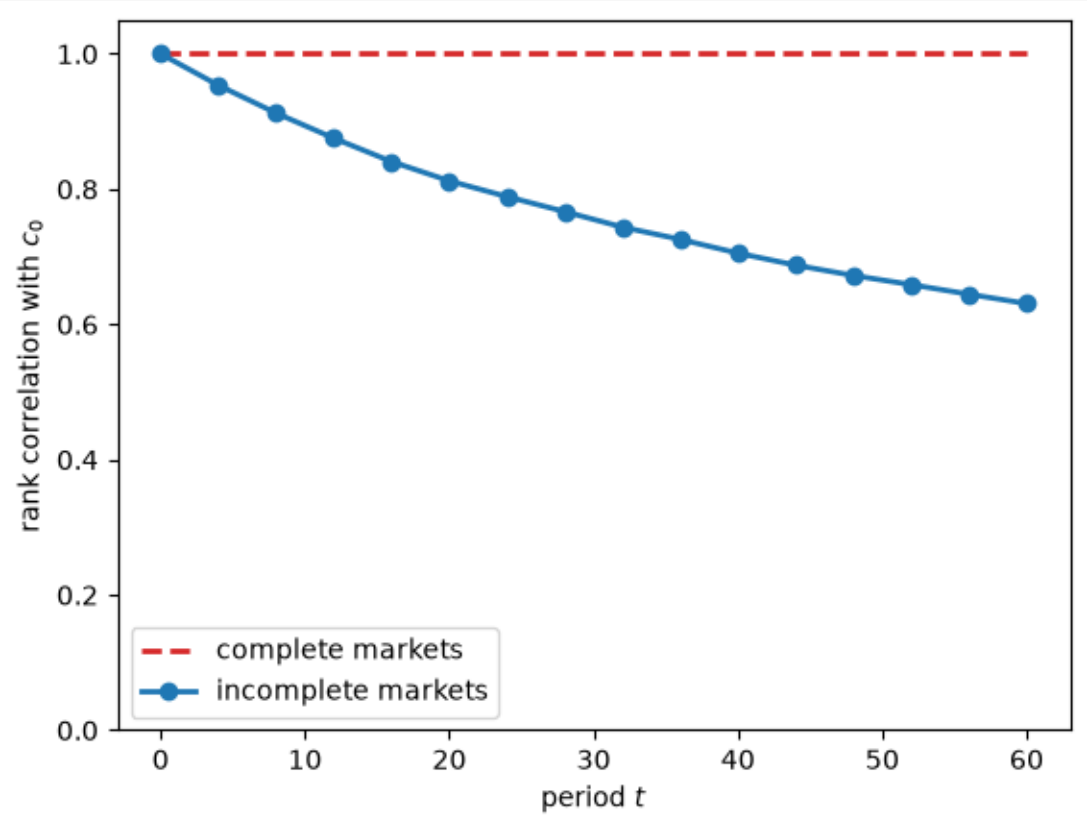
Under complete markets consumption is constant, so a consumer's position in the cross-section distribution never

changes; under incomplete markets the random walk gradually scrambles ranks.

1. Simulate consumption paths under both market structures, starting from `c_bew_t0`.
2. Compute the Spearman rank correlation between consumption at $t = 0$ and at later dates t under each market structure, and plot it against t.
3. Interpret the result.

Solution

Here is one solution:



```
from scipy.stats import spearmanr

rng = np.random.default_rng(3)
T = 60
c0 = c_bew_t0

c_inc = np.zeros((len(c0), T + 1))
c_inc[:, 0] = c0
for t in range(T):
    c_inc[:, t + 1] = c_inc[:, t] + rng.standard_normal((len(c0), 2)) @ h_vec

dates = np.arange(0, T + 1, 4)
rank_inc = [spearmanr(c_inc[:, 0], c_inc[:, t]).statistic for t in dates]
rank_comp = [1.0 for _ in dates]   # constant consumption ⇒ ranks fixed

fig, ax = plt.subplots()
ax.plot(dates, rank_comp, lw=2, linestyle='--', color='C3',
        label='complete markets')
ax.plot(dates, rank_inc, lw=2, marker='o', color='C0',
        label='incomplete markets')
ax.set_xlabel('period $t$')
ax.set_ylabel(r'rank correlation with $c_0$')
ax.set_ylim(0, 1.05)
ax.legend()
plt.show()
```

Under complete markets the rank correlation stays exactly one: each consumer keeps the rank determined by the initial draw z_0^i forever.

Under incomplete markets the rank correlation decays toward zero as the accumulated random walk reshuffles who is rich and who is poor, even though every consumer faces the same income process.

88.1 Overview

This lecture studies a robust version of the LQ permanent income model due to Hansen *et al.* [1999] and Hansen and Sargent [2008].

A consumer who distrusts his specification of the labor income process engages in a form of precautionary savings.

This is the third of four lectures on the LQ permanent income model.

It builds on *The LQ Permanent Income Model*, which develops the standard model, and *Consumption Smoothing with Incomplete and Complete Markets*, which studies its cross-section and market-structure implications.

The sequel, *A Robust LQ Bewley Model*, uses the results developed here to build a Bewley economy populated by consumers who differ in how much they distrust their income model.

Our description of the model with concerns about robustness includes

- how, for quantities, a concern for robustness is observationally equivalent to an increase in impatience
- how the worst-case model that the consumer uses to shape his decision rule distorts the baseline model's endowment process toward greater persistence
- a **breakdown point** beyond which the robust control problem ceases to have a solution
- a frequency-domain representation of the effects of concerns about misspecification of the endowment process
- a detection-error-probability characterization of the amount of model uncertainty

A recurring theme is that a single scalar α^2, the variance of the innovation to the consumer's marginal utility, summarises everything about the endowment process that matters for robustness.

Let's begin with some imports.

```
import numpy as np
import matplotlib.pyplot as plt
```

88.2 A brief review

We recall the essentials from *The LQ Permanent Income Model* and *Consumption Smoothing with Incomplete and Complete Markets*.

88.2.1 Notation

Because a robust decision maker guards against distortions to the mean of a shock, we need separate symbols for the shock and for the distortion.

We therefore adopt the following conventions, which differ in three places from the two preceding lectures.

Note

- w_{t+1} is the baseline IID shock, as in *The LQ Permanent Income Model*, and v_{t+1} is a **distortion** to its conditional mean, as in *Robust Permanent Income and Pricing*.
- $\sigma \leq 0$ is the **robustness parameter**. The standard deviations of the two endowment shocks, written σ_1 and σ_2 in the preceding lectures, are renamed η_1 and η_2 here so that σ is free.
- a_t denotes the consumer's **net assets**, equal to minus the debt b_t of *The LQ Permanent Income Model*. This frees b_t for the preference shifter of Hansen *et al.* [1999].

88.2.2 The model

A consumer with quadratic utility and discount factor β faces the endowment process

$$
\begin{aligned}
z_{t+1} &= \check{A}\, z_t + \check{C}\, w_{t+1} \\
y_t &= \check{G}\, z_t
\end{aligned}
\tag{88.1}
$$

The optimal decision rule has a state-space representation in which the state is current consumption c_t and the exogenous endowment state z_t:

$$\begin{aligned} c_{t+1} &= c_t + (1-\beta)\,\check{G}(I-\beta\check{A})^{-1}\check{C}\,w_{t+1} \\ a_t &= \frac{1}{1-\beta}\,c_t - \check{G}(I-\beta\check{A})^{-1}z_t \\ y_t &= \check{G}\,z_t \\ z_{t+1} &= \check{A}\,z_t + \check{C}\,w_{t+1} \end{aligned} \tag{88.2}$$

We again use the two-factor endowment $y_t = z_{1t} + z_{2t}$,

$$\begin{pmatrix} z_{1,t+1} \\ z_{2,t+1} \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} z_{1t} \\ z_{2t} \end{pmatrix} + \begin{pmatrix} \eta_1 & 0 \\ 0 & \eta_2 \end{pmatrix} \begin{pmatrix} w_{1,t+1} \\ w_{2,t+1} \end{pmatrix} \tag{88.3}$$

with z_{1t} a permanent component and z_{2t} a purely transitory component.

88.2.3 The consumption innovation

One scalar built from (88.2) will do all of the work below.

The first line of (88.2) says that consumption is a random walk whose innovation is $h\,w_{t+1}$, where

$$h = (1-\beta)\,\check{G}(I-\beta\check{A})^{-1}\check{C} \tag{88.4}$$

Define α^2 to be the variance of that innovation,

$$\alpha^2 = hh^\top = (1-\beta)^2\,\check{G}(I-\beta\check{A})^{-1}\check{C}\check{C}^\top(I-\beta\check{A}^\top)^{-1}\check{G}^\top \tag{88.5}$$

For the two-factor endowment (88.3) we have $\check{A} = \mathrm{diag}(1,0)$, $\check{C} = \mathrm{diag}(\eta_1,\eta_2)$ and $\check{G} = \begin{pmatrix} 1 & 1 \end{pmatrix}$, so that $(I-\beta\check{A})^{-1} = \mathrm{diag}((1-\beta)^{-1},1)$ and

$$h = \begin{pmatrix} \eta_1 & (1-\beta)\eta_2 \end{pmatrix}, \qquad \alpha^2 = \eta_1^2 + (1-\beta)^2\,\eta_2^2 \tag{88.6}$$

The permanent shock variance η_1^2 enters with coefficient 1 because a unit permanent shock is *fully* capitalised into consumption.

The transitory shock variance η_2^2 enters with the small coefficient $(1-\beta)^2$ because only its annuity value is consumed.

This scalar does triple duty across the three lectures of this suite.

Note

α^2 is simultaneously

- the variance of the consumption innovation in *The LQ Permanent Income Model*,
- the rate at which the cross-section variance of consumption grows with age in *Consumption Smoothing with Incomplete and Complete Markets*, and
- the quantity that, multiplied by σ, governs every robustness result in this lecture.

Robust Permanent Income and Pricing writes the same object as θ^2.

The following cell fixes the calibration used below.

```
β = 0.95        # discount factor, so R = 1/β
η1 = 0.15       # std of permanent shock
η2 = 0.30       # std of transitory shock

R = 1 / β
α2 = η1**2 + (1 - β)**2 * η2**2
α = np.sqrt(α2)

print(f"α^2 = {α2:.6f}")
print(f"  permanent  η1^2          = {η1**2:.6f} "
      f"({100 * η1**2 / α2:5.1f}% of α^2)")
print(f"  transitory (1-β)^2 η2^2 = {(1 - β)**2 * η2**2:.6f} "
      f"({100 * (1 - β)**2 * η2**2 / α2:5.1f}% of α^2)")
```

```
α^2 = 0.022725
  permanent  η1^2          = 0.022500 ( 99.0% of α^2)
  transitory (1-β)^2 η2^2 = 0.000225 (  1.0% of α^2)
```

Permanent shocks account for almost all of α^2 in this calibration.

88.3 A robust permanent income model

88.3.1 Robustness and precautionary savings

We now study a consumer who *distrusts* his specification of the stochastic process governing his labor income.

The model is due to Hansen *et al.* [1999] (HST), who estimated it on US quarterly consumption and investment data.

For a fuller treatment of the HST model and its asset-pricing implications, see *Robust Permanent Income and Pricing*.

A consumer who fears model misspecification engages in a form of **precautionary savings** that is distinct from the usual precautionary motive, which requires a convex marginal utility.

Here, the precautionary motive arises because the consumer wants to protect against misspecification of the **conditional means** of income shocks, and it operates even with quadratic preferences.

HST showed an important **observational equivalence** result: for quantities (c_t, i_t) alone, a concern for robustness is indistinguishable from an increase in impatience, that is, a decrease in β.

We develop this result carefully below.

88.3.2 The HST model

HST's model features a planner with preferences over consumption streams $\{c_t\}$, mediated through **service streams** $\{s_t\}$.

Let b be a preference shifter, or utility bliss point.

The **Bellman equation for the robust planner** is

$$-x^\top P x - p = \sup_c \inf_{v^*} \left\{ -(s-b)^2 + \beta\left(\theta\,(v^*)^\top v^* - \mathbb{E}\,(x^*)^\top P x^* - p\right)\right\} \tag{88.7}$$

subject to the household technology, capital accumulation, endowment dynamics, and the state law:

$$\begin{aligned} s &= (1+\lambda)c - \lambda h \\ h^* &= \delta_h h + (1-\delta_h)c \\ k^* &= \delta_k k + i \\ c + i &= \gamma k + d \\ \begin{pmatrix} d \\ b \end{pmatrix} &= Uz \\ z^* &= A_{22} z + C_2(w^* + v^*) \end{aligned} \tag{88.8}$$

Here * denotes the next-period value; c is consumption; s is the scalar service measure; h is a habit stock; k is the capital stock; i is investment; d is an endowment shock; b is a **preference shock**; γ is the marginal product of capital; $w^* \sim N(0, I)$ is the baseline shock; and v^* is a **distortion** to the conditional mean of w^* chosen by a minimizing agent.

The penalty parameter θ governs the consumer's concern about robustness.

A large θ makes distortions expensive and so restrains the minimizing agent.

We use the transformation

$$\sigma = -\theta^{-1} \leq 0, \qquad \theta \in (0, \infty] \tag{88.9}$$

so that $\sigma = 0$, equivalently $\theta = \infty$, corresponds to no robustness concern, and $\sigma < 0$ to an increasing concern.

When $\lambda > 0$ and $\delta_h \in (0, 1)$, the technology (88.8) accommodates **habit persistence** or durability, and the stock h_t is a geometric weighted average of current and past consumption.

Equation $c_t + k_t = Rk_{t-1} + d_t$ with $R = \delta_k + \gamma$ combines capital accumulation with a linear production technology, so R is the physical gross return on capital.

Let $x_t^\top = [h_{t-1},\, k_{t-1},\, z_t^\top]$.

The state transition equation is

$$x_{t+1} = A\, x_t + B\, u_t + C(w_{t+1} + v_{t+1}) \tag{88.10}$$

where $u_t = c_t$ and v_{t+1} is the distortion to the conditional mean of w_{t+1}.

HST estimated the model on US quarterly data from 1970Q1 to 1996Q3, using nondurables plus services for consumption and durable consumption plus gross private investment for investment.

They imposed $\beta R = 1$ and $\delta_k = 0.975$, so γ is pinned down once β is estimated.

Two of their preference estimates are worth recording.

Parameter	Habit	No habit
β	0.997	0.997
δ_h	0.682	—
λ	2.443	0
$2 \times \log L$	779.05	762.55

At a quarterly frequency, $\beta = 0.997$ implies an annual real interest rate of $\beta^{-4} - 1 \approx 1.2\%$.

The remaining estimated parameters govern the exogenous d_t and b_t processes and are reported in Appendix A of Hansen *et al.* [1999].

88.3.3 Solution when $\sigma = 0$

When $\sigma = 0$ the objective reduces to

$$\mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \{-(s_t - b_t)^2\} \tag{88.11}$$

Forming a Lagrangian and deriving first-order conditions yields

$$\begin{aligned} \mu_{st} &= b_t - s_t \\ \mu_{ct} &= (1+\lambda)\mu_{st} + (1-\delta_h)\mu_{ht} \\ \mu_{ht} &= \beta \mathbb{E}_t[\delta_h \mu_{h,t+1} - \lambda \mu_{s,t+1}] \\ \mu_{ct} &= \beta R \, \mathbb{E}_t \mu_{c,t+1} \end{aligned} \tag{88.12}$$

Here μ_{st} is the **marginal valuation of consumption services**, which summarises the endogenous state variables h_{t-1} and k_{t-1}.

The last line of (88.12) implies $\mathbb{E}_t \mu_{c,t+1} = (\beta R)^{-1} \mu_{ct}$, so μ_{st} is a martingale when $\beta R = 1$:

$$\mu_{st} = \mu_{s,t-1} + \nu^\top w_t \tag{88.13}$$

for some vector ν.

Solving forward and substituting gives

$$\mu_{st} = \Psi_1 k_{t-1} + \Psi_2 h_{t-1} + \Psi_3 \sum_{j=0}^{\infty} R^{-j} \mathbb{E}_t b_{t+j} + \Psi_4 \sum_{j=0}^{\infty} R^{-j} \mathbb{E}_t d_{t+j} \tag{88.14}$$

where

$$\Psi_1 = -(1+\lambda) R (1 - R^{-2}\beta^{-1}) \left[\frac{1 - R^{-1}\tilde{\delta}_h}{1 - R^{-1}\tilde{\delta}_h + \lambda(1 - \tilde{\delta}_h)} \right], \quad \Psi_4 = R^{-1}\Psi_1 \tag{88.15}$$

and $\tilde{\delta}_h = (\delta_h + \lambda)/(1+\lambda)$.

In the widely-studied special case $\lambda = \delta_h = 0$, we have $s_t = c_t$ and $\mu_{st} = b_t - c_t$, and the marginal propensity to consume out of **non-human wealth** $R k_{t-1}$ equals that out of **human wealth** $\sum_{j=0}^{\infty} R^{-j} \mathbb{E}_t d_{t+j}$, a well-known feature of the LQ model.

The formula for μ_{st} can be written as $\mu_{st} = M_s x_t$ where x_t follows (88.10).

It follows that

$$\nu^\top = M_s C, \qquad \alpha = \sqrt{\nu^\top \nu} = \sqrt{M_s C C^\top M_s^\top} \tag{88.16}$$

This α is the same scalar we met in (88.5).

To see why, set $\lambda = \delta_h = 0$ and hold b_t fixed, so that $\mu_{st} = b - c_t$ and the innovation to μ_{st} is minus the innovation to c_t.

Hence $\nu^\top = -h$ and $\alpha^2 = \nu^\top \nu = h h^\top$, exactly as in (88.5).

The sign is irrelevant because only α^2 ever appears.

88.4 Observational equivalence

HST state an observational-equivalence theorem.

Theorem 88.4.1 (Observational equivalence, I)

Fix all parameters except (σ, β) and suppose $\beta R = 1$ when $\sigma = 0$.

There exists $\underline{\sigma} < 0$ such that for any $\sigma \in (\underline{\sigma}, 0)$, the optimal consumption-investment plan for $(0, \beta)$ is also chosen by a robust decision maker with parameters $(\sigma, \hat{\beta}(\sigma))$, where

$$\hat{\beta}(\sigma) = \frac{1}{R} + \frac{\sigma\alpha^2}{R-1} = \beta + \frac{\sigma\alpha^2\beta}{1-\beta} \tag{88.17}$$

and $\hat{\beta}(\sigma) < \beta$.

The second equality in (88.17) uses $R = \beta^{-1}$ and will be the form we use in computations.

Since $R > 1$ and $\alpha^2 > 0$, a more negative σ, meaning a stronger robustness concern, lowers $\hat{\beta}$.

A robust consumer wants to save more because his alter ego, a utility-minimizing agent, makes future income look worse than the approximating model predicts.

A lower discount factor makes a consumer less patient and therefore reduces saving.

When these two forces are balanced according to (88.17), consumption plans are identical across $(\sigma, \hat{\beta}(\sigma))$ pairs.

Proof. When $\beta R = 1$ and $\sigma = 0$, the marginal utility μ_{st} obeys the martingale

$$\mu_{st} = \mu_{s,t-1} + \alpha \tilde{w}_t \tag{88.18}$$

where $\tilde{w}_t$ is scalar IID with mean zero and unit variance.

Activating a concern about robustness, $\sigma < 0$, leads the utility-minimizing alter ego to set

$$\tilde{v}_t = K(\sigma, \hat{\beta})\, \mu_{s,t-1} \tag{88.19}$$

making the worst-case model for μ_{st}

$$\mu_{st} = \zeta\, \mu_{s,t-1} + \alpha\, \tilde{w}_t, \qquad \zeta \equiv 1 + \alpha\, K(\sigma, \hat{\beta}) \tag{88.20}$$

For the allocation to remain the same, we require the robust Euler equation $\hat{\beta} R\, \hat{\mathbb{E}}_t \mu_{s,t+1} = \mu_{st}$ to hold under the worst-case model, which gives

$$\zeta = (\hat{\beta} R)^{-1} \tag{88.21}$$

The minimizing agent's Bellman equation, a pure forecasting problem, yields

$$\zeta = \frac{1}{1 - \sigma \alpha^2 P(\hat{\beta})} \tag{88.22}$$

where $P(\hat{\beta})$ solves the scalar Bellman equation

$$P(\hat{\beta}) = \frac{\hat{\beta} - 1 + \sigma\alpha^2 + \sqrt{(\hat{\beta} - 1 + \sigma\alpha^2)^2 + 4\sigma\alpha^2}}{-2\sigma\alpha^2} \tag{88.23}$$

Solving (88.21)-(88.23) for $\hat{\beta}$ gives exactly (88.17).

Equation (88.17) is the useful numerical object because it gives a straight-line map from the robustness parameter to the observationally equivalent discount factor.

88.4.1 Precautionary savings interpretation

The consumer's concern about model misspecification activates the precautionary savings motive that underlies the observational-equivalence theorem.

A concern about robustness makes the consumer save *more*.

Decreasing β makes the consumer save *less*.

The observational-equivalence theorem says that these two forces can be made to offset each other exactly.

In the special case $\lambda = \delta_h = 0$, $s_t = c_t$ and the consumption rule is

$$c_t = (1 - R^{-2}\beta^{-1}) \left[R k_{t-1} + \mathbb{E}_t \sum_{j=0}^{\infty} R^{-j} d_{t+j} \right] + \left(\frac{(R\beta)^{-1} - 1}{R - 1} \right) b \tag{88.24}$$

The **marginal propensity to consume** out of non-human wealth $R k_{t-1}$ *equals* that out of human wealth $\mathbb{E}_t \sum R^{-j} d_{t+j}$.

This equal-propensity property is a hallmark of the LQ model and *persists* when a concern for robustness is present, in contrast to usual precautionary-savings models with convex marginal utility.

Theorem 88.4.1 says that with $\sigma < 0$, the observationally equivalent $\hat{\beta}$ satisfies $\hat{\beta} < \beta$.

If the starting point has $\beta R = 1$, then $\hat{\beta} R < 1$.

For a non-robust consumer with discount factor $\hat{\beta}$ at the same interest rate, the Euler equation implies $\mathbb{E}_t c_{t+1} < c_t$, so expected consumption declines over time.

This downward drift is the impatience offset in *Theorem 88.4.1*.

It cancels the robust consumer's precautionary-savings motive, leaving the consumption and investment quantities unchanged.

The classical precautionary motive arises because

$$u'''(c) > 0 \;\Rightarrow\; \mathbb{E}_t u'(c_{t+1}) > u'(\mathbb{E}_t c_{t+1}) \;\Rightarrow\; \mathbb{E}_t c_{t+1} > c_t \tag{88.25}$$

This channel requires *convexity of marginal utility* and is absent with quadratic preferences.

In contrast, the robustness-based precautionary motive operates through distortions of **conditional means** of shocks, shifting the first moment of the innovation to non-financial income.

88.4.2 Observational equivalence and distorted expectations

The observational-equivalence result can be interpreted using a **Stackelberg multiplier game**.

After the minimizing agent has committed to a distortion process $\{v_{t+1}\}$, the maximizing consumer faces the following worst-case law of motion for the state X_t:

$$\begin{aligned} X_{t+1} &= (A - BF(\sigma, \hat{\beta}) + CK(\sigma, \hat{\beta}))X_t + C\, w_{t+1} \\ \begin{pmatrix} b_t \\ d_t \end{pmatrix} &= S X_t \end{aligned} \tag{88.26}$$

A robust consumer forms expectations of future income using the **distorted transition matrix** $A - BF + CK$ rather than the approximating transition matrix $A - BF$.

The distorted expectations operator $\hat{\mathbb{E}}_t$ satisfies

$$\hat{\mathbb{E}}_t X_{t+j} = (A - BF(\sigma, \hat{\beta}) + CK(\sigma, \hat{\beta}))^j X_t \tag{88.27}$$

Observational equivalence requires that the modified human-wealth formula

$$\hat{\Psi}_4 \sum_{j=0}^{\infty} R^{-j} \hat{\mathbb{E}}_t d_{t+j} \tag{88.28}$$

equals its benchmark counterpart $\Psi_4 \sum_{j=0}^{\infty} R^{-j} \mathbb{E}_t d_{t+j}$.

This is achieved by a mutual adjustment of the coefficients $\hat{\Psi}_j$ through $\hat{\beta}$ and of the distorted expectation operator $\hat{\mathbb{E}}_t$ through σ.

The worst-case eigenvalue of $A - BF + CK$ exceeds that of $A - BF$ in modulus, so the worst-case distortions make the income process *more persistent* than under the approximating model.

This is the precautionary motive in state-space form: the minimizing agent makes future income look more risky by introducing low-frequency persistence.

In the scalar reduction of the next section, this eigenvalue is ζ, and we verify that $\zeta > 1$ while the approximating model has a unit root.

88.4.3 Another observational equivalence result

Theorem 88.4.2 (Observational equivalence, II)

Fix all parameters except (σ, β) and consider a consumption-investment allocation for $(\hat{\sigma}, \hat{\beta})$ where $\hat{\beta}R = 1$ and $\hat{\sigma} < 0$.

Then there exists $\tilde{\beta} > \hat{\beta}$ such that the $(\hat{\sigma}, \hat{\beta})$ allocation also solves the $(0, \tilde{\beta})$ problem.

Theorem 88.4.1 showed that starting from a benchmark with $\beta R = 1$, activating robustness is equivalent to *reducing* β.

Theorem 88.4.2 goes in the opposite direction: the effects of activating a concern for robustness from a starting point with $\beta R = 1$ are replicated by *increasing* β while setting $\sigma = 0$.

In other words, when $\beta R = 1$, a concern for robustness operates like an *increase* in the discount factor, pushing $\beta R > 1$ and imparting an *upward drift* to the expected consumption profile.

Proof. With $\hat{\beta}R = 1$ and $\hat{\sigma} < 0$, the robust Euler equation implies

$$\hat{\mathbb{E}}_t \mu_{c,t+1} = \mu_{ct} \tag{88.29}$$

One seeks $\tilde{\beta} > \hat{\beta}$ and $\sigma = 0$ such that the same allocation solves the non-robust problem with discount factor $\tilde{\beta}$.

The key step is to observe that the worst-case distortion $K(\hat{\sigma}, \hat{\beta})$ introduces a drift in the marginal utility process that is equivalent to the drift produced by raising the discount factor above $\hat{\beta}$.

Equating the two drifts and solving the scalar Bellman equation for K yields

$$\tilde{\beta}(\hat{\sigma}) = \frac{\hat{\beta}(1+\hat{\beta})}{2(1+\hat{\sigma}\alpha^2)} \left[1 + \sqrt{1 - 4\hat{\beta}\,\frac{1+\hat{\sigma}\alpha^2}{(1+\hat{\beta})^2}} \right] \tag{88.30}$$

Setting $\hat{\sigma} = 0$ makes the square root equal $(1-\hat{\beta})/(1+\hat{\beta})$, so that $\tilde{\beta} = \hat{\beta}$.

Since $1 + \hat{\sigma}\alpha^2$ decreases as $\hat{\sigma}$ falls below zero, both the prefactor and the square root increase, so $\tilde{\beta} > \hat{\beta}$ whenever $\hat{\sigma} < 0$.

88.4.4 Comparing the two loci

Both (88.17) and (88.30) are closed forms, so we can plot them directly.

We start from a benchmark with $\beta R = 1$.

```
σ_grid = np.linspace(0.0, -0.16, 60)

# locus I: non-robust agent fixed at βR=1, report the robust twin's β̂(σ)
β_hat = β + σ_grid * α2 * β / (1 - β)

# locus II: robust agent fixed at βR=1, report the non-robust twin's β̃(σ̂)
q = 1 + σ_grid * α2
β_tilde = β * (1 + β) / (2 * q) * (1 + np.sqrt(1 - 4 * β * q / (1 + β)**2))
```

(continues on next page)

(continued from previous page)

```
fig, ax = plt.subplots()
ax.plot(-σ_grid, β_hat, lw=2, color='C3',
        label=r'locus I: robust twin $\hat\beta(\sigma) < \beta$')
ax.plot(-σ_grid, β_tilde, lw=2, color='C0',
        label=r'locus II: non-robust twin $\tilde\beta(\hat\sigma) > \beta$')
ax.axhline(β, color='k', linestyle=':', lw=1,
           label=r'benchmark $\beta$ ($\beta R = 1$)')
ax.set_xlabel(r'robustness concern $|\sigma|$')
ax.set_ylabel('discount factor of the equivalent agent')
ax.legend()
plt.show()
```

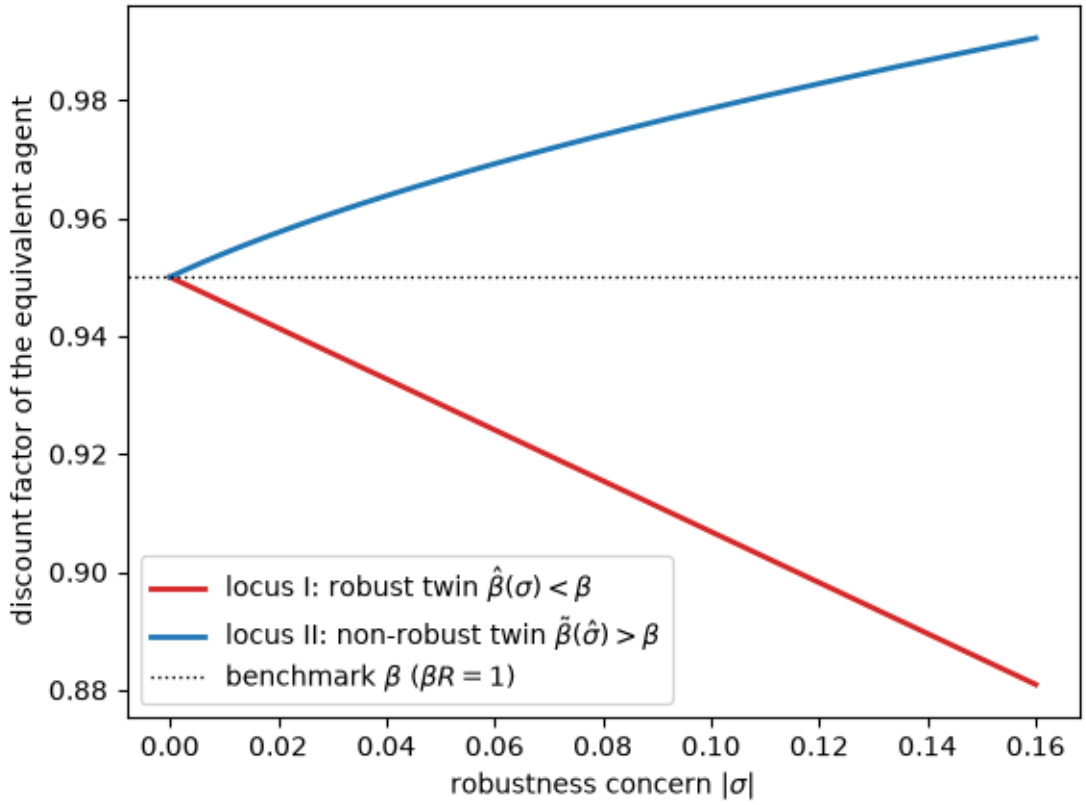

Fig. 88.1: Two observational-equivalence experiments. Locus I holds the *non-robust* agent fixed at $\beta R = 1$ and reports the *robust* twin's discount factor $\hat\beta(\sigma)$; locus II holds the *robust* agent fixed at $\beta R = 1$ and reports the *non-robust* twin's discount factor $\tilde\beta(\hat\sigma)$.

Both loci pass through the benchmark β at $\sigma = 0$ and separate as the robustness concern grows.

The key to reading Fig. 88.1 is that the two loci hold *different* agents fixed, so the discount factor plotted on the vertical axis refers to a different agent on each curve.

Locus I, from *Theorem 88.4.1*, holds the **non-robust** agent fixed at the benchmark $(\sigma = 0, \beta)$ with $\beta R = 1$ and reports the discount factor $\hat\beta(\sigma) < \beta$ of the **robust** agent that mimics it.

This is the sense in which HST call a concern for robustness observationally equivalent to a *lower* discount factor: because robustness already makes the agent save more, its discount factor must be lowered to hold the allocation at the benchmark.

Because the non-robust benchmark has $\beta R = 1$, its optimal consumption is a martingale, $\mathbb{E}_t c_{t+1} = c_t$.

The robust twin chooses the identical consumption process, so it too satisfies $\mathbb{E}_t c_{t+1} = c_t$.

The lower $\hat{\beta}$, which has $\hat{\beta} R < 1$, would on its own impart a downward drift, but the robust agent's precautionary saving offsets it exactly, leaving expected consumption flat.

Locus II, from *Theorem 88.4.2*, instead holds the **robust** agent fixed at $(\hat{\sigma}, \beta)$ with $\beta R = 1$ and reports the discount factor $\tilde{\beta}(\hat{\sigma}) > \beta$ of the **non-robust** agent that mimics it.

Here there is no impatience offset, so the common allocation inherits the robust agent's precautionary *upward* drift, which the non-robust twin reproduces through $\tilde{\beta} R > 1$.

The two experiments encode the *same* economics: a concern for robustness adds precautionary saving that acts like extra patience.

They differ only in which agent is anchored at $\beta R = 1$, and hence in whether the common saving motive shows up as an exactly-offsetting impatience adjustment, as in locus I where expected consumption is flat, or as an upward drift in expected consumption, as in locus II.

88.5 The scalar worst-case model

The proof of *Theorem 88.4.1* reduced the robust problem to a scalar forecasting problem in the marginal utility μ_{st}.

That scalar problem can be solved in closed form, which is worth doing because it makes the worst-case dynamics, the breakdown point, and the frequency-domain results all transparent.

88.5.1 A closed-form solution

Combining (88.21) with (88.17) and $R = \beta^{-1}$ gives the worst-case persistence directly:

$$\zeta(\sigma) = \frac{1}{\hat{\beta}(\sigma) R} = \frac{\beta}{\hat{\beta}(\sigma)} = \left[1 + \frac{\sigma \alpha^2}{1 - \beta}\right]^{-1} \tag{88.31}$$

This is the central formula of the lecture.

The worst-case persistence of marginal utility is exactly the ratio of the two discount factors.

Since $\hat{\beta}(\sigma) < \beta$ for $\sigma < 0$, we have $\zeta(\sigma) > 1$: the approximating model for μ_{st} has a unit root, and the worst-case model is mildly explosive.

That is the scalar counterpart of the statement in (88.26) that the worst-case transition matrix has a larger eigenvalue than the approximating one.

We can also solve (88.23) explicitly.

Write $u = \sigma \alpha^2$ and $\delta = 1 - \beta$, so that (88.17) reads $\hat{\beta} - 1 + u = (u - \delta^2)/\delta$.

The discriminant in (88.23) is then a **perfect square**:

$$(\hat{\beta} - 1 + u)^2 + 4u = \frac{(u - \delta^2)^2}{\delta^2} + 4u = \left(\frac{u + \delta^2}{\delta}\right)^2 \tag{88.32}$$

so the two roots of (88.23) are available in closed form:

$$P = -\frac{1}{1 - \beta} \qquad \text{and} \qquad P = \frac{1 - \beta}{\sigma \alpha^2} \tag{88.33}$$

Substituting into (88.22), the first root reproduces (88.31) while the second gives the constant $\zeta = R$, which violates the Euler equation (88.21) except at the single point where the two roots coincide.

So the economically relevant root is the constant $P = -(1-\beta)^{-1}$, independent of σ.

Note

Selecting the root numerically, by taking whichever of the two is closer to the target $(\hat{\beta}R)^{-1}$, is treacherous.

Because (88.32) is a perfect square, the square root is $|u+\delta^2|/\delta$, and the *sign* in front of it that selects $P = -(1-\beta)^{-1}$ flips as u crosses $-\delta^2$.

A solver that picks the root by a distance criterion will silently switch branches there.

88.5.2 The breakdown point

Theorem 88.4.1 asserts the existence of a lower bound $\underline{\sigma} < 0$ without saying what it is.

The scalar model tells us.

The minimizing agent's problem has a finite value only if the discounted worst-case state is square summable, that is, only if $\hat{\beta}\,\zeta^2 < 1$.

Using $\hat{\beta} = \beta/\zeta$ from (88.31), this condition is $\beta\zeta < 1$, or equivalently $\zeta < R$.

Substituting (88.31) and solving gives the **breakdown point**

$$\underline{\sigma} = -\frac{(1-\beta)^2}{\alpha^2} \tag{88.34}$$

At $\sigma = \underline{\sigma}$ three things happen at once.

- The discriminant (88.32) has a double root, so the two roots in (88.33) coincide.
- The worst-case persistence reaches $\zeta = R$, so $\hat{\beta}\zeta^2 = 1$ exactly.
- The observationally equivalent discount factor reaches $\hat{\beta} = \beta^2$.

For $\sigma < \underline{\sigma}$ the robust control problem has no solution, and any numerical answer reported there is meaningless.

We therefore restrict every plot below to $\sigma \in (\underline{\sigma}, 0]$.

88.5.3 Verifying the closed form

The following cell solves the quadratic (88.23) numerically and checks it against the closed forms (88.31) and (88.33).

```
def worst_case_persistence(σ, β, α2):
    """
    Worst-case persistence ζ(σ) of marginal utility on the
    observational-equivalence locus, from eq:rcs-zeta.
    """
    return 1 / (1 + σ * α2 / (1 - β))

def solve_scalar_riccati(σ, β, α2):
    """
    Solve the scalar Bellman equation eq:rcs-riccati by brute force and
    return both roots together with the implied persistence ζ = 1/(1-σα²P).
```

(continues on next page)

(continued from previous page)

```
    """
    β_hat = β + σ * α2 * β / (1 - β)
    u = σ * α2
    disc = (β_hat - 1 + u)**2 + 4 * u
    roots = np.array([(β_hat - 1 + u + s * np.sqrt(disc)) / (-2 * u)
                      for s in (1.0, -1.0)])
    return roots, 1 / (1 - u * roots)

σ_lo = -(1 - β)**2 / α2               # breakdown point, eq:rcs-breakdown
print(f"breakdown point  σ̲  = {σ_lo:.6f}")
print(f"there            β  = {β + σ_lo * α2 * β / (1 - β):.6f} "
      f"(β² = {β**2:.6f})")
print(f"                 ζ   = {worst_case_persistence(σ_lo, β, α2):.6f} "
      f"(R = {R:.6f})")

print(f"\n{'σ':>10}{'P (numerical roots)':>28}{'-1/(1-β)':>12}"
      f"{'ζ (num)':>12}{'ζ (closed)':>12}")
for σ in [-0.02, -0.05, -0.09, -0.105]:
    roots, ζs = solve_scalar_riccati(σ, β, α2)
    keep = np.argmin(np.abs(roots + 1 / (1 - β)))
    print(f"{σ:10.3f}{str(np.round(roots, 4)):>28}{-1 / (1 - β):12.4f}"
          f"{ζs[keep]:12.6f}{worst_case_persistence(σ, β, α2):12.6f}")
```

```
breakdown point  σ̲  = -0.110011
there            β  = 0.902500 (β² = 0.902500)
                 ζ   = 1.052632 (R = 1.052632)

         σ          P (numerical roots)    -1/(1-β)      ζ (num)   ζ (closed)
    -0.020          [ -20.    -110.011]    -20.0000    1.009173    1.009173
    -0.050          [-20.     -44.0044]    -20.0000    1.023253    1.023253
    -0.090          [-20.     -24.4469]    -20.0000    1.042650    1.042650
    -0.105          [-20.     -20.9545]    -20.0000    1.050114    1.050114
```

One root is pinned at $-(1-\beta)^{-1} = -20$ for every σ, exactly as (88.33) predicts, and the implied ζ agrees with the closed form to displayed precision.

Notice also that the two roots approach each other as σ falls toward $\underline{\sigma} \approx -0.11$.

The next figure plots the worst-case impulse response ζ^h over the admissible range.

```
horizons = np.arange(31)

fig, ax = plt.subplots()
for frac in [0.0, 0.4, 0.8, 0.98]:
    σ = frac * σ_lo
    ζ = worst_case_persistence(σ, β, α2)
    ax.plot(horizons, ζ**horizons, lw=2,
            label=rf'$\sigma={σ:.3f}$, $\zeta={ζ:.3f}$')

ax.set_xlabel('horizon $h$')
ax.set_ylabel(r'response of $\mu_{s,t+h}$')
ax.legend()
plt.show()
```

Fig. 88.2 shows that as σ falls, the minimizing agent converts the unit root of the approximating model into mild explo-

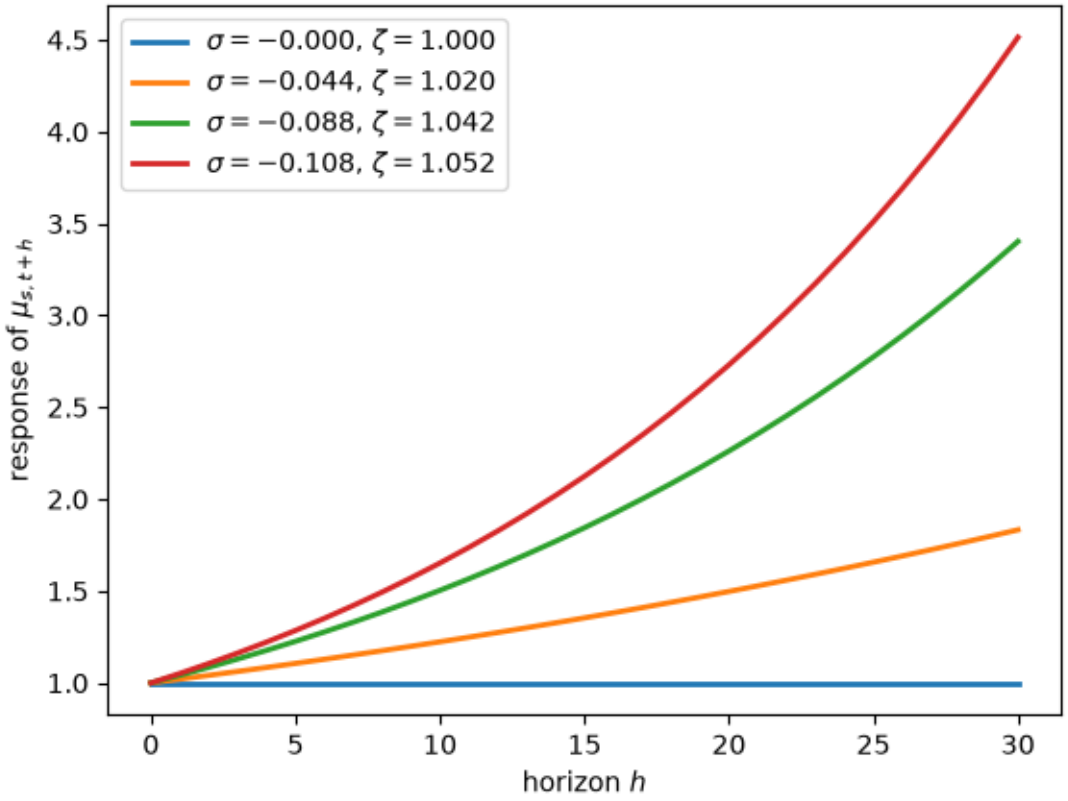

Fig. 88.2: Worst-case impulse response of marginal utility. The approximating model has a unit root; the worst-case model is increasingly explosive as σ falls toward the breakdown point $\underline{\sigma}$.

siveness.

At the breakdown point the response would grow at the gross interest rate R, so that the discounted worst-case state ceases to be square summable.

88.6 Frequency domain interpretation

The LQ permanent income framework has a natural frequency-domain interpretation.

The consumer's concave utility makes him dislike **high-frequency** fluctuations in consumption, which he smooths by adjusting savings.

High-frequency fluctuations are easy to smooth, so the consumer is automatically robust to misspecification of high-frequency features of the income process.

Low-frequency fluctuations are harder to smooth because they are more persistent.

In the frequency-domain notation of HST, the transfer function from shocks w_t to the target $s_t - b_t$ is $G(\cdot)$, and the frequency decomposition of the H_2 criterion is

$$H_2 = -\frac{1}{2\pi}\int_{-\pi}^{\pi} \text{trace}\big[G(\sqrt{\beta}\,e^{i\omega})^\top G(\sqrt{\beta}\,e^{i\omega})\big]\,d\omega \tag{88.35}$$

The evaluation at $\sqrt{\beta}\,e^{i\omega}$ rather than at $e^{i\omega}$ is essential and not merely conventional.

Both the approximating model and the worst-case model for μ_{st} are non-stationary, the first with a unit root and the second explosive, so neither has an ordinary spectral density.

Discounting by $\sqrt{\beta}$ is exactly what makes the object in (88.35) finite.

In the scalar model of *The scalar worst-case model*, the target is $s_t - b_t = -\mu_{st}$, and from (88.20) we can read off the transfer function and the discounted spectral density

$$G(z) = \frac{\alpha}{1-\zeta z}, \qquad S(\omega;\sigma) = \left|G(\sqrt{\hat\beta}\,e^{i\omega})\right|^2 = \frac{\alpha^2}{\left|1-\zeta\sqrt{\hat\beta}\,e^{i\omega}\right|^2} \tag{88.36}$$

This is finite precisely when $\zeta\sqrt{\hat\beta} < 1$, which is the condition $\hat\beta\zeta^2 < 1$ that defines the breakdown point (88.34).

So the frequency-domain object and the breakdown point are two views of the same restriction.

At $\sigma = 0$ we have $\zeta = 1$ and $\hat\beta = \beta$, and (88.36) reduces to the discounted spectral density of a random walk.

```
ω = np.linspace(0, np.pi, 400)

def spectrum(σ, β, α2):
    ζ = worst_case_persistence(σ, β, α2)
    β_hat = β / ζ
    return α2 / np.abs(1 - ζ * np.sqrt(β_hat) * np.exp(1j * ω))**2

S0 = spectrum(0.0, β, α2)

fig, axes = plt.subplots(1, 2, figsize=(11, 4))

for frac in [0.0, 0.4, 0.8, 0.95]:
    σ = frac * σ_lo
```

(continues on next page)

(continued from previous page)

```
    S = spectrum(σ, β, α2)
    axes[0].plot(ω, S, lw=2, label=rf'$\sigma={σ:.3f}$')
    axes[1].plot(ω, S / S0, lw=2, label=rf'$\sigma={σ:.3f}$')

axes[0].set_yscale('log')
axes[0].set_xlabel(r'frequency $\omega$')
axes[0].set_ylabel(r'$S(\omega;\sigma)$')
axes[0].set_title('discounted spectral density')
axes[0].legend()

axes[1].set_yscale('log')
axes[1].set_xlabel(r'frequency $\omega$')
axes[1].set_ylabel(r'$S(\omega;\sigma)\,/\,S(\omega;0)$')
axes[1].set_title('relative to the approximating model')
axes[1].legend()

fig.tight_layout()
plt.show()
```

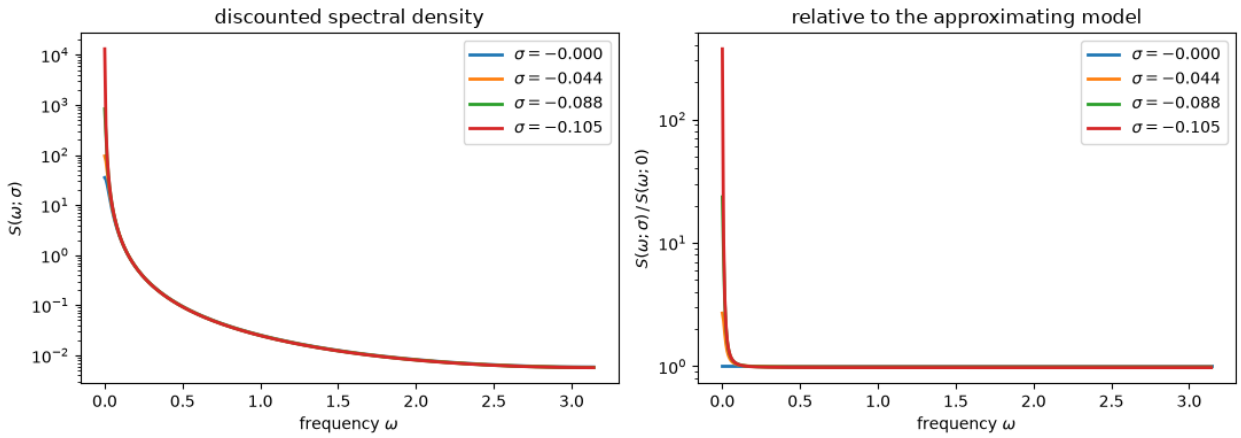

Fig. 88.3: Left: the discounted spectral density of the robust consumer's target. Right: the same densities relative to the approximating model. The minimizing agent concentrates its distortion at low frequencies, where the permanent income consumer is least able to smooth.

The left panel of Fig. 88.3 shows that $S(\omega;\sigma)$ is largest at $\omega \approx 0$, where the consumer's welfare is most sensitive to income variability.

The right panel makes the key point: the ratio $S(\omega;\sigma)/S(\omega;0)$ is sharply decreasing in ω.

Recognizing where the consumer is vulnerable, the minimizing agent concentrates the worst-case distortions at low frequencies, and it does so more aggressively as $|\sigma|$ grows.

The peak at $\omega = 0$ equals $\alpha^2/(1-\sqrt{\beta\zeta})^2$ and diverges as $\sigma \to \underline{\sigma}$, which is another way of seeing the breakdown point.

Because the distortion is $v_t = K\mu_{s,t-1}$ by (88.19), the spectral density of the distortion process is K^2 times the density of $\mu_{s,t-1}$, so it inherits the same low-frequency concentration.

88.7 Detection error probabilities

A natural way to discipline the choice of σ is to ask: **how difficult would it be to distinguish the approximating model from the worst-case model statistically?**

For a sample of length T, one can use a **log-likelihood ratio test** to compare the two hypotheses.

The **detection error probability** (DEP) is the probability of making the wrong decision using the log-likelihood ratio statistic when one does not know which model generated the data:

$$\text{DEP}(\sigma) = \frac{1}{2}\big[\mathbb{P}\{\text{prefer approximating} \mid \text{worst-case is true}\} + \mathbb{P}\{\text{prefer worst-case} \mid \text{approximating is true}\}\big] \tag{88.37}$$

When $\sigma = 0$ the two models are identical and DEP $= 0.5$.

As $|\sigma|$ increases the models diverge and the DEP falls toward zero.

In the scalar model the two hypotheses are fully explicit:

$$\text{approximating:}\quad \mu_{t+1} = \mu_t + \alpha w_{t+1}, \qquad \text{worst-case:}\quad \mu_{t+1} = \zeta(\sigma)\,\mu_t + \alpha w_{t+1} \tag{88.38}$$

Both have Gaussian innovations with the same variance α^2, so the log-likelihood ratio is a difference of sums of squares.

```
def simulate_paths(ζ, α, T, n_paths, seed):
    "Simulate n_paths draws of μ_{t+1} = ζ μ_t + α w_{t+1} from μ_0 = 0."
    rng = np.random.default_rng(seed)
    paths = np.zeros((n_paths, T + 1))
    shocks = rng.standard_normal((n_paths, T))
    for t in range(T):
        paths[:, t + 1] = ζ * paths[:, t] + α * shocks[:, t]
    return paths

def log_likelihood_ratio(paths, ζ, α):
    "Return log p_worst(path) - log p_approx(path)."
    lag, lead = paths[:, :-1], paths[:, 1:]
    return 0.5 * (np.sum(((lead - lag) / α)**2, axis=1)
                  - np.sum(((lead - ζ * lag) / α)**2, axis=1))

def detection_error_probability(ζ, α, T=40, n_paths=10_000, seed=1234):
    "Finite-sample DEP for the approximating and worst-case scalar laws."
    if np.isclose(ζ, 1.0):
        return 0.5
    approx = simulate_paths(1.0, α, T, n_paths, seed)
    worst = simulate_paths(ζ, α, T, n_paths, seed + 1)
    return 0.5 * (np.mean(log_likelihood_ratio(worst, ζ, α) < 0)
                  + np.mean(log_likelihood_ratio(approx, ζ, α) > 0))
```

We use $T = 40$, which is ten years of quarterly data.

Before plotting, it is worth noting a property that makes the DEP the right way to report a robustness concern.

The parameter σ is *not* scale free: it always enters through the product $\sigma\alpha^2$, and α^2 has the units of consumption squared.

Doubling the units in which consumption is measured therefore changes the numerical value of σ that represents a given concern for robustness.

The DEP has no such problem, because α cancels from the likelihood ratio in (88.38).

```
ζ_test = worst_case_persistence(0.6 * σ_lo, β, α2)
for scale in [0.5, 1.0, 2.0]:
    dep = detection_error_probability(ζ_test, scale * α)
    print(f"α scaled by {scale:>4}:  DEP = {dep:.4f}")
```

```
α scaled by  0.5:  DEP = 0.3334
α scaled by  1.0:  DEP = 0.3334
α scaled by  2.0:  DEP = 0.3334
```

The DEP depends only on ζ and on the sample size T.

```
σ_vals = np.linspace(0.0, 0.999 * σ_lo, 31)
ζ_vals = worst_case_persistence(σ_vals, β, α2)

fig, ax = plt.subplots()
for T, color in [(40, 'C0'), (160, 'C2')]:
    dep_vals = np.array([detection_error_probability(ζ, α, T=T)
                         for ζ in ζ_vals])
    ax.plot(-σ_vals, dep_vals, lw=2, color=color, label=f'$T = {T}$')

ax.set_ylim(0.0, 0.52)
ax.legend()
plt.show()
```

Note

HST suggested that a DEP above 0.2 is "plausible", meaning the models are still hard enough to distinguish statistically that a concern for robustness is warranted.

Values of σ with DEP ≥ 0.2 therefore define a set of plausible worst-case models.

Fig. 88.4 shows that the two disciplines interact in an interesting way.

At $T = 40$ the DEP curve reaches the 0.2 threshold essentially exactly at the breakdown point.

In other words, with ten years of quarterly data, every robustness concern that this model can represent at all is also statistically plausible: the mathematical limit binds first, and the statistical one is slack.

```
for frac in [0.6, 0.9, 0.999]:
    ζ = worst_case_persistence(frac * σ_lo, β, α2)
    print(f"σ = {frac * σ_lo:.5f}  (= {frac:.3f} σ̲):  "
          f"DEP = {detection_error_probability(ζ, α):.4f}")
```

```
σ = -0.06601  (= 0.600 σ̲):  DEP = 0.3334
σ = -0.09901  (= 0.900 σ̲):  DEP = 0.2329
σ = -0.10990  (= 0.999 σ̲):  DEP = 0.2034
```

That near-coincidence is a property of this calibration and of $T = 40$, not a theorem.

At $T = 160$ the ordering reverses, and statistical detectability binds well before the breakdown point.

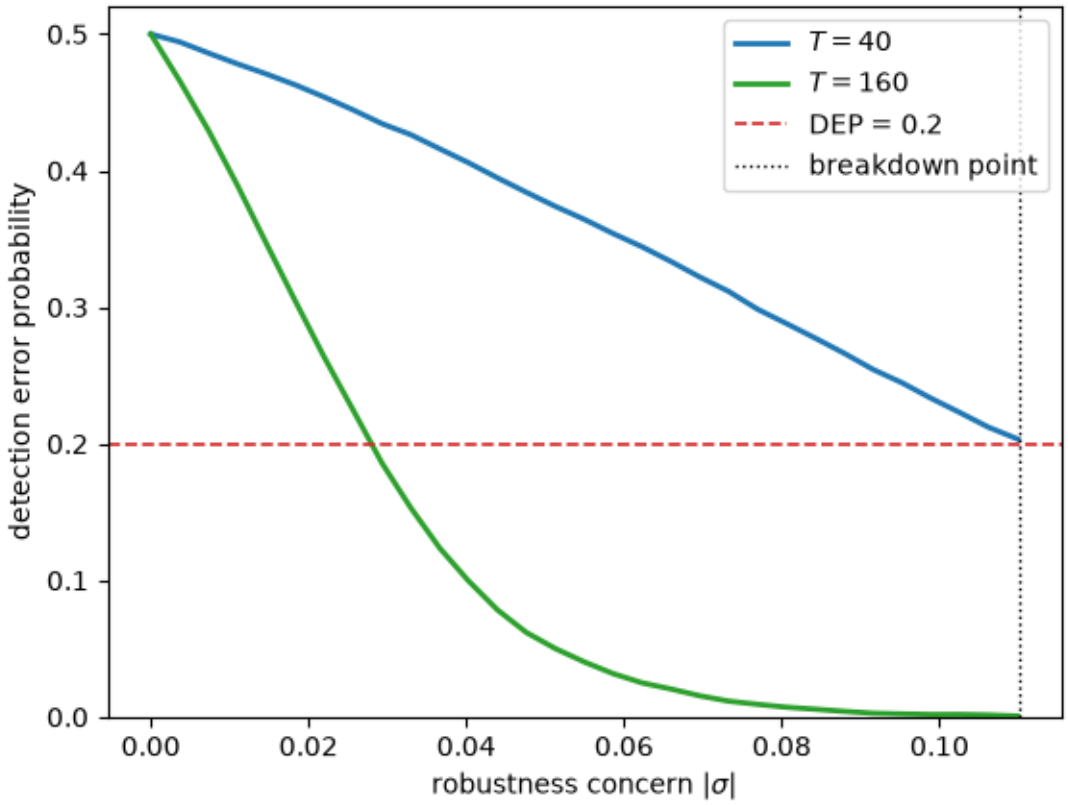

Fig. 88.4: Finite-sample detection error probability against the robustness concern, over the admissible range $(\underline{\sigma}, 0]$, for two sample lengths. Values below the dashed line are the ones HST regard as implausible, because the approximating and worst-case models would then be too easy to tell apart.

```
σ_report = 0.6 * σ_lo
ζ_report = worst_case_persistence(σ_report, β, α2)
print(f"at σ = {σ_report:.4f}  (ζ = {ζ_report:.4f}):")
for T in [20, 40, 80, 160]:
    print(f"  T = {T:>3}:  DEP = "
          f"{detection_error_probability(ζ_report, α, T=T):.4f}")
```

```
at σ = -0.0660  (ζ = 1.0309):
  T =  20:  DEP = 0.4147
  T =  40:  DEP = 0.3334
  T =  80:  DEP = 0.1507
  T = 160:  DEP = 0.0203
```

The lesson is that the plausible amount of model uncertainty depends on how much data the econometrician is imagined to have.

88.8 Robustness of decision rules

A natural follow-up question is whether robust decision rules perform better than the non-robust rule when the data are in fact generated by a distorted model.

Define the **payoff** when the decision rule is designed for robustness parameter σ^r and the data are generated by the distorted model associated with σ^d:

$$\pi(\sigma^d;\sigma^r) = -\mathbb{E}_{0,\sigma^d}\sum_{t=0}^{\infty}\beta^t\, x_t^\top H(\sigma^r)^\top H(\sigma^r)\, x_t \tag{88.39}$$

where the state evolves under decision rule $F(\sigma^r)$ and worst-case shocks $K(\sigma^d)$:

$$x_{t+1} = (A - BF(\sigma^r) + CK(\sigma^d))x_t + C\, w_{t+1} \tag{88.40}$$

There is an important caveat about *which* family of rules to compare, and it follows directly from *Theorem 88.4.1*.

Along the observational-equivalence locus $(\sigma, \hat{\beta}(\sigma))$, every agent chooses the *same* decision rule.

So $F(\sigma^r)$ does not vary along the locus, and $\pi(\sigma^d;\sigma^r)$ is constant in σ^r there.

A meaningful comparison of rules must therefore move *off* the locus, for example by holding β fixed at the benchmark and varying σ^r alone.

That experiment requires solving the full HST matrix problem rather than the scalar reduction of *The scalar worst-case model*, because once we leave the locus the marginal-utility process no longer summarises the decision rule.

Robust Permanent Income and Pricing carries out that computation with the QuantEcon `LQ` and robust-control routines.

88.9 Concluding remarks

A concern for model misspecification, parameterised by $\sigma = -\theta^{-1} \le 0$, alters the permanent income model in ways that are subtle rather than dramatic.

A concern for robustness generates a precautionary savings motive even under quadratic preferences, by distorting the conditional means of income shocks.

The distorted worst-case model makes the income process **more persistent**, shifting power toward the low frequencies where the permanent income consumer is most vulnerable.

The observational equivalence theorem *Theorem 88.4.1* shows that for quantities (c_t, i_t) alone, a concern for robustness is indistinguishable from a reduction in β.

The reverse theorem *Theorem 88.4.2* shows that, starting from $\beta R = 1$, robustness is observationally equivalent to an *increase* in β, which imparts an upward drift to expected consumption.

Two disciplines bound how large a robustness concern can sensibly be.

The breakdown point (88.34) is a hard mathematical limit beyond which no solution exists.

Detection error probabilities provide a softer and scale-free statistical discipline: choose $|\sigma|$ small enough that the approximating and worst-case models remain difficult to distinguish.

The observationally equivalent $(\sigma, \hat{\beta})$ pairs **do** have different implications for asset prices, a point pursued in *Robust Permanent Income and Pricing*.

They also have different implications for the *beliefs* that agents hold, which is the subject of *A Robust LQ Bewley Model*.

88.10 Exercises

Exercise 88.10.1

This exercise derives the breakdown point (88.34).

1. Using (88.31), show that $\hat{\beta}(\sigma)\,\zeta(\sigma)^2 = \beta\,\zeta(\sigma)$.
2. The minimizing agent's problem has a finite value only if $\hat{\beta}\zeta^2 < 1$. Use part 1 to show that this is equivalent to $\zeta < R$, and hence that $\underline{\sigma} = -(1-\beta)^2/\alpha^2$.
3. Verify that $\hat{\beta}(\underline{\sigma}) = \beta^2$.
4. Explain why the breakdown point moves toward zero when the endowment becomes more volatile.

Solution

Here is one solution.

1. From (88.31), $\zeta = \beta/\hat{\beta}$, so $\hat{\beta} = \beta/\zeta$ and therefore $\hat{\beta}\zeta^2 = (\beta/\zeta)\zeta^2 = \beta\zeta$.
2. By part 1 the condition $\hat{\beta}\zeta^2 < 1$ is $\beta\zeta < 1$, that is, $\zeta < \beta^{-1} = R$.

   Substituting the closed form (88.31) gives

   $$\left[1 + \frac{\sigma\alpha^2}{1-\beta}\right]^{-1} < \frac{1}{\beta} \iff 1 + \frac{\sigma\alpha^2}{1-\beta} > \beta \iff \sigma\alpha^2 > -(1-\beta)^2,$$

   which is $\sigma > -(1-\beta)^2/\alpha^2 = \underline{\sigma}$.
3. At $\sigma = \underline{\sigma}$ we have $\sigma\alpha^2 = -(1-\beta)^2$, so $\zeta = [1-(1-\beta)]^{-1} = \beta^{-1} = R$ and $\hat{\beta} = \beta/\zeta = \beta^2$.
4. A more volatile endowment raises α^2, and $\underline{\sigma} = -(1-\beta)^2/\alpha^2$ is therefore closer to zero.

   The economics is that σ only ever matters through $\sigma\alpha^2$, so when the consumer faces more income risk a *smaller* $|\sigma|$ already buys a given amount of pessimism.

Exercise 88.10.2

This exercise explains why a naive numerical solver for (88.23) misbehaves.

1. Verify algebraically that on the locus (88.17) the discriminant of (88.23) equals $\left[(\sigma\alpha^2 + (1-\beta)^2)/(1-\beta)\right]^2$.
2. Conclude that the square root equals $|\sigma\alpha^2 + (1-\beta)^2|/(1-\beta)$ and hence that the two roots are those in (88.33).
3. Write code that, for a grid of σ in $(\underline{\sigma}, 0)$, records which *sign* in front of the square root in (88.23) yields the economically relevant root $P = -(1-\beta)^{-1}$.

   Confirm that the answer flips at $\sigma = \underline{\sigma}$.

Solution

Here is one solution.

1. With $u = \sigma\alpha^2$ and $\delta = 1 - \beta$, equation (88.17) gives $\hat{\beta} - 1 = -\delta + u/\delta \cdot \beta/\beta$, more directly $\hat{\beta} - 1 + u = (u - \delta^2)/\delta$.

   Hence the discriminant is

$$\frac{(u-\delta^2)^2}{\delta^2} + 4u = \frac{(u-\delta^2)^2 + 4u\delta^2}{\delta^2} = \frac{(u+\delta^2)^2}{\delta^2}.$$

2. Taking the square root gives $|u + \delta^2|/\delta$, and substituting the two signs into (88.23) gives $P = -1/\delta$ and $P = \delta/u$.
3. The sign flips exactly where $u + \delta^2$ changes sign, that is at $u = -\delta^2$, which is $\sigma = \underline{\sigma}$.

```
σ_test = np.linspace(-0.01, 1.4 * σ_lo, 40)
signs = []
for σ in σ_test:
    roots, _ = solve_scalar_riccati(σ, β, α2)
    signs.append('+' if np.argmin(np.abs(roots + 1 / (1 - β))) == 0 else '-')

print(''.join(signs))
flip = next(i for i in range(1, len(signs)) if signs[i] != signs[i - 1])
print(f"sign flips between σ = {σ_test[flip - 1]:.5f} "
      f"and σ = {σ_test[flip]:.5f}")
print(f"breakdown point σ = {σ_lo:.5f}")
```

```
++++++++++++++++++++++++++++++------------
sign flips between σ = -0.10970 and σ = -0.11340
breakdown point σ = -0.11001
```

Exercise 88.10.3

This exercise calibrates σ using the detection error probability.

Write a bisection that finds the σ at which $\text{DEP}(\sigma) = 0.2$, and report the associated $\hat{\beta}$, ζ, and the ratio $\sigma/\underline{\sigma}$.

Run it for $T = 40$ and $T = 160$.

Take care: the target need not be attained on the admissible range $(\underline{\sigma}, 0]$, and your code should say so rather than silently return an endpoint.

Solution

The DEP is decreasing in $|\sigma|$, so a bisection works, but we must first check that the target lies within reach.

```
def σ_for_target_dep(target, T, β, α2, tol=1e-5):
    """
    Find σ ∈ (σ̲, 0) with DEP(σ) = target by bisection.

    Returns None if the DEP never falls to the target on the admissible
    range, which happens when the breakdown point binds before statistical
    detectability does.
    """
    α_loc = np.sqrt(α2)
    lo, hi = 0.999 * (-(1 - β)**2 / α2), 0.0     # lo is the more negative end

    def dep_at(σ):
        return detection_error_probability(
            worst_case_persistence(σ, β, α2), α_loc, T=T)

    if dep_at(lo) > target:
        return None

    while hi - lo > tol:
        mid = 0.5 * (lo + hi)
        if dep_at(mid) < target:
            lo = mid                # too easy to detect, move toward zero
        else:
            hi = mid
    return 0.5 * (lo + hi)

for T in [40, 160]:
    σ_star = σ_for_target_dep(0.2, T, β, α2)
    if σ_star is None:
        print(f"T = {T:>3}:  DEP stays above 0.2 on the whole admissible "
              f"range; the breakdown point binds first")
    else:
        ζ_star = worst_case_persistence(σ_star, β, α2)
        print(f"T = {T:>3}:  σ = {σ_star:.5f}   β = {β / ζ_star:.5f}   "
              f"ζ = {ζ_star:.5f}   σ/σ̲ = {σ_star / σ_lo:.3f}")
```

```
T =  40:  DEP stays above 0.2 on the whole admissible range; the breakdown␣
↪point binds first
T = 160:  σ = -0.02806   β = 0.93788   ζ = 1.01292   σ/σ̲ = 0.255
```

A longer sample makes the two models easier to distinguish, so the σ that keeps the DEP at 0.2 moves closer to zero.

At $T = 40$ no admissible σ has a DEP as low as 0.2, so the breakdown point is the binding constraint.

At $T = 160$ statistical detectability binds first, at about a quarter of the way to the breakdown point.

89.1 Overview

This lecture embeds the Bewley economy of *Consumption Smoothing with Incomplete and Complete Markets* in the robust permanent income framework of *Robust Consumption Smoothing and Precautionary Savings*.

It is the last of four lectures on the LQ permanent income model.

The result is a family of economies in which consumers disagree about the model generating their income, yet behave identically.

Using the observational-equivalence theorem of Hansen *et al.* [1999], we show

- how a continuum of consumers i can differ in their robustness parameters $\sigma_i \leq 0$ and their discount factors β_i, provided each pair (σ_i, β_i) lies on an observational-equivalence locus
- how every such consumer chooses the **same consumption-saving rule** as a benchmark $(\sigma = 0, \beta)$ agent who fully trusts the endowment process
- how the equilibrium interest rate $R = \beta^{-1}$ and all aggregate and cross-section dynamics therefore coincide with those of the plain-vanilla Bewley model

- how, despite all of this, distinct (σ_i, β_i) agents hold genuinely different subjective models of their non-financial income

The economy is a pure endowment economy, so there is no physical capital and investment plays no role.

We read *Robust Consumption Smoothing and Precautionary Savings* as a prerequisite and carry over its notation.

> **Note**
>
> As in *Robust Consumption Smoothing and Precautionary Savings*, w_{t+1} is the baseline shock and v_{t+1} a distortion to its conditional mean, $\sigma \leq 0$ is the robustness parameter, η_1 and η_2 are the standard deviations of the permanent and transitory endowment shocks, and a_t denotes net assets.

Let's begin with some imports.

```
import numpy as np
import matplotlib.pyplot as plt
```

89.2 Mapping the Bewley economy into the HST framework

We specialise the robust model of *Robust Consumption Smoothing and Precautionary Savings* to $\lambda = \delta_h = 0$, so there are no habits and no durable goods, and to a pure endowment economy with no physical capital, $k_t = 0$.

In this case services equal consumption, $s_t = c_t$.

The only traded security is a one-period risk-free bond, and a_t denotes the household's net asset position, so that positive a_t is wealth.

The endowment process follows the state-space representation

$$
\begin{aligned}
z_{t+1} &= \check{A}\, z_t + \check{C}\, w_{t+1} \\
y_t &= \check{G}\, z_t
\end{aligned}
\tag{89.1}
$$

with the two-factor specification $y_t = z_{1t} + z_{2t}$, $\check{A} = \mathrm{diag}(1, 0)$ and $\check{C} = \mathrm{diag}(\eta_1, \eta_2)$.

The household's augmented state vector is $x_t = [a_t,\ z_t^\top]^\top$, and the law of motion of *Robust Consumption Smoothing and Precautionary Savings* specialises to

$$
\begin{pmatrix} a_{t+1} \\ z_{t+1} \end{pmatrix}
= \underbrace{\begin{pmatrix} R & R\check{G} \\ 0 & \check{A} \end{pmatrix}}_{A}
\begin{pmatrix} a_t \\ z_t \end{pmatrix}
+ \underbrace{\begin{pmatrix} -R \\ 0 \end{pmatrix}}_{B} c_t
+ \underbrace{\begin{pmatrix} 0 \\ \check{C} \end{pmatrix}}_{C} (w_{t+1} + v_{t+1})
\tag{89.2}
$$

The objective is $\mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t [-(c_t - b)^2]$, which is the HST criterion with $\sigma = 0$ and a constant bliss level $b_t \equiv b$.

The period return is written without a factor of $\frac{1}{2}$, and that choice is not cosmetic: it fixes the scale of the robustness parameter σ used throughout, since rescaling the return rescales σ by the same factor.

The robust Bellman equation with $\sigma = 0$ therefore reduces exactly to the LQ problem of *The LQ Permanent Income Model*, confirming that the HST framework nests the Bewley model.

89.3 The robustness scalar for this economy

Everything about the endowment process that matters for robustness is summarised by the scalar α^2 derived in *Robust Consumption Smoothing and Precautionary Savings*.

For the two-factor endowment it is

$$\alpha^2 = \eta_1^2 + (1-\beta)^2\,\eta_2^2 \tag{89.3}$$

This is the variance of the consumption innovation $h\,w_{t+1}$, where $h = (1-\beta)\check{G}(I-\beta\check{A})^{-1}\check{C} = \begin{pmatrix}\eta_1 & (1-\beta)\eta_2\end{pmatrix}$.

In the present setting α^2 has a second, equally concrete meaning that we met in *Consumption Smoothing with Incomplete and Complete Markets*.

Because individual consumption is a random walk with innovation variance α^2, the cross-section variance of consumption among agents of age t who started from a common initial condition is exactly $t\,\alpha^2$.

So the same scalar that governs how much a consumer's robustness concern bites also governs how fast the Bewley cross-section fans out.

89.4 The Bewley observational-equivalence locus

Applying the observational-equivalence theorem *Theorem 88.4.1* of *Robust Consumption Smoothing and Precautionary Savings* at the equilibrium interest rate $R = \beta^{-1}$ gives the **Bewley observational-equivalence locus**

$$\hat{\beta}(\sigma) = \beta + \frac{\sigma\,\alpha^2\,\beta}{1-\beta} \tag{89.4}$$

For $\sigma < 0$ we have $\hat{\beta}(\sigma) < \beta$.

An agent with the pair $(\sigma, \hat{\beta}(\sigma))$ is more concerned about model misspecification, because σ is lower, but also more impatient, because $\hat{\beta}$ is lower.

The two forces cancel exactly, leaving the consumption decision rule unchanged.

The locus is admissible only down to the breakdown point of *Robust Consumption Smoothing and Precautionary Savings*,

$$\underline{\sigma} = -\frac{(1-\beta)^2}{\alpha^2}, \qquad \text{at which} \qquad \hat{\beta}(\underline{\sigma}) = \beta^2 \tag{89.5}$$

Below $\underline{\sigma}$ the individual robust control problem has no solution, so there is no economy to describe.

The bound has a transparent reading in terms of the worst-case dynamics derived below.

Since $\zeta(\sigma) = \beta/\hat{\beta}(\sigma)$ is the growth rate that agent σ fears for its own marginal utility, the breakdown point is exactly the σ at which

$$\zeta(\underline{\sigma}) = \frac{1}{\beta} = R, \qquad \text{equivalently} \qquad \beta\,\zeta(\underline{\sigma}) = 1 \tag{89.6}$$

So $\underline{\sigma}$ is the robustness level at which the feared growth in marginal utility just reaches the gross interest rate, and the agent's discounted worst-case objective ceases to converge.

Any stronger concern for robustness would have the agent guarding against a future it cannot value.

89.5 Equilibrium with heterogeneous types

We can now populate the economy with a continuum of types that differ in their concern for robustness.

Proposition 89.5.1 (A robust Bewley equilibrium)

Let each agent i in the unit interval be indexed by a robustness parameter $\sigma_i \in (\underline{\sigma}, 0]$, distributed according to any distribution Φ, and let agent i have discount factor

$$\beta_i = \hat{\beta}(\sigma_i) = \beta + \frac{\sigma_i \, \alpha^2 \, \beta}{1 - \beta} \tag{89.7}$$

so that every pair (σ_i, β_i) lies on the locus (89.4).

Then

1. every agent's optimal consumption plan is identical to that of the plain-vanilla $(\sigma = 0, \beta)$ agent,
2. $R = \beta^{-1}$ is an equilibrium gross interest rate, independently of Φ, and
3. the aggregate and cross-section dynamics coincide with those of the benchmark Bewley economy of *Consumption Smoothing with Incomplete and Complete Markets*.

Proof. By *Theorem 88.4.1*, an agent with parameters $(\sigma_i, \hat{\beta}(\sigma_i))$ facing gross interest rate $R = \beta^{-1}$ chooses the same consumption-saving rule as the benchmark $(0, \beta)$ agent.

This holds agent by agent and does not require the σ_i to be equal, which gives part 1.

Since all individual rules coincide with the benchmark rule, the goods-market clearing condition $\int c_t^i \, di = Y$ and the bond-market condition $\int a_t^i \, di = 0$ are the benchmark conditions, so they are satisfied at $R = \beta^{-1}$ for exactly the reason given in *Consumption Smoothing with Incomplete and Complete Markets*.

Because market clearing never refers to Φ, neither does the rate that clears the market, which gives part 2.

The argument is a verification: the locus (89.4) is itself constructed at $R = \beta^{-1}$, so what we have shown is that this rate reproduces itself as an equilibrium for any Φ, not that no other rate could.

Part 3 follows because aggregate and cross-section objects are integrals of individual paths, and the individual paths are the benchmark paths.

The distribution Φ of robustness types is therefore completely unidentified by quantity data.

An econometrician who observes $\{c_t^i, a_t^i\}$ for every agent and every date cannot tell whether the economy is populated entirely by $\sigma_i = 0$ agents, entirely by σ_i near $\underline{\sigma}$ agents, or by any mixture.

One feature of this equilibrium deserves comment, because it runs against a familiar result.

In a model with heterogeneous discount factors and a common interest rate, the most patient type ordinarily comes to hold all of the wealth, and the long-run distribution degenerates.

Here every type with $\sigma_i < 0$ has $\beta_i R < 1$ and so is impatient at the market rate, yet no type decumulates relative to any other.

The reason is that impatience and the precautionary motive are offset at every date, not merely on average, so asset paths as well as consumption paths coincide across types.

Robustness type is therefore uncorrelated with wealth at every horizon, and the usual sorting force is exactly neutralized rather than merely slowed.

89.6 Where the agents genuinely differ

Agents on the locus are indistinguishable in what they *do* but not in what they *believe*.

An agent with $\sigma_i < 0$ applies a worst-case distortion $v^i_{t+1} = K(\sigma_i, \beta_i)\, \mu^i_{s,t}$ to its conditional expectations, while an agent with $\sigma_i = 0$ takes the approximating model at face value.

From *Robust Consumption Smoothing and Precautionary Savings*, the worst-case law for agent i's marginal utility is

$$\mu^i_{s,t+1} = \zeta_i\, \mu^i_{st} + \alpha\, w_{t+1}, \qquad \zeta_i = \frac{\beta}{\beta_i} = \left[1 + \frac{\sigma_i \alpha^2}{1-\beta}\right]^{-1} \geq 1 \tag{89.8}$$

with equality only for the fully trusting type $\sigma_i = 0$.

With $\lambda = \delta_h = 0$ and a constant bliss point we have $\mu_{st} = b - c_t$, so agent i's **worst-case expected consumption path** is

$$\hat{\mathbb{E}}_t\, c^i_{t+h} = b - \zeta_i^h\, (b - c_t) \tag{89.9}$$

Under the approximating model, by contrast, consumption is a martingale, $\mathbb{E}_t c_{t+h} = c_t$ for every h.

Equation (89.9) says that a robust agent below its bliss point expects, under its worst-case model, that consumption will *drift away* from bliss at the geometric rate ζ_i.

The more robust the agent, the faster the drift it guards against, and the more precautionary saving it does.

That extra saving is exactly offset by the lower β_i, which is why the realized path is the same for all types.

89.7 Computation

We use the calibration of the preceding lectures.

```
β = 0.95         # benchmark discount factor, R = 1/β
η1 = 0.15        # std of permanent shock
η2 = 0.30        # std of transitory shock
b = 1.0          # bliss point

R = 1 / β
h = np.array([η1, (1 - β) * η2])       # consumption innovation loadings
α2 = h @ h
α = np.sqrt(α2)
σ_lo = -(1 - β)**2 / α2                # breakdown point, eq:rbew-breakdown

print(f"α^2 = {α2:.6f}   α = {α:.6f}")
print(f"breakdown σ̲ = {σ_lo:.6f},  where β = {β + σ_lo * α2 * β / (1 - β):.6f}"
      f"  (β² = {β**2:.6f})")
```

```
α^2 = 0.022725   α = 0.150748
breakdown σ̲ = -0.110011,  where β = 0.902500  (β² = 0.902500)
```

Next we build a set of types spread across the admissible range and record what distinguishes them.

We reuse the detection error probability of *Robust Consumption Smoothing and Precautionary Savings* to report how hard each type's worst-case model would be to detect in a sample of $T = 40$ quarters.

```
def worst_case_persistence(σ, β, α2):
    "Worst-case persistence ζ(σ) of marginal utility, eq:rbew-zeta."
    return 1 / (1 + σ * α2 / (1 - β))

def simulate_paths(ζ, α, T, n_paths, seed):
    "Simulate n_paths draws of μ_{t+1} = ζ μ_t + α w_{t+1} from μ_0 = 0."
    rng = np.random.default_rng(seed)
    paths = np.zeros((n_paths, T + 1))
    shocks = rng.standard_normal((n_paths, T))
    for t in range(T):
        paths[:, t + 1] = ζ * paths[:, t] + α * shocks[:, t]
    return paths

def log_likelihood_ratio(paths, ζ, α):
    "Return log p_worst(path) - log p_approx(path)."
    lag, lead = paths[:, :-1], paths[:, 1:]
    return 0.5 * (np.sum(((lead - lag) / α)**2, axis=1)
                  - np.sum(((lead - ζ * lag) / α)**2, axis=1))

def detection_error_probability(ζ, α, T=40, n_paths=10_000, seed=1234):
    "Finite-sample DEP for the approximating and worst-case scalar laws."
    if np.isclose(ζ, 1.0):
        return 0.5
    approx = simulate_paths(1.0, α, T, n_paths, seed)
    worst = simulate_paths(ζ, α, T, n_paths, seed + 1)
    return 0.5 * (np.mean(log_likelihood_ratio(worst, ζ, α) < 0)
                  + np.mean(log_likelihood_ratio(approx, ζ, α) > 0))
```

```
σ_types = np.array([0.0, 0.3, 0.6, 0.9]) * σ_lo
β_types = β + σ_types * α2 * β / (1 - β)
ζ_types = worst_case_persistence(σ_types, β, α2)
dep_types = np.array([detection_error_probability(ζ, α) for ζ in ζ_types])

print(f"{'σ_i':>10}{'β_i':>10}{'ζ_i':>10}{'DEP':>8}")
for σ_i, β_i, ζ_i, dep in zip(σ_types, β_types, ζ_types, dep_types):
    print(f"{σ_i:10.4f}{β_i:10.4f}{ζ_i:10.4f}{dep:8.3f}")
```

```
       σ_i       β_i       ζ_i     DEP
   -0.0000    0.9500    1.0000   0.500
   -0.0330    0.9357    1.0152   0.426
   -0.0660    0.9215    1.0309   0.333
   -0.0990    0.9072    1.0471   0.233
```

These four types differ substantially in patience and in the pessimism of their worst-case model.

We now confirm that they nonetheless behave identically.

Proposition 89.5.1 asserts that each type, solving *its own* problem at (σ_i, β_i), arrives at the benchmark decision rule.

Testing that claim means solving each type's robust problem separately and comparing the rules that come out.

Assuming the common rule and then reporting that the resulting paths coincide would establish nothing.

We reuse the risk-sensitive LQ solver of *Robust Permanent Income and Pricing*, renaming its state-cost argument to `Rc` because R is the gross interest rate here.

The period return below is $-(c_t - b)^2$, matching the normalization of σ fixed above.

```
def solve_rslq(A, B, C, Q, Rc, β, σ, N=None, tol=1e-12, max_iter=50_000):
    "Risk-sensitive LQ regulator; returns F in the rule c = -F x."
    A, B, C, Q, Rc = map(np.atleast_2d, (A, B, C, Q, Rc))
    n, kw = A.shape[0], C.shape[1]
    if N is None:
        N = np.zeros((B.shape[1], n))
    Ω, Iw = -np.eye(n), np.eye(kw)
    for _ in range(max_iter):
        M = Iw - σ * C.T @ Ω @ C
        D = Ω + σ * Ω @ C @ np.linalg.solve(M, C.T @ Ω)
        F = np.linalg.solve(Q - β * B.T @ D @ B, N - β * B.T @ D @ A)
        Acl = A - B @ F
        Ω_new = -Rc - F.T @ Q @ F + (F.T @ N + N.T @ F) + β * Acl.T @ D @ Acl
        if np.max(np.abs(Ω_new - Ω)) < tol:
            return F
        Ω = Ω_new
    raise RuntimeError('risk-sensitive Riccati iteration did not converge')
```

Write the agent's problem with state $x_t = \begin{pmatrix} 1 & a_t & z_{1t} & z_{2t} \end{pmatrix}'$ and control c_t, matching the timing of (89.2).

The constant carries the bliss point, and every agent faces the same market rate $R = \beta^{-1}$; only β_i and σ_i differ across types.

```
def bewley_lq(b, η1, η2, R):
    "State-space matrices for the agent's problem, period return -(c-b)^2."
    A_x = np.array([[1, 0, 0, 0],
                    [0, R, R, R],
                    [0, 0, 1, 0],
                    [0, 0, 0, 0]], float)
    B_x = np.array([[0.], [-R], [0.], [0.]])
    C_x = np.array([[0, 0], [0, 0], [η1, 0], [0, η2]], float)
    Q_x = np.array([[1.0]])
    Rc_x = np.zeros((4, 4))
    Rc_x[0, 0] = b**2
    N_x = np.array([[-b, 0, 0, 0]], float)
    return A_x, B_x, C_x, Q_x, Rc_x, N_x

A_x, B_x, C_x, Q_x, Rc_x, N_x = bewley_lq(b, η1, η2, R)
F_bench = solve_rslq(A_x, B_x, C_x, Q_x, Rc_x, β, 0.0, N_x)

print("benchmark rule  c = "
      + " + ".join(f"{v:.4f}·{n}" for v, n in
                   zip(-F_bench.ravel(), ["1", "a", "z1", "z2"])))
print(f"implied consumption innovation  {np.round((-F_bench @ C_x).ravel(), 6)}")
print(f"analytic h                      {np.round(h, 6)}")
```

```
benchmark rule  c = 0.0000·1 + 0.0500·a + 1.0000·z1 + 0.0500·z2
implied consumption innovation  [0.15  0.015]
analytic h                      [0.15  0.015]
```

The benchmark rule reproduces the analytic innovation loadings h, which checks that the state-space setup is the one the algebra describes.

Now solve each type's own problem and compare.

```
F_types = [solve_rslq(A_x, B_x, C_x, Q_x, Rc_x, β_i, σ_i, N_x)
           for σ_i, β_i in zip(σ_types, β_types)]

print(f"{'σ_i':>10}{'β_i':>10}{'max |F_i - F_bench|':>22}")
for σ_i, β_i, F_i in zip(σ_types, β_types, F_types):
    print(f"{σ_i:10.4f}{β_i:10.4f}{np.max(np.abs(F_i - F_bench)):22.2e}")
```

```
       σ_i       β_i   max |F_i - F_bench|
   -0.0000    0.9500              0.00e+00
   -0.0330    0.9357              1.27e-12
   -0.0660    0.9215              2.32e-12
   -0.0990    0.9072              9.43e-12
```

Every coefficient of every type's rule agrees with the benchmark to eleven decimal places or better, which is *Proposition 89.5.1* part 1.

To see that this test has power, move each discount factor one percent off the locus, keeping σ_i fixed, and solve again.

```
print(f"{'σ_i':>10}{'on locus':>12}{'+1% off':>12}{'-1% off':>12}")
for σ_i, β_i in zip(σ_types[1:], β_types[1:]):
    devs = []
    for mult in (1.0, 1.01, 0.99):
        F_off = solve_rslq(A_x, B_x, C_x, Q_x, Rc_x, β_i * mult, σ_i, N_x)
        devs.append(np.max(np.abs(F_off - F_bench)))
    print(f"{σ_i:10.4f}" + "".join(f"{d:12.1e}" for d in devs))
```

```
       σ_i    on locus     +1% off     -1% off
   -0.0330     1.3e-12     2.6e-01     2.7e-01
   -0.0660     2.3e-12     4.5e-01     4.7e-01
   -0.0990     9.4e-12     1.7e+00     1.0e+00
```

A one percent departure from the locus moves the rule in the first decimal place, so the agreement above is not an artifact of the comparison.

Finally, simulate each type using **its own** solved rule, with common shocks.

```
T = 60
rng = np.random.default_rng(42)
shocks = rng.standard_normal((T, 2))          # common shocks for all types

c_paths = np.zeros((len(σ_types), T + 1))
for i, F_i in enumerate(F_types):
    x = np.array([1.0, 0.0, 0.0, 0.0])        # [1, a_t, z_1, z_2]
    for t in range(T + 1):
        c_paths[i, t] = -(F_i @ x).item()
        if t < T:
            x = A_x @ x + B_x.ravel() * c_paths[i, t] + C_x @ shocks[t]

print("max absolute difference across types:"
      f" {np.abs(c_paths - c_paths[0]).max():.2e}")
print("max deviation from the random walk with innovation h:"
      f" {np.abs(c_paths[0] - np.concatenate([[0], np.cumsum(shocks @ h)])).max():.2e}
 ↪")
```

```
max absolute difference across types: 1.12e-11
max deviation from the random walk with innovation h: 5.78e-14
```

The paths coincide, and each reproduces the random walk with innovation h that the algebra predicts.

The next figure contrasts what the types do with what they believe.

```
fig, axes = plt.subplots(1, 2, figsize=(11, 4))

for i, σ_i in enumerate(σ_types):
    axes[0].plot(c_paths[i], lw=3 - 0.6 * i, alpha=0.9,
                 label=rf'$\sigma_i={σ_i:.3f}$')
axes[0].set_xlabel('$t$')
axes[0].set_ylabel('$c_t$')
axes[0].set_title('realized consumption')
axes[0].legend()

horizons = np.arange(41)
c_now = c_paths[0, 20]
axes[1].axhline(c_now, color='k', linestyle=':', lw=1.2,
                label='approximating model')
for σ_i, ζ_i in zip(σ_types, ζ_types):
    if σ_i == 0.0:
        continue
    axes[1].plot(horizons, b - ζ_i**horizons * (b - c_now), lw=2,
                 label=rf'worst case, $\sigma_i={σ_i:.3f}$')
axes[1].set_xlabel('horizon $h$')
axes[1].set_ylabel(r'$\hat{\mathbb{E}}_t\,c_{t+h}$')
axes[1].set_title('expected consumption under each belief')
axes[1].legend()

fig.tight_layout()
plt.show()
```

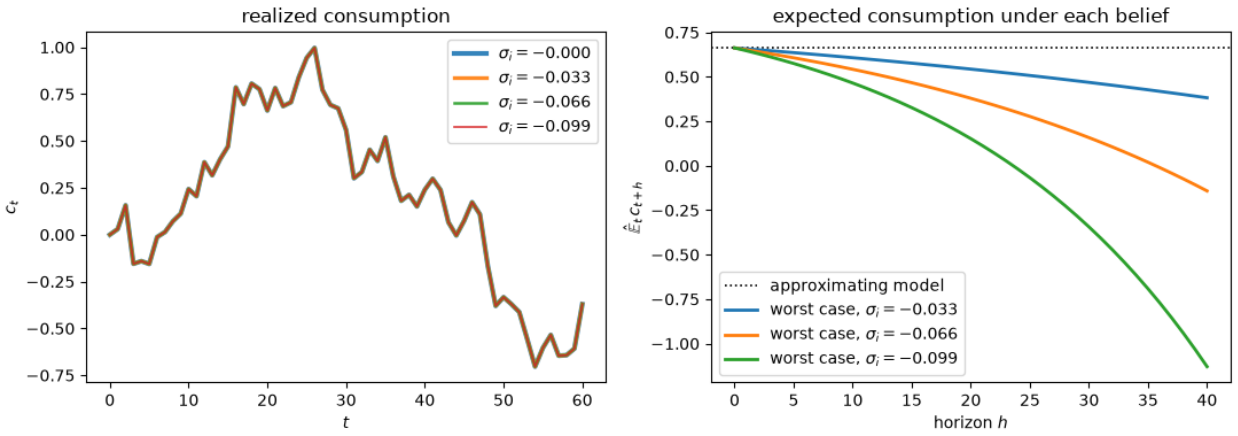

Fig. 89.1: Same actions, different beliefs. Left: realized consumption paths for four robustness types facing common shocks; the curves lie exactly on top of one another. Right: each type's worst-case expected consumption path from a common date, against the flat martingale forecast of the approximating model.

The left panel of Fig. 89.1 shows four curves drawn on top of one another.

The right panel shows that the same four agents expect very different futures.

The $\sigma_i = 0$ agent expects consumption to stay where it is.

Every robust agent guards against a future in which consumption drifts away from the bliss point, and the drift is faster the more robust the agent.

Finally we check part 3 of *Proposition 89.5.1*, that the cross-section behaves as in the benchmark Bewley economy.

We simulate a large population spread over the admissible range of types, giving each agent its own shocks and solving each type's own problem, and compare the cross-section variance of consumption to the benchmark prediction $t\,\alpha^2$.

```
n_agents, T_pop = 20_000, 40
rng = np.random.default_rng(1234)

# a population spread over the admissible range, each solving its own problem
σ_pop = np.linspace(0.99 * σ_lo, 0.0, 12)
β_pop = β + σ_pop * α2 * β / (1 - β)
F_pop = [solve_rslq(A_x, B_x, C_x, Q_x, Rc_x, β_j, σ_j, N_x)
         for σ_j, β_j in zip(σ_pop, β_pop)]

type_of = rng.integers(0, len(σ_pop), size=n_agents)
pop_shocks = rng.standard_normal((n_agents, T_pop, 2))
c_pop = np.zeros((n_agents, T_pop + 1))

for j, F_j in enumerate(F_pop):
    m = type_of == j
    x = np.zeros((m.sum(), 4))
    x[:, 0] = 1.0                                  # the constant
    for t in range(T_pop + 1):
        c_pop[m, t] = -(x @ F_j.ravel())
        if t < T_pop:
            x = (x @ A_x.T + np.outer(c_pop[m, t], B_x.ravel())
                 + pop_shocks[m, t] @ C_x.T)

print(f"{'t':>5}{'cross-section var':>20}{'t·α²':>12}")
for t in [10, 20, 30, 40]:
    print(f"{t:5d}{c_pop[:, t].var():20.5f}{t * α2:12.5f}")
print(f"\ncorrelation between σ_i and c_T: "
      f"{np.corrcoef(σ_pop[type_of], c_pop[:, T_pop])[0, 1]:+.4f}")
```

```
    t   cross-section var        t·α²
   10             0.22836     0.22725
   20             0.46220     0.45450
   30             0.68968     0.68175
   40             0.91503     0.90900

correlation between σ_i and c_T: -0.0002
```

The cross-section variance grows linearly at rate α^2, exactly as in *Consumption Smoothing with Incomplete and Complete Markets*.

Robustness type and consumption are uncorrelated, so the distribution of types leaves no trace in the data even though each agent has genuinely solved a different problem.

89.8 Concluding remarks

We embedded the single-agent robust permanent income model in a Bewley equilibrium with a continuum of agents who differ in how much they distrust their income process.

Provided each agent's pair (σ_i, β_i) lies on the observational-equivalence locus (89.4), every agent chooses the benchmark consumption rule.

The equilibrium interest rate $R = \beta^{-1}$, the aggregate dynamics, and the linear growth of the cross-section variance of consumption are all inherited unchanged from the plain-vanilla Bewley model of *Consumption Smoothing with Incomplete and Complete Markets*.

This is a strong non-identification result.

Quantity data pin down the decision rule, but they cannot decompose it into a degree of impatience and a degree of concern about misspecification.

What the agents do *not* share is their view of the world: each robust type acts as if its consumption were about to drift away from bliss at its own rate ζ_i.

Two routes lead out of this observational equivalence.

One is to look at asset prices, which do distinguish the $(\sigma, \hat{\beta})$ pairs, and which are studied in *Robust Permanent Income and Pricing*.

The other is to bound the plausible range of σ statistically, using the detection error probabilities of *Robust Consumption Smoothing and Precautionary Savings*.

89.9 Exercises

Exercise 89.9.1

This exercise asks you to carry out the translation from the benchmark Bewley economy into HST notation.

Specialise the robust-control setup to the no-habit, no-capital LQ Bewley environment, so $\lambda = \delta_h = 0$ and $k_t = 0$, and let the endowment follow the two-factor model.

1. Write the household state as $x_t = [a_t, z_t^\top]^\top$, where a_t is net assets, and derive the matrices (A, B, C) in (89.2).
2. Show that when $\sigma = 0$ the Bellman problem coincides with the LQ permanent-income problem of *The LQ Permanent Income Model*.
3. HST define $\alpha^2 = \nu^\top \nu$ with $\nu^\top = M_s C$, where $\mu_{st} = M_s x_t$. Compute M_s for this economy and verify that this route delivers the same α^2 as (89.3).

Solution

Here is one solution.

1. With budget law $a_{t+1} = R(a_t + y_t - c_t)$, $y_t = \check{G} z_t$ and $z_{t+1} = \check{A} z_t + \check{C} w_{t+1}$, stacking gives

$$\begin{pmatrix} a_{t+1} \\ z_{t+1} \end{pmatrix} = \underbrace{\begin{pmatrix} R & R\check{G} \\ 0 & \check{A} \end{pmatrix}}_{A} \begin{pmatrix} a_t \\ z_t \end{pmatrix} + \underbrace{\begin{pmatrix} -R \\ 0 \end{pmatrix}}_{B} c_t + \underbrace{\begin{pmatrix} 0 \\ \check{C} \end{pmatrix}}_{C} w_{t+1}.$$

The sign of B is negative because higher c_t reduces asset accumulation.

2. At $\sigma = 0$ the minimizing agent is absent, the distortion term drops out of the Bellman equation, and the objective is $\mathbb{E}_0 \sum \beta^t[-(c_t - b)^2]$ subject to a linear law of motion.

That is precisely the LQ permanent-income problem.

3. With $\lambda = \delta_h = 0$ and constant bliss, $\mu_{st} = b - c_t$, and the optimal rule is

$$c_t = (1-\beta)[a_t + \check{G}(I - \beta\check{A})^{-1} z_t] + \text{constant},$$

so $M_s = -(1-\beta)\begin{pmatrix} 1 & \check{G}(I-\beta\check{A})^{-1}\end{pmatrix}$ up to the constant.

Since $C = [0;\ \check{C}]$, the first column of M_s is annihilated and

$$\nu^\top = M_s C = -(1-\beta)\check{G}(I-\beta\check{A})^{-1}\check{C} = -h.$$

Hence $\alpha^2 = \nu^\top \nu = hh^\top = \eta_1^2 + (1-\beta)^2\eta_2^2$, matching (89.3).

The minus sign is immaterial because only α^2 appears.

Exercise 89.9.2

This exercise works through the equilibrium logic of *Proposition 89.5.1*.

Fix a benchmark pair $(\beta, \sigma = 0)$ with $R = \beta^{-1}$ and let a unit interval of consumers be indexed by i, with type $\sigma_i \in (\underline{\sigma}, 0]$ and discount factor $\beta_i = \hat{\beta}(\sigma_i)$ from (89.4).

1. Use *Theorem 88.4.1* of *Robust Consumption Smoothing and Precautionary Savings* to show that each type has the same consumption rule as the benchmark $(\beta, 0)$ agent.
2. Show that goods- and bond-market clearing imply the same equilibrium interest rate $R = \beta^{-1}$ as in the plain-vanilla Bewley model, whatever the distribution of types.
3. Explain why agents can be observationally equivalent in quantities while holding different worst-case subjective models.
4. Suppose instead that agents share a common β but differ in σ_i, so that they are *not* on the locus. Explain why $R = \beta^{-1}$ would then generally fail to clear the bond market.

Solution

Here is one solution.

1. *Theorem 88.4.1* says that if (σ_i, β_i) satisfies $\beta_i = \beta + \sigma_i\alpha^2\beta/(1-\beta)$, then type i chooses the same decision rule as the benchmark agent, so all types share the policy function $c_t = \mathcal{C}(a_t, z_t)$.
2. Since all individual rules coincide with the benchmark rule, aggregating over i reproduces the benchmark market-clearing conditions, which hold at $R = \beta^{-1}$.

The type distribution never enters, so it cannot affect the equilibrium rate.

3. Observational equivalence is a statement about quantities generated by optimal rules.

The minimizing feedback $K(\sigma_i, \beta_i)$ still differs across types, so the agents attach different worst-case conditional means to the same shock process while making identical choices.

4. Off the locus the impatience offset is missing.

An agent with $\sigma_i < 0$ and discount factor β has a precautionary motive that is not cancelled, so it wants to save more

than the benchmark agent at $R = \beta^{-1}$.

With positive net demand for bonds in the aggregate, the equilibrium interest rate must fall below β^{-1} to clear the market, and the equilibrium then depends on the whole distribution of types.

Exercise 89.9.3

This exercise separates quantities from beliefs for two individual agents.

Consider agents a and b with $\sigma^a < \sigma^b \leq 0$, both on the locus (89.4).

1. Show that the two agents have the same consumption innovation $h\, w_{t+1}$.
2. Show that if they start from the same (a_t, z_t) and observe the same shock w_{t+1}, their next-period consumption and assets coincide.
3. Using (89.9), compute the ratio of the two agents' worst-case forecasts of $b - c_{t+h}$ and show that it grows geometrically in h.
4. Summarise what is and is not identified by data on quantities alone.

Solution

Here is one solution.

1. Both pairs lie on (89.4), so by *Theorem 88.4.1* both use the benchmark rule and hence the same innovation vector h.
2. With a common state and a common shock, both agents apply the same policy function and the same law of motion, so $c^a_{t+1} = c^b_{t+1}$ and $a^a_{t+1} = a^b_{t+1}$.
3. From (89.9), $\widehat{\mathbb{E}}_t(b - c^j_{t+h}) = \zeta_j^h (b - c_t)$, so the ratio is $(\zeta_a/\zeta_b)^h$.

Since $\sigma^a < \sigma^b$ implies $\zeta_a > \zeta_b$, the ratio grows geometrically: the two agents' beliefs diverge without bound as the horizon lengthens, even though their actions never differ at all.

4. Quantities identify the equilibrium decision rule, and hence the single combination of parameters that appears in it.

They do not identify the decomposition of that rule into impatience β_i and robustness σ_i along the locus.

Exercise 89.9.4

This exercise asks how much belief heterogeneity is statistically plausible.

Restrict attention to types whose worst-case model has a detection error probability of at least 0.25 in a sample of $T = 40$.

1. Find the most robust admissible type $\sigma^{\min}$ by bisection.
2. For that type, report β_i, ζ_i, and the horizon h at which its worst-case forecast of $b - c_{t+h}$ is twice the approximating model's forecast.
3. Repeat part 1 with $T = 160$ and comment on what a longer sample does to the plausible amount of belief heterogeneity.

Solution

Here is one solution.

The approximating model forecasts $b - c_{t+h} = b - c_t$ for every h, while the worst-case forecast is $\zeta_i^h(b - c_t)$, so the doubling horizon solves $\zeta_i^h = 2$.

```
def σ_for_target_dep(target, T, β, α2, tol=1e-5):
    """
    Find σ ∈ (σ̲, 0) with DEP(σ) = target by bisection.

    Returns None if the DEP never falls to the target on the admissible
    range, in which case the breakdown point is the binding constraint.
    """
    α_loc = np.sqrt(α2)
    lo, hi = 0.999 * (-(1 - β)**2 / α2), 0.0

    def dep_at(σ):
        return detection_error_probability(
            worst_case_persistence(σ, β, α2), α_loc, T=T)

    if dep_at(lo) > target:
        return None

    while hi - lo > tol:
        mid = 0.5 * (lo + hi)
        if dep_at(mid) < target:
            lo = mid
        else:
            hi = mid
    return 0.5 * (lo + hi)

for T in [40, 160]:
    σ_min = σ_for_target_dep(0.25, T, β, α2)
    if σ_min is None:
        σ_min = 0.999 * σ_lo        # breakdown binds before detectability
        note = ' (breakdown point binds)'
    else:
        note = ''
    ζ_min = worst_case_persistence(σ_min, β, α2)
    print(f"T = {T:>3}:  σ_min = {σ_min:.5f}   β_i = {β / ζ_min:.5f}   "
          f"ζ_i = {ζ_min:.5f}   doubling horizon = "
          f"{np.log(2) / np.log(ζ_min):.1f} quarters{note}")
```

```
T =  40:  σ_min = -0.09313   β_i = 0.90979   ζ_i = 1.04420   doubling horizon =␣
↪16.0 quarters
T = 160:  σ_min = -0.02322   β_i = 0.93997   ζ_i = 1.01067   doubling horizon =␣
↪65.3 quarters
```

At $T = 40$ statistical detectability binds before the breakdown point does, so the most robust plausible type is interior.

At $T = 160$ it binds far sooner and the plausible set of types shrinks sharply toward $\sigma = 0$.

The doubling horizon lengthens correspondingly: with more data, only agents whose pessimism accumulates slowly remain statistically credible.

Note

The detection error probability is estimated by simulation, so a target close to the value attained at $\underline{\sigma}$ makes the answer sensitive to the random seed.
At $T = 40$ the DEP at the breakdown point is almost exactly 0.2, which is why the target here is 0.25.

90.1 Overview

This lecture can be viewed as an application of this *quantecon lecture* about linear quadratic control theory.

It formulates a discounted dynamic program for a firm that chooses a production schedule to balance

- minimizing costs of production across time, against
- keeping costs of holding inventories low

In the tradition of a classic book by Holt, Modigliani, Muth, and Simon [Holt *et al.*, 1960], we simplify the firm's problem by formulating it as a linear quadratic discounted dynamic programming problem of the type studied in this *quantecon lecture*.

Because its costs of production are increasing and quadratic in production, the firm holds inventories as a buffer stock in order to smooth production across time, provided that holding inventories is not too costly.

But the firm also wants to make its sales out of existing inventories, a preference that we represent by a cost that is quadratic in the difference between sales in a period and the firm's beginning of period inventories.

We compute examples designed to indicate how the firm optimally smooths production while keeping inventories close to sales.

To introduce components of the model, let

- S_t be sales at time t
- Q_t be production at time t
- I_t be inventories at the beginning of time t
- $\beta \in (0,1)$ be a discount factor
- $c(Q_t) = c_1 Q_t + c_2 Q_t^2$, be a cost of production function, where $c_1 > 0, c_2 > 0$, be an inventory cost function
- $d(I_t, S_t) = d_1 I_t + d_2 (S_t - I_t)^2$, where $d_1 > 0, d_2 > 0$, be a cost-of-holding-inventories function, consisting of two components:
  - a cost $d_1 I_t$ of carrying inventories, and
  - a cost $d_2 (S_t - I_t)^2$ of having inventories deviate from sales
- $p_t = a_0 - a_1 S_t + v_t$ be an inverse demand function for a firm's product, where $a_0 > 0, a_1 > 0$ and v_t is a demand shock at time t
- $\pi_t = p_t S_t - c(Q_t) - d(I_t, S_t)$ be the firm's profits at time t
- $\sum_{t=0}^{\infty} \beta^t \pi_t$ be the present value of the firm's profits at time 0
- $I_{t+1} = I_t + Q_t - S_t$ be the law of motion of inventories
- $z_{t+1} = A_{22} z_t + C_2 \epsilon_{t+1}$ be a law of motion for an exogenous state vector z_t that contains time t information useful for predicting the demand shock v_t
- $v_t = G z_t$ link the demand shock to the information set z_t
- the constant 1 be the first component of z_t

To map our problem into a linear-quadratic discounted dynamic programming problem (also known as an optimal linear regulator), we define the **state** vector at time t as

$$x_t = \begin{bmatrix} I_t \\ z_t \end{bmatrix}$$

and the **control** vector as

$$u_t = \begin{bmatrix} Q_t \\ S_t \end{bmatrix}$$

The law of motion for the state vector x_t is evidently

$$\begin{bmatrix} I_{t+1} \\ z_t \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & A_{22} \end{bmatrix} \begin{bmatrix} I_t \\ z_t \end{bmatrix} + \begin{bmatrix} 1 & -1 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} Q_t \\ S_t \end{bmatrix} + \begin{bmatrix} 0 \\ C_2 \end{bmatrix} \epsilon_{t+1}$$

or

$$x_{t+1} = A x_t + B u_t + C \epsilon_{t+1}$$

(At this point, we ask that you please forgive us for using Q_t to be the firm's production at time t, while below we use Q as the matrix in the quadratic form $u_t' Q u_t$ that appears in the firm's one-period profit function)

We can express the firm's profit as a function of states and controls as

$$\pi_t = -(x_t' R x_t + u_t' Q u_t + 2 u_t' N x_t)$$

To form the matrices R, Q, N in an LQ dynamic programming problem, we note that the firm's profits at time t function can be expressed

$$
\begin{aligned}
\pi_t =& p_t S_t - c\left(Q_t\right) - d\left(I_t, S_t\right) \\
=& \left(a_0 - a_1 S_t + v_t\right) S_t - c_1 Q_t - c_2 Q_t^2 - d_1 I_t - d_2 \left(S_t - I_t\right)^2 \\
=& a_0 S_t - a_1 S_t^2 + G z_t S_t - c_1 Q_t - c_2 Q_t^2 - d_1 I_t - d_2 S_t^2 - d_2 I_t^2 + 2 d_2 S_t I_t \\
=& - \left(\underbrace{d_1 I_t + d_2 I_t^2}_{x_t' R x_t} + \underbrace{a_1 S_t^2 + d_2 S_t^2 + c_2 Q_t^2}_{u_t' Q u_t} \underbrace{- a_0 S_t - G z_t S_t + c_1 Q_t - 2 d_2 S_t I_t}_{2 u_t' N x_t} \right) \\
=& - \Bigg(\begin{bmatrix} I_t & z_t' \end{bmatrix} \underbrace{\begin{bmatrix} d_2 & \frac{d_1}{2} S_c \\ \frac{d_1}{2} S_c' & 0 \end{bmatrix}}_{\equiv R} \begin{bmatrix} I_t \\ z_t \end{bmatrix} + \begin{bmatrix} Q_t & S_t \end{bmatrix} \underbrace{\begin{bmatrix} c_2 & 0 \\ 0 & a_1 + d_2 \end{bmatrix}}_{\equiv Q} \begin{bmatrix} Q_t \\ S_t \end{bmatrix} + 2 \begin{bmatrix} Q_t & S_t \end{bmatrix} \underbrace{\begin{bmatrix} 0 & \frac{c_1}{2} S_c \\ -d_2 & -\frac{a_0}{2} S_c - \frac{G}{2} \end{bmatrix}}_{\equiv N} \begin{bmatrix} I \\ z \end{bmatrix}
\end{aligned}
$$

where $S_c = [1, 0]$.

Remark on notation: The notation for cross product term in the QuantEcon library is N.

The firms' optimum decision rule takes the form

$$u_t = -F x_t$$

and the evolution of the state under the optimal decision rule is

$$x_{t+1} = (A - BF) x_t + C \epsilon_{t+1}$$

The firm chooses a decision rule for u_t that maximizes

$$E_0 \sum_{t=0}^{\infty} \beta^t \pi_t$$

subject to a given x_0.

This is a stochastic discounted LQ dynamic program.

Here is code for computing an optimal decision rule and for analyzing its consequences.

```

Notice that the above code sets parameters at the following default values

- discount factor $\beta = 0.96$,
- inverse demand function: $a0 = 10, a1 = 1$
- cost of production $c1 = 1, c2 = 1$
- costs of holding inventories $d1 = 1, d2 = 1$

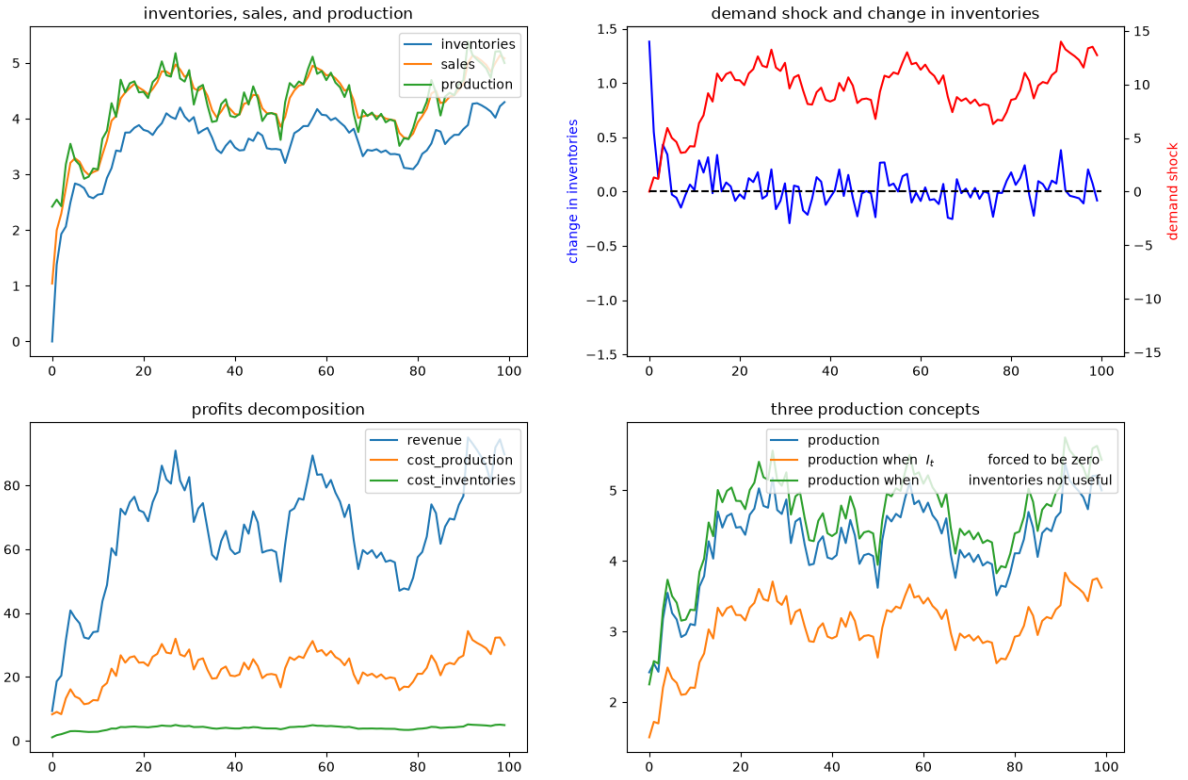
In the examples below, we alter some or all of these parameter values.

90.2 Example 1

In this example, the demand shock follows AR(1) process:

$$\nu_t = \alpha + \rho \nu_{t-1} + \epsilon_t,$$

which implies



$$z_{t+1} = \begin{bmatrix} 1 \\ v_{t+1} \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ \alpha & \rho \end{bmatrix} \underbrace{\begin{bmatrix} 1 \\ v_t \end{bmatrix}}_{z_t} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} \epsilon_{t+1}.$$

We set $\alpha = 1$ and $\rho = 0.9$, their default values.

We'll calculate and display outcomes, then discuss them below the pertinent figures.

```
ex1 = SmoothingExample()

x0 = [0, 1, 0]
ex1.simulate(x0)
```

The figures above illustrate various features of an optimal production plan.

Starting from zero inventories, the firm builds up a stock of inventories and uses them to smooth costly production in the face of demand shocks.

Optimal decisions evidently respond to demand shocks.

Inventories are always less than sales, so some sales come from current production, a consequence of the cost, $d_1 I_t$ of holding inventories.

The lower right panel shows differences between optimal production and two alternative production concepts that come from altering the firm's cost structure – i.e., its technology.

These two concepts correspond to these distinct altered firm problems.

- a setting in which inventories are not needed
- a setting in which they are needed but we arbitrarily prevent the firm from holding inventories by forcing it to set $I_t = 0$ always

We use these two alternative production concepts in order to shed light on the baseline model.

90.3 Inventories Not Useful

Let's turn first to the setting in which inventories aren't needed.

In this problem, the firm forms an output plan that maximizes the expected value of

$$\sum_{t=0}^{\infty} \beta^t \{p_t Q_t - C(Q_t)\}$$

It turns out that the optimal plan for Q_t for this problem also solves a sequence of static problems $\max_{Q_t} \{p_t Q_t - c(Q_t)\}$.

When inventories aren't required or used, sales always equal production.

This simplifies the problem and the optimal no-inventory production maximizes the expected value of

$$\sum_{t=0}^{\infty} \beta^t \left\{p_t Q_t - C\left(Q_t\right)\right\}.$$

The optimum decision rule is

$$Q_t^{ni} = \frac{a_0 + \nu_t - c_1}{c_2 + a_1}.$$

90.4 Inventories Useful but are Hardwired to be Zero Always

Next, we turn to a distinct problem in which inventories are useful – meaning that there are costs of $d_2(I_t - S_t)^2$ associated with having sales not equal to inventories – but we arbitrarily impose on the firm the costly restriction that it never hold inventories.

Here the firm's maximization problem is

$$\max_{\{I_t, Q_t, S_t\}} \sum_{t=0}^{\infty} \beta^t \left\{p_t S_t - C\left(Q_t\right) - d\left(I_t, S_t\right)\right\}$$

subject to the restrictions that $I_t = 0$ for all t and that $I_{t+1} = I_t + Q_t - S_t$.

The restriction that $I_t = 0$ implies that $Q_t = S_t$ and that the maximization problem reduces to

$$\max_{Q_t} \sum_{t=0}^{\infty} \beta^t \left\{ p_t Q_t - C\left(Q_t\right) - d\left(0, Q_t\right) \right\}$$

Here the optimal production plan is

$$Q_t^h = \frac{a_0 + \nu_t - c_1}{c_2 + a_1 + d_2}.$$

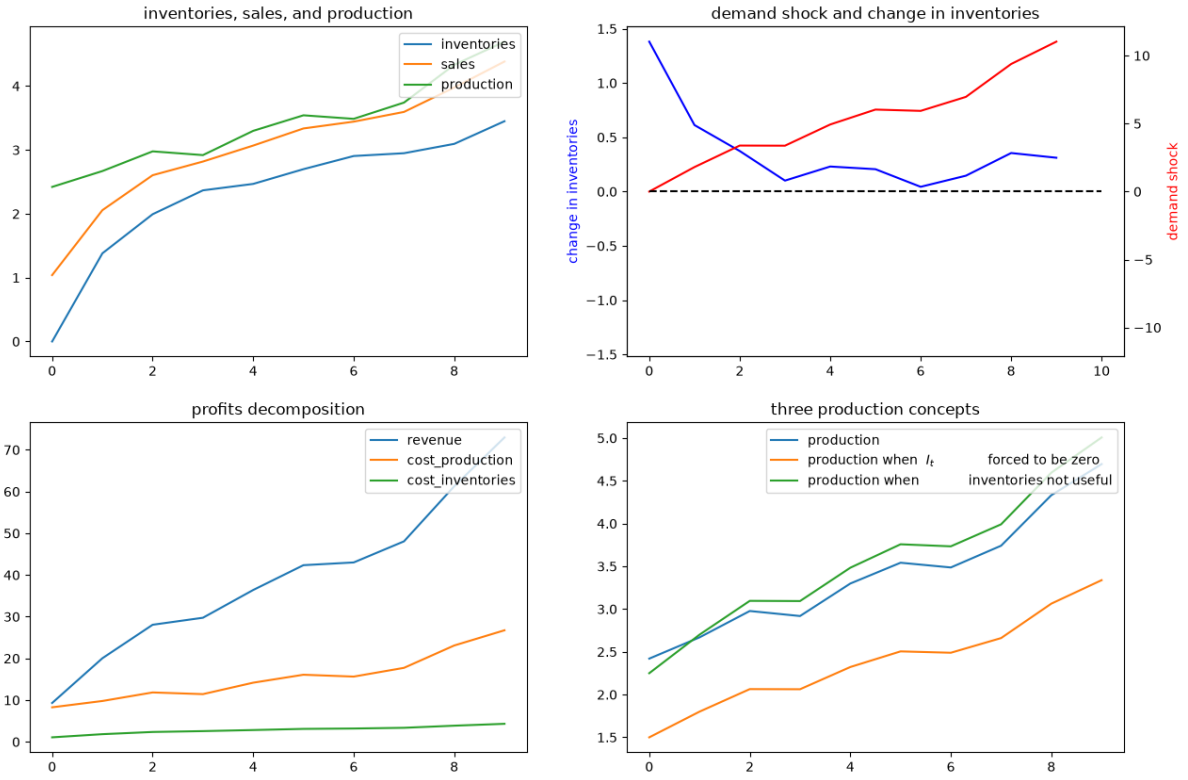
We introduce this I_t **is hardwired to zero** specification in order to shed light on the role that inventories play by comparing outcomes with those under our two other versions of the problem.

The bottom right panel displays a production path for the original problem that we are interested in (the blue line) as well with an optimal production path for the model in which inventories are not useful (the green path) and also for the model in which, although inventories are useful, they are hardwired to zero and the firm pays cost $d(0, Q_t)$ for not setting sales $S_t = Q_t$ equal to zero (the orange line).

Notice that it is typically optimal for the firm to produce more when inventories aren't useful. Here there is no requirement to sell out of inventories and no costs from having sales deviate from inventories.

But "typical" does not mean "always".

Thus, if we look closely, we notice that for small t, the green "production when inventories aren't useful" line in the lower right panel is below optimal production in the original model.



High optimal production in the original model early on occurs because the firm wants to accumulate inventories quickly in order to acquire high inventories for use in later periods.

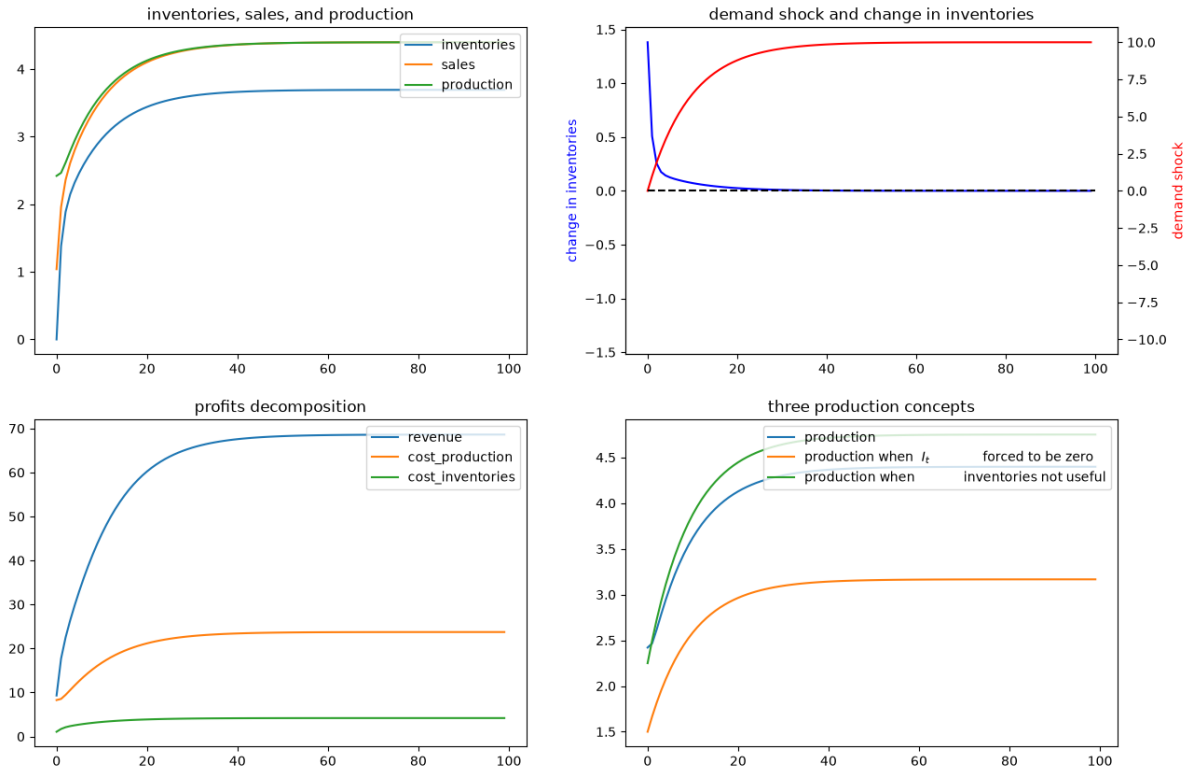
But how the green line compares to the blue line early on depends on the evolution of the demand shock, as we will see in a deterministically seasonal demand shock example to be analyzed below.

In that example, the original firm optimally accumulates inventories slowly because the next positive demand shock is in the distant future.

To make the green-blue model production comparison easier to see, let's confine the graphs to the first 10 periods:

```
ex1.simulate(x0, T=10)
```

90.5 Example 2



Next, we shut down randomness in demand and assume that the demand shock ν_t follows a deterministic path:

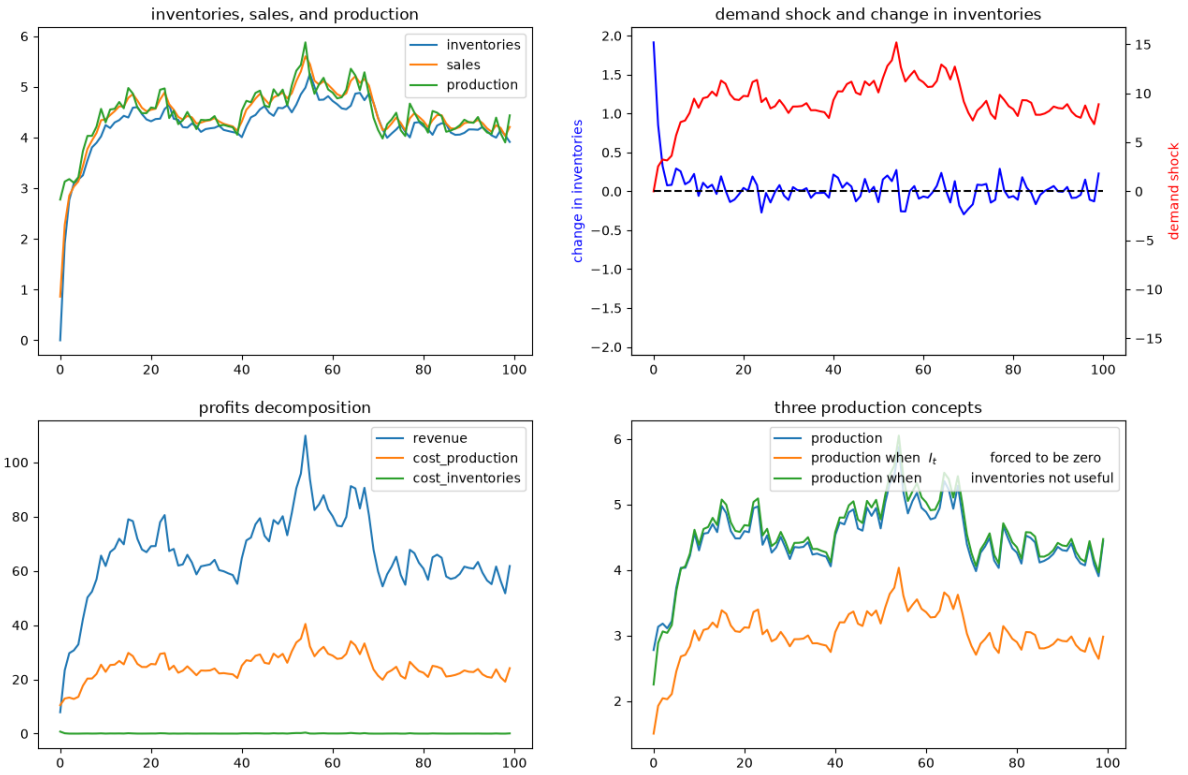
$$\nu_t = \alpha + \rho \nu_{t-1}$$

Again, we'll compute and display outcomes in some figures

```
ex2 = SmoothingExample(C2=[[0], [0]])

x0 = [0, 1, 0]
ex2.simulate(x0)
```

90.6 Example 3



Now we'll put randomness back into the demand shock process and also assume that there are zero costs of holding inventories.

In particular, we'll look at a situation in which $d_1 = 0$ but $d_2 > 0$.

Now it becomes optimal to set sales approximately equal to inventories and to use inventories to smooth production quite well, as the following figures confirm

```
ex3 = SmoothingExample(d1=0)

x0 = [0, 1, 0]
ex3.simulate(x0)
```

90.7 Example 4

To bring out some features of the optimal policy that are related to some technical issues in linear control theory, we'll now temporarily assume that it is costless to hold inventories.

When we completely shut down the cost of holding inventories by setting $d_1 = 0$ and $d_2 = 0$, something absurd happens (because the Bellman equation is opportunistic and very smart).

(Technically, we have set parameters that end up violating conditions needed to assure **stability** of the optimally controlled state.)

The firm finds it optimal to set $Q_t \equiv Q^* = \frac{-c_1}{2c_2}$, an output level that sets the costs of production to zero (when $c_1 > 0$, as it is with our default settings, then it is optimal to set production negative, whatever that means!).

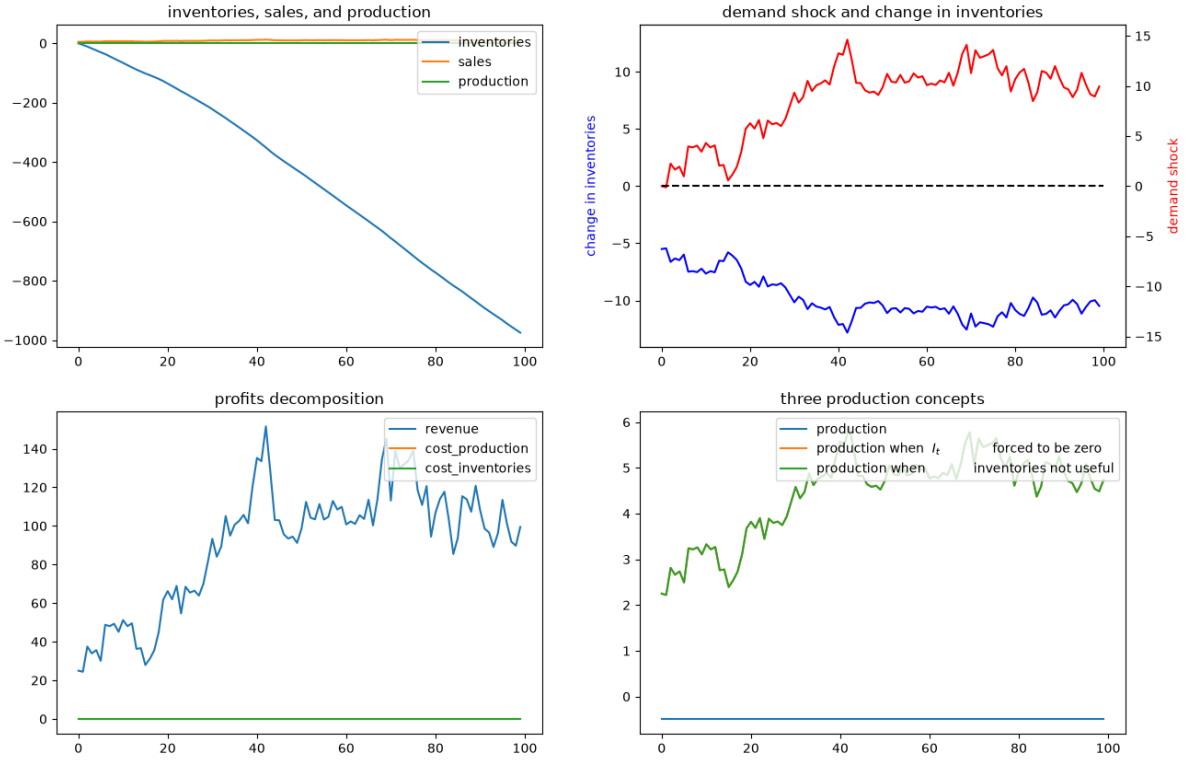
Recall the law of motion for inventories

$$I_{t+1} = I_t + Q_t - S_t$$

So when $d_1 = d_2 = 0$ so that the firm finds it optimal to set $Q_t = \frac{-c_1}{2c_2}$ for all t, then

$$I_{t+1} - I_t = \frac{-c_1}{2c_2} - S_t < 0$$

for almost all values of S_t under our default parameters that keep demand positive almost all of the time.

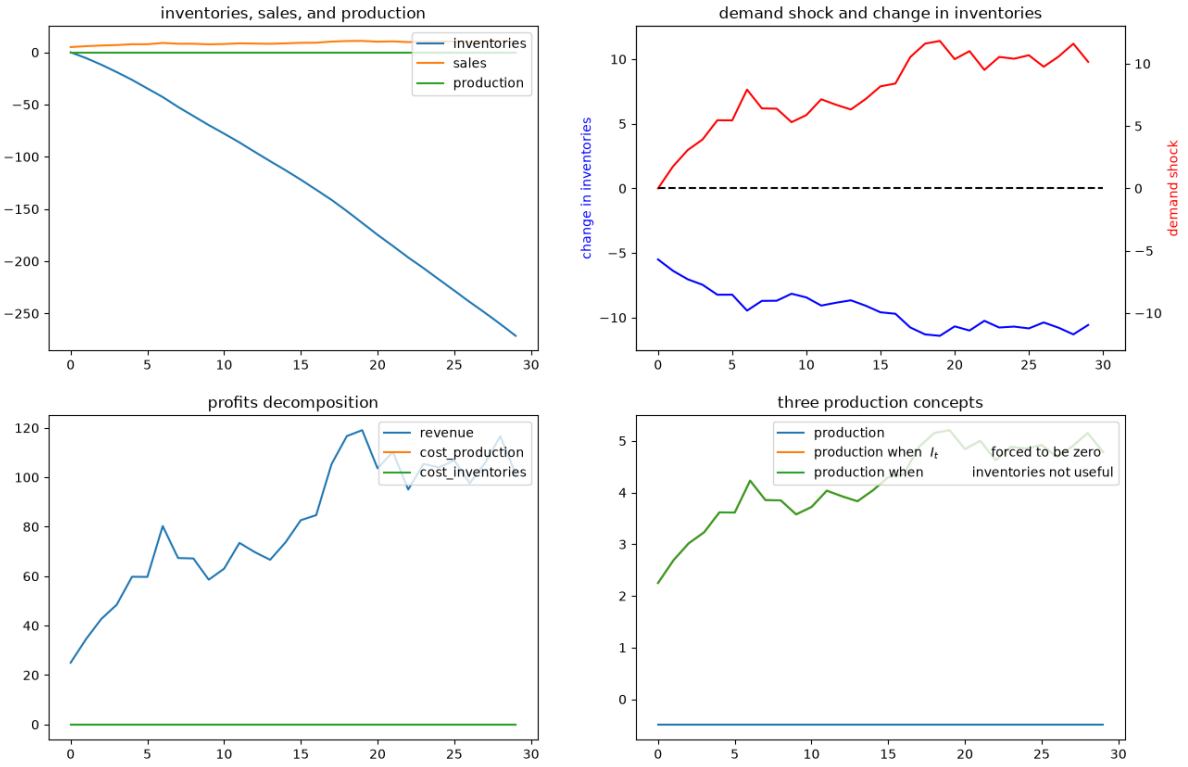


The dynamic program instructs the firm to set production costs to zero and to **run a Ponzi scheme** by running inventories down forever.

(We can interpret this as the firm somehow **going short in** or **borrowing** inventories)

The following figures confirm that inventories head south without limit

```
ex4 = SmoothingExample(d1=0, d2=0)



x0 = [0, 1, 0]
ex4.simulate(x0)
```

Let's shorten the time span displayed in order to highlight what is going on.

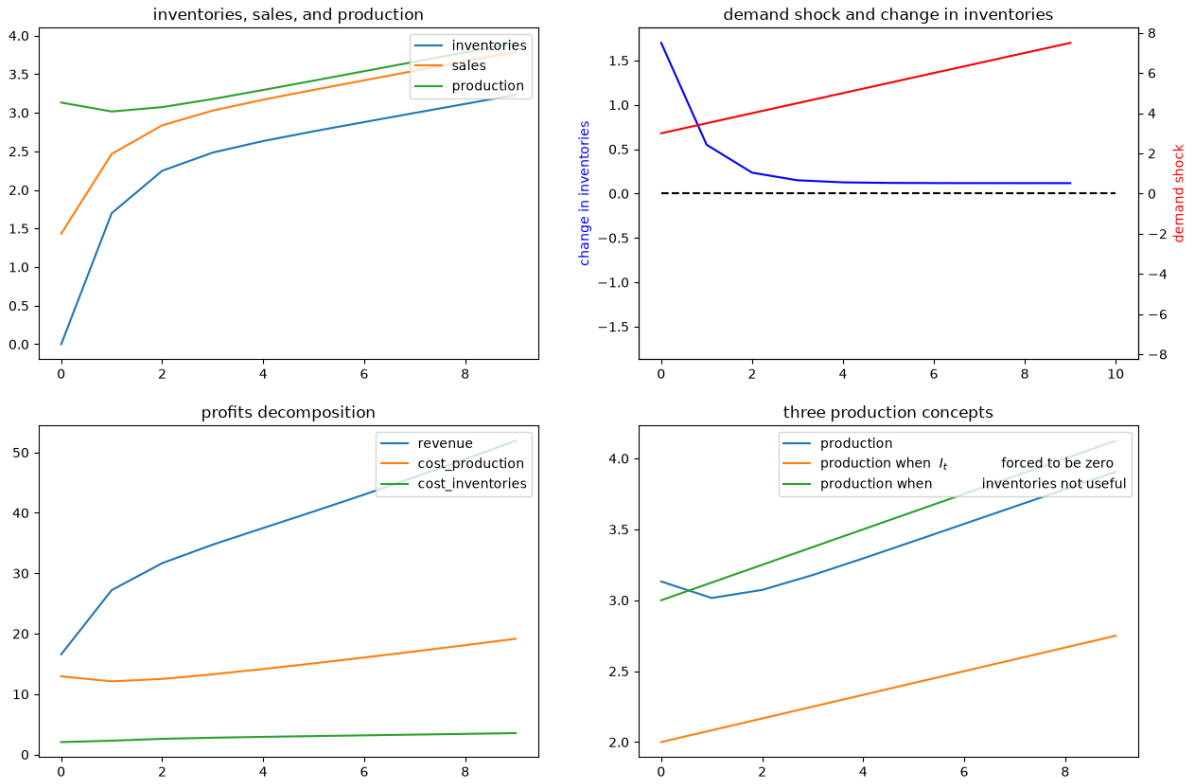
We'll set the horizon $T = 30$ with the following code

```
# shorter period
ex4.simulate(x0, T=30)
```

90.8 Example 5

Now we'll assume that the demand shock that follows a linear time trend

$$v_t = b + at, a > 0, b > 0$$



To represent this, we set $C_2 = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$ and

$$A_{22} = \begin{bmatrix} 1 & 0 \\ 1 & 1 \end{bmatrix}, x_0 = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, G = \begin{bmatrix} b & a \end{bmatrix}$$

```
# Set parameters
a = 0.5
b = 3.
```

```
ex5 = SmoothingExample(A22=[[1, 0], [1, 1]], C2=[[0], [0]], G=[b, a])

x0 = [0, 1, 0] # set the initial inventory as 0
ex5.simulate(x0, T=10)
```

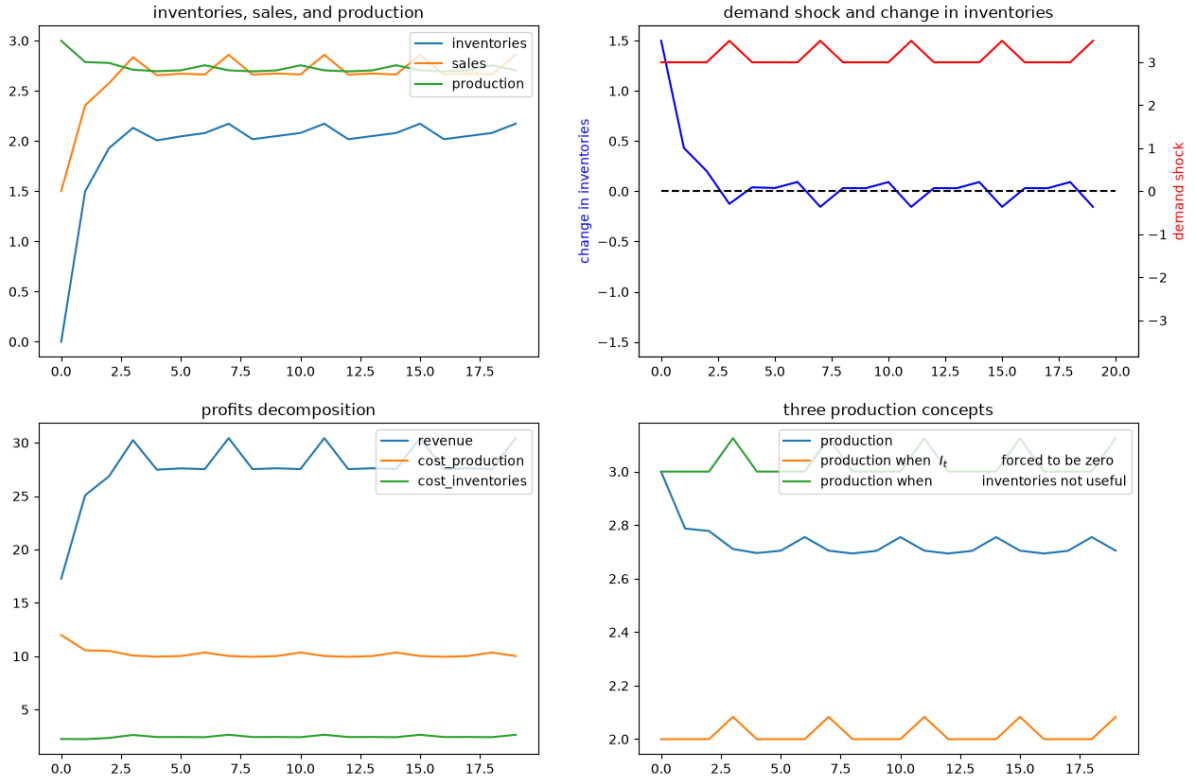
90.9 Example 6

Now we'll assume a deterministically seasonal demand shock.

To represent this we'll set

$$A_{22} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{bmatrix}, C_2 = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}, G' = \begin{bmatrix} b \\ a \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

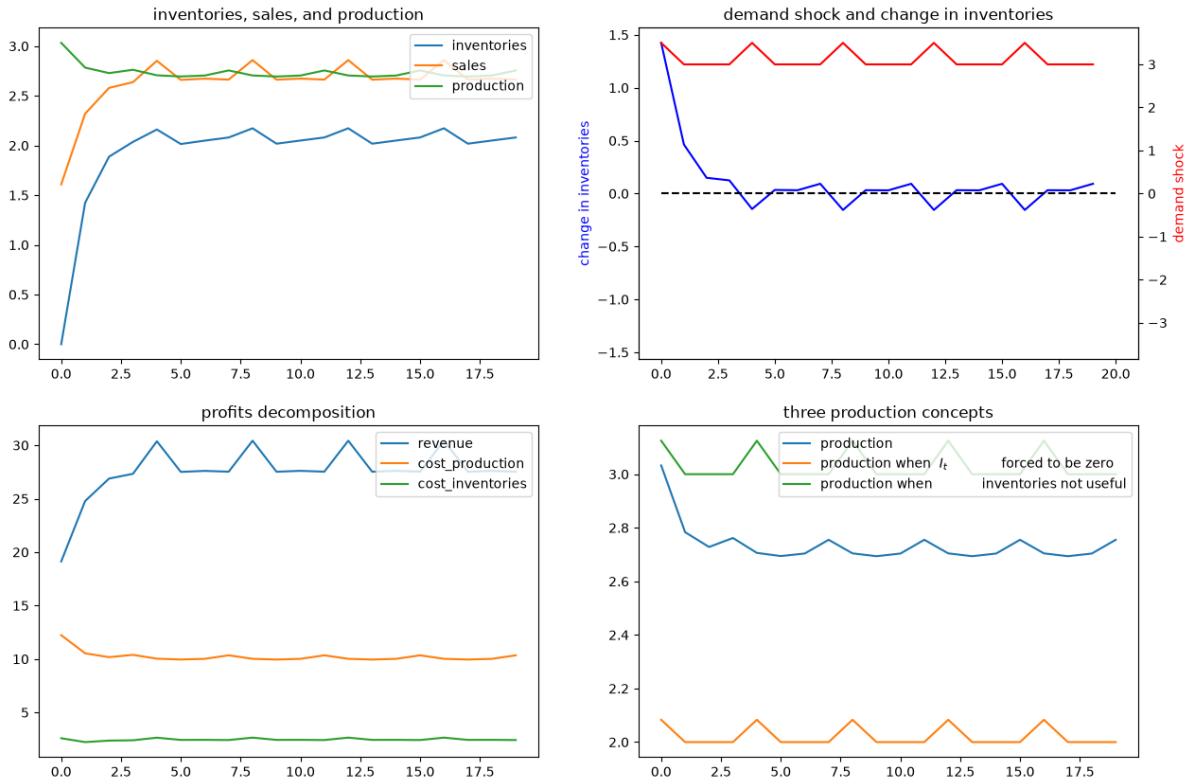
where $a > 0, b > 0$ and



$$x_0 = \begin{bmatrix} 1 \\ 0 \\ 1 \\ 0 \\ 0 \end{bmatrix}$$

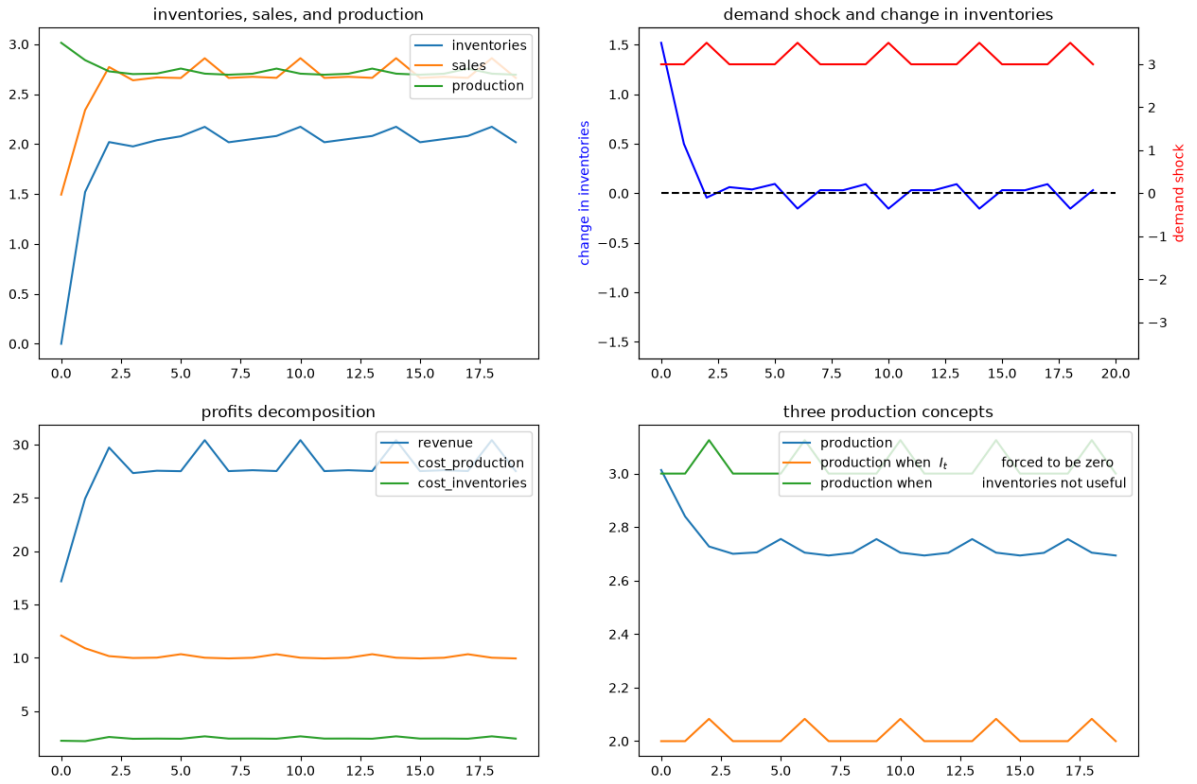
```
ex6 = SmoothingExample(A22=[[1, 0, 0, 0, 0],
                           [0, 0, 0, 0, 1],
                           [0, 1, 0, 0, 0],
                           [0, 0, 1, 0, 0],
                           [0, 0, 0, 1, 0]],
                       C2=[[0], [0], [0], [0], [0]],
                       G=[b, a, 0, 0, 0])
```

(continues on next page)

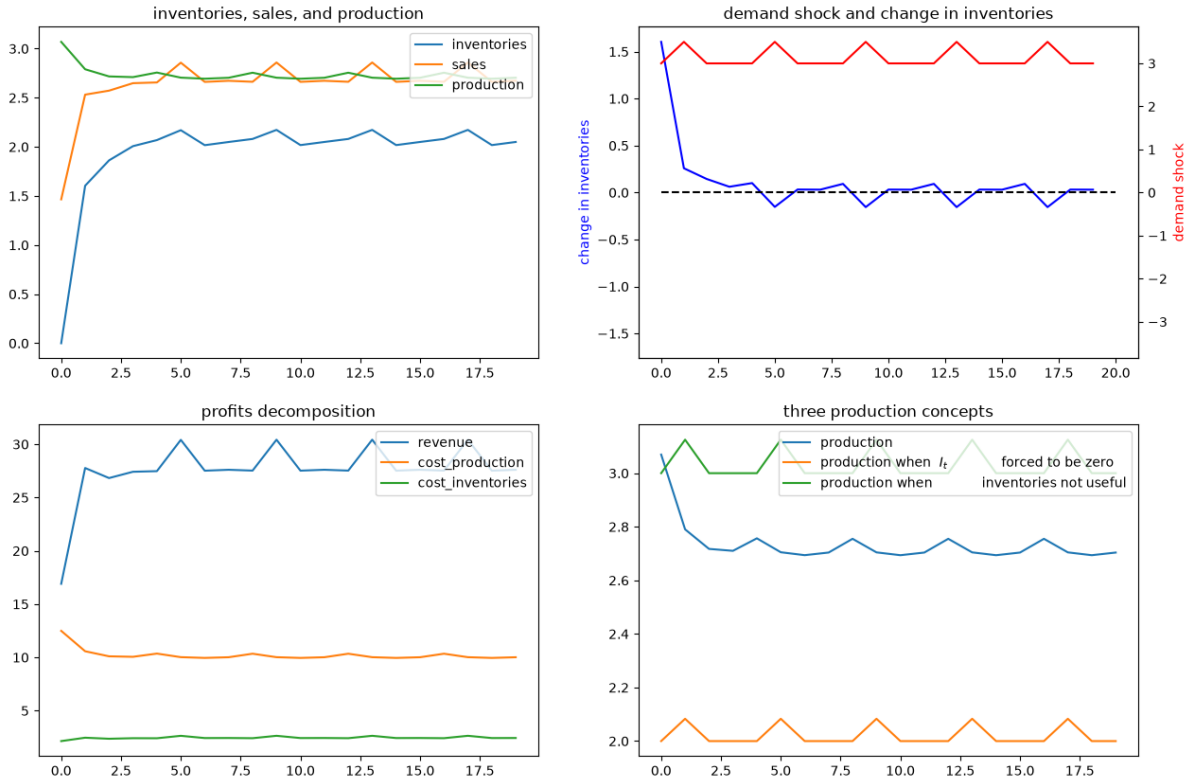


(continued from previous page)

```
x00 = [0, 1, 0, 1, 0, 0] # Set the initial inventory as 0
ex6.simulate(x00, T=20)
```



Now we'll generate some more examples that differ simply from the initial **season** of the year in which we begin the demand shock



```
x01 = [0, 1, 1, 0, 0, 0]
ex6.simulate(x01, T=20)
```

```
x02 = [0, 1, 0, 0, 1, 0]
ex6.simulate(x02, T=20)
```

```
x03 = [0, 1, 0, 0, 0, 1]
ex6.simulate(x03, T=20)
```

90.10 Exercises

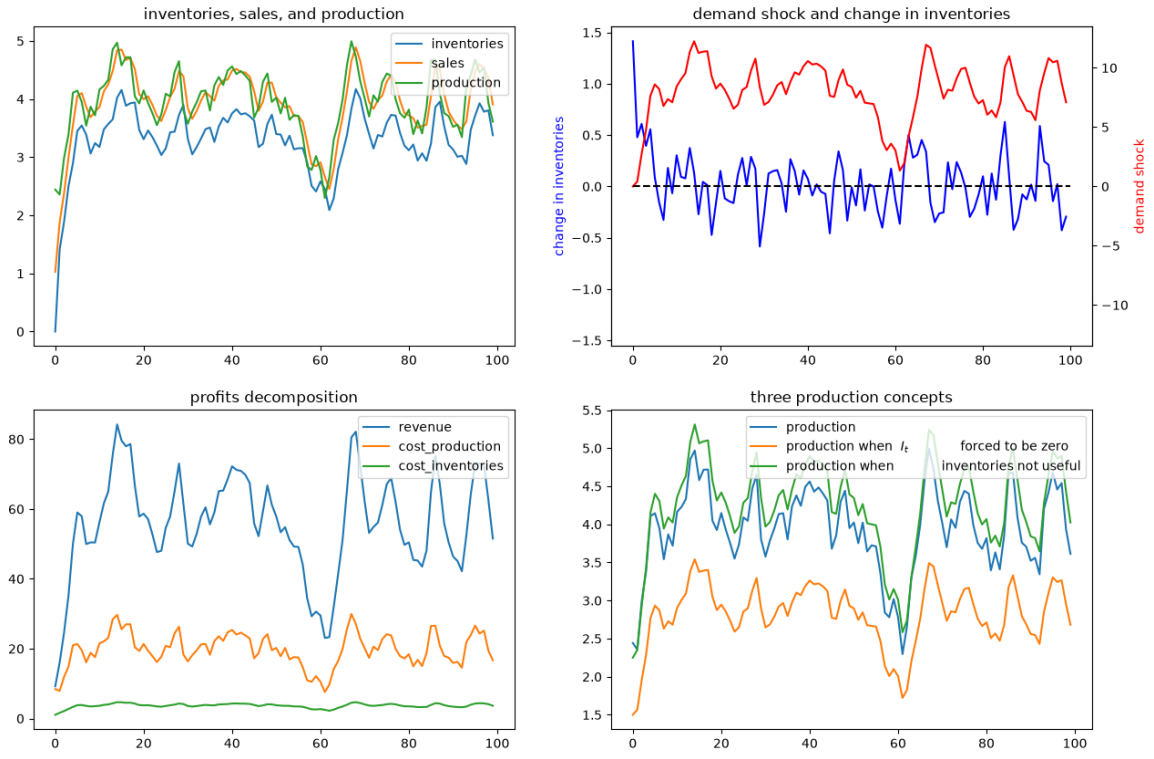
Please try to analyze some inventory sales smoothing problems using the `SmoothingExample` class.

Exercise 90.10.1

Assume that the demand shock follows AR(2) process below:

$$\nu_t = \alpha + \rho_1 \nu_{t-1} + \rho_2 \nu_{t-2} + \epsilon_t.$$

where $\alpha = 1$, $\rho_1 = 1.2$, and $\rho_2 = -0.3$. You need to construct $A22$, C, and G matrices properly and then to input them as the keyword arguments of `SmoothingExample` class. Simulate paths starting from the initial condition $x_0 = [0, 1, 0, 0]'$.



After this, try to construct a very similar `SmoothingExample` with the same demand shock process but exclude the randomness ϵ_t. Compute the stationary states $\bar{x}$ by simulating for a long period. Then try to add shocks with different magnitude to $\bar{\nu}_t$ and simulate paths. You should see how firms respond differently by staring at the production plans.

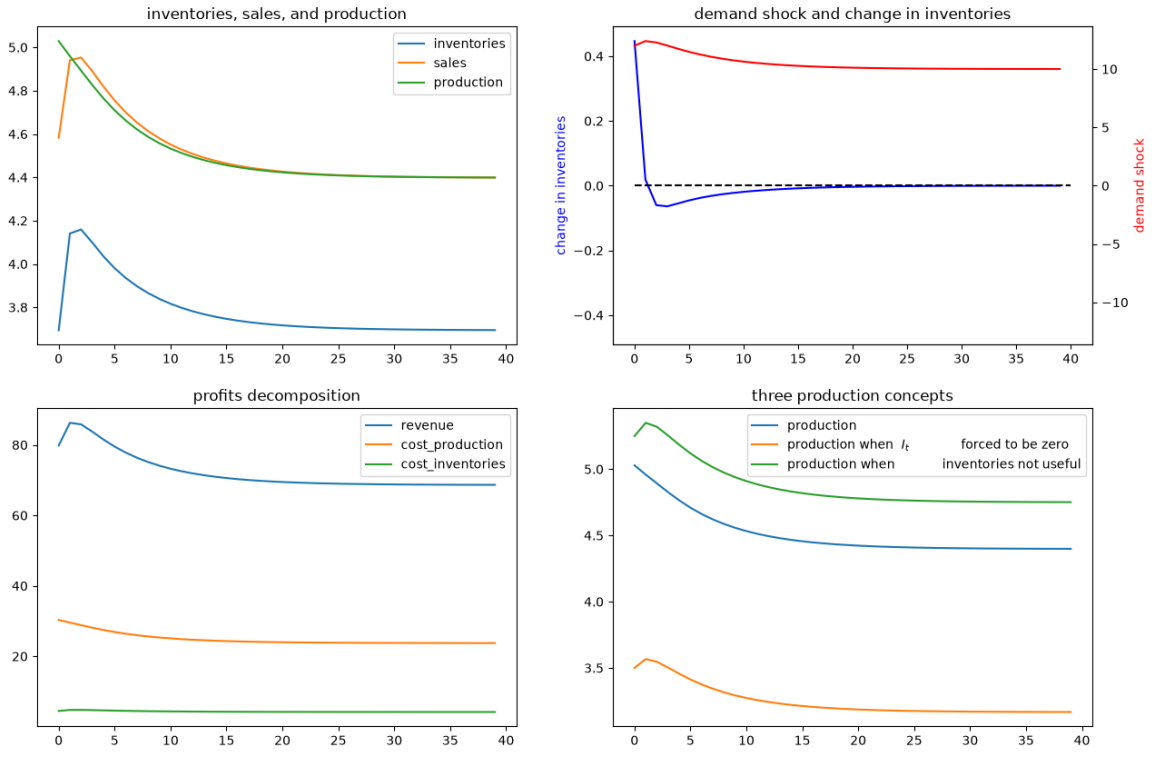
Solution

```
# set parameters
a = 1
```

```
ρ1 = 1.2
ρ2 = -.3
# construct matrices
A22 =[[1,  0,  0],
      [1, ρ1, ρ2],
      [0,  1,  0]]
C2 = [[0], [1], [0]]
G = [0, 1, 0]
ex1 = SmoothingExample(A22=A22, C2=C2, G=G)

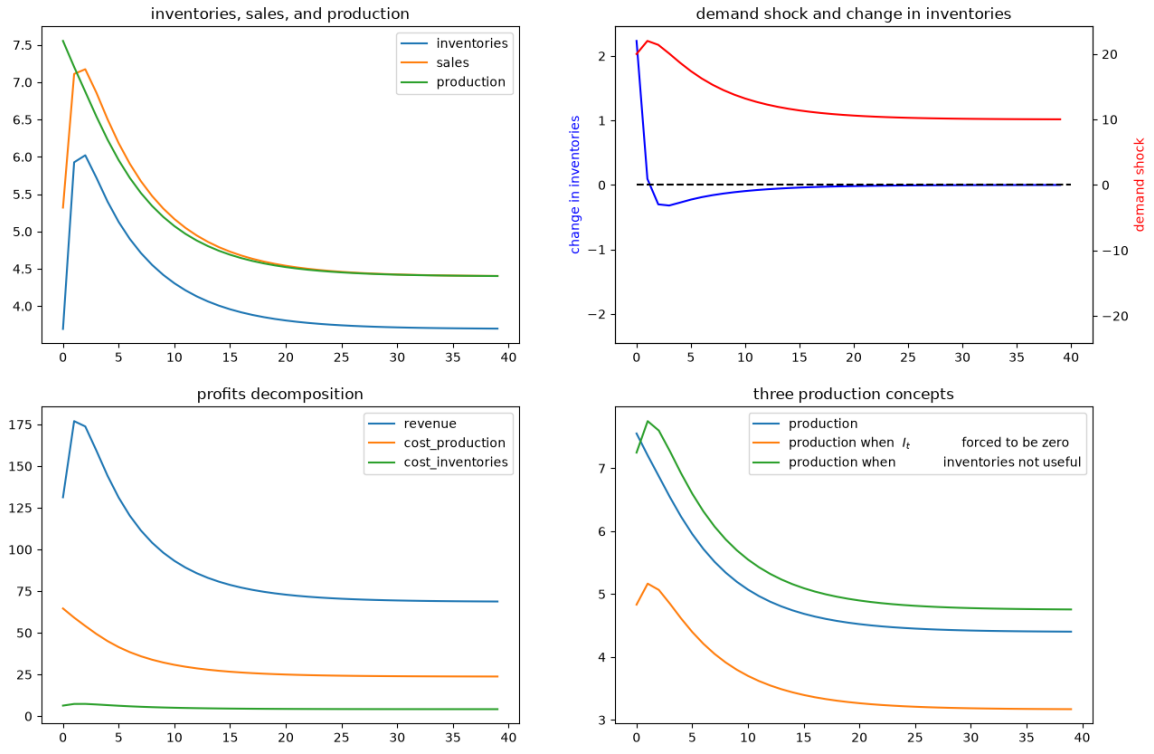
x0 = [0, 1, 0, 0] # initial condition
ex1.simulate(x0)
```

```
# now silence the noise
ex1_no_noise = SmoothingExample(A22=A22, C2=[[0], [0], [0]], G=G)



# initial condition
x0 = [0, 1, 0, 0]

# compute stationary states
x_bar = ex1_no_noise.LQ.compute_sequence(x0, ts_length=250)[0][:, -1]
x_bar
```



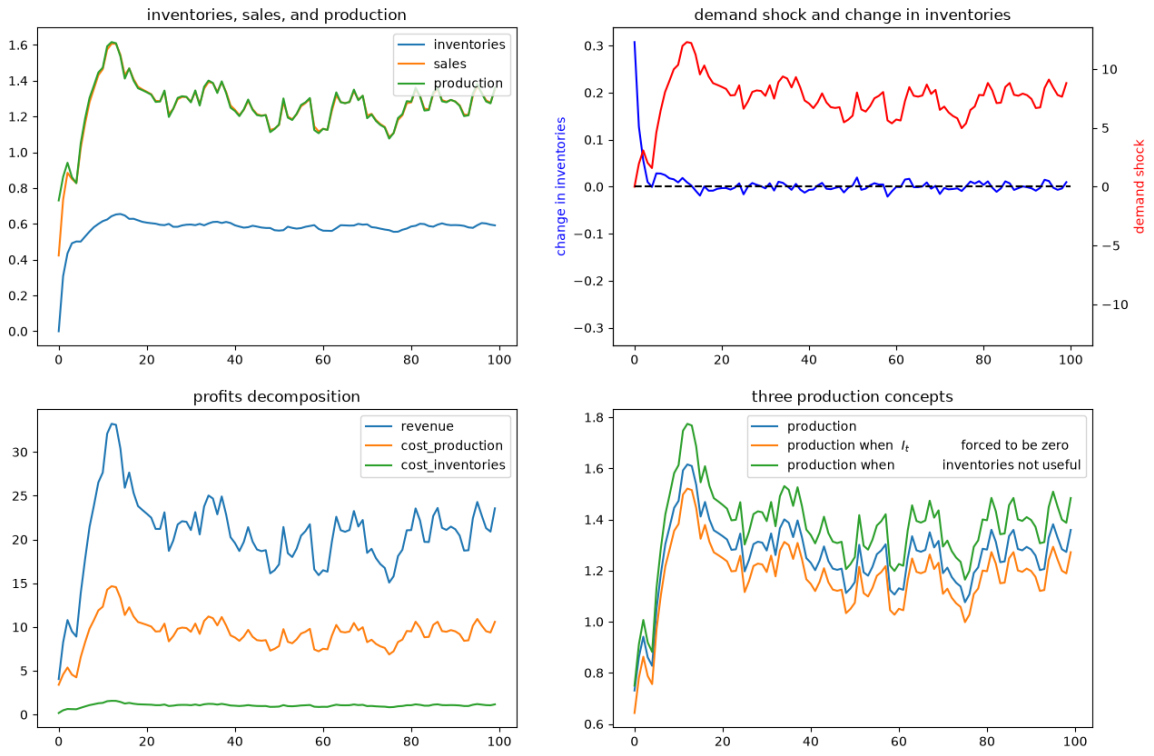
```
array([ 3.69387755,  1.        , 10.        , 10.        ])
```

In the following, we add small and large shocks to $\bar{\nu}_t$ and compare how firm responds differently in quantity. As the shock is not very persistent under the parameterization we are using, we focus on a short period response.

```
T = 40
# small shock
x_bar1 = x_bar.copy()
x_bar1[2] += 2
ex1_no_noise.simulate(x_bar1, T=T)
```

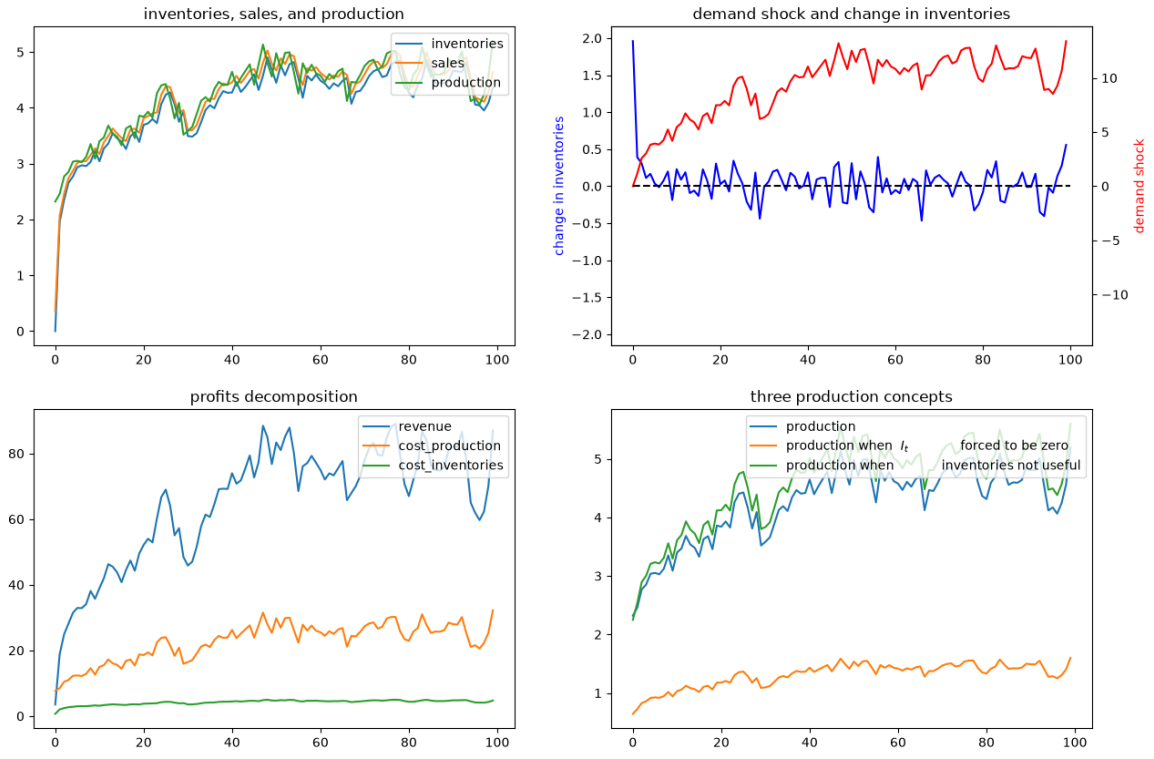
```
# large shock
x_bar1 = x_bar.copy()
x_bar1[2] += 10
ex1_no_noise.simulate(x_bar1, T=T)
```

Exercise 90.10.2



Change parameters of $C(Q_t)$ and $d(I_t, S_t)$.

1. Make production more costly, by setting $c_2 = 5$.
2. Increase the cost of having inventories deviate from sales, by setting $d_2 = 5$.



Solution

```
x0 = [0, 1, 0]
```

```
SmoothingExample(c2=5).simulate(x0)
```

```
SmoothingExample(d2=5).simulate(x0)
```

Bounded Rationality in Macroeconomics

CHAPTER

NINETYONE

A PECULIAR DEFINITION OF BOUNDED RATIONALITY

Contents

- *A Peculiar Definition of Bounded Rationality*
  - *Overview*
  - *Rational expectations as a fixed point*
  - *One recursion, many learners*
  - *Money and prices*
  - *Two currencies*
  - *Where this leaves us*
  - *Exercises*

91.1 Overview

This lecture opens a series based on Sargent [1993] about Bounded Rationality in Macroeconomics, from one point of view in the late 1980s and early 1990s.

Those were years when the Soviet Union ended and formerly Warsaw Pact countries were rearranging their political economies.

For those countries, those were thus truly *regime changes* in the technical sense of modern dynamic macroeconomics.

As *What the program is good for* explains, rational expectations models handle such changes less comfortably than their users usually suppose.

Two generations of work on economic dynamics — in game theory, macroeconomics, and general equilibrium theory — had produced theories that embraced the rational expectations assumption, models that were designed to understand settings in which people face recurrent situations they have lived through many times before.

The transitions across regimes underway in Eastern Europe in the early 1990s were not like that.

People there were confronted with unprecedented opportunities, new and ill-defined rules, and a daily struggle to figure out the mechanism that would eventually govern trade and production.

Economists with good models of a market economy had ample *equilibrium theories* describing how a system behaves once it has fully adjusted to a new and coherent set of rules and expectations.

They knew much less about the dynamics of *transitions* from a Soviet system to a market economy.

They might hold prejudices and anecdotes about how to manage such a transition, but no empirically confirmed formal theory of it.

Against this background, some economists ventured into what Sims [1980] called the "wilderness" of irrational expectations and bounded rationality.

The aim was partly to build theories of transition dynamics, partly to understand the properties of equilibrium dynamics themselves, and partly to study systems that never settle down.

This series follows Sargent [1993] a little way into that wilderness.

91.1.1 The knowledge that rational expectations imputes

To see what bounded rationality retreats *from*, start with rational expectations, which imposes **two** requirements:

1. **Individual rationality** — each artificial agent's behavior maximizes an objective function subject to perceived constraints.
2. **Mutual consistency** — the constraints perceived by everybody in the system agree with one another and with the outcomes that their decisions jointly generate.

The second requirement is Muth's *rational expectations* assumption [Muth, 1961].

In an economy one person's decisions are part of another person's constraints, so consistency requires each person to hold correct beliefs about everyone else's decisions, decision processes, and beliefs.

Consistency is also what gives rational expectations its power: without some restriction on perceptions, a model in which behavior depends on arbitrary assumptions about subjective beliefs can produce almost any outcome at all.

But look at what that requirement imputes to people once a model is taken to data.

The agents inside a rational expectations model evaluate their Euler equations using *equilibrium* probability distributions.

Those are the very distributions that the econometrician studying them is still struggling to estimate.

The agents, in other words, have somehow already solved the inference problem that the economist is only part way through.

91.1.2 Sargent's formulation of bounded rationality

Sargent's **bounded rationality** program keeps individual rationality and retreats from mutual consistency in a particular way, chosen to remove the asymmetry just described between the agents in a model and the econometrician who studies them.

Sargent's version of a bounded rationality program is (Sargent [1993], ch. 1):

> I interpret a proposal to build models with 'boundedly rational' agents as a call to retreat from the second piece of rational expectations (mutual consistency of perceptions) by expelling rational agents from our model environments and replacing them with 'artificially intelligent' agents who behave like econometricians. These 'econometricians' theorize, estimate, and adapt in attempting to learn about probability distributions which, under rational expectations, they already know.

The agents are made more like the people who build the models: they gather data, form theories, estimate, and adapt.

Note

Why "peculiar"?

For Herbert Simon, who coined the term, bounded rationality meant limits on people's capacity to gather and process information, so that they *satisfice* rather than optimize.

Sargent's agents are bounded in a different way: they compute like econometricians, but they do not know the equilibrium probability distributions.

The book credits Simon with the aim of removing the asymmetry between agents and econometrician, but Simon rejected this way of doing it.

After he saw the manuscript of the book, Simon wrote Sargent a letter objecting to the formulation and recommending that Sargent not call it "bounded rationality".

Simon particularly disliked making the agents inside the model act like econometricians, a pretense that he found preposterous.

Rational expectations and bounded rationality share a birthplace: in the 1950s Muth and Simon were colleagues and coauthors at the Carnegie Institute of Technology, now Carnegie Mellon University [Holt *et al.*, 1960].

Sargent's proposal makes work harder for the model builder, not easier.

Withdrawing the assumption of a commonly understood environment means we must put something in its place, and there are many plausible somethings to choose among (Sargent [1993], ch. 1):

> This area is wilderness because the researcher faces so many choices after he decides to forgo the discipline provided by equilibrium theorizing. The commitment to equilibrium theorizing made many choices for him by requiring that people be modelled as optimal decision-makers within a commonly understood environment. When we withdraw the assumption of a commonly understood environment, we have to replace it with something, and there are so many plausible possibilities.

91.1.3 What the program is good for

Chapter 2 of Sargent [1993] lists four payoffs that might justify the effort.

1. **Equilibrium selection.** When a model has many equilibria, adaptive agents may converge to only some of them, turning learning into a device for selecting among rational expectations equilibria; where the equilibrium is unique, agents who learn their way to it lend it a plausibility it lacked as a mere assumption.
2. **Computation.** Learning algorithms double as algorithms for computing equilibria too complicated to solve by hand, and the literatures that supply the agents' "brains" also supply economists with new methods of optimization and estimation.
3. **Transition dynamics and regime changes.** Adaptive dynamics hold out the hope of a theory of the out-of-equilibrium adjustment that the Eastern European reformers had to manage blind.
4. **New sources of dynamics.** Where rational expectations makes a sharp prediction that the data reject, adaptive agents can supply what is missing; the book's leading example is the no-trade theorem of finance, under which no trade can occur in equilibrium.

The third payoff answers a criticism that the book levels at standard practice.

A common use of rational expectations models is to compute one equilibrium under a "pre-reform" policy rule and another under a "post-reform" rule, and to read the difference as the effect of the reform.

That comparison is itself inconsistent with rational expectations: each equilibrium assumes a government committed forever to its rule, so the comparison predicts what would happen if the government did what the agents were certain it never would.

The book illustrates with the abrupt ends of the German and Austrian hyperinflations, where the shortcut seems to cost little, and with two stories about the onset of the Great Depression, each of which works only by backing off rational

expectations at some point.

A theory of how people learn their way into a new regime would fill that gap.

That promise is the least fulfilled, as the series will acknowledge; selection and computation are the surer payoffs.

This lecture sets up the selection problem in its sharpest form: models with **too many equilibria**.

When a rational expectations model has a continuum of equilibria, the physical description of the economy plus the equilibrium concept fail to pin down what happens.

Something else must choose, and a plausible account of how people grope toward equilibrium is a natural candidate for that something.

We build two monetary examples that later lectures return to, both with a continuum of rational expectations equilibria:

- a quantity-theory model of money and prices in which the price level is determined only up to an arbitrary **bubble** term, and
- a two-currency version in which the *exchange rate is completely unrestricted*.

Along the way we set up the machinery — the fixed-point view of equilibrium, the relaxation algorithm, adaptive expectations, Muth's inverse optimal-prediction problem, and the stochastic-approximation recursion whose associated differential equation governs where adaptive agents end up — that later lectures use to expel the rational agents and put adaptive ones in their place.

91.1.4 The rest of the series

- *Adaptive Agents in an Overlapping Generations Monetary Economy* — adaptive households in Samuelson's overlapping generations monetary model.
  - Least squares learning selects the low-inflation equilibrium that the rational expectations dynamics reject, and laboratory subjects go the same way.
  - A government learning a Phillips curve closes the lecture.
- *Learning, Approximation, and Equilibrium Computation* — what an agent must give up when the state is continuous and a separate response for each contingency is out of the question, which brings in approximate equilibria and the resemblance between learning algorithms and equilibrium computation algorithms.
- *Exchange Rate Indeterminacy, Learning, and Experiments* — the two-currency model of this lecture with adaptive agents, where learning pins the exchange rate down only by making it depend on history, while a genetic-algorithm economy instead produces volatility that never dies.
- *Networks, Genetic Algorithms, and Classifier Systems* — a catalogue of candidate brains, from Holland and the connectionists: perceptrons, associative memories, genetic algorithms, classifier systems.
- *Money as a Medium of Exchange among Artificially Intelligent Agents* — populations of classifier systems that discover, from scratch, which good will serve as money.
- *1993 Prospects for Bounded Rationality in Macroeconomics* — the 1993 ledger of what the program achieved and what it did not, and a postscript on the three decades since.

The lectures are ordered by how much the modeller tells the agents, a gradient of *prompting*:

- Bray's least squares learners, met *below*, know everything about their environment except one coefficient.
- The Robbins–Monro agents of *Adaptive Agents in an Overlapping Generations Monetary Economy* know their utility function but not the distribution of the returns they face.
- The agents of *Learning, Approximation, and Equilibrium Computation* must also choose a functional form for what they learn.

- The Newton learners of *Exchange Rate Indeterminacy, Learning, and Experiments* know the gradient of their own payoff; its genetic-algorithm strings, like the classifier systems of *Networks, Genetic Algorithms, and Classifier Systems* and *Money as a Medium of Exchange among Artificially Intelligent Agents*, see only a payoff signal.

1993 Prospects for Bounded Rationality in Macroeconomics then enters the prompting on the debit side of the ledger.

91.1.5 Notation across the series

Each lecture follows the notation of its sources, so some symbols change jobs from lecture to lecture.

symbol	in this lecture	later in the series
λ	relaxation parameter (gain); growth rate of the bubble	portfolio share (*Exchange Rate Indeterminacy, Learning, and Experiments*); trade decision (*Money as a Medium of Exchange among Artificially Intelligent Agents*)
γ	curvature of cost; coefficient on money in the price level	learning gain (*Adaptive Agents in an Overlapping Generations Monetary Economy* – *Networks, Genetic Algorithms, and Classifier Systems*); consumption decision (*Money as a Medium of Exchange among Artificially Intelligent Agents*)
θ	Muth's moving-average coefficient; generic belief parameters	Phillips-curve slope (*Adaptive Agents in an Overlapping Generations Monetary Economy*); approximation coefficients (*Learning, Approximation, and Equilibrium Computation*)
w_1, u	endowments are $2w_1, 2w_2$	endowments are w_1, w_2 (*Adaptive Agents in an Overlapping Generations Monetary Economy* – *Exchange Rate Indeterminacy, Learning, and Experiments*); weights (*Networks, Genetic Algorithms, and Classifier Systems*)
π	—	gross inflation (*Adaptive Agents in an Overlapping Generations Monetary Economy*); choice and holding probabilities (*Networks, Genetic Algorithms, and Classifier Systems*, *Money as a Medium of Exchange among Artificially Intelligent Agents*)
s	—	saving (*Adaptive Agents in an Overlapping Generations Monetary Economy* – *Exchange Rate Indeterminacy, Learning, and Experiments*); network state (*Networks, Genetic Algorithms, and Classifier Systems*); storage cost (*Money as a Medium of Exchange among Artificially Intelligent Agents*)
N	(the number of firms is n)	cohort size (*Adaptive Agents in an Overlapping Generations Monetary Economy*, *Exchange Rate Indeterminacy, Learning, and Experiments*); population or pattern size (*Exchange Rate Indeterminacy, Learning, and Experiments*, *Networks, Genetic Algorithms, and Classifier Systems*)

From *Adaptive Agents in an Overlapping Generations Monetary Economy* on, R is reserved for gross returns and M for estimated moment or curvature matrices.

Adaptive expectations means Cagan's and Friedman's geometric distributed lag below, while *adaptive agents* means agents who revise any rule — a forecast, a regression coefficient, the strength of a rule of thumb — in light of experience.

The learning gain is written λ_t here, because γ is taken, and γ_t from *Adaptive Agents in an Overlapping Generations Monetary Economy* on.

Let's start with some imports.

```
import numpy as np
import pandas as pd
import matplotlib.pyplot as plt
from scipy.signal import lfilter
```

91.2 Rational expectations as a fixed point

91.2.1 A static market

Take a competitive industry with a large number n of identical firms.

Each firm chooses output x to maximize

$$\Pi(x, p) = px - c(x),$$

where c is an increasing, convex cost function, and price is determined by a downward-sloping inverse demand curve

$$p = p(nX)$$

in which X is the output of the *average* firm.

Each firm is a price-taker and an X-taker: it takes p as given and sets marginal cost equal to price, $p = c'(x)$.

Write the solution as $x = g(p)$.

Substituting the demand curve gives the **best-response map**

$$x = g(p(nX)) \equiv h(X), \tag{91.1}$$

which sends a conjectured industry average X to the individual output an optimizing firm would choose against it.

That is the first component of rational expectations, and it is all that individual rationality delivers.

The second component — consistency — requires that what each firm chooses coincides with what it assumed the average firm was choosing:

$$X = h(X). \tag{91.2}$$

A static rational expectations equilibrium is a **fixed point of the best-response map**.

For a concrete example, take a quadratic cost function $c(x) = \frac{\gamma}{2}x^2$ and a linear inverse demand curve $p = a - bnX$.

Then $p = c'(x) = \gamma x$ gives $x = p/\gamma$, so

$$h(X) = \frac{a - bnX}{\gamma}, \qquad \text{with fixed point} \qquad X^* = \frac{a}{\gamma + bn}.$$

```
a, b, n, γ = 10.0, 0.3, 5, 1.0

def h(X):
    "Best response of an individual firm to an industry average X."
    return (a - b * n * X) / γ

X_star = a / (γ + b * n)
print(f"X*     = {X_star}")
print(f"h(X*)  = {h(X_star)}")
print(f"h'(X)  = {-b * n / γ}")
```

```
X*     = 4.0
h(X*)  = 4.0
h'(X)  = -1.5
```

91.2.2 Computing the fixed point

Now suppose we want to *find* X^* without solving for it in closed form.

A natural starting point is the **relaxation algorithm**: carry an estimate X_k^* of the equilibrium, compute the best response to it, and move part of the way toward that best response,

$$X_k^* = X_{k-1}^* + \lambda(h(X_{k-1}^*) - X_{k-1}^*), \tag{91.3}$$

where $\lambda \in (0, 1]$ is a **relaxation parameter**.

With $\lambda = 1$ this is simple iteration on h, the classic cobweb.

```
def relax(λ, X0=1.0, n_iter=12):
    "Iterate the relaxation algorithm, returning the whole path."
    path = np.empty(n_iter + 1)
    path[0] = X0
    for k in range(n_iter):
        path[k + 1] = path[k] + λ * (h(path[k]) - path[k])
    return path

fig, axes = plt.subplots(1, 2, figsize=(11, 4))

axes[0].plot(relax(1.0), 'o-', ms=4, lw=1, color='C0',
             label=r"$\lambda = 1.0$ (cobweb)")
axes[0].set_title(r"$\lambda = 1$: the cobweb")
axes[0].set_ylabel("$X^*_k$")

for i, λ in enumerate((0.8, 0.5, 0.3)):
    axes[1].plot(relax(λ), 'o-', ms=4, lw=1, color=f'C{i+1}',
                 label=fr"$\lambda = {λ}$")
axes[1].set_title(r"$\lambda < 1$: relaxation")
axes[1].set_ylim(-1, 9)

for ax in axes:
    ax.axhline(X_star, color='k', lw=0.8, ls='--', label="$X^*$")
    ax.set_xlabel("$k$")
    ax.legend(frameon=False, fontsize=9)
plt.tight_layout()
plt.show()
```

The naive cobweb $\lambda = 1$ **diverges**, oscillating ever further away from the equilibrium it is trying to find; note the scale on the left panel.

Since h is affine, iteration (91.3) has multiplier $1 + \lambda(h' - 1)$, so it converges if and only if

$$\big|1 + \lambda(h' - 1)\big| < 1 \qquad \iff \qquad \lambda < \frac{2}{1 + bn/\gamma}.$$

```
λ_max = 2 / (1 + b * n / γ)
print(f"converges iff λ < {λ_max}")
print(f"λ = 1.0 : multiplier = {1 + 1.0 * (-b*n/γ - 1):+.2f}   (diverges)")
print(f"λ = 0.8 : multiplier = {1 + 0.8 * (-b*n/γ - 1):+.2f}   (period-2 cycle)")
print(f"λ = 0.5 : multiplier = {1 + 0.5 * (-b*n/γ - 1):+.2f}   (converges)")
```

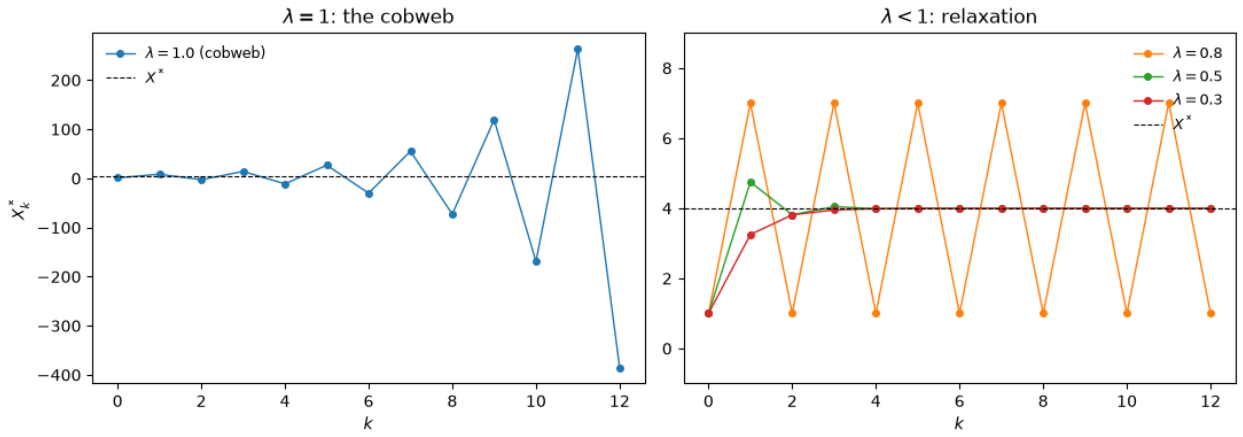

Fig. 91.1: Relaxation algorithm paths: the cobweb and three smaller relaxation parameters

```
converges iff λ < 0.8
λ = 1.0 : multiplier = -1.50   (diverges)
λ = 0.8 : multiplier = -1.00   (period-2 cycle)
λ = 0.5 : multiplier = -0.25   (converges)
```

At $\lambda = 0.8$ the multiplier is exactly -1: the scheme maps $X \mapsto 8 - X$ and so bounces forever between 1 and 7 without either converging or diverging, which is the zigzag that never dies down in the right panel.

Damping the adjustment enough makes the algorithm find the equilibrium; not damping it enough makes the algorithm chase its own tail.

Hold on to that observation.

A recurring theme of this series is that *how* you adapt determines where, and whether, you end up.

91.2.3 Adaptive expectations

Equation (91.3) was introduced as an algorithm running in iteration count k.

Reinterpret k as **calendar time** t, read X_t^* as the value people *expect*, and $X_t = h(X_{t-1}^*)$ as what actually happens, and it becomes a theory of expectation formation:

$$X_t^* = (1-\lambda)X_{t-1}^* + \lambda X_t = \lambda \sum_{j=0}^{\infty} (1-\lambda)^j X_{t-j}. \tag{91.4}$$

This is the **adaptive expectations** scheme that Cagan [Cagan, 1956] used to study hyperinflations and that Friedman [1957] used to study consumption.

Expectations are a geometrically declining distributed lag of past observations, with a single free parameter λ describing beliefs.

Cagan and Friedman took λ as a free parameter and left open the question of *why* anyone would form expectations this way.

91.2.4 Muth's inverse problem

Muth [1960] set out to eliminate λ as a free parameter by turning the question around.

Instead of asking what forecasts a given environment implies, he asked: **for what environment would exponential smoothing be the optimal forecast?**

His answer is that (91.4) is the least-squares forecast of X_{t+k} at every horizon k if and only if X_t follows

$$X_t = X_{t-1} + \epsilon_t - \theta \epsilon_{t-1}, \tag{91.5}$$

with $\{\epsilon_t\}$ a martingale difference sequence and $\theta \in [0, 1)$, and the smoothing weight tied to the moving-average coefficient by

$$\lambda = 1 - \theta \in (0, 1].$$

Note

Sargent writes both the smoothing weight in (91.4) and the moving-average coefficient in (91.5) as λ.

We use θ for the second to keep the relationship $\lambda = 1 - \theta$ visible; *Notation across the series* lists the other symbols that change jobs.

The forecasting rule inherits its one parameter from the stochastic process being forecast.

Let's confirm this numerically at horizon $k = 1$ (Exercise 91.7.4 checks a longer horizon): simulate (91.5), run exponential smoothing at a range of weights, and see which weight forecasts best.

```
def smoothing_mse(x, λ, k=1):
    "MSE of exponential smoothing with weight λ as a forecast k steps ahead."
    # f_i = λ x_i + (1 - λ) f_{i-1}, started at f_0 = x_0
    f, _ = lfilter([λ], [1, λ - 1], x, zi=[(1 - λ) * x[0]])
    return np.mean((x[k:] - f[:-k]) ** 2)

rng = np.random.default_rng(0)
T = 200_000
ε = rng.standard_normal(T + 1)            # one shock path, shared across all λ
grid = np.linspace(0.02, 0.98, 97)

fig, ax = plt.subplots(figsize=(7, 4))
for θ in (0.2, 0.5, 0.8):
    X = np.cumsum(ε[1:] - θ * ε[:-1])     # Muth's process
    mse = np.array([smoothing_mse(X, λ) for λ in grid])
    line, = ax.plot(grid, mse, lw=1.2, label=fr"$\theta = {θ}$")
    ax.axvline(1 - θ, color=line.get_color(), lw=0.8, ls='--')
    print(f"θ = {θ}:  best λ = {grid[mse.argmin()]:.2f},  1 - θ = {1 - θ:.2f},"
          f"  min MSE = {mse.min():.4f}")
ax.set_xlabel(r"smoothing weight $\lambda$")
ax.set_ylabel("forecast MSE")
ax.set_ylim(0.9, 3)
ax.legend(frameon=False)
plt.show()
```

```
θ = 0.2:  best λ = 0.80,  1 - θ = 0.80,  min MSE = 1.0024
θ = 0.5:  best λ = 0.50,  1 - θ = 0.50,  min MSE = 1.0024
θ = 0.8:  best λ = 0.20,  1 - θ = 0.20,  min MSE = 1.0024
```

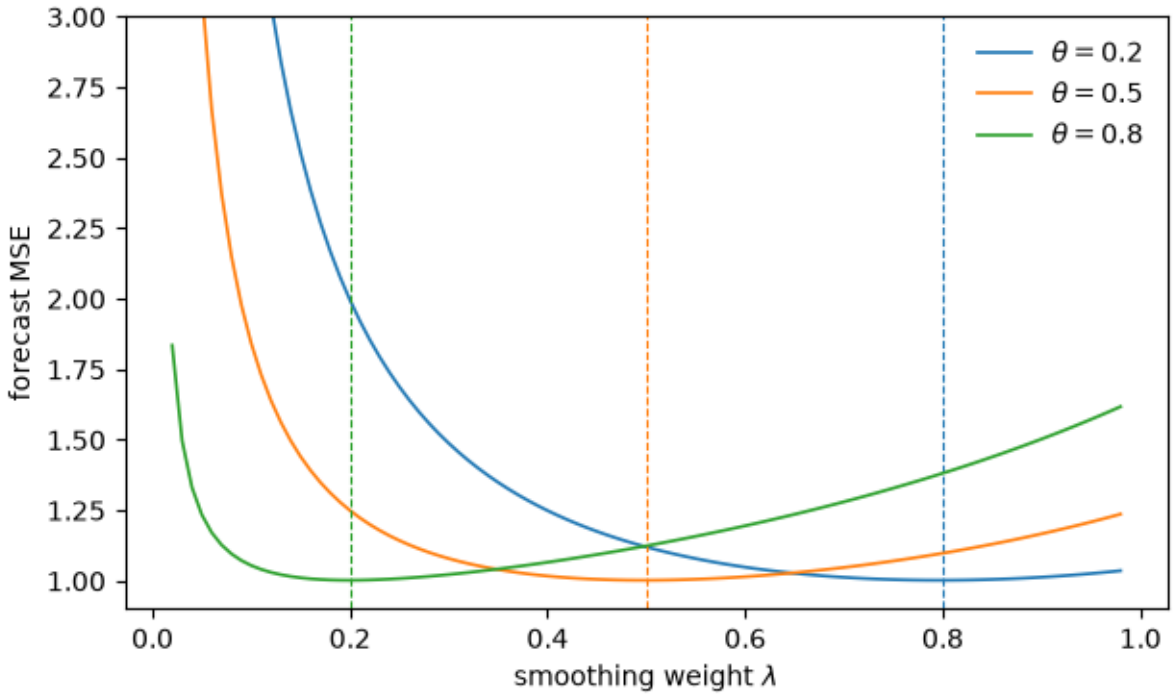

Fig. 91.2: Forecast MSE of exponential smoothing

Each curve bottoms out exactly at its dashed line $\lambda = 1 - \theta$, and the minimized mean squared error is $\mathbb{V}[\epsilon_t] = 1$ up to simulation noise — exponential smoothing at that weight *is* the conditional expectation, and nothing can beat it.

Muth's exercise was the first application of the rational expectations idea in the form that became standard: find the restrictions that link a forecasting scheme to the environment in which it is used.

It also pushed later researchers [Lucas and Prescott, 1971] to treat the **forecasting scheme itself** as the object in terms of which equilibrium is defined.

91.2.5 The dynamic analogue

That is exactly what happens when we move from static to dynamic models.

Let each agent choose a sequence rather than a single action, a contingency plan for x_t that maximizes

$$E \sum_{t=0}^{\infty} \beta^t \, \Pi(x_t, x_{t-1}, p_t),$$

taking as given a price equation $p_t = p(X_t, u_t)$ and a **perceived law of motion** for the aggregate state,

$$X_t = H(X_{t-1}, u_t),$$

where $\{u_t\}$ is IID and $\beta \in (0, 1)$ is a discount factor.

The Euler equation for this problem is

$$\Pi_1(x_t, x_{t-1}, p_t) + \beta \int \Pi_2(x_{t+1}, x_t, p_{t+1}) \, dF(p_{t+1} \mid X_t) = 0,$$

where Π_i is the derivative with respect to the ith argument and $F(\cdot \mid X_t)$ is the distribution of next period's price that the perceived law of motion H induces.

In a rational expectations equilibrium F is the *equilibrium* distribution, the very object that, as we saw at the start, the econometrician is still trying to estimate.

Solving the agent's dynamic program yields an individual decision rule $x_t = h(x_{t-1}, X_{t-1}, u_t)$.

Imposing that the representative agent is representative, $x_t = X_t$, delivers the **actual law of motion**

$$X_t = h(X_{t-1}, X_{t-1}, u_t) \equiv H^*(X_{t-1}, u_t),$$

and hence a map from perceived to actual laws of motion,

$$H^* = T(H). \tag{91.6}$$

A dynamic rational expectations equilibrium is a fixed point $H = T(H)$, the same idea as (91.2), but the fixed point now lives in a space of *functions* rather than a space of numbers.

The relaxation algorithm carries over unchanged,

$$H^*_k = H^*_{k-1} + \lambda(T(H^*_{k-1}) - H^*_{k-1}), \tag{91.7}$$

except that it now revises entire expectations-generating functions in response to the gap between what they predicted and what happened.

The econometric learners of this series are versions of (91.7) in which the revision is driven by data rather than by an exact evaluation of T, and in which the gain λ sometimes declines over time and sometimes stays constant.

The next section makes that family precise.

See also

Rational Expectations Equilibrium develops the T map in detail for a Lucas–Prescott industry model and computes its fixed point, and *Investment Under Uncertainty* studies the Lucas–Prescott model itself.

Least Squares Learning in Self-Referential Models studies what happens when agents estimate the perceived law of motion by least squares while living inside the system their estimates help determine.

91.3 One recursion, many learners

The relaxation algorithm is the simplest member of a family of recursions that runs through the whole series; to see the family, put some noise into the static market and let the firms learn.

91.3.1 From relaxation to learning: Bray's market

Suppose firms must commit to output before they see what the average firm produces.

Each firm enters period t with a belief X^*_{t-1} about average output, formed from data through $t-1$, and produces its best response $h(X^*_{t-1})$; a common supply shock u_t, IID with mean zero and variance σ_u^2, then determines what actually happens, and firms revise their belief toward it:

$$X_t = h(X^*_{t-1}) + u_t, \qquad X^*_t = X^*_{t-1} + \lambda_t(X_t - X^*_{t-1}). \tag{91.8}$$

Without the shock and with a constant gain $\lambda_t = \lambda$, this is the relaxation algorithm (91.3) run in calendar time, that is, adaptive expectations.

With the gain $\lambda_t = 1/t$, X_t^* is the sample mean of $X_1, \ldots, X_t$, the least squares estimate of a constant, and the model is, up to notation, that of Bray [1982], whose feedback coefficient is our h' (Bray writes it b, a letter that here denotes the slope of demand).

The belief error $e_t = X_t^* - X^*$ obeys

$$e_t = [1 + \lambda_t(h' - 1)]e_{t-1} + \lambda_t u_t,$$

so each period applies the relaxation multiplier at that period's gain.

A constant gain above the bound $2/(1 + bn/\gamma)$ makes beliefs explode, as the cobweb did; below the bound they do not explode, but each shock moves them by λu_t, so they wander forever in a band around X^*.

A declining gain eventually falls below any bound, and as $\lambda \to 0$ the stability condition $|1 + \lambda(h' - 1)| < 1$ collapses to $h' < 1$, Bray's condition for least squares learners to converge, which the cobweb market, with $h' = -bn/\gamma < 0$, satisfies however steep it is.

The next cell puts firms in this lecture's market, where $h' = -1.5$ and fixed gains above 0.8 explode, and compares three gains on one path of shocks.

```
def learn(gain, u, X0=1.0):
    "Beliefs X*_t of firms that update with gain(t) in the market with shocks u."
    X = np.empty(len(u) + 1)
    X[0] = X0
    for t in range(1, len(u) + 1):
        X_t = h(X[t-1]) + u[t-1]                    # what actually happens
        X[t] = X[t-1] + gain(t) * (X_t - X[t-1])    # belief revision
    return X

σ_u, T_b = 0.5, 2_000
u = σ_u * np.random.default_rng(1).standard_normal(T_b)
t_b = np.arange(1, T_b + 1)

fig, ax = plt.subplots(figsize=(8, 4))
for label, gain, lw in [(r"$\lambda_t = 0.9$", lambda t: 0.9, 1.0),
                        (r"$\lambda_t = 0.3$", lambda t: 0.3, 0.5),
                        (r"$\lambda_t = 1/t$", lambda t: 1 / t, 1.0)]:
    ax.plot(t_b, np.abs(learn(gain, u)[1:] - X_star), lw=lw, label=label)
ax.plot(t_b, σ_u / np.sqrt(t_b), 'k--', lw=0.8, label=r"$\sigma_u / \sqrt{t}$")
ax.set_xscale('log')
ax.set_yscale('log')
ax.set_ylim(1e-4, 1e3)
ax.set_xlabel("$t$")
ax.set_ylabel(r"$|X^*_t - X^*|$")
ax.legend(frameon=False, fontsize=9, ncol=2)
plt.show()
```

The fixed gain above the bound explodes, and the fixed gain below it hovers in a band whose width is set by the gain (Exercise 91.7.5 computes it).

Only the declining gain converges, with an error that shrinks like $t^{-1/2}$, the rate at which a sample mean settles down.

Least Squares Learning in Self-Referential Models analyzes Bray's model in detail, including the case $h' > 1$ in which least squares diverges, and *Optimal Misspecified Beliefs* revisits it with a constant gain.

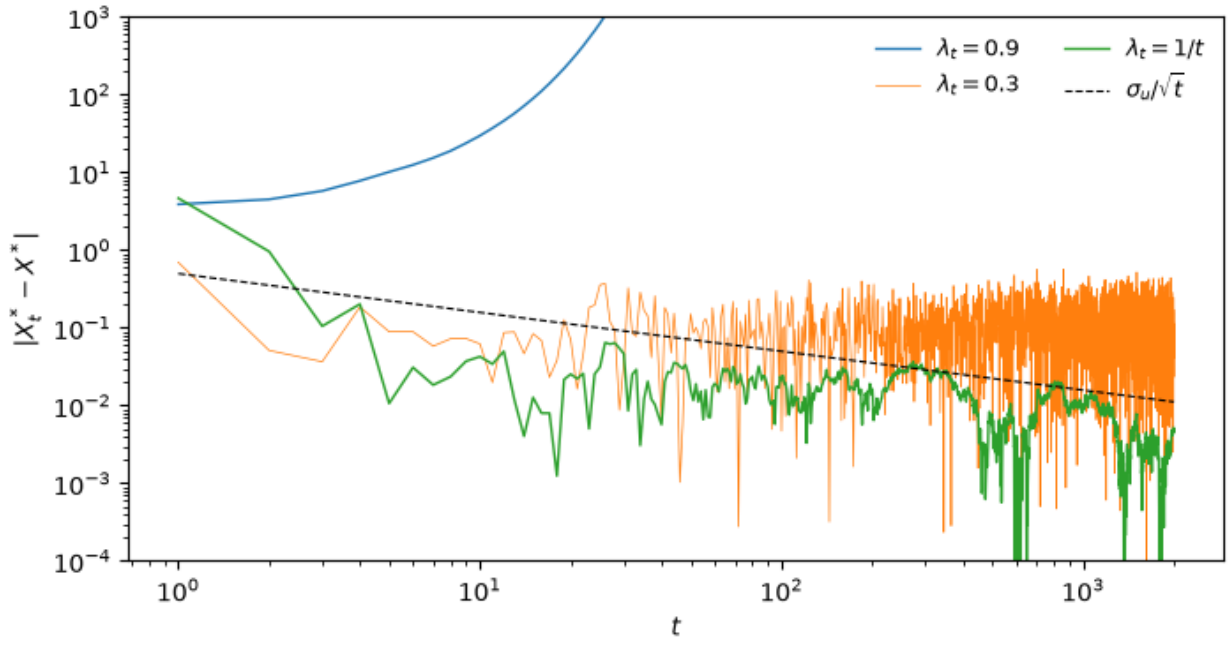

Fig. 91.3: Belief errors in Bray's market under fixed and declining gains

91.3.2 Stochastic approximation and E-stability

Most learners in this series update a vector of beliefs θ_t by a recursion of the form

$$\theta_t = \theta_{t-1} + \lambda_t \, Q(\theta_{t-1}, x_t), \tag{91.9}$$

where x_t is the latest data, λ_t is the gain, and Q is a direction of improvement, such as a forecast error or a gradient, sometimes premultiplied by the inverse of an estimated moment or curvature matrix, as in recursive least squares and Newton's method.

Equation (91.8) is the case $\theta = X^*$ and $Q = X_t - X^*_{t-1}$.

Robbins and Monro [1951] introduced such recursions to find a zero of a function observed only with noise, and Ljung [1977] showed that for small gains they follow, on average, the differential equation $d\theta/d\tau = E\,Q(\theta, x)$ in the rescaled time $\tau_t = \lambda_1 + \cdots + \lambda_t$, with the expectation taken holding θ fixed.

When agents estimate a perceived law of motion by least squares, the average update points from the perceived law toward the actual one, and the differential equation becomes

$$\frac{d\theta}{d\tau} = T(\theta) - \theta, \tag{91.10}$$

where T is the map (91.6) from perceived to actual laws of motion.

For Bray's market $T = h$, and (91.10) is $dX/d\tau = h(X) - X$, the equation that Sargent [1993] (ch. 2) already attaches to the relaxation algorithm.

A fixed point $\theta^* = T(\theta^*)$ is a rational expectations equilibrium; it is **E-stable** (expectationally stable) if it is a stable rest point of (91.10), which requires every eigenvalue of the Jacobian $DT(\theta^*)$ to have real part less than one.

What learners do near an E-stable equilibrium depends on the gain.

- With a **decreasing gain** ($\sum_t \lambda_t = \infty$ and $\sum_t \lambda_t^2 < \infty$, as for $\lambda_t = 1/t$), recursive least squares converges to an E-stable equilibrium, under regularity conditions that may include a projection facility keeping beliefs in bounds, and it converges to an E-unstable one with probability zero.

- With a **constant gain** in a stochastic environment, beliefs never settle: they fluctuate around the E-stable equilibrium in an ergodic distribution whose variance is proportional to the gain when the gain is small, with occasional large escapes [Cho *et al.*, 2002, Sargent, 1999, Williams, 2019].
- In a deterministic environment there is nothing to average away, and a small enough constant gain converges too, as the relaxation algorithm does.

E-stability is the right condition for least squares learning near an equilibrium, but it is not a theorem about every algorithm: stochastic-gradient learners can fail to converge to an E-stable equilibrium [Giannitsarou, 2005].

Population algorithms, such as the genetic algorithms and classifier systems of later lectures, lie outside the theory; drawing on Arifovic's 1991 dissertation, the book (ch. 5) reports that a genetic-algorithm population can sometimes learn its way to the equilibrium of Bray's model even when $h' > 1$.

The core of the theory predates the book, whose chapter 5 (footnote 73 and the section "An associated ordinary differential equation") uses (91.10) to study least squares learning.

The idea goes back to DeCanio [1979] and Evans [1985], Evans [1989], who used the T map to define expectational stability, and to Marcet and Sargent [1989] and Woodford [1990], who showed that it governs the convergence of least squares learning, using the method of Ljung [1977]; Evans and Honkapohja [2001] later systematized and generalized the theory.

Least Squares Learning in Self-Referential Models develops it, and *Adaptive Learning and Escape Dynamics* gives a compact primer on recursive algorithms, mean dynamics, and constant-gain escapes.

91.3.3 How the series uses it

lecture	learners and gains	what the differential equation explains
Adaptive Agents in an Overlapping Generations Monetary Economy	Robbins–Monro saving rules, declining gain	convergence to the stationary equilibrium
	least squares on inflation, weights growing with the price level (an effectively constant gain)	*the stability reversal*: $T' = \frac{1}{2} < 1$ at the low steady state $\pi = 2$, $T' = 2 > 1$ at the high one $\pi = 3$
	a government learning a Phillips curve, constant gain	recurrent escapes
Learning, Approximation, and Equilibrium Computation	online *parameterized expectations*, declining gain	slow convergence, at a rate set by the largest eigenvalue of DT
Exchange Rate Indeterminacy, Learning, and Experiments	Newton–Raphson portfolio rules, constant gain	a continuum of rest points with no drift along it, so the limit depends on where beliefs started
	a genetic algorithm	outside the theory
Networks, Genetic Algorithms, and Classifier Systems, *Money as a Medium of Exchange among Artificially Intelligent Agents*	classifier systems, $1/\tau$ averaging of rule strengths	rest points that value future payoffs as if the agents were very impatient

91.4 Money and prices

We now build the first of the two models that motivate everything that follows.

A representative money-holder chooses nominal balances m_t to carry from t to $t+1$ to maximize

$$\ln\left(2w_1 - \frac{m_t}{p_t}\right) + \ln\left(2w_2 + \frac{m_t}{p^*_{t+1}}\right), \qquad w_1 > w_2 > 0, \tag{91.11}$$

where p_t is the current price level and p^*_{t+1} is the price level expected next period.

The first term is consumption today, reduced by the real resources m_t/p_t given up to acquire currency; the second is consumption tomorrow, augmented by the goods m_t/p^*_{t+1} that the currency is expected to command.

Differentiating (91.11) with respect to m_t and rearranging gives the demand for money

$$\frac{m_t}{p_t} = w_1 - w_2\frac{p^*_{t+1}}{p_t}. \tag{91.12}$$

Real balances fall when currency is expected to lose value faster.

This is a version of the demand function Cagan [Cagan, 1956] used to study hyperinflations, and it also arises in Samuelson's [Samuelson, 1958] overlapping generations model.

Following the book, the endowments are written $2w_1$ and $2w_2$, so that the demand for real balances is $w_1 - w_2\pi$ with $\pi = p^*_{t+1}/p_t$.

From *Adaptive Agents in an Overlapping Generations Monetary Economy* on the endowments are w_1 and w_2, so the same household saves $(w_1 - w_2\pi)/2$.

To close the model we need a theory of p^*_{t+1}.

Suppose the money supply grows at a constant rate,

$$M_{t+1} = \mu M_t, \tag{91.13}$$

and that the household believes the price level is related to the money supply by

$$p_t = \gamma M_t + \lambda^t c, \tag{91.14}$$

for constants (γ, λ, c) that summarize its beliefs, with $\gamma > 0$, $\lambda > 0$ and $c \geq 0$ so that the price level stays positive.

Knowing μ, the household forecasts $p^*_{t+1} = \gamma\mu M_t + \lambda^{t+1}c$.

Substituting the forecast and (91.14) into (91.12) gives money demand as a function of the current money supply,

$$m_t = \gamma(w_1 - w_2\mu)M_t + \lambda^t(w_1 - w_2\lambda)c. \tag{91.15}$$

Notice a feature common to models in which expectations matter: the *demand* for money depends on its *supply*, because today's demand depends on tomorrow's expected price level, which is believed to depend on tomorrow's money supply.

91.4.1 Equilibrium

Setting demand equal to supply, $m_t = M_t$, turns (91.15) into a functional equation,

$$M_t = \gamma(w_1 - w_2\mu)M_t + \lambda^t(w_1 - w_2\lambda)c,$$

which must hold at every date.

Matching the two terms gives

$$\gamma = (w_1 - \mu w_2)^{-1}, \qquad \lambda = \frac{w_1}{w_2}, \qquad c \geq 0 \text{ arbitrary}, \tag{91.16}$$

so the equilibrium price level is

$$p_t = (w_1 - \mu w_2)^{-1} M_t + \left(\frac{w_1}{w_2}\right)^t c. \tag{91.17}$$

The parameters γ and λ are pinned down.

The constant c is not.

Every $c \geq 0$ is a rational expectations equilibrium, and expectations formed from (91.14) are always exactly right in each of them.

Let's verify that the residual really does vanish for any c we care to try.

```
w1, w2, μ, M0 = 2.0, 1.0, 1.5, 1.0
γ_m, λ_m = 1 / (w1 - μ * w2), w1 / w2

t = np.arange(12)
M = M0 * μ ** t

def price_path(c):
    "Equilibrium price level for bubble constant c."
    return γ_m * M + λ_m ** t * c

for c in (0.0, 0.5, 3.0, 25.0):
    p = price_path(c)
    p_star = γ_m * μ * M + λ_m ** (t + 1) * c      # forecast of next period's price
    m = w1 * p - w2 * p_star                       # money demand
    print(f"c = {c:5}:  max |demand - supply| = {np.max(np.abs(m - M)):.2e}")
```

```
c =   0.0:  max |demand - supply| = 0.00e+00
c =   0.5:  max |demand - supply| = 0.00e+00
c =   3.0:  max |demand - supply| = 0.00e+00
c =  25.0:  max |demand - supply| = 0.00e+00
```

Money demand equals money supply exactly, at every date, for every c.

91.4.2 The bubble

Since $w_1 > w_2$, the second term in (91.17) grows at the gross rate $\lambda = w_1/w_2 > 1$.

In the equilibrium with $c = 0$ the price level is proportional to the money supply: the quantity theory in its textbook form.

In every other equilibrium the price level carries a component that has nothing to do with the money supply and grows exponentially: a purely speculative **bubble**.

```
fig, axes = plt.subplots(1, 2, figsize=(11, 4))

for c in (0.0, 0.5, 3.0):
    lab = f"$c = {c}$" + (" (quantity theory)" if c == 0 else "")
    axes[0].plot(t, price_path(c), 'o-', ms=3, lw=1, label=lab)
    axes[1].plot(t, M / price_path(c), 'o-', ms=3, lw=1, label=lab)
```

(continues on next page)

(continued from previous page)

```
axes[0].set_yscale('log')
axes[0].set_ylabel("$p_t$  (log scale)")
axes[1].set_ylabel("real balances  $M_t / p_t$")
axes[1].axhline(w1 - μ * w2, color='k', lw=0.8, ls='--')
axes[1].set_ylim(0, 0.6)
for ax in axes:
    ax.set_xlabel("$t$")
    ax.legend(frameon=False, fontsize=9)
plt.tight_layout()
plt.show()
```

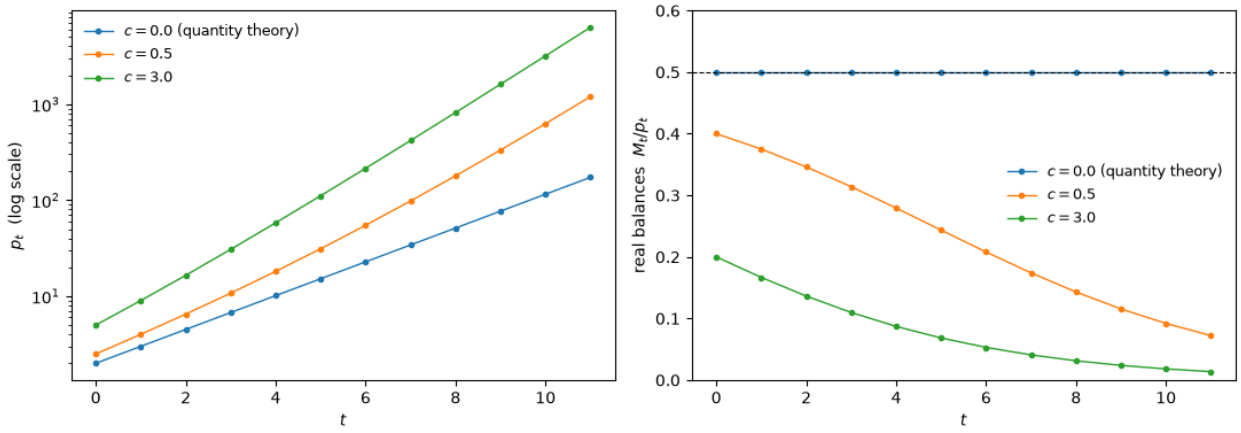

Fig. 91.4: Price levels and real balances under bubbles

The left panel shows the price level diverging further and further from the quantity-theory path as c rises.

The right panel shows what that does to the real value of the money stock: with $c = 0$ real balances are constant at $w_1 - \mu w_2$, while with $c > 0$ the bubble drives them steadily toward zero.

Along a bubble path the gross inflation rate climbs toward w_1/w_2, which from (91.12) is precisely the rate at which the demand for real balances vanishes.

The economy demonetizes itself, purely because everyone expects it to.

```
infl = pd.DataFrame(
    {f"c = {c}": price_path(c)[1:] / price_path(c)[:-1] for c in (0.0, 0.5, 3.0)},
    index=pd.Index(t[1:], name="t"),
).round(3)
infl
```

```
     c = 0.0  c = 0.5  c = 3.0
t
1        1.5    1.600    1.800
2        1.5    1.625    1.833
3        1.5    1.654    1.864
4        1.5    1.686    1.890
5        1.5    1.721    1.913
6        1.5    1.757    1.932
7        1.5    1.792    1.947
8        1.5    1.826    1.959
```

(continues on next page)

(continued from previous page)

```
9       1.5    1.857    1.969
10      1.5    1.885    1.976
11      1.5    1.908    1.982
```

There is nothing in the model — no preference, no technology, no policy — that says which c we are in.

As Sargent puts it, "Rational expectations alone is not a sufficiently restrictive principle to determine outcomes."

Adaptive Agents in an Overlapping Generations Monetary Economy returns to this household with a constant money supply ($\mu = 1$, which is a zero deficit there).

Its two stationary inflation rates are then $\pi = 1$, the bubbleless equilibrium here, and $\pi = w_1/w_2$, the limit of every bubble path.

Perfect-foresight dynamics lead away from $\pi = 1$, but that lecture shows that least squares learners converge to it: learning kills the bubble.

91.5 Two currencies

The indeterminacy gets worse when we allow more than one currency.

Versions of the result below are due to Russell Boyer (1971) and Kareken and Wallace [1981].

Keep (91.12) as the demand for currency *in total*, and suppose there are two fiat currencies in supplies M_{1t} and M_{2t} that are perfect substitutes as long as their rates of return are equal:

$$\frac{p^*_{1,t+1}}{p_{1t}} = \frac{p^*_{2,t+1}}{p_{2t}}. \tag{91.18}$$

This indifference about *which* currency to hold is what makes the exchange rate indeterminate.

Let people believe the price levels are given by

$$p_{1t} = \gamma_1 M_{1t} + \gamma_2 e M_{2t} + c\lambda^t, \qquad p_{2t} = e^{-1} p_{1t}, \tag{91.19}$$

where e is a constant exchange rate.

Requiring that the demand for currency, valued in units of currency 1, equal the total supply $M_{1t} + eM_{2t}$ gives

$$\gamma_1 = (w_1 - \mu_1 w_2)^{-1}, \quad \gamma_2 = (w_1 - \mu_2 w_2)^{-1}, \quad \lambda = \frac{w_1}{w_2}, \quad c \geq 0, \quad e \in [0, \infty). \tag{91.20}$$

These equations are remarkable for what they leave out.

The exchange rate e is *entirely unrestricted* — if the equations have a solution for one e, they have a solution for every other — and the formulas for γ_1 and γ_2 do not involve e at all.

Take the simplest case: two currencies in fixed supply, $\mu_1 = \mu_2 = 1$, and set $c = 0$.

Then $\gamma_1 = \gamma_2 = (w_1 - w_2)^{-1}$ and the price levels are constant.

```
w1, w2 = 2.0, 1.0
H1, H2 = 100.0, 120.0                  # fixed supplies of the two currencies
γ_e = 1 / (w1 - w2)

def two_currency(e):
    "Price levels and the real allocation at exchange rate e."
    p1 = γ_e * (H1 + e * H2)
```

(continues on next page)

(continued from previous page)

```
    p2 = p1 / e
    supply = H1 + e * H2              # total currency, in units of currency 1
    demand = (w1 - w2) * p1           # money demand, with p* = p since prices are␣
 ↪constant
    return p1, p2, supply / p1, demand - supply

pd.DataFrame(
    [two_currency(e) for e in (0.25, 0.5, 1.0, 2.0, 4.0)],
    index=pd.Index([0.25, 0.5, 1.0, 2.0, 4.0], name="e"),
    columns=["$p_1$", "$p_2$", "real balances", "excess demand"],
).round(4)
```

e	p_1	p_2	real balances	excess demand
0.25	130.0	520.0	1.0	0.0
0.50	160.0	320.0	1.0	0.0
1.00	220.0	220.0	1.0	0.0
2.00	340.0	170.0	1.0	0.0
4.00	580.0	145.0	1.0	0.0

Every row is an equilibrium.

The nominal price levels move around a great deal as e varies.

Since e is the value of a unit of currency 2 in units of currency 1, a larger e means currency 2 is worth more, which raises p_1 and lowers p_2.

But the last two columns tell the real story: total real balances are $w_1 - w_2 = 1$ regardless of e, and markets clear exactly.

The real allocation is identical in every one of these equilibria.

The model determines what people consume and how much purchasing power the currency stock commands; it says nothing whatever about the rate at which the two monies exchange.

This is a sharp version of a problem that has haunted international monetary theory.

The indeterminacy is not a matter of a few isolated equilibria: every $e \geq 0$ is one.

That e leaves the real allocation untouched does depend on equal money growth rates, as Exercise 91.7.3 shows.

91.6 Where this leaves us

We now have two models in which rational expectations is silent about something we would very much like to predict.

There are three ways to respond.

The first is to add restrictions to the environment until the equilibrium becomes unique.

The second is to declare the indeterminacy a genuine feature of the world and, in a tradition that runs back to Ricardo and Wicksell, to criticize the arrangements that cause it; the book calls a regime that leaves the exchange rate history-dependent "an ill-formed mechanism".

The third — the one this series pursues — is to ask what happens when we **replace the rational agents with adaptive ones** and watch where the system goes.

This is a substantive change, not a technicality.

An adaptive agent is not endowed with the equilibrium; it has beliefs, a rule for revising them, and initial conditions.

Those extra objects are exactly what the rational expectations equilibrium conditions failed to pin down, so a system of adaptive agents can select an outcome where rational expectations could not.

The rest of this series takes that idea seriously, and the results are mixed in an instructive way.

In the overlapping generations monetary economy of *Adaptive Agents in an Overlapping Generations Monetary Economy*, least squares learning selects the *opposite* equilibrium from the one the rational expectations dynamics converge to (with no deficit, the bubbleless one), and human experimental subjects side with the adaptive model.

In the two-currency model of *Exchange Rate Indeterminacy, Learning, and Experiments*, adaptive agents do pin the exchange rate down, but only by making it depend on where their beliefs started and on how their algorithm is tuned.

The rest points of the learning algorithm reproduce the indeterminacy exactly; what fixes the outcome is what the book calls *the dead hand of history*, and it grants that this "may seem a weak reed on which to base exchange rate determination."

Learning does not select an exchange rate so much as remember one.

In a Kiyotaki–Wright search economy, the classifier-system agents of *Money as a Medium of Exchange among Artificially Intelligent Agents* learn to use a medium of exchange.

But in *one of its economies*, where the speculative equilibrium is the unique stationary equilibrium for patient agents, they settle on the fundamental pattern of trade instead.

That is not learning selecting among equilibria; it is convergence to an outcome that is not an equilibrium of the economy the agents live in.

Marimon, McGrattan and Sargent suspected early myopia, and *that lecture shows why*: the way the classifier systems assign credit makes the agents effectively very impatient.

In the first two cases the algorithm supplies what the equilibrium concept did not; in the third it overrides the equilibrium concept.

Whether such outcomes are discoveries about economies or artifacts of the algorithm is the question the series keeps returning to, and *1993 Prospects for Bounded Rationality in Macroeconomics* renders a verdict.

91.7 Exercises

Exercise 91.7.1

The relaxation algorithm (91.3) converges for the static market if and only if $\lambda < 2/(1 + bn/\gamma)$.

The ratio bn/γ measures the slope of demand relative to the curvature of costs, so a market with steep demand and near-linear costs is one in which the naive cobweb ($\lambda = 1$) is badly behaved.

1. Verify the stability boundary numerically: for a grid of values of bn/γ, find the largest λ (on a fine grid) for which the algorithm converges, and compare with the analytical prediction.
2. Now let the relaxation parameter decline with the iteration count, $\lambda_k = 1/k$. Show that the algorithm converges to X^* for every slope, including slopes at which the cobweb and most fixed values of λ fail. Explain why, using the differential equation $dX/d\tau = h(X) - X$ of *One recursion, many learners*.

Solution

For part 1, we test convergence by iterating 400 times and asking whether the last step is smaller than 10^{-8}.

```
def converges(slope, λ, n_iter=400, tol=1e-8):
    """Does the relaxation algorithm converge when h'(X) = -slope?"""
```

```
    a_, X = 10.0, 1.0
    for _ in range(n_iter):
        X_new = X + λ * ((a_ - slope * X) - X)
        if not np.isfinite(X_new) or abs(X_new) > 1e12:
            return False
        X, X_prev = X_new, X
    return abs(X - X_prev) < tol

λ_grid = np.linspace(0.01, 1.5, 300)
rows = []
for slope in (0.5, 1.0, 1.5, 2.0, 4.0):
    ok = [λ for λ in λ_grid if converges(slope, λ)]
    rows.append((slope, max(ok) if ok else np.nan, 2 / (1 + slope)))

pd.DataFrame(rows, columns=["$bn/\\gamma$", "largest $\\lambda$ found",
                            "$2/(1 + bn/\\gamma)$"]).round(3)
```

	bn/γ	largest λ found	$2/(1 + bn/\gamma)$
0	0.5	1.296	1.333
1	1.0	0.972	1.000
2	1.5	0.777	0.800
3	2.0	0.648	0.667
4	4.0	0.389	0.400

The numerical boundary sits consistently a little *below* the analytical one, and that gap is not grid spacing; it is a real feature of the test.

As λ approaches the boundary the multiplier $m = 1 - \lambda(1 + bn/\gamma)$ approaches -1, so convergence becomes arbitrarily slow, and a test with a fixed iteration count and tolerance declares failure just before the true boundary.

The size of the gap is predictable.

Starting from $X_0 = 1$, the last step of the test has size $|X_{400} - X_{399}| = \lambda\,|9 - bn/\gamma|\,|m|^{399}$, so the test passes only while that is below 10^{-8}.

```
fine = np.linspace(0.01, 1.5, 1_000_001)
predicted = []
for slope in (0.5, 1.0, 1.5, 2.0, 4.0):
    m = np.abs(1 - fine * (1 + slope))
    with np.errstate(over='ignore'):
        passes = (m < 1) & (fine * abs(9 - slope) * m ** 399 < 1e-8)
    predicted.append(fine[passes].max())

pd.DataFrame({"$bn/\\gamma$": [0.5, 1.0, 1.5, 2.0, 4.0],
              "found": [r[1] for r in rows],
              "predicted by the test": predicted,
              "true boundary": [r[2] for r in rows]}).round(3)
```

	bn/γ	found	predicted by the test	true boundary
0	0.5	1.296	1.299	1.333
1	1.0	0.972	0.975	1.000
2	1.5	0.777	0.780	0.800
3	2.0	0.648	0.650	0.667
4	4.0	0.389	0.391	0.400

The predicted cutoffs lie just above the grid values found, within one grid step.

Note the first row: when $bn/\gamma < 1$ the boundary exceeds one, so the naive cobweb converges on its own and no damping is needed.

Damping is what buys convergence in the steep markets, and with a fixed λ the steeper the market the more damping is required.

For part 2, we run the declining-gain version from the same starting point and report the distance from X^* after 400 and 4000 iterations.

```
def relax_declining(slope, n_iter):
    "Distance from X* after n_iter steps of relaxation with λ_k = 1/k."
    a_, X = 10.0, 1.0
    for k in range(1, n_iter + 1):
        X = X + (1 / k) * ((a_ - slope * X) - X)
    return abs(X - a_ / (1 + slope))

slopes = (0.25, 0.5, 1.5, 4.5, 19.5)
pd.DataFrame({"$bn/\\gamma$": slopes,
              "fixed-λ bound": [2 / (1 + s_) for s_ in slopes],
              "error, k = 400": [relax_declining(s_, 400) for s_ in slopes],
              "error, k = 4000": [relax_declining(s_, 4000) for s_ in slopes]})
```

	bn/γ	fixed-λ bound	error, k = 400	error, k = 4000
0	0.25	1.600000	7.986362e-04	4.489482e-05
1	0.50	1.333333	2.000047e-04	6.319365e-06
2	1.50	0.800000	3.985628e-07	1.255046e-09
3	4.50	0.363636	6.861178e-14	1.088019e-14
4	19.50	0.097561	1.110223e-16	1.110223e-16

Every slope converges, including $bn/\gamma = 19.5$, where any fixed λ above 0.1 fails.

With $\lambda_k = 1/k$ the error is multiplied at step k by $1 - (1 + bn/\gamma)/k$; once $k > (1 + bn/\gamma)/2$ every step contracts, and the product of the multipliers behaves like $k^{-(1+bn/\gamma)}$, which goes to zero whatever the slope.

The differential equation says the same thing: in the rescaled time $\tau_k = 1 + \frac{1}{2} + \cdots + \frac{1}{k} \approx \log k$ the iteration tracks $dX/d\tau = h(X) - X$, whose solution $X(\tau) - X^* = e^{(h'-1)\tau}(X(0) - X^*) \approx k^{h'-1}(X(0) - X^*)$ is stable whenever $h' < 1$, which every downward-sloping h satisfies.

With a declining gain, then, a steeper market converges *faster*, the reverse of the fixed-gain case; the cost is that in flat markets the error shrinks only like a power of k (compare the two error columns in the first row), where a well-chosen fixed λ would shrink it geometrically.

Exercise 91.7.2

The equilibrium (91.16) was derived without checking that it makes economic sense.

Show that a monetary equilibrium requires $\mu < w_1/w_2$, by finding what goes wrong with the demand for real balances when money grows faster than that.

Solution

Along the $c = 0$ equilibrium, real balances are constant at $M_t/p_t = \gamma^{-1} = w_1 - \mu w_2$.

This is positive only when $\mu < w_1/w_2$.

If money grows faster, (91.16) still "solves" the functional equation, but it asks the household to hold a negative quantity of currency.

```
w1, w2 = 2.0, 1.0
μ_grid = np.array([0.5, 1.0, 1.5, 1.9, 2.0, 2.5])
```

```
with np.errstate(divide='ignore'):        # γ is infinite exactly at μ = w1/w2
    table = pd.DataFrame({
        "$\\mu$": μ_grid,
        "$\\gamma = (w_1 - \\mu w_2)^{-1}$": 1 / (w1 - μ_grid * w2),
        "real balances $w_1 - \\mu w_2$": w1 - μ_grid * w2,
        "monetary equilibrium?": np.where(μ_grid < w1 / w2, "yes", "no"),
    }).round(3)
table
```

```
   $\mu$  $\gamma = (w_1 - \mu w_2)^{-1}$  real balances $w_1 - \mu w_2$  \
0    0.5                           0.667                           1.5
1    1.0                           1.000                           1.0
2    1.5                           2.000                           0.5
3    1.9                          10.000                           0.1
4    2.0                             inf                           0.0
5    2.5                          -2.000                          -0.5

  monetary equilibrium?
0                   yes
1                   yes
2                   yes
3                   yes
4                    no
5                    no
```

At $\mu = w_1/w_2 = 2$ the demand for real balances hits zero and γ blows up; beyond it, both are negative.

The intuition runs through (91.12): the household holds currency only if the expected loss of purchasing power, p^*_{t+1}/p_t, is smaller than w_1/w_2.

Money growing at rate μ produces inflation at rate μ, so $\mu \geq w_1/w_2$ drives the demand for money to zero, the same boundary that the *bubble* equilibria approach asymptotically from below.

Exercise 91.7.3

In the two-currency example we set $\mu_1 = \mu_2 = 1$ and found that the real allocation was the same at every exchange rate.

That is special.

Repeat the calculation with $\mu_1 \neq \mu_2$ — say $\mu_1 = 1.0$ and $\mu_2 = 1.3$, with $w_1 = 2$, $w_2 = 1$, $M_{1,0} = M_{2,0} = 100$, and $c = 0$ — and compute total real balances at several exchange rates over the first several periods.

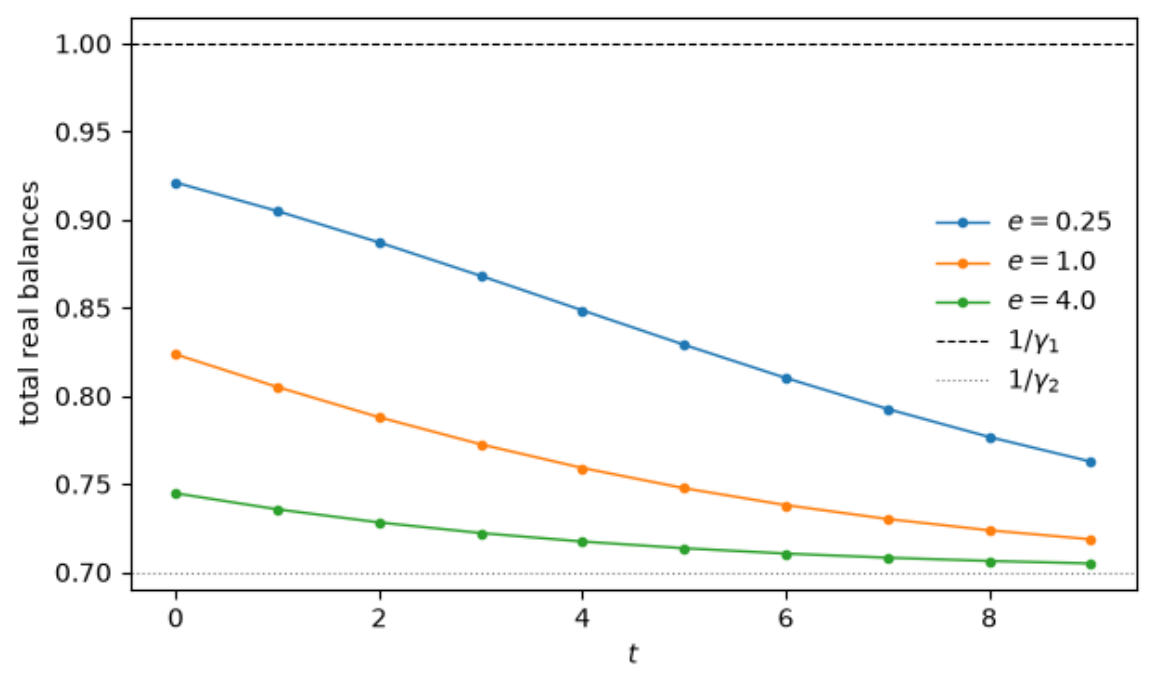
Does the choice of e still leave the real allocation untouched?

Solution

With $c = 0$, total real balances in units of currency 1 are $(M_{1t} + eM_{2t})/(\gamma_1 M_{1t} + \gamma_2 eM_{2t})$.

```
w1, w2 = 2.0, 1.0
μ1, μ2 = 1.0, 1.3
γ1, γ2 = 1 / (w1 - μ1 * w2), 1 / (w1 - μ2 * w2)
t = np.arange(10)
M1, M2 = 100.0 * μ1 ** t, 100.0 * μ2 ** t

def real_balances(e):
```



```
    p1 = y1 * M1 + y2 * e * M2
    return (M1 + e * M2) / p1

pd.DataFrame({f"e = {e}": real_balances(e) for e in (0.25, 1.0, 4.0)},
             index=pd.Index(t, name="t")).round(4)
```

t	e = 0.25	e = 1.0	e = 4.0
0	0.9211	0.8235	0.7447
1	0.9049	0.8050	0.7356
2	0.8871	0.7879	0.7282
3	0.8681	0.7725	0.7221
4	0.8485	0.7591	0.7173
5	0.8290	0.7476	0.7135
6	0.8101	0.7380	0.7105
7	0.7926	0.7301	0.7081
8	0.7767	0.7237	0.7063
9	0.7627	0.7186	0.7049

The same paths in a figure:

```
fig, ax = plt.subplots(figsize=(7, 4))
for e in (0.25, 1.0, 4.0):
    ax.plot(t, real_balances(e), 'o-', ms=3, lw=1, label=f"$e = {e}$")
ax.axhline(1 / y1, color='k', lw=0.8, ls='--', label=r"$1/\gamma_1$")
ax.axhline(1 / y2, color='gray', lw=0.8, ls=':', label=r"$1/\gamma_2$")
ax.set_xlabel("$t$")
ax.set_ylabel("total real balances")
ax.legend(frameon=False)
plt.show()
```

No.

With unequal money growth rates the exchange rate affects the real allocation, and the allocation is no longer even constant over time.

The reason is that $\gamma_1 \neq \gamma_2$: the two currencies are valued differently because they are expected to be diluted at different rates, so the *composition* of the currency stock matters, and e is what fixes that composition.

Since currency 2 grows faster, it comes to dominate the stock whatever e we choose, and real balances converge to $1/\gamma_2$ from wherever e starts them.

So the irrelevance of e for the real allocation is a knife-edge: it needs $\mu_1 = \mu_2$ (with any common growth rate μ, real balances are $w_1 - \mu w_2$ at every e).

The indeterminacy of e is not a knife-edge: every e in the table is still an equilibrium, but now the choice among them has real consequences.

Exercise 91.7.4

Muth's result says that exponential smoothing with $\lambda = 1 - \theta$ is the optimal forecast of X_{t+k} at *every* horizon k, but Fig. 91.2 checked only $k = 1$.

1. Show that for (91.5) the conditional expectation $E_t X_{t+k}$ is the same for every $k \geq 1$, that it equals the exponentially smoothed value with $\lambda = 1 - \theta$, and that the k-step forecast error has variance $1 + (k-1)(1-\theta)^2$ when $\mathbb{V}[\epsilon_t] = 1$.
2. Verify the result numerically at $k = 4$, reusing `smoothing_mse`.

Solution

Write $X_{t+k} = X_t + \sum_{j=1}^{k} (\epsilon_{t+j} - \theta \epsilon_{t+j-1})$.

Every shock dated after t has conditional mean zero, so $E_t X_{t+k} = X_t - \theta \epsilon_t \equiv f_t$ for every $k \geq 1$.

Since $\epsilon_t = X_t - f_{t-1}$, we have $f_t = X_t - \theta(X_t - f_{t-1}) = (1-\theta) X_t + \theta f_{t-1}$, which is (91.4) with $\lambda = 1 - \theta$.

The forecast error is

$$X_{t+k} - f_t = \epsilon_{t+k} + (1-\theta)(\epsilon_{t+1} + \cdots + \epsilon_{t+k-1}),$$

whose variance is $1 + (k-1)(1-\theta)^2$.

Here is the numerical check, on the same shocks as the figure.

```
k = 4
rows = []
for θ in (0.2, 0.5, 0.8):
    X = np.cumsum(ε[1:] - θ * ε[:-1])
    mse = np.array([smoothing_mse(X, λ, k) for λ in grid])
    rows.append((θ, grid[mse.argmin()], 1 - θ, mse.min(), 1 + (k - 1) * (1 - θ) **␣
↪2))

pd.DataFrame(rows, columns=["$\\theta$", "best $\\lambda$", "$1 - \\theta$",
                            "min MSE", "$1 + (k-1)(1-\\theta)^2$"]).round(3)
```

	θ	best λ	$1 - \theta$	min MSE	$1 + (k-1)(1-\theta)^2$
0	0.2	0.79	0.8	2.916	2.92
1	0.5	0.50	0.5	1.749	1.75
2	0.8	0.20	0.2	1.121	1.12

At horizon 4 the best weight is again $1 - \theta$, up to the grid and sampling noise, and the minimized mean squared error matches the formula.

The error variance grows with the horizon, but the forecast does not change: the same smoothed value is optimal at every horizon.

Exercise 91.7.5

In Bray's market (91.8) with a constant gain λ below the stability bound, beliefs never settle down.

1. Show that the belief error $e_t = X_t^* - X^*$ is a stationary first-order autoregression with variance

$$V(\lambda) = \frac{\lambda \sigma_u^2}{(1-h')(2-\lambda(1-h'))}.$$

2. Using `learn` from *From relaxation to learning: Bray's market*, simulate 100,000 periods for $\lambda \in \{0.025, 0.05, 0.1, 0.2, 0.4\}$ and compare the sample variance of e_t with $V(\lambda)$. How does the spread of beliefs scale with the gain?

Solution

From (91.8), $e_t = \rho e_{t-1} + \lambda u_t$ with $\rho = 1 - \lambda(1-h')$.

Below the bound $|\rho| < 1$, so e_t is a stationary autoregression with variance $\lambda^2\sigma_u^2/(1-\rho^2)$, and $1-\rho^2 = \lambda(1-h')(2-\lambda(1-h'))$ gives the formula.

The simulation starts beliefs at X^* and drops the first 1,000 periods.

```
u_long = σ_u * np.random.default_rng(2).standard_normal(100_000)
h_prime = -b * n / γ

rows = []
for λ in (0.025, 0.05, 0.1, 0.2, 0.4):
    e = learn(lambda t: λ, u_long, X0=X_star)[1_000:] - X_star
    V = λ * σ_u**2 / ((1 - h_prime) * (2 - λ * (1 - h_prime)))
    rows.append((λ, e.var(), V, e.var() / λ))

pd.DataFrame(rows, columns=["gain $\\lambda$", "sample variance", "$V(\\lambda)$",
                            "variance / $\\lambda$"]).round(5)
```

	gain λ	sample variance	$V(\lambda)$	variance / λ
0	0.025	0.00129	0.00129	0.05147
1	0.050	0.00266	0.00267	0.05318
2	0.100	0.00570	0.00571	0.05704
3	0.200	0.01332	0.01333	0.06661
4	0.400	0.03991	0.04000	0.09978

The sample variances match the formula.

For small gains $V(\lambda) \approx \lambda\sigma_u^2/(2(1-h'))$, so the variance of beliefs is proportional to the gain and their standard deviation to its square root; the ratio in the last column creeps up at larger gains because of the second factor in the denominator.

A constant-gain learner therefore converges only in distribution, to a cloud around X^* that collapses to a point only as $\lambda \to 0$.

Adaptive Learning and Escape Dynamics shows what such a cloud can do in a model with richer feedback: escape.

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

92.1 Overview

A Peculiar Definition of Bounded Rationality studied monetary models with many rational expectations equilibria, among them a Cagan money-demand model whose equilibria include a continuum of bubbles.

This lecture works with a close relative: the overlapping generations model of fiat money of Samuelson [1958], in the version that Bryant, Wallace and others used to study inflationary finance, in which a government prints currency to pay for its expenditures.

We replace agents who forecast with the equilibrium law of motion for the price level by "adaptive" ones who do not.

We do this twice, for two different purposes.

Part 1 puts a *stochastic* government deficit into the model and asks whether successive generations, groping their way by trial and error, can somehow as a society converge to a rational expectations equilibrium.

They can.

Each generation observes what happened to its predecessors and adjusts their saving decision in a utility-improving direction, using a **Robbins–Monro** recursion.

Given enough time the economy converges to a stationary equilibrium that we compute independently, and of the two such equilibria it finds only the low-inflation one.

This exercise also shows how sensitive learning is to the complexity of what must be learned: a deficit state that occurs rarely is learned about slowly, because the observations arrive slowly.

Part 2 removes the randomness and turns to a sharper question.

With a *constant* deficit the model has **two** stationary equilibria, one with low inflation and one with high inflation.

The low-inflation equilibrium Pareto-dominates the other.

Under the rational expectations dynamics, the low-inflation equilibrium is **unstable** and the high-inflation one is stable: theory pushes the economy toward the bad outcome.

Under least squares learning, the stability is **reversed**.

The reversal is not a numerical accident: it follows from *E-stability*, the stability condition for learning that *A Peculiar Definition of Bounded Rationality* sets out in *One recursion, many learners*.

And when Marimon and Sunder [1993] ran the economy as a laboratory experiment with paid human subjects, the subjects behaved like the adaptive model, not like the rational expectations model.

That is the strongest evidence in Sargent [1993] that adaptive dynamics are doing real work as a selection device, tempered by a counterexample, due to Benjamin Bental, warning against concluding that adaptation reliably selects the *good* equilibrium.

We then close with a **third application**, in which the adaptive agent is a government learning a Phillips curve.

Least squares learning now converges to the model's unique self-confirming equilibrium, which has an inflation bias, while a government that keeps a constant gain makes recurrent **escapes** toward the zero-inflation Ramsey outcome, which is not an equilibrium at all.

That phenomenon seeded Sargent's later work on *The Conquest of American Inflation*, and the Phillips curve lectures that begin with *The Rise and Fall of U.S. Inflation* study it in depth.

Let's start with some imports.

```
import numpy as np
import pandas as pd
import quantecon as qe
import matplotlib.pyplot as plt
from scipy.optimize import fsolve
```

92.2 The environment

The economy consists of overlapping generations of two-period-lived agents.

At each date $t \geq 1$, N identical agents are born, endowed with w_1 units of a single consumption good when young and w_2 units when old.

A young agent's preferences over lifetime consumption (c_1, c_2) are ordered by the expected value of $u(c_1) + u(c_2)$.

Throughout we use logarithmic utility, $u(c) = \ln c$.

A government prints currency to finance expenditures G_t, subject to the budget constraint

$$G_t = \frac{H_t - H_{t-1}}{p_t}, \tag{92.1}$$

where H_t is the stock of currency carried by the young at t into $t+1$, and p_t is the price level.

Currency is the only store of value, so a young agent's saving s_t is entirely in the form of real balances, and market clearing requires

$$\frac{H_t}{p_t} = s_t N. \tag{92.2}$$

Write $R_t = p_t / p_{t+1}$ for the gross rate of return on currency between t and $t+1$.

Combining (92.1) and (92.2) gives a relation we will use constantly: the return on currency is determined entirely by saving behavior and the deficit,

$$R_t = \frac{N s_{t+1} - G_{t+1}}{N s_t}. \tag{92.3}$$

Currency holds its value only if the next generation is willing to absorb the outstanding stock plus the new issue.

Note

(92.3) is worth pausing on, because it is what makes this a *self-referential* system, the property studied at length in *Least Squares Learning in Self-Referential Models*.

The return that today's young earn on their saving depends on how much tomorrow's young choose to save, which in turn depends on what tomorrow's young expect to earn.

Nobody's beliefs are about an exogenous process.

92.3 Part 1: a stochastic deficit

Now let government expenditures follow a Markov chain with transition probabilities

$$P(i,j) = \text{Prob}\{G_{t+1} = \bar{G}_j \mid G_t = \bar{G}_i\},$$

over a finite list of levels $G = [\bar{G}_1, \dots, \bar{G}_n]$.

(Sargent writes $\pi(i,j)$; we reserve π for inflation.)

92.3.1 Stationary rational expectations equilibrium

In a stationary equilibrium, saving depends on the current deficit state, so it is described by an $n \times 1$ vector $s = [s_1, \dots, s_n]$, and the return on currency by an $n \times n$ matrix $R(i,j)$.

A young agent who observes $G_t = \bar{G}_i$ chooses s_i to maximize

$$V(s_i) = u(w_1 - s_i) + \sum_j u(w_2 + s_i R(i,j)) P(i,j),$$

with first-order condition

$$u'(w_1 - s_i) = \sum_{j=1}^{n} u'(w_2 + s_i R(i,j)) R(i,j) P(i,j). \tag{92.4}$$

Substituting (92.3) — which in the stationary equilibrium reads $R(i,j) = (s_j N - \bar{G}_j)/(s_i N)$ — turns (92.4) into a system of n nonlinear equations in the saving rates alone:

$$u'(w_1 - s_i) = \sum_{j=1}^{n} u'\left(w_2 + \frac{s_j N - \bar{G}_j}{N}\right) \cdot \frac{s_j N - \bar{G}_j}{s_i N} \cdot P(i,j). \tag{92.5}$$

A stationary equilibrium exists if and only if (92.5) has a solution with $s_i \in (0, w_1)$ for every i and with every return positive, that is, $s_j N > \bar{G}_j$ for every j.

The code below solves (92.5) from an initial guess and checks both conditions.

```
w1, w2, N = 20.0, 10.0, 1.0

def u_prime(c):
    return 1 / c                          # log utility

def equilibrium_residual(s, G, P):
    "Left minus right side of the equilibrium condition, one entry per deficit state."
    n = len(s)
    out = np.empty(n)
    for i in range(n):
        rhs = sum(u_prime(w2 + (s[j]*N - G[j])/N)
                  * (s[j]*N - G[j])/(s[i]*N)
                  * P[i, j] for j in range(n))
        out[i] = u_prime(w1 - s[i]) - rhs
    return out

def stationary_equilibrium(G, P, guess=4.0):
    "Solve the equilibrium condition from `guess`; check that the solution is an␣
↪equilibrium."
    s, _, ier, msg = fsolve(equilibrium_residual, np.full(len(G), guess),
                            args=(G, P), full_output=True)
    R = np.array([[(s[j]*N - G[j])/(s[i]*N) for j in range(len(s))]
                  for i in range(len(s))])
    assert ier == 1, msg
    assert np.all((s > 0) & (s < w1)) and np.all(R > 0), "not an equilibrium"
    return s, R
```

Following Sargent [1993], we study two economies that differ only in the process for government expenditures, with $w_1 = 20$, $w_2 = 10$ and $N = 1$, so that $\bar{G}$ is measured per young person.

In the first, the deficit is always zero and the chain is a fair coin.

```
G1, P1 = np.array([0.0, 0.0]), np.full((2, 2), 0.5)
s1, R1 = stationary_equilibrium(G1, P1)
print(f"saving rates      {np.round(s1, 4)}")
print(f"returns\n{np.round(R1, 4)}")
```

```
saving rates      [5. 5.]
returns
[[1. 1.]
 [1. 1.]]
```

With no deficit to finance, currency simply holds its value: agents save 5 in either state and $R \equiv 1$.

In the second economy the deficit is 0.8 in state 1 and zero in state 2, and the chain is persistent.

```
G2 = np.array([0.8, 0.0])
P2 = np.array([[0.75, 0.25],
               [0.50, 0.50]])
s2, R2 = stationary_equilibrium(G2, P2)
print(f"saving rates      {np.round(s2, 4)}      (Sargent reports 4.211, 4.364)")
print(f"returns\n{np.round(R2, 4)}")
print("Sargent reports  [[0.81, 1.0362], [0.7817, 1.00]]")
```

```
saving rates       [4.2111 4.3637]       (Sargent reports 4.211, 4.364)
returns
[[0.81   1.0362]
 [0.7817 1.    ]]
Sargent reports  [[0.81, 1.0362], [0.7817, 1.00]]
```

Both match the values reported in the text.

Notice the pattern in R: the return on currency is poor whenever the government is about to run a deficit (the first column), because new issue dilutes the outstanding stock.

The system (92.5) is nonlinear, and Sargent warns that in general it has more than one solution.

Economy 2 has a second stationary equilibrium, which the solver finds if we start it at low saving rates.

```
s2_hi, R2_hi = stationary_equilibrium(G2, P2, guess=1.2)    # the high-inflation␣
↪equilibrium
print(f"saving rates       {np.round(s2_hi, 4)}")
print(f"returns\n{np.round(R2_hi, 4)}")
```

```
saving rates       [1.1896 1.6343]
returns
[[0.3275 1.3738]
 [0.2384 1.    ]]
```

Saving is far lower, so each deficit must be financed by a large proportional issue of new currency, and the return on currency held into a deficit state falls from about 0.8 to between 0.24 and 0.33.

All its returns are positive, so this is a genuine stationary equilibrium, with much higher inflation.

The learning economy below never finds it, and Exercise 92.7.3 shows why.

92.3.2 Learning by successive generations

Now withdraw the equilibrium from the agents.

They are still assumed to know their own utility function and to remember the experience of earlier agents like themselves, but they are *not* told the distribution of returns, which is exactly the object that (92.4) requires.

Instead, each generation adjusts its predecessors' saving decision in the direction that *realized* experience suggests would have been better.

The realized lifetime utility of an agent who saved s and earned R is

$$U(s) = u(w_1 - s) + u(w_2 + sR),$$

with derivatives

$$U'(s) = -u'(w_1 - s) + u'(w_2 + sR)R, \qquad U''(s) = u''(w_1 - s) + u''(w_2 + sR)R^2.$$

The connection to equilibrium is that in a rational expectations equilibrium $V'(s_i) = E_t U'(s_i)$ and $V''(s_i) = E_t U''(s_i)$, where E_t conditions on $G_t = \bar{G}_i$.

So an agent who could compute $E_t U'$ would just set it to zero and be done.

Our agents cannot, and must estimate it from experience instead.

They use a **Robbins–Monro** algorithm, applied state by state.

Let τ_i count the number of times the deficit state $\bar{G}_i$ has been visited so far, and let γ_τ be a decreasing gain sequence.

The rules are

$$\begin{aligned} M(i,\tau_i+1) &= M(i,\tau_i) + \gamma_{\tau_i}\left(U''(s(i,\tau_i)) - M(i,\tau_i)\right), \\ s(i,\tau_i+1) &= s(i,\tau_i) - \gamma_{\tau_i} M(i,\tau_i+1)^{-1} U'(s(i,\tau_i)). \end{aligned} \tag{92.6}$$

M accumulates a running estimate of $E_i U''$, and the saving rule takes a Newton step against it.

The gain γ_τ plays the role of the relaxation parameter λ in *A Peculiar Definition of Bounded Rationality*: each observation moves the rule a fraction γ_τ of the way toward what that observation suggests.

In the relaxation algorithm the gain was constant; here it declines, as it does for Bray's least squares learners in that lecture, so each new observation moves the rule less than the one before.

Sargent sets $\gamma_\tau = 1/\tau$ and starts M at -1.

Our code uses $\gamma_\tau = 1/(\tau + 20)$, which keeps the first steps cautious, as if the initial rule had already been learned from 20 observations, and starts M at $U''(s,1)$, the curvature the initial rule would have if currency held its value.

The algorithm is set up so that, *if* the saving rules converge, $M(i,\tau_i) \to E_i U''$ and the limit solves $E_i U'(s_i) = 0$, which is exactly the equilibrium condition (92.4).

Whether they converge, and to which solution when (92.5) has several, is governed by the stability of an associated ordinary differential equation, as explained in *One recursion, many learners*.

Two features of the setup deserve comment.

Two classes of agent. To evaluate a saving decision we must wait until *two* periods of that agent's consumption are known, so the population is split into an "odd" and an "even" subsequence.

Odd agents reset their rule in odd periods and learn only from earlier odd agents; even agents likewise.

Sargent notes that this alternation resembles the designs of laboratory experiments.

Marimon and Sunder [1993], whose experiment appears in Part 2, drew their young subjects afresh at random each period, but the two-currency experiment of Arifovic [1996], discussed in *Exchange Rate Indeterminacy, Learning, and Experiments*, split its subjects into two fixed groups that were young in alternate periods, just like the odd and even classes here.

A projection facility. Nothing in (92.6) prevents a Newton step from pushing saving below the deficit.

The price level implied by (92.1) and (92.2), $p_t = H_{t-1}/(N s_t - G_t)$, would then fail to be positive, and the economy would cease to exist.

We therefore confine each state's saving rate to the interval $[\bar{G}_i/N + 0.4,\ w_1 - 0.4]$, a region where an equilibrium price level exists.

Devices of this kind are needed for the convergence theorems too; *Least Squares Learning in Self-Referential Models* discusses the projection facility in detail.

The simulation draws the whole path of deficit states first, then lets the two classes of agent learn along it.

```
def U_prime(s, R):
    return -1/(w1 - s) + R/(w2 + s*R)

def U_double(s, R):
    return -1/(w1 - s)**2 - R**2/(w2 + s*R)**2

def simulate(G, P, T=50_000, s0=None, seed=0, tau0=20, band=0.4, gain=None):
    """
    Overlapping generations learning a state-contingent saving rule.

    The gain is 1/(τ + tau0), where τ counts a class's visits to a state,
```

(continues on next page)

(continued from previous page)

```
    unless a constant `gain` is supplied.  Returns the history of saving
    rules, shape (T, 2, n) = (time, class, state), and the deficit states.
    """
    n = len(G)
    states = qe.MarkovChain(P).simulate(ts_length=T, init=0, random_state=seed)
    s = np.array(s0, float)
    M = np.array([[U_double(s[j, k], 1.0) for k in range(n)] for j in range(2)])
    τ = np.zeros((2, n), int)
    floor = G/N + band                  # projection facility: saving must cover the␣
↪deficit
    ceiling = w1 - band

    hist = np.empty((T, 2, n))
    prev = None

    for t in range(T):
        i = states[t]                   # today's deficit state
        j = t % 2                       # which class is young this period
        s_t = s[j, i]

        if prev is not None:            # last period's young now learn their return
            j_p, i_p, s_p = prev
            R = (N*s_t - G[i]) / (N*s_p)          # the return on currency
            τ[j_p, i_p] += 1
            γ = 1 / (τ[j_p, i_p] + tau0) if gain is None else gain
            M[j_p, i_p] += γ * (U_double(s_p, R) - M[j_p, i_p])
            s_new = s[j_p, i_p] - γ * U_prime(s_p, R) / M[j_p, i_p]
            s[j_p, i_p] = min(max(s_new, floor[i_p]), ceiling)

        prev = (j, i, s_t)
        hist[t] = s

    return hist, states
```

Note

The simulation never computes a price level.

Because (92.3) expresses the return on currency purely in terms of saving rates and the deficit, the *real* side of the model is self-contained.

This is more than a convenience: the nominal money stock in these economies grows without bound whenever the government runs a deficit, so a simulation that tracked H_t and p_t directly would overflow long before the learning converged.

92.3.3 Do they find it?

We start both classes of agent far from equilibrium, with asymmetric rules, and let each economy run for 50,000 periods.

```
start = [[8.0, 2.0],
         [2.0, 8.0]]                    # deliberately far from equilibrium, and␣
↪asymmetric

hist1, _ = simulate(G1, P1, s0=start)
hist2, _ = simulate(G2, P2, s0=start)

fig, axes = plt.subplots(1, 2, figsize=(11, 4), sharex=True)
for ax, hist, s_star, title in [(axes[0], hist1, s1, "Economy 1:  $\\bar G = (0, 0)$
↪"),
                                (axes[1], hist2, s2, "Economy 2:  $\\bar G = (0.8, 0)$
↪")]:
    for k, colour in enumerate(['C0', 'C1']):
        ax.plot(hist[:, 0, k], color=colour, lw=1, label=f"state {k+1}, even")
        ax.plot(hist[:, 1, k], color=colour, lw=1, ls=':', label=f"state {k+1}, odd")
        ax.axhline(s_star[k], color='k', lw=0.8, ls='--')
    ax.set_xscale('log')
    ax.set_xlabel("$t$  (log scale)")
    ax.set_title(title)
axes[0].set_ylabel("saving rate")
axes[0].legend(frameon=False, fontsize=8)
plt.tight_layout()
plt.show()
```

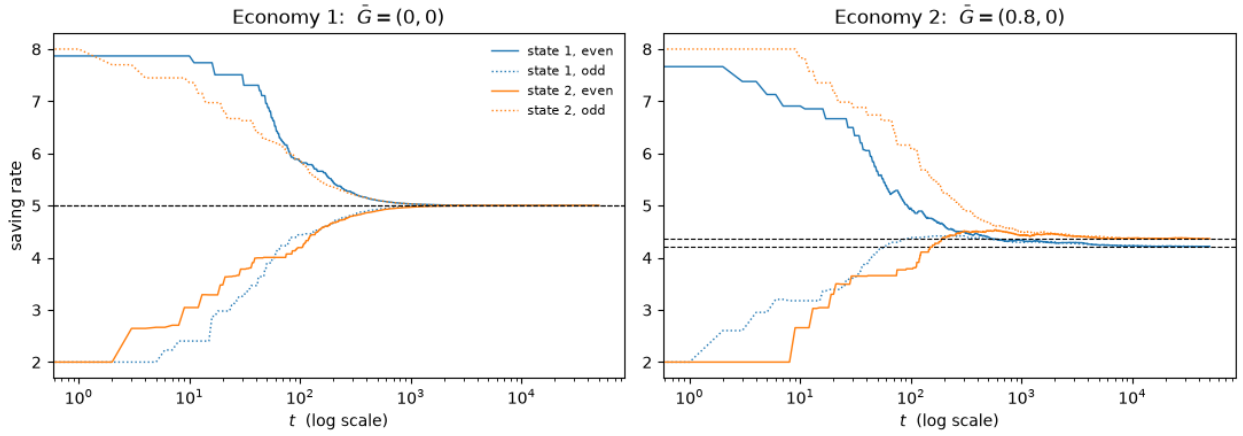

Fig. 92.1: Saving rates converge in both economies

Fig. 92.1 shows that both economies converge, and that both classes of agent converge to the same rule even though neither learns from the other.

The dashed black lines are the equilibrium saving rates computed earlier from (92.5), objects that no agent in the simulation has access to.

The table reports the learned rules, averaged over the two classes, at three horizons.

```
rows = []

Convergence is slow, which is what a gain of order $1/\tau$ buys you, but it is convergence, and to the low-inflation equilibrium of economy 2.

92.3.4 How much do the agents have to be told?

The agents learn a *separate* saving rate for each level of the deficit: in effect they learn the policy function $s = f(G)$ **non-parametrically**, one number per state.

That is feasible here because there are only two states, and even so it has a cost.

A state that is rarely visited is learned about slowly, because its observations arrive slowly; Exercise 92.7.1 makes this concrete.

When the number of states is large, or the state is continuous, one number per state is hopeless, and agents must learn a parametric rule instead.

Learning, Approximation, and Equilibrium Computation takes up what that buys and what it costs.

92.4 Part 2: a constant deficit and two steady states

Now strip out the randomness.

Let the government finance a *constant* deficit G per young person, and let utility be $\ln c_1 + \ln c_2$ as before.

With perfect foresight over the price level, the young save

$$s_t = \frac{w_1 - w_2 \pi_t}{2}, \qquad \pi_t \equiv \frac{p_{t+1}}{p_t}, \tag{92.7}$$

where π_t is the gross inflation rate, the reciprocal of the return on currency.

Let $h_t = H_t/(N p_t)$ be real balances per young person.

The government's budget constraint in real terms is $h_t = h_{t-1}/\pi_{t-1} + G$, and equilibrium requires $h_t = s_t$.

Eliminating h between these gives an autonomous difference equation in the inflation rate,

$$\pi_{t+1} = g(\pi_t) \equiv A_1 - \frac{A_2}{\pi_t}, \qquad A_1 = \frac{w_1 + w_2 - 2G}{w_2}, \qquad A_2 = \frac{w_1}{w_2}. \tag{92.8}$$

Stationary equilibria are the fixed points of g, and since g is a hyperbola there are generically two of them.

We use the parameters of Marimon and Sunder [1993]'s "Economy 7C": $w_1 = 6$, $w_2 = 1$, $G = 1$.

```
w1_d, w2_d, G_d = 6.0, 1.0, 1.0
A1 = (w1_d + w2_d - 2*G_d) / w2_d
A2 = w1_d / w2_d

def g_map(π):
    return A1 - A2/π

π_low, π_high = np.sort(np.roots([1, -A1, A2]))
print(f"A1 = {A1},  A2 = {A2}")
print(f"stationary gross inflation rates: {π_low} and {π_high}")
print(f"   i.e. net inflation of {100*(π_low-1):.0f}% and {100*(π_high-1):.0f}% per␣
↪period")
print(f"\nslope of g at the low  rate: {A2/π_low**2:.4f}   -> unstable under RE␣
↪dynamics")
print(f"slope of g at the high rate: {A2/π_high**2:.4f}   -> stable under RE dynamics
↪")
```

```
A1 = 5.0,  A2 = 6.0
stationary gross inflation rates: 2.0 and 3.0
   i.e. net inflation of 100% and 200% per period

slope of g at the low  rate: 1.5000   -> unstable under RE dynamics
slope of g at the high rate: 0.6667   -> stable under RE dynamics
```

There it is: the *low*-inflation stationary equilibrium is **unstable** under the rational expectations dynamics, and the high-inflation one is stable.

The case $G = 0$ connects this model to the bubbles of *A Peculiar Definition of Bounded Rationality*.

With no deficit, $A_1 = 1 + w_1/w_2$, and the fixed points of g are $\pi = 1$ and $\pi = w_1/w_2$.

These are the bubbleless, quantity-theory equilibrium of *The bubble* with a constant money supply, and the inflation rate that every one of its bubble paths approaches.

The scales differ.

That lecture endows agents with $2w_1$ and $2w_2$, so its demand for real balances is $w_1 - w_2\pi$, while saving here is $(w_1 - w_2\pi)/2$.

It also fixes the growth rate μ of the money supply where we fix the deficit G, and the two models coincide when $\mu = 1$ and $G = 0$.

The stability analysis below therefore answers that lecture's question of which bubble we are in: least squares learners kill the bubble (Exercise 92.7.5).

```
π_grid = np.linspace(1.35, 4.2, 400)

fig, ax = plt.subplots(figsize=(6.5, 5.5))
ax.plot(π_grid, g_map(π_grid), lw=1.6, label=r"$g(\pi) = A_1 - A_2/\pi$")
ax.plot(π_grid, π_grid, 'k--', lw=0.8, label="45 degree line")
```

(continues on next page)

(continued from previous page)

```
# cobweb the RE dynamics away from the low steady state
π = π_low + 0.05
for _ in range(30):
    nxt = g_map(π)
    ax.plot([π, π], [π, nxt], color='C3', lw=0.9)

ax.legend(frameon=False, loc='upper left')
plt.show()
```

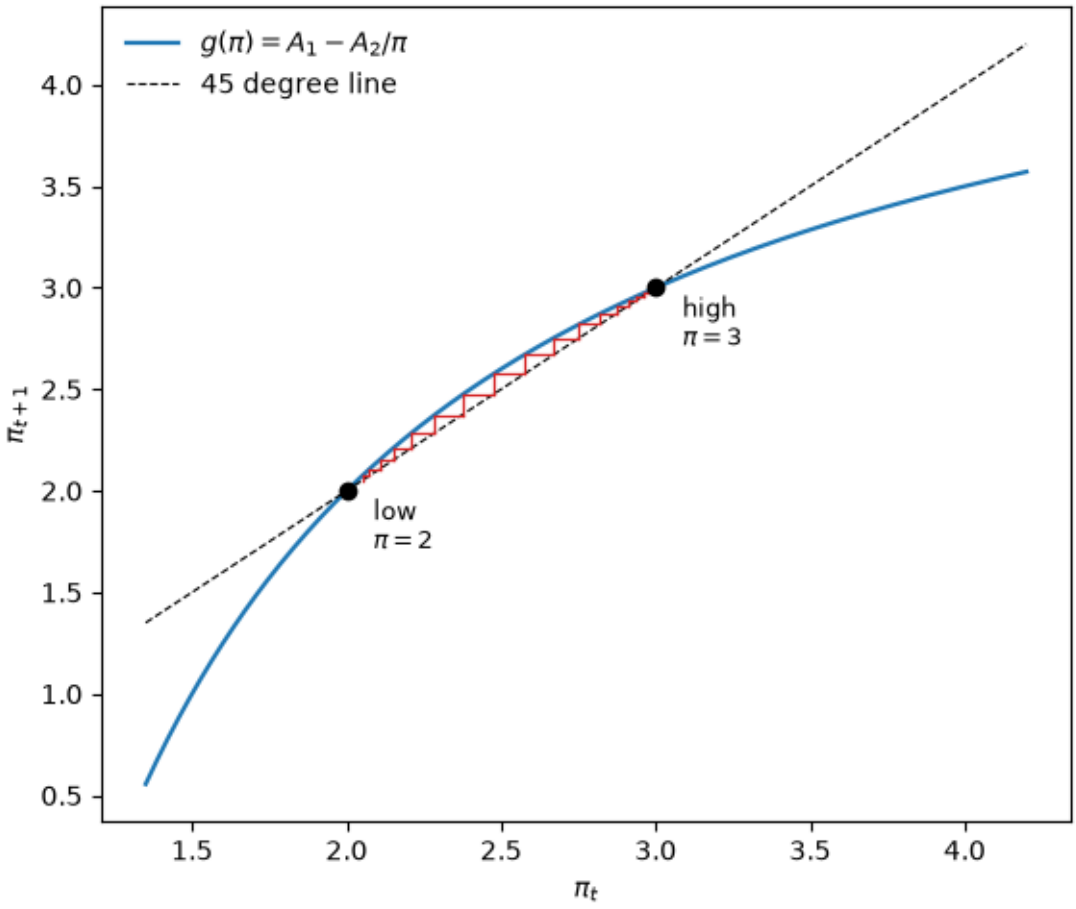

Fig. 92.2: Rational expectations inflation dynamics

In Fig. 92.2 the red staircase starts just above the low-inflation steady state and marches away from it, toward the high-inflation one.

The table follows rational expectations paths from four initial inflation rates.

```
def re_path(π0, T=25):
    path = [π0]
    for _ in range(T):
        nxt = g_map(path[-1])
        path.append(nxt if nxt > 0 else np.nan)
    return np.array(path)

pd.DataFrame({f"$\\pi_0 = {p}$": re_path(p) for p in (1.99, 2.01, 2.5, 4.0)}
             ).rename_axis("t").round(4).iloc[[0, 1, 2, 5, 10, 25]]
```

t	$\pi_0 = 1.99$	$\pi_0 = 2.01$	$\pi_0 = 2.5$	$\pi_0 = 4.0$
0	1.9900	2.0100	2.5000	4.0000
1	1.9849	2.0149	2.6000	3.5000
2	1.9772	2.0222	2.6923	3.2857
5	1.9187	2.0712	2.8836	3.0705
10	0.6693	2.3681	2.9830	3.0087
25	NaN	2.9961	3.0000	3.0000

Started fractionally below the low steady state the economy collapses (inflation computed from (92.8) turns negative, so no positive price level exists); started fractionally above it, the economy converges to $\pi = 3$.

This matters because of how the two equilibria rank.

The comparative statics of the low-inflation equilibrium are "classical": raising the deficit G lowers A_1, which raises the low stationary inflation rate.

The comparative statics of the high-inflation equilibrium are the reverse, because the economy is on the wrong side of an inflation-tax **Laffer curve**; see Exercise 92.7.4.

And the low-inflation equilibrium Pareto-dominates every other equilibrium of this model, stationary or not.

(The ranking relies on everyone in a generation being alike; Sargent notes that in versions with borrowers and lenders within a generation the equilibria are not Pareto-comparable.)

So the rational expectations dynamics repel the economy from the Pareto-optimal outcome, and most classical doctrine in monetary theory depends on selecting the equilibrium that those dynamics reject.

92.4.1 Least squares dynamics

Marcet and Sargent [1989] studied a version of this economy in which agents do not have perfect foresight but instead **run a regression**.

Each period they regress the price level on its own lagged value and use the fitted slope as their forecast of gross inflation,

$$\beta_t = \frac{\sum_{s<t} p_s p_{s-1}}{\sum_{s<t} p_{s-1}^2}, \qquad \pi_t^e = \beta_t,$$

and then save $s_t = (w_1 - w_2\beta_t)/2$ according to (92.7).

Since β_t uses data through $t-1$ only, there is no simultaneity: beliefs determine saving, saving determines the price level, and the new price level enters next period's regression.

Because $p_s = \pi_{s-1} p_{s-1}$, the estimator can be written

$$\beta_t = \frac{\sum_{s<t} \pi_{s-1}\, p_{s-1}^2}{\sum_{s<t} p_{s-1}^2},$$

a weighted average of *past realized inflation rates*, with weights proportional to p_{s-1}^2.

Those weights are far from equal.

Written recursively,

$$\beta_{t+1} = \beta_t + \gamma_t\,(\pi_{t-1} - \beta_t), \qquad \gamma_t = \frac{p_{t-1}^2}{\sum_{s\le t} p_{s-1}^2},$$

least squares is adaptive expectations whose gain γ_t is the newest observation's share of the weight.

During an inflation the price level grows geometrically, so that share does not shrink: when p grows at gross rate π, γ_t tends to $1 - 1/\pi^2$, which is 0.75 at $\pi = 2$.

So least squares in levels does not average a long history; during an inflation it behaves like adaptive expectations with a large gain.

The same form makes the recursion easy to compute.

The price level grows geometrically, so the two sums overflow quickly, but if we rescale both by the newest weight at each step everything stays of order one.

The code treats the initial belief π_0 as a single pseudo-observation.

```
def ls_dynamics(π_init, T=3000, G=G_d):
    """
    Least squares dynamics.  Carries the two regression sums rescaled by the
    newest p^2, so nothing overflows even though the price level does not stop
    growing.  Returns (beliefs, realized inflation, survived?).
    """
    s_prev = (w1_d - w2_d*π_init) / 2
    num, den, π_last = π_init, 1.0, π_init
    betas, infl = [], []

    for t in range(T):
        β = num / den
        s_t = (w1_d - w2_d*β) / 2
        if s_t <= G or not np.isfinite(s_t):
            return np.array(betas), np.array(infl), False   # no positive price level
        π_t = s_prev / (s_t - G)                            # realized gross inflation
        num = num/π_last**2 + π_t

92.4.2 The stability reversal

Least squares learning converges to the **low**-inflation equilibrium from every initial belief below 3 in the table, within 20 periods, even from beliefs just below 3, the steady state that the rational expectations dynamics converge *to*.

A belief just above 3 ends the monetary economy: expected inflation rises until saving no longer covers the deficit.

Fig. 92.3 sets least squares paths beside rational expectations paths.

```
fig, ax = plt.subplots(figsize=(8, 4.5))

for π0 in (1.5, 2.5, 2.95):
    _, infl, _ = ls_dynamics(π0, T=60)
    ax.plot(infl, color='C0', lw=1.2,
            label="least squares dynamics" if π0 == 1.5 else None)

for π0 in (2.05, 2.5, 4.0):
    ax.plot(re_path(π0, 60), color='C3', lw=1.2, ls='--',
            label="rational expectations dynamics" if π0 == 2.05 else None)

ax.axhline(π_low, color='k', lw=0.8, ls=':')
ax.axhline(π_high, color='k', lw=0.8, ls=':')
ax.annotate("low", (52, π_low + 0.04), fontsize=9)
ax.annotate("high", (52, π_high + 0.04), fontsize=9)
ax.set_xlim(0, 60)
ax.set_ylim(1.2, 4.2)
ax.set_xlabel("$t$")
ax.set_ylabel("gross inflation")
ax.legend(frameon=False)
plt.show()
```

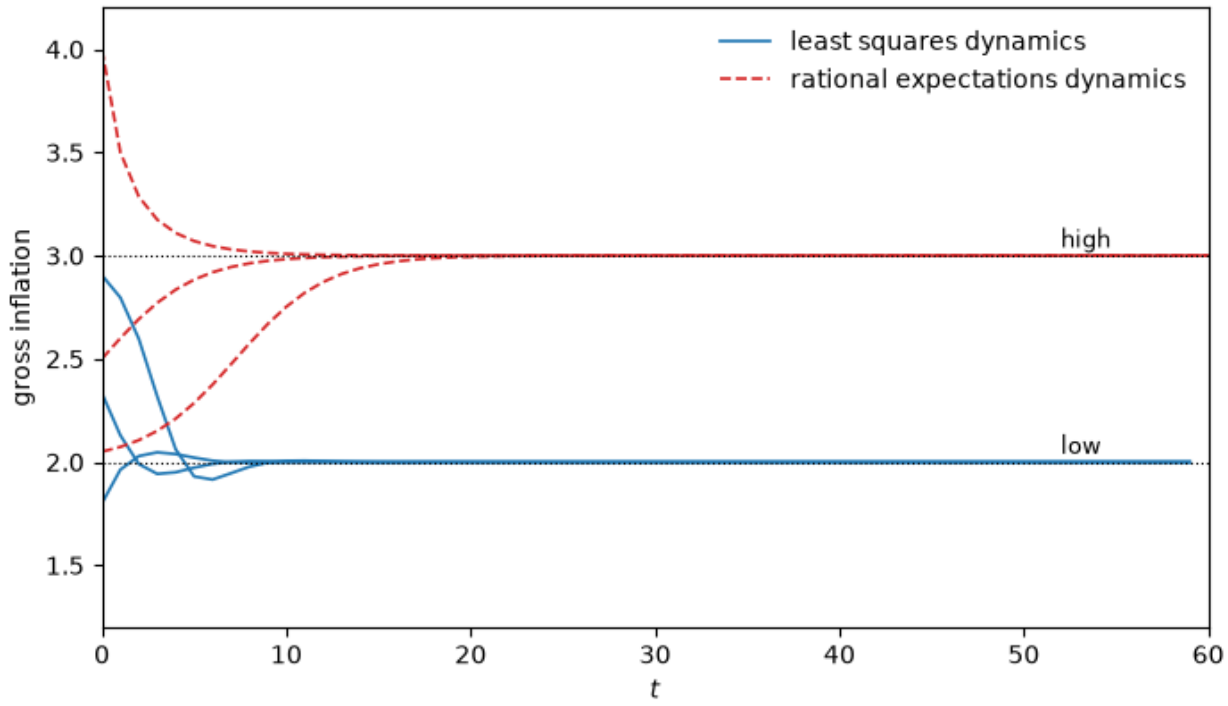

Fig. 92.3: Least squares and rational expectations inflation paths

The two families of paths run in opposite directions.

A bisection locates the edge of the least squares basin of attraction.

```
lo, hi = 2.5, 3.7
for _ in range(40):                        # bisect for the edge of the basin
    mid = (lo + hi) / 2
    lo, hi = (mid, hi) if ls_dynamics(mid)[2] else (lo, mid)
print(f"least squares dynamics survive for initial beliefs up to {lo:.6f}")
print(f"the rational-expectations-stable steady state is      {π_high}")
```

```
least squares dynamics survive for initial beliefs up to 3.000000
the rational-expectations-stable steady state is      3.0
```

The edge of the basin is π_{high} itself.

At exactly $\pi_0 = 3$, beliefs stay put: π_{high} is a rest point of the least squares dynamics, but an unstable one.

We never start at exactly 3, because in floating-point arithmetic a rounding error of order 10^{-16} eventually grows, and the economy then falls to π_{low} or collapses, depending on the sign of the error.

So the steady state that the rational expectations dynamics single out as *the* stable one is precisely the edge of the basin of attraction of the learning dynamics toward the other one.

Here the initial belief matters permanently, because it decides whether the monetary economy survives.

Why the reversal? E-stability

Fix a belief β and suppose agents held it forever.

Saving would be constant at $s(\beta) = (w_1 - w_2\beta)/2$, and the budget constraint $h_t = h_{t-1}/\pi_{t-1} + G$ with $h_t = s(\beta)$ would deliver constant actual inflation

$$T(\beta) = \frac{s(\beta)}{s(\beta) - G}. \tag{92.9}$$

T maps perceived inflation into actual inflation; it is this model's version of the T-map of *A Peculiar Definition of Bounded Rationality*, and its fixed points are the stationary equilibria.

Least squares moves beliefs toward the inflation they produce, so when the gain is small the average motion of beliefs follows the ordinary differential equation

$$\frac{d\beta}{d\tau} = T(\beta) - \beta.$$

A fixed point β^* is stable under this equation, or **E-stable**, if $T'(\beta^*) < 1$ (*One recursion, many learners*, and *Least Squares Learning in Self-Referential Models* for the general theory).

At Economy 7C's parameters $T(\beta) = (6 - \beta)/(4 - \beta)$, so $T'(\beta) = 2/(4 - \beta)^2$.

```
def T_map(β, G=G_d):
    "Actual gross inflation when the belief β is held forever."
    s = (w1_d - w2_d*β) / 2
    return s / (s - G)

def slope(f, x, h=1e-6):
    return (f(x + h) - f(x - h)) / (2*h)

for π_star, name in [(π_low, "low "), (π_high, "high")]:
    print(f"{name} steady state π = {π_star:.0f}:   T'(π) = {slope(T_map, π_star):.3f}
↪,"
          f"   g'(π) = {slope(g_map, π_star):.3f}")
```

```
low  steady state π = 2:   T'(π) = 0.500,   g'(π) = 1.500
high steady state π = 3:   T'(π) = 2.000,   g'(π) = 0.667
```

So $T'(2) = 1/2$ and $T'(3) = 2$: the low steady state is E-stable and the high one is not.

Every slope lies on the opposite side of one from the corresponding slope of g.

Under perfect foresight, a belief slightly above π_{low} is *validated and amplified*, because g has slope 1.5 there.

Under learning, the same belief lowers saving and so raises actual inflation, but only half as much, since T has slope $1/2$; realized inflation comes in *below* the belief, and the belief is revised back down.

At π_{high} it is the other way around.

This is not a coincidence of Economy 7C's parameters.

At every steady state with positive saving, $\operatorname{sign}(T' - 1) = -\operatorname{sign}(g' - 1)$, so whenever there are two steady states, the lower is E-stable and unstable under rational expectations, and the higher is the reverse; Exercise 92.7.6 asks you to prove it.

The reversal is a theorem about this model.

There is a second way to see why the two dynamics disagree.

Under perfect foresight nothing in the past pins down the initial inflation rate, so the rational-expectations-stable high steady state is approached by a continuum of equilibrium paths, while near the unstable low one the only equilibrium path is the stationary one.

Learning selects the steady state that is locally unique.

One caveat remains.

The differential equation describes the average motion of beliefs when each observation moves them only a little, and we saw above that least squares here gives the newest observation a weight near $1 - 1/\pi^2$, three quarters at π_{low}.

So we check the verdict directly.

Near a steady state π^* least squares behaves like adaptive expectations $\beta_{t+1} = \beta_t + \gamma(\pi_{t-1} - \beta_t)$ with $\gamma = 1 - 1/\pi^{*2}$.

Realized inflation $\pi_{t-1} = s(\beta_{t-1})/(s(\beta_t) - G)$ depends on two successive beliefs, so this is a second-order difference equation in β.

The code linearizes it at each steady state and reports its largest root in modulus, at the least squares gain and across all gains between 0 and 1.

```
def local_modulus(π_star, γ):
    "Largest root, in modulus, of the adaptive-expectations recursion linearized at π_
↪star."
    s = (w1_d - w2_d*π_star) / 2
    a = -(w2_d/2) / (s - G_d)                    # ∂π_{t-1} / ∂β_{t-1}
    b = (w2_d/2) * s / (s - G_d)**2              # ∂π_{t-1} / ∂β_t
    return np.max(np.abs(np.roots([1, -(1 - γ + γ*b), -γ*a])))

γ_grid = np.linspace(0.01, 1, 100)
for π_star, name in [(π_low, "low "), (π_high, "high")]:
    γ_ls = 1 - 1/π_star**2
    moduli = [local_modulus(π_star, γ) for γ in γ_grid]
    print(f"{name}: least squares gain {γ_ls:.3f}, largest root {local_modulus(π_star,
↪ γ_ls):.3f};"
          f"  over gains in (0, 1]: from {min(moduli):.3f} to {max(moduli):.3f}")
```

```
low : least squares gain 0.750, largest root 0.612;  over gains in (0, 1]: from 0.
↪500 to 0.995
high: least squares gain 0.889, largest root 2.409;  over gains in (0, 1]: from 1.
↪010 to 2.618
```

At π_{low} every root lies inside the unit circle, whatever the gain; at π_{high} some root lies outside it, whatever the gain.

The E-stability verdict survives the large gain.

It also explains why Bruno and Fischer [1990] found the same reversal in a closely related model using Friedman-style adaptive expectations instead of least squares.

Sargent nevertheless cites Bullard and Duffy [1993] as a warning not to overgeneralize from this result.

In overlapping generations economies whose agents live n periods, they found that for $n \geq 4$ least squares learning fails to converge locally to a rational expectations equilibrium.

92.4.3 Marimon and Sunder's experiment

Which set of dynamics describes people?

Marimon and Sunder [1993] built a laboratory economy to find out.

A fixed number of paying subjects were assigned roles as "young" and "old" in an implementation of exactly this model.

Each period the young submitted a schedule saying how much output they were willing to supply to the old for money at each price, and the experimenters cleared the market against the demand from the old and from the government.

Subjects temporarily on the sidelines played a **forecasting game** with its own cash prize, so the experiment produced a direct record of the price expectations driving the economy.

The session length was unknown to the subjects but governed by publicly announced rules that made the economy equivalent, from their point of view, to one that never ends.

Two findings matter here.

First, the experimental inflation paths were much better approximated by the least squares dynamics converging to the **low** stationary rate than by the rational expectations dynamics converging to the high one.

Sargent reports that this pattern is indicative of all of their results: *on average*, the experimental dynamics are much better approximated by the adaptive dynamics than by the rational expectations dynamics.

Second, the sideliners' forecast errors were comparable in size to those a least squares forecaster would have made using the same data.

The subjects were not doing something exotic, they were doing roughly what the adaptive model says.

The equilibrium that theory calls unstable is the one that both the algorithm and the humans select.

Note

Experimental evidence is not the only way to discriminate.

İmrohoroğlu [1993] estimated a rational expectations version of this model on German hyperinflation data and found the opposite: his estimated equilibrium slides along the *bad* side of the Laffer curve toward the high stationary rate, which is inconsistent with the equilibrium the adaptive dynamics select.

92.4.4 A warning

It is tempting to conclude that adaptive dynamics reliably select the Pareto-superior equilibrium.

Sargent offers a counterexample, shown to him by Benjamin Bental, built from a special case of Brock [1974]'s money-in-the-utility-function model.

An infinitely lived household with endowment y maximizes $\sum_t \delta^t (\ln c_t + \phi \ln(m_t/p_t))$ subject to a sequence of budget constraints, while the government finances a fixed expenditure $G > 0$ by printing currency.

(Sargent writes β and γ for the discount factor δ and the weight ϕ; we keep β for beliefs and γ for gains.)

Under the parameter restriction $\phi(y - G) > G$ the model has a unique stationary equilibrium, with gross inflation

$$\pi = \frac{(y - G)\phi - \delta G}{(y - G)\phi - G},$$

which has the classical property of rising with the deficit.

```
ψ_b, δ_b, y_b = 1.0, 1/1.05, 11.0

def brock_π(G):
    return ((y_b - G)*ψ_b - δ_b*G) / ((y_b - G)*ψ_b - G)

G_vals = (0.5, 1.0, 1.5, 2.0)
pd.DataFrame({
    "$G$": G_vals,
    "restriction $\\phi(y-G) > G$": [ψ_b*(y_b - G) > G for G in G_vals],
    "stationary $\\pi$": [brock_π(G) for G in G_vals],
    "return on currency $1/\\pi$": [1/brock_π(G) for G in G_vals],
}).round(5)
```

```
   $G$  restriction $\phi(y-G) > G$  stationary $\pi$  \
0  0.5                         True           1.00238
1  1.0                         True           1.00529
2  1.5                         True           1.00893
3  2.0                         True           1.01361

   return on currency $1/\pi$
0                     0.99762
1                     0.99474
2                     0.99115
3                     0.98658
```

But the model *also* has a continuum of non-stationary equilibria, indexed by initial price levels below the stationary one, in all of which the gross inflation rate converges to δ — that is, the economy ends in **deflation**, with the return on currency approaching $1/\delta = 1.05$ and real balances exploding.

These exist because the demand for currency implied by $\phi \ln(m/p)$ is so elastic with respect to the rate of return that the government can raise enough seigniorage to finance G even while paying interest on currency through deflation.

Sargent reports that least squares learning here selects the *classical stationary* equilibrium, just as in the overlapping generations model.

The T-map makes that easy to check.

With consumption constant at $y - G$, the household's first-order condition for money gives real balances $h(\pi^e) = \phi(y - G)\pi^e/(\pi^e - \delta)$ when expected inflation is π^e.

The budget constraint $h = h/\pi + G$ then turns a belief held forever into actual inflation $T(\pi^e) = h(\pi^e)/(h(\pi^e) - G)$.

```
def brock_T(πe, G):
    "Actual gross inflation when expected inflation πe is held forever."
    h = ψ_b * (y_b - G) * πe / (πe - δ_b)
    return h / (h - G)

G_b = 1.0
print(f"stationary π = {brock_π(G_b):.5f},   T'(π) = {slope(lambda x: brock_T(x, G_b),
 ↪ brock_π(G_b)):.3f}")
```

```
stationary π = 1.00529,   T'(π) = 0.095
```

The slope is far below one, so the classical stationary equilibrium is E-stable.

The difference from the overlapping generations model is the welfare ranking: in the Brock model, the non-stationary equilibria all Pareto-dominate the classical stationary one that learning picks.

So in both examples least squares dynamics select the *classical* equilibrium.

Whether that equilibrium is the good one is a separate question, and the answer depends on the model.

92.5 A government learning the Phillips curve

The examples so far put adaptive *households* into a monetary economy.

We close with an application in which the adaptive agent is the **government**, learning an econometric relationship that it acts on.

The model, due to Sims [1988] and estimated by Chung [1990], extends the Phillips curve example of Kydland and Prescott [1977].

It nests two stories about post-war U.S. inflation: a government misled by an apparently exploitable Phillips curve, and Phillips-curve fitters whose adaptive methods caught the adverse shift in time.

The Phillips curve lectures that begin with *The Rise and Fall of U.S. Inflation* develop this material in depth, with the same calibration; here we give a condensed version.

92.5.1 The model

Inflation is decomposed into an expected and an unexpected part,

$$\pi_t = g_{t-1} + \eta_t, \tag{92.10}$$

where g_{t-1} is the inflation the public expects (and which the government controls) and η_t is the public's forecast error, orthogonal to earlier information.

The *true* Phillips curve is the natural-rate one: only the **surprise** η_t moves unemployment:

$$U_t = U^* - \theta(\pi_t - g_{t-1}) + u_t = U^* - \theta\eta_t + u_t, \qquad \theta > 0. \tag{92.11}$$

The government does not know this.

It believes unemployment depends on the *level* of inflation, and fits the non-expectational regression

$$U_t = \alpha_0 + \alpha_1 \pi_t + \epsilon_t. \tag{92.12}$$

Each period it minimizes $\frac{1}{2}\mathbb{E}(U_t^2 + \pi_t^2)$ subject to its perceived model, which yields the myopic target

$$g_{t-1} = -\frac{\alpha_0\,\alpha_1}{1+\alpha_1^2}. \tag{92.13}$$

The system is **self-referential**: the government's beliefs α set its policy g through (92.13); the policy shapes the joint distribution of (π, U); and that distribution is what the government's regression (92.12) estimates.

Note

We follow Sargent [1993]'s notation, in which π_t is *net* inflation in percent.

The table translates to *Escaping Nash Inflation* and *Priors, Escapes, and Learning Cycles*; *A note on notation* covers the rest of the Phillips curve lectures.

object	here	*Escaping Nash Inflation*, *Priors, Escapes, and Learning Cycles*
inflation	π_t	π_n
government's target (systematic) inflation	g_{t-1}	x_n
natural rate of unemployment	U^*	u
inflation surprise	η_t	$\sigma_2 W_{2n}$
unemployment shock	u_t	$\sigma_1 W_{1n}$
belief: intercept, slope	α_0, α_1	γ_{-1}, γ_1 (escaping_nash); a, b (priors)
constant gain	γ	ε
equilibrium with the inflation bias	self-confirming (Kydland–Prescott's "consistent")	self-confirming (Nash)

```
U_star, θ_pc = 5.0, 1.0              # natural rate 5%, Phillips slope
σ_η, σ_u = 0.3, 0.3                  # inflation-surprise and unemployment shocks

def govt_target(α):
    "Government's myopic optimal target inflation."
    α0, α1 = α
    return -α0 * α1 / (1 + α1**2)
```

92.5.2 The self-confirming equilibrium

Kydland and Prescott's **consistent** equilibrium is what the Phillips curve lectures call a **self-confirming** equilibrium: a belief vector α whose induced policy generates data whose regression returns the same α.

Under a constant policy g, the surprise η_t is the only thing moving inflation around its mean, so the population regression of U on π has slope exactly $-\theta$ and intercept $U^* + \theta g$.

Solving that fixed point with the decision rule (92.13) gives Kydland and Prescott's time-consistent outcome,

$$\alpha_0 = (1 + \theta^2)U^*, \qquad \alpha_1 = -\theta, \qquad g = \theta U^*.$$

```
α_consistent = np.array([(1 + θ_pc**2) * U_star, -θ_pc])
g_consistent = θ_pc * U_star
print(f"self-confirming beliefs α = {α_consistent},  target inflation g = {g_
 ↪consistent}")
print(f"optimal (Ramsey) outcome:                    target inflation g = 0")
```

```
self-confirming beliefs α = [10. -1.],  target inflation g = 5.0
optimal (Ramsey) outcome:                    target inflation g = 0
```

This is the **inflation bias**.

The government inflates at rate θU^* and gets nothing for it: because only surprises move unemployment, average unemployment is U^* either way.

Had the government understood the true model (92.11), it would have chosen $g = 0$, the Ramsey outcome, with the same unemployment and none of the inflation.

The self-confirming equilibrium is unique, and the Ramsey outcome is not an equilibrium: to choose $g = 0$ the government would have to believe there is no tradeoff, but the data that $g = 0$ generates show the slope $-\theta$.

The self-confirming equilibrium is E-stable, so a government that believes its coefficients are constant and estimates them by least squares with a decreasing gain is drawn toward it asymptotically (*Self-Confirming Equilibria*, *Adaptive Learning and Escape Dynamics*); in finite samples a falling gain can also let an early escape stick, because it slows the return as well.

That is the natural-rate story: the government keeps inflating because its own policy keeps producing data that confirm the tradeoff it believes in.

92.5.3 Constant-gain learning and escapes

Sims [1988] and Chung [1990] made the government *less* sure that its coefficients are constant: it suspects they drift as a random walk and estimates them with a Kalman filter (see *A First Look at the Kalman Filter*), which discounts old data in favor of recent data.

Sims found two kinds of history.

Some stayed near the self-confirming equilibrium; others converged to a process that spends most of its time near the zero-inflation Ramsey outcome, because a government willing to entertain drifting coefficients learns, without a big inflation, that the tradeoff is poor.

Which kind emerges depends partly on parameters, especially the drift variances the government entertains.

Our government learns in a simpler way, by **constant-gain recursive least squares**, the version studied by Sargent [1999] and Cho *et al.* [2002], which approximates a Kalman filter with a particular prior about the drift [Sargent and Williams, 2005].

With $x_t = (1, \pi_t)^\top$ and a constant gain γ, it sets g_{t-1} by (92.13) using its estimate α_t, observes (π_t, U_t), and updates

$$M_t = M_{t-1} + \gamma(x_t x_t^\top - M_{t-1}), \qquad \alpha_{t+1} = \alpha_t + \gamma M_t^{-1} x_t (U_t - x_t^\top \alpha_t).$$

Unlike a $1/t$ gain, which eventually freezes the estimates, a constant gain keeps the government paying attention to what just happened.

We start it at the self-confirming beliefs, with $M_0 = I$ and $\gamma = 0.02$.

```
def constant_gain(T=40_000, gain=0.02, seed=1):
    """
    Government estimates its Phillips curve by constant-gain recursive least
    squares, starting from the self-confirming beliefs.  Returns the paths of
    target inflation g_{t-1}, inflation π_t and unemployment U_t.
    """
    rng = np.random.default_rng(seed)
    α = α_consistent.copy()
    M = np.eye(2)                                          # moment-matrix estimate
    g_path, π_path, U_path = np.empty(T), np.empty(T), np.empty(T)
    for t in range(T):
        g = govt_target(α)
        η = σ_η * rng.standard_normal()
        π = g + η
        U = U_star - θ_pc * η + σ_u * rng.standard_normal()    # true Phillips curve
        x = np.array([1.0, π])
        M = M + gain * (np.outer(x, x) - M)
        α = α + gain * np.linalg.solve(M, x * (U - x @ α))
        g_path[t], π_path[t], U_path[t] = g, π, U
    return g_path, π_path, U_path

g_path, _, _ = constant_gain()
```

```

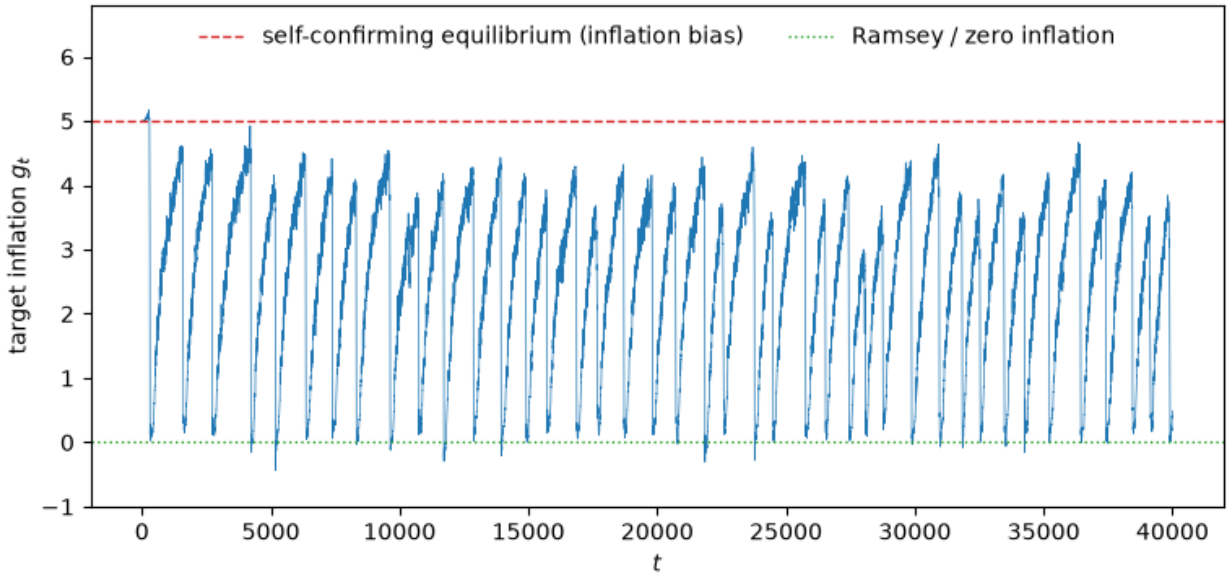

Fig. 92.4: Constant-gain learning and recurrent escapes toward zero inflation

Fig. 92.4 shows that the constant-gain government does not settle at the inflation bias.

It repeatedly and abruptly **escapes** toward zero inflation, then climbs back toward the inflation bias, and at this gain it usually escapes again before it gets there: a recurring sawtooth.

The escapes reinforce themselves.

A run of shocks that makes unemployment look unresponsive to inflation flattens the estimated slope α_1, and the government cuts inflation.

That predictable fall in inflation does not raise unemployment, since only surprises move it, so the government's own policy generates data that confirm the flatter slope and push inflation further toward zero.

This recurrent escape-and-return is the dynamics of Sargent [1999] and Cho *et al.* [2002], not Sims's, whose escaping histories stayed near the Ramsey outcome; *Priors, Escapes, and Learning Cycles* traces the difference to how the government sets up its Kalman filter.

Adaptive Learning and Escape Dynamics and *Escaping Nash Inflation* show how the frequency of escapes depends on the gain, and how Sargent [1999] turned them into a theory of how U.S. inflation was conquered in the early 1980s.

Chung went further and estimated the government's learning rule itself on post-war U.S. data; Exercise 92.7.7 asks you to solve a stripped-down version of his problem.

92.6 Concluding remarks

Part 1 showed that a system of adaptive agents can find a rational expectations equilibrium it was never told about.

It also showed that *which* equilibrium it finds is not up to the agents: economy 2 has two stationary equilibria, and learning finds only the low-inflation one.

And it made visible how much the complexity of the environment governs the speed of learning: a rare deficit state is learned about slowly.

Part 2 sharpened the selection result.

Where the model has two steady states, least squares learning picks out the one that the rational expectations dynamics reject, and laboratory subjects go the same way.

E-stability explains why: at every steady state with positive saving the slopes of the T-map and of the rational expectations map lie on opposite sides of one.

The same logic disposes of the bubbles of *A Peculiar Definition of Bounded Rationality* (Exercise 92.7.5).

That is the best case in Sargent [1993] for treating adaptive dynamics as an equilibrium selection device.

The Brock counterexample marks its limit.

In both models learning selects the classical equilibrium, which is the good one in one model and a bad one in the other.

The selection is a fact about the dynamics, not a welfare theorem, and *1993 Prospects for Bounded Rationality in Macroeconomics* returns to how much weight it can bear.

The Phillips curve application turned the *gain* into the object of interest.

With a decreasing gain the government settles at the inflation bias; with a constant gain it keeps escaping toward the Ramsey outcome, which is not an equilibrium at all.

The Phillips curve lectures that begin with *The Rise and Fall of U.S. Inflation* take this up in depth.

Learning, Approximation, and Equilibrium Computation takes up the question Part 1 left open: what an agent must give up when the state is continuous.

Exchange Rate Indeterminacy, Learning, and Experiments then returns to this overlapping generations economy with two currencies, where the rational expectations equilibria form a continuum and the limit of learning depends on where beliefs start.

Further ahead, *Money as a Medium of Exchange among Artificially Intelligent Agents* takes the selection question to a setting where the competing equilibria are not high and low inflation but different *monetary institutions*: which good becomes money.

92.7 Exercises

Exercise 92.7.1

Because agents learn a separate saving rate for each deficit state, they can only learn about a state as fast as that state occurs.

Compare two economies with $\bar{G} = (0.8, 0)$ that differ only in the transition matrix: one where the two states are equally likely, and one where the high-deficit state is rare.

For each, compute the stationary equilibrium, run the learning simulation for 30,000 periods, and report how far each state's learned saving rate is from its target along with how often that state was visited.

A single run can mislead, so repeat the comparison across 20 seeds.

Solution

For each chain we record, in every run, the error of each state's learned rule (averaged over the two classes) and the number of periods spent in each state.

```
G_ex = np.array([0.8, 0.0])
cases = {"equally likely": np.array([[0.5, 0.5], [0.5, 0.5]]),
         "high deficit rare": np.array([[0.5, 0.5], [0.03, 0.97]])}
seeds = range(20)

rows, ratios = [], {}
for name, P in cases.items():
    s_star, _ = stationary_equilibrium(G_ex, P)
    errors, visits = [], []
    for seed in seeds:
        hist, states = simulate(G_ex, P, T=30_000, s0=start, seed=seed)
        errors.append(np.abs(hist[-1].mean(axis=0) - s_star))
        visits.append(np.bincount(states, minlength=2))
    errors, visits = np.array(errors), np.array(visits)
    rmse = np.sqrt(np.mean(errors**2, axis=0))
    ratios[name] = errors[:, 0] / errors[:, 1]
    for k in (0, 1):
        rows.append([name, k+1, visits[:, k].mean(), s_star[k], rmse[k]])

display(pd.DataFrame(rows, columns=["chain", "state", "visits (mean over seeds)",
                                    "equilibrium $s_i$", "RMS error over seeds"]
                     ).set_index(["chain", "state"]).round(4))

for name, r in ratios.items():
    print(f"{name:18s}: error ratio state 1 / state 2 across seeds: "
          f"median {np.median(r):.1f}, range {r.min():.1f} to {r.max():.1f}, "
          f"state 1 worse in {np.sum(r > 1)} of {len(r)} seeds")
```

```
                         visits (mean over seeds)  equilibrium $s_i$  \

                  2                    0.0051
high deficit rare 1                    0.0108
                  2                    0.0015
```

```
equally likely    : error ratio state 1 / state 2 across seeds: median 0.8,␣
↪range 0.0 to 181.2, state 1 worse in 9 of 20 seeds
high deficit rare : error ratio state 1 / state 2 across seeds: median 9.1,␣
↪range 0.2 to 39.8, state 1 worse in 15 of 20 seeds
```

When the two states are equally likely the chain is IID, so both states face the same distribution of future returns and the equilibrium has $s_1 = s_2$.

Each state is visited about half the time, and the two rules are learned about equally well.

When the high-deficit state is rare it is visited only about 6 percent of the time, roughly 1,700 periods out of 30,000, and the root-mean-square error in its rule is several times that of the common state, even though both have had 30,000 periods of calendar time to settle.

The ratio is large in most runs but varies a good deal from seed to seed, which is why a single run is a poor basis for the comparison.

Sargent's comment is worth keeping in mind: in terms of *unconditional expected utility*, failing to learn what to do in a rarely visited state may cost very little.

The cost of slow learning is not proportional to the size of the error.

Note also that changing the transition matrix changes the equilibrium itself — beliefs about the persistence of deficits feed straight into (92.5) — so the comparison has to be against a separately recomputed target for each chain.

Exercise 92.7.2

In a stochastic environment, the declining gain $\gamma_\tau = 1/(\tau + 20)$ is what makes (92.6) converge.

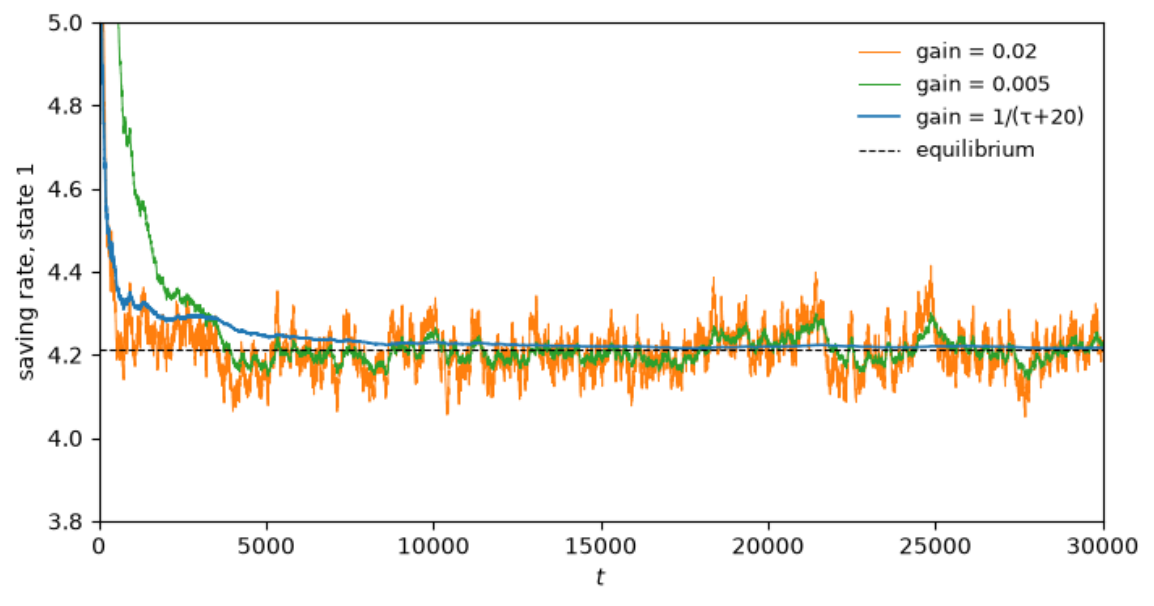
An agent who suspected the environment might be drifting would use a **constant gain** instead, weighting recent experience more heavily forever.

Use the `gain` argument of `simulate` to give the agents a constant gain, and describe what happens to the limiting behavior of the saving rules.

Compare gains of 0.02 and 0.005 against the declining-gain benchmark, in both economy 1 and economy 2.

Solution

For each economy and gain we average the last 5,000 periods of the rules (over the two classes), and report the mean error relative to equilibrium and the standard deviation.



```
rows, paths = [], {}
for G, P, s_star, econ in [(G1, P1, s1, "economy 1"), (G2, P2, s2, "economy 2")]:
    for label, gain in [("0.02", 0.02), ("0.005", 0.005), ("1/(τ+20)", None)]:
        hist, _ = simulate(G, P, T=30_000, s0=start, gain=gain)
        paths[econ, label] = hist[:, 0, 0]
        tail = hist[-5_000:].mean(axis=1)        # average the two classes
        rows.append([econ, label,
                     *[f"{e:.1e}" for e in tail.mean(axis=0) - s_star],
                     *[f"{d:.1e}" for d in tail.std(axis=0)]])

pd.DataFrame(rows, columns=["economy", "gain", "mean error $s_1$", "mean error $s_2
↪$",
                            "s.d. $s_1$", "s.d. $s_2$"]).set_index(["economy",
↪"gain"])
```

economy	gain	mean error s_1	mean error s_2	s.d. s_1	s.d. s_2
economy 1	0.02	-8.9e-16	-8.9e-16	2.2e-14	2.2e-14
	0.005	-4.4e-15	-4.4e-15	8.3e-14	8.3e-14
	1/(τ+20)	1.7e-04	1.6e-04	9.3e-06	8.2e-06
economy 2	0.02	-2.9e-03	2.2e-02	3.7e-02	3.9e-02
	0.005	2.5e-03	2.1e-02	1.8e-02	1.6e-02
	1/(τ+20)	9.1e-03	1.0e-02	1.1e-03	1.8e-03

The figure follows the even class's rule for state 1 in economy 2.

```
fig, ax = plt.subplots(figsize=(8, 4))
for label, colour, lw in [("0.02", 'C1', 0.7), ("0.005", 'C2', 0.7), ("1/(τ+20)",
 ↪'C0', 1.2)]:
    ax.plot(paths["economy 2", label], color=colour, lw=lw, label=f"gain = {label}
 ↪")
ax.axhline(s2[0], color='k', lw=0.8, ls='--', label="equilibrium")
ax.set_xlim(0, 30_000)
ax.set_ylim(3.8, 5.0)
ax.set_xlabel("$t$")
ax.set_ylabel("saving rate, state 1")
ax.legend(frameon=False, fontsize=9)
plt.show()
```

In economy 2 the constant-gain rules do not converge.

They settle into a *neighborhood* of the equilibrium and then keep rattling around inside it forever, because each new observation is always given the same weight and so never stops moving the estimate.

Shrinking the gain tightens the band but does not eliminate it.

In economy 1, by contrast, the constant-gain rules converge to the equilibrium to machine precision, and faster than the declining-gain rule.

Nothing random hits the agents at that equilibrium: with no deficit, $R \equiv 1$ in every state, so once the rules are right every observation confirms them.

So the correct statement is conditional.

When there are intrinsic shocks at the equilibrium, only a gain that declines to zero delivers convergence to a point, which is why the convergence theorems for these systems require it.

Without such shocks a constant gain converges too, and quickly.

The table also shows the price of a declining gain in economy 2.

After 30,000 periods the $1/(\tau+20)$ rule is still about 0.01 above the equilibrium in both states, and since its standard deviation is several times smaller, that error is bias: the rule has not yet arrived.

The constant-gain rules, by contrast, wander around the equilibrium with standard deviations of about 0.02 to 0.04, slowly enough that even a 5,000-period average can sit a couple of hundredths away from it.

What the constant-gain agent buys in exchange for its permanent noise is speed and adaptability: if the deficit process were to change, the declining-gain agent would barely notice, while the constant-gain agent would track the change.

That trade-off reappears throughout this literature, and in the Phillips curve application above.

Exercise 92.7.3

Economy 2 has a second, high-inflation stationary equilibrium, `s2_hi`, computed above.

In the simulations of Fig. 92.1 the projection facility keeps state 1's saving above $\bar{G}_1 + 0.4 = 1.2$, which already rules it out, since its s_1 is below 1.2.

1. Lower the projection band to 0.01, start both classes at the high-inflation equilibrium, and run the learning economy for 20,000 periods with 20 different seeds. Where do the saving rules go, and how often does the projection facility bind?
2. Explain the result with the associated ordinary differential equation. When both classes use the rule s, the average Newton step in state i is $-E_i U'(s_i)/E_i U''(s_i)$, where E_i averages over next period's state with the returns $R(i,j) = (Ns_j - \bar{G}_j)/(Ns_i)$. Compute the eigenvalues of the Jacobian of this map at both equilibria.

Solution

We start every run exactly at the high-inflation equilibrium and record where the rules (averaged over the two classes) end up, and whether state 1's rule ever hits the floor $\bar{G}_1 + 0.01$.

```
band = 0.01
floor_1 = G2[0]/N + band
final, hit_floor = [], []
for seed in range(20):
    hist, _ = simulate(G2, P2, T=20_000, s0=np.tile(s2_hi, (2, 1)), seed=seed,␣
 ↪band=band)
    final.append(hist[-1].mean(axis=0))
    hit_floor.append(np.any(np.isclose(hist[:, :, 0], floor_1)))
final, hit_floor = np.array(final), np.array(hit_floor)
climbed = final[:, 0] > s2_hi[0] + 1

print(f"climbed toward the low-inflation equilibrium:  {climbed.sum()} of 20 runs,"
      f"  mean final rule {np.round(final[climbed].mean(axis=0), 3)}")
print(f"fell to the projection floor:                  {(~climbed).sum()} of 20␣
 ↪runs,"
      f"  mean final rule {np.round(final[~climbed].mean(axis=0), 3)}")
print(f"hit the floor at least once:                   {hit_floor.sum()} of 20 runs
 ↪")
print(f"low-inflation equilibrium:                     {np.round(s2, 3)}")
```

```
climbed toward the low-inflation equilibrium:  15 of 20 runs,  mean final rule␣
 ↪[4.096 4.254]
fell to the projection floor:                  5 of 20 runs,  mean final rule␣
 ↪[0.81  0.348]
hit the floor at least once:                   12 of 20 runs
low-inflation equilibrium:                     [4.211 4.364]
```

Learning never stays at the high-inflation equilibrium, even when it starts exactly there.

Most runs climb toward the low-inflation equilibrium, covering most of the distance in 20,000 periods and still climbing.

The rest go the other way: state 1's rule falls to the floor, where saving barely covers the deficit, and state 2's rule sinks far below its starting point.

Without the projection facility those economies would end, and many of the runs that eventually climb also touch the floor on the way.

The mean dynamics explain both outcomes.

```
def mean_newton_step(s, G, P):
    "Average Newton step -E_i U'/E_i U'' in each state when both classes use the␣
↪rule s."
    R = (N*s[None, :] - G[None, :]) / (N*s[:, None])
    EU1 = (P * U_prime(s[:, None], R)).sum(axis=1)
    EU2 = (P * U_double(s[:, None], R)).sum(axis=1)
    return -EU1 / EU2

def jacobian(f, x, h=1e-6):
    J = np.empty((len(x), len(x)))
    for k in range(len(x)):
        e = np.zeros(len(x))
        e[k] = h
        J[:, k] = (f(x + e) - f(x - e)) / (2*h)
    return J

for s_eq, name in [(s2, "low inflation "), (s2_hi, "high inflation")]:
    eig = np.linalg.eigvals(jacobian(lambda s: mean_newton_step(s, G2, P2), s_eq))
    print(f"{name} equilibrium {np.round(s_eq, 4)}:  eigenvalues {np.round(np.
↪sort(eig.real), 3)}")
```

```
low inflation  equilibrium [4.2111 4.3637]:  eigenvalues [-1.948 -0.795]
high inflation equilibrium [1.1896 1.6343]:  eigenvalues [-3.696  3.263]
```

At the low-inflation equilibrium both eigenvalues are negative, so it is a stable rest point of the associated differential equation.

At the high-inflation equilibrium one eigenvalue is positive: it is a saddle, and the noise in realized returns pushes the rules off it along the unstable direction, which leads up toward the low-inflation equilibrium on one side and down toward collapse on the other.

This is Part 2's stability reversal in a stochastic economy: as with π_{high} there, the high-inflation equilibrium is the boundary between convergence to the low-inflation equilibrium and the end of the monetary economy.

Learning by itself excludes the high-inflation equilibrium; the projection facility matters on the downside, where it keeps collapsing economies alive.

Exercise 92.7.4

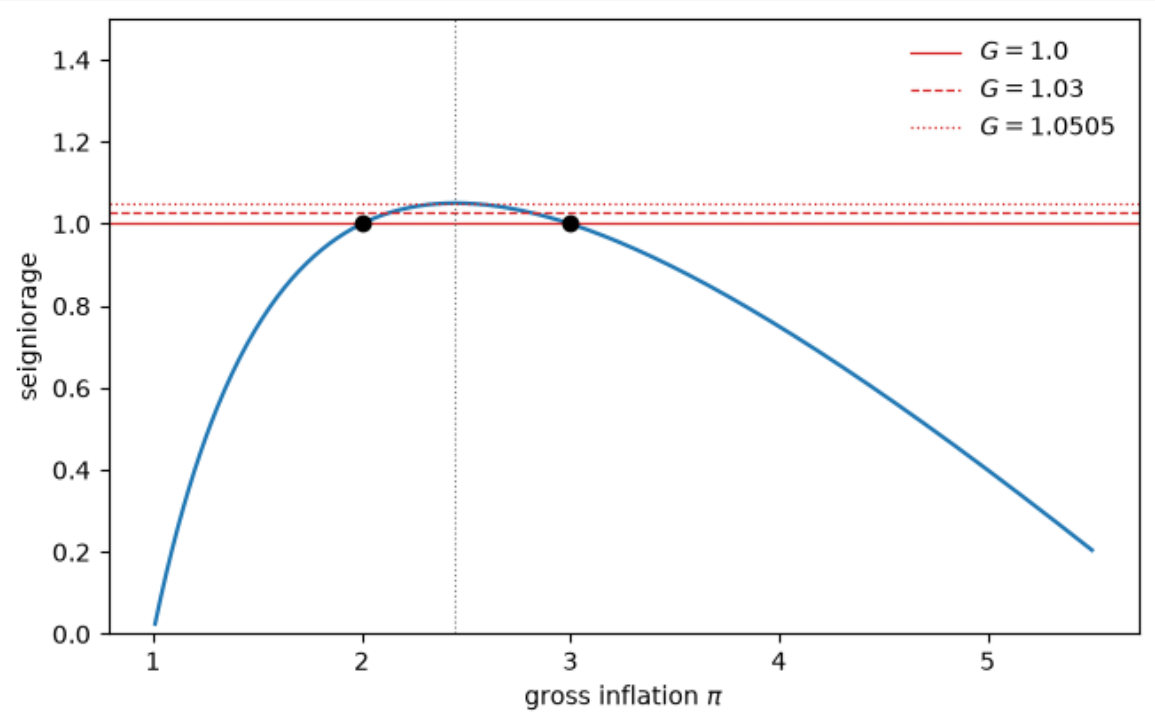
The claim that the high-inflation steady state sits on "the wrong side of a Laffer curve" can be made precise.

In a stationary equilibrium with gross inflation π, real balances are $h = (w_1 - w_2\pi)/2$ and the government collects seigniorage $h(1 - 1/\pi)$.

Plot seigniorage as a function of π, mark the two stationary equilibria, and use the picture to explain why raising G

raises the low stationary inflation rate but *lowers* the high one, and what happens when G gets too large.

Solution



Here is the inflation-tax Laffer curve for Economy 7C.

```
def seigniorage(π):
    return (w1_d - w2_d*π)/2 * (1 - 1/π)

π_grid = np.linspace(1.01, 5.5, 500)
peak = π_grid[np.argmax(seigniorage(π_grid))]

fig, ax = plt.subplots(figsize=(7.5, 4.5))
ax.plot(π_grid, seigniorage(π_grid), lw=1.6)
for G_try, style in [(1.0, '-'), (1.03, '--'), (1.0505, ':')]:
    ax.axhline(G_try, color='C3', lw=0.9, ls=style, label=f"$G = {G_try}$")
ax.plot([π_low, π_high], [seigniorage(π_low), seigniorage(π_high)], 'ko', ms=6)
ax.axvline(peak, color='gray', lw=0.8, ls=':')
ax.set_xlabel(r"gross inflation $\pi$")
ax.set_ylabel("seigniorage")
ax.set_ylim(0, 1.5)
ax.legend(frameon=False)
plt.show()

print(f"peak of the Laffer curve at π = {peak:.4f}, raising {seigniorage(peak):.4f}
↪")
print(f"the two steady states raise {seigniorage(π_low):.4f} and {seigniorage(π_
↪high):.4f}")
```

```
peak of the Laffer curve at π = 2.4497, raising 1.0505
the two steady states raise 1.0000 and 1.0000
```

The two stationary equilibria are the two inflation rates at which the inflation-tax Laffer curve crosses the required revenue G, one on each side of the peak.

The low one sits on the rising branch, so financing a larger deficit there requires *more* inflation: the classical comparative static.

The high one sits on the falling branch, where more inflation raises *less* revenue, so a larger deficit is financed by a *lower* stationary inflation rate, the anti-classical comparative static that makes the high equilibrium so awkward.

As G rises the horizontal line moves up and the two intersections converge.

Past the peak of the curve there is no stationary equilibrium at all: the deficit exceeds the maximum revenue the inflation tax can raise.

The table tracks the two roots as G rises.

```
rows = []
for G_try in (0.8, 1.0, 1.04, 1.05, 1.0505, 1.06):
    A1_try = (w1_d + w2_d - 2*G_try)/w2_d
    disc = A1_try**2 - 4*A2
    if disc < 0:
        rows.append([G_try, np.nan, np.nan, "none"])
    else:
        r = np.sort(np.roots([1, -A1_try, A2]))
        rows.append([G_try, r[0], r[1], "two"])

pd.DataFrame(rows, columns=["$G$", "low $\\pi$", "high $\\pi$",
                            "stationary equilibria"]).round(4)
```

	G	low π	high π	stationary equilibria
0	0.8000	1.5642	3.8358	two
1	1.0000	2.0000	3.0000	two
2	1.0400	2.2328	2.6872	two
3	1.0500	2.4000	2.5000	two
4	1.0505	2.4424	2.4566	two
5	1.0600	NaN	NaN	none

The two roots move toward each other as G rises and collide at $G \approx 1.0505$, after which the model has no stationary equilibrium at all.

That number is not a coincidence.

Setting the discriminant of (92.8)'s fixed-point equation to zero gives a double root at $\pi = \sqrt{A_2} = \sqrt{w_1/w_2}$, and the deficit at which it occurs is exactly the peak of the Laffer curve computed above.

```
G_max = (w1_d + w2_d - 2*np.sqrt(A2)*w2_d) / 2
print(f"roots collide at G       = {G_max:.6f},  where π = √(w1/w2) = {np.
 ↪sqrt(A2):.6f}")
print(f"peak of the Laffer curve = {seigniorage(np.sqrt(A2)):.6f}  at π = {np.
 ↪sqrt(A2):.6f}")
```

```
roots collide at G       = 1.050510,  where π = √(w1/w2) = 2.449490
peak of the Laffer curve = 1.050510  at π = 2.449490
```

The largest deficit the government can finance is the maximum of the inflation tax, and at that deficit the two stationary equilibria have merged into one.

Exercise 92.7.5

This exercise brings the bubbles of *The bubble* into Part 2's model.

Set $G = 0$, keeping $w_1 = 6$ and $w_2 = 1$.

1. Show that the stationary inflation rates are $\pi = 1$ and $\pi = w_1/w_2 = 6$, and identify them with equilibria of *A Peculiar Definition of Bounded Rationality*'s money model with a constant money supply.
2. Show that the T-map (92.9) is constant, and say what that implies for least squares learning.
3. Run `ls_dynamics` with `G=0` from several initial beliefs below 6, and compare with the rational expectations paths from the same starting points. Which bubble does a society of least squares learners select?

Solution

With $G = 0$, $A_1 = 1 + w_1/w_2$ and $A_2 = w_1/w_2$, so the fixed-point equation $\pi^2 - A_1\pi + A_2 = 0$ factors as $(\pi - 1)(\pi - w_1/w_2) = 0$.

With no deficit the money supply is constant, so this is *A Peculiar Definition of Bounded Rationality*'s money model with $\mu = 1$.

There, $\pi = 1$ is the quantity-theory equilibrium $c = 0$, in which the price level is proportional to the (constant) money supply, and $\pi = w_1/w_2$ is the inflation rate that every bubble path with $c > 0$ approaches as real balances shrink to zero.

At $\pi = w_1/w_2$ saving is $(w_1 - w_2\pi)/2 = 0$, so it is the limit of a demonetizing economy, not a monetary steady state.

With $G = 0$ the T-map is $T(\beta) = s(\beta)/s(\beta) = 1$ for every belief that leaves saving positive: if agents expected *any* constant inflation rate, they would save a constant amount, and a constant stock of money chasing constant real balances means a constant price level.

So the differential equation for beliefs is $d\beta/d\tau = 1 - \beta$, and least squares beliefs should converge to 1 from anywhere below 6.

```
print("T-map at G = 0:", [T_map(β, G=0.0) for β in (0.5, 2.0, 4.0, 5.9)])

def re_path_G0(π0, T=25):
    "Rational expectations path π_{t+1} = A1 - A2/π_t with G = 0."
    A1_0, A2_0 = (w1_d + w2_d) / w2_d, w1_d / w2_d
    path = [π0]
    for _ in range(T):
        nxt = A1_0 - A2_0/path[-1]
        path.append(nxt if path[-1] > 0 and nxt > 0 else np.nan)
    return np.array(path)

dates = (10, 100, 1_000, 20_000)
rows = []
for π0 in (0.5, 1.5, 3.0, 5.0, 5.9):
    b, infl, ok = ls_dynamics(π0, T=dates[-1], G=0.0)

From every starting point below 6, least squares beliefs head to $\pi = 1$: the learners select $c = 0$, and learning kills the bubble.

Convergence is slow, though, and slowest from high initial beliefs.

Without inflation the price level stops growing, so least squares weights observations roughly equally and its gain falls like $1/t$, unlike the large effective gain we found in Part 2.

And from a belief near 6 the first realized inflation rate is exactly 1, which pulls the belief down at once, and the second is a deep deflation: saving jumps up from almost nothing, the price level collapses, and the early observations, taken at high price levels, dominate the regression for thousands of periods.

The rational expectations paths from the same starting points above 1 do the opposite: they are bubble paths, and inflation rises toward $w_1/w_2 = 6$.

(From a starting point below 1 the rational expectations path has no positive price level.)

The sign result of Exercise 92.7.6 does not apply at $\pi = 6$, where saving is zero and the T-map is undefined.

Exercise 92.7.6

This exercise proves that the stability reversal of *The stability reversal* is a theorem about the model, not a property of Economy 7C's parameters.

Let $F(x) = x^2 - A_1 x + A_2$, so that the stationary inflation rates are the roots of F, and let $s(\beta) = (w_1 - w_2\beta)/2$.

1. Show that $g(\pi) - \pi = -F(\pi)/\pi$ and $T(\beta) - \beta = \dfrac{w_2}{2}\,\dfrac{F(\beta)}{s(\beta) - G}$.
2. Deduce that at every steady state with positive saving, $\operatorname{sign}(T' - 1) = -\operatorname{sign}(g' - 1)$. Conclude that whenever there are two such steady states, the lower one is E-stable and unstable under the rational expectations dynamics, and the higher one is the reverse.
3. Check the result numerically for randomly drawn (w_1, w_2, G) with two steady states.

Solution

For the first identity,

$$g(\pi) - \pi = A_1 - \frac{A_2}{\pi} - \pi = -\frac{\pi^2 - A_1\pi + A_2}{\pi} = -\frac{F(\pi)}{\pi}.$$

For the second,

$$T(\beta) - \beta = \frac{s - \beta(s-G)}{s-G} = \frac{s(1-\beta) + G\beta}{s-G},$$

and

$$2\big[s(1-\beta) + G\beta\big] = (w_1 - w_2\beta)(1-\beta) + 2G\beta = w_2\beta^2 - (w_1 + w_2 - 2G)\beta + w_1 = w_2 F(\beta).$$

At a steady state π^* we have $F(\pi^*) = 0$, so differentiating the two identities gives

$$g'(\pi^*) - 1 = -\frac{F'(\pi^*)}{\pi^*}, \qquad T'(\pi^*) - 1 = \frac{w_2}{2}\,\frac{F'(\pi^*)}{s(\pi^*) - G}.$$

If saving is positive at the steady state, then $\pi^* = s/(s-G) > 0$ forces $s - G > 0$, so both denominators are positive and

$$\operatorname{sign}(T' - 1) = \operatorname{sign} F'(\pi^*) = -\operatorname{sign}(g' - 1).$$

F is an upward-opening parabola, so $F' < 0$ at its smaller root and $F' > 0$ at its larger one.

At π_{low}, therefore, $T' < 1$ (E-stable) and $g' > 1$ (unstable under rational expectations, since $g' = A_2/\pi^2 > 0$); at π_{high}, $T' > 1$ and $g' < 1$.

When the two roots merge, at the largest financeable deficit of Exercise 92.7.4, $F' = 0$ and both slopes equal one.

Here is a numerical check, using $T'(\beta) = (w_2/2)\,G/(s(\beta) - G)^2$ and $g'(\pi) = A_2/\pi^2$.

```
rng = np.random.default_rng(0)
checked = 0
while checked < 1_000:
    w2_r = rng.uniform(0.5, 5)
    w1_r = w2_r * rng.uniform(1.1, 10)                # w1 > w2
    G_r = rng.uniform(0, (np.sqrt(w1_r) - np.sqrt(w2_r))**2 / 2)    # below the␣
 ↪largest deficit
    A1_r, A2_r = (w1_r + w2_r - 2*G_r) / w2_r, w1_r / w2_r
    for π_star in np.roots([1, -A1_r, A2_r]).real:
        s = (w1_r - w2_r*π_star) / 2
        T_slope = (w2_r/2) * G_r / (s - G_r)**2
        g_slope = A2_r / π_star**2
        assert s > G_r and np.sign(T_slope - 1) == -np.sign(g_slope - 1)
    checked += 1
print(f"sign(T' - 1) = -sign(g' - 1) at both steady states in all {checked}␣
 ↪economies")
```

```
sign(T' - 1) = -sign(g' - 1) at both steady states in all 1000 economies
```

Exercise 92.7.7

Chung [1990] estimated the government's learning rule itself: he treated the parameters of the government's Kalman filter as free parameters of a likelihood function for post-war U.S. data on inflation and unemployment.

Here is a stripped-down version of his problem.

Simulate 16,000 periods of (π_t, U_t) from `constant_gain` with gain 0.02.

Suppose an econometrician knows everything about the model except the gain: θ, U^*, σ_η, σ_u, and the government's initial beliefs and moment matrix.

1. Explain why, for any candidate gain γ, the econometrician can reconstruct the government's beliefs and target inflation $g_{t-1}(\gamma)$ from the data.
2. Using the first T observations, compute the Gaussian log likelihood of inflation, $\ell_T(\gamma) = -\sum_{t \le T} (\pi_t - g_{t-1}(\gamma))^2 / (2\sigma_\eta^2)$ up to a constant, on a grid of gains around 0.02, for $T = 250$, 1,000, 4,000 and 16,000. How does the shape of ℓ_T change as T grows?
3. Why does information about the gain keep accumulating?

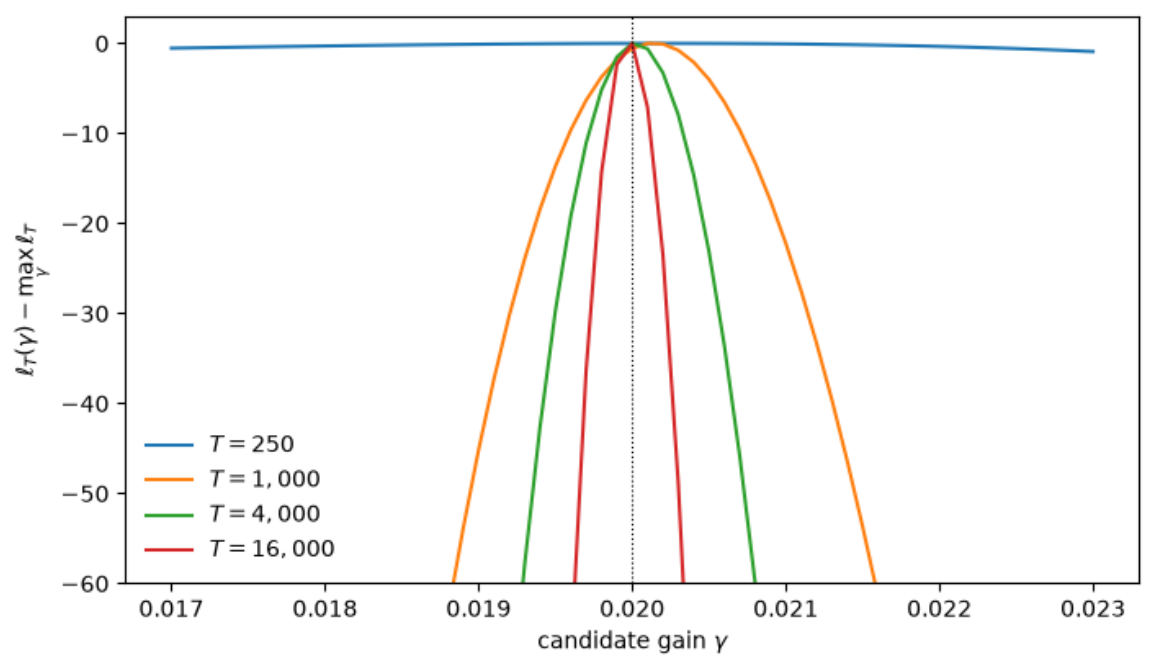
Solution

The government's beliefs are a deterministic function of the data: given the initial beliefs and moment matrix, the recursion that updates (α_t, M_t) uses only the observed (π_t, U_t) and the gain.

So for each candidate gain the econometrician can rerun the government's recursion on the data and read off the targets $g_{t-1}(\gamma)$ from (92.13).

The function below does this for a whole grid of gains at once.

```
def reconstruct_targets(π, U, gains):
    """
    Target inflation g_{t-1}(γ) that a government with gain γ would have chosen,
    reconstructed from data on (π_t, U_t), for each candidate γ in `gains`.
    """
    gains = np.asarray(gains)
    K = len(gains)
    α = np.tile(α_consistent, (K, 1))
    M = np.tile(np.eye(2), (K, 1, 1))
    targets = np.empty((len(π), K))
    for t in range(len(π)):
        targets[t] = -α[:, 0] * α[:, 1] / (1 + α[:, 1]**2)
        x = np.array([1.0, π[t]])
        M = M + gains[:, None, None] * (np.outer(x, x) - M)
        err = U[t] - α @ x
        step = np.linalg.solve(M, (err[:, None] * x)[:, :, None])[:, :, 0]
        α = α + gains[:, None] * step
    return targets



true_gain = 0.02
g_true, π_data, U_data = constant_gain(T=16_000, gain=true_gain, seed=1)
gains = np.round(np.linspace(0.017, 0.023, 61), 6)    # includes 0.02 exactly
targets = reconstruct_targets(π_data, U_data, gains)
print(f"largest error in reconstructed targets at the true gain: "
      f"{np.max(np.abs(targets[:, 30] - g_true)):.1e}")
print(f"first period with target inflation below 1: {np.argmax(g_true < 1)}")
```

```
largest error in reconstructed targets at the true gain: 8.9e-16
first period with target inflation below 1: 307
```

Now the log likelihood, normalized to zero at its maximum, for four sample sizes.

```
fig, ax = plt.subplots(figsize=(8, 4.5))
rows = []
for T in (250, 1_000, 4_000, 16_000):
    ssr = np.sum((π_data[:T, None] - targets[:T])**2, axis=0)
    loglik = -ssr / (2 * σ_η**2)
    loglik -= loglik.max()
    ax.plot(gains, loglik, label=f"$T = {T:,}$")
    rows.append([T, gains[np.argmax(loglik)], loglik[20], loglik[40]])
ax.axvline(true_gain, color='k', lw=0.8, ls=':')
ax.set_ylim(-60, 3)
ax.set_xlabel(r"candidate gain $\gamma$")
ax.set_ylabel(r"$\ell_T(\gamma) - \max_\gamma \ell_T$")
ax.legend(frameon=False)
plt.show()

pd.DataFrame(rows, columns=["T", "maximizing gain",
                            f"drop at γ = {gains[20]:.3f}",
                            f"drop at γ = {gains[40]:.3f}"]).set_index("T").
↪round(4)
```

T	maximizing gain	drop at γ = 0.019	drop at γ = 0.021
250	0.0202	-0.0980	-0.0601
1000	0.0201	-45.1487	-22.2241
4000	0.0200	-118.9857	-93.1558
16000	0.0200	-488.2670	-462.3829

At the true gain the reconstructed targets equal the actual ones, so the residuals are exactly the surprises η_t.

Any other gain implies a different history of beliefs and targets, and the log likelihood penalizes it.

With 250 observations the likelihood is nearly flat.

The sample ends before the first escape, and while beliefs sit near the self-confirming equilibrium they hardly move

whatever the gain, so the data say little about it.

Once escapes begin, the likelihood becomes sharply peaked at the true gain, and the drop at a fixed wrong gain keeps growing with T, roughly in proportion to T in the later samples.

Information about the gain keeps accumulating because a constant gain never stops shaping beliefs: every period the government responds to its newest observations with the same weight, so every period carries fresh evidence about that weight, and most of it arrives during escapes, when beliefs move a lot.

With a decreasing gain the influence of the gain's parameters on beliefs would die away, and so would the information about them; *1993 Prospects for Bounded Rationality in Macroeconomics* takes up this contrast.

Chung's problem was harder than this one: he also estimated θ, U^*, the shock variances and the government's prior, from a few decades of quarterly data rather than thousands of periods.

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

93.1 Overview

In *Adaptive Agents in an Overlapping Generations Monetary Economy* a system of adaptive agents found a rational expectations equilibrium it was never told about.

The agents there learned a *separate* saving rate for each level of the government deficit — a **non-parametric** rule, one number per state.

That works when there are two states.

It runs into two walls otherwise, both noted in Sargent [1993]:

- a state that occurs rarely is learned about slowly, because its observations arrive slowly;
- when the number of states is large — and especially when the state is *continuous* — one parameter per state is hopeless.

The econometrician's response is to impose a **parametric** form on the decision rule, $s = f(G, \theta)$, with θ of low dimension, and use every observation to estimate θ.

This lecture works through what that buys and what it costs.

The costs and benefits are two sides of one idea.

A parametric family can be learned quickly because every observation informs every state.

But a learning scheme confined to a family of functions can converge to a rational expectations equilibrium *only if some member of the family supports one*.

Otherwise the best it can reach is an **approximate equilibrium**.

Working this out surfaces a theme that runs through the whole bounded-rationality program: algorithms that model learning and algorithms that compute equilibria resemble each other.

Marcet's method of parameterized expectations [den Haan and Marcet, 1990, Marcet and Marshall, 1992] is a standard tool for *computing* rational expectations equilibria.

Written recursively, it becomes a model of adaptive agents learning in real time.

An equilibrium computation is a centralized learning algorithm run by the modeller; a learning economy is a decentralized equilibrium computation run by the agents.

The two are different recursions, but they share their fixed points and, through a differential equation that both of them track, their stability condition.

The plan:

1. Put a deficit that takes many values — a fine discretization of a continuous process — into the overlapping generations model of *Adaptive Agents in an Overlapping Generations Monetary Economy*, turning the equilibrium condition into a **functional equation** in the saving rule $f(G)$.
2. Compute a benchmark solution, so we have ground truth to measure against.
3. Solve it by **parameterized expectations** with families of increasing richness, and watch approximate equilibria give way to the exact one.
4. Show that the recursive, real-time version of the same algorithm **is** a learning economy, and that one eigenvalue of the T map sets how fast it learns.
5. Learn the saving rule **non-parametrically** with a kernel estimator, and weigh the trade-off against the parametric route.

Let's start with some imports.

```
import warnings
import numpy as np
import pandas as pd
import quantecon as qe
import matplotlib.pyplot as plt
```

93.2 A continuous-state functional equation

We keep the overlapping generations monetary economy of *Adaptive Agents in an Overlapping Generations Monetary Economy* — two-period lived agents, log utility, endowments w_1 when young and w_2 when old, currency the only store of value, and a government financing a deficit by printing money.

We also keep the calibration of Part 1 of that lecture: $w_1 = 20$, $w_2 = 10$ and $N = 1$.

The one change: the deficit G_t now follows a **continuous** Markov process, with transition kernel $F(G', G) = \text{Prob}\{G_{t+1} \leq G' \mid G_t = G\}$.

We look for a stationary equilibrium in which saving is a *function* of the current deficit, $s_t = f(G_t)$.

The household's first-order condition, evaluated at $s_t = f(G_t)$, is

$$u'(w_1 - f(G_t)) = \mathbb{E}_t[u'(w_2 + f(G_t)R_t)\, R_t], \qquad \mathbb{E}_t(\cdot) = \mathbb{E}(\cdot \mid G_t),$$

and the government budget constraint with market clearing gives the return on currency in terms of the saving rule, exactly as before (with $N = 1$),

$$R_t = \frac{f(G_{t+1}) - G_{t+1}}{f(G_t)}.$$

Substituting R_t, and using $f(G_t)R_t = f(G_{t+1}) - G_{t+1}$ for old-age consumption, turns the first-order condition into a **functional equation** in f:

$$u'(w_1 - f(G_t)) = \mathbb{E}_t\left[u'(w_2 + f(G_{t+1}) - G_{t+1}) \cdot \frac{f(G_{t+1}) - G_{t+1}}{f(G_t)}\right]. \tag{93.1}$$

Because $f(G_t)$ is known at t, it pulls out of the expectation, whatever the utility function.

Writing

$$\psi(G_t) \equiv \mathbb{E}_t[u'(w_2 + f(G_{t+1}) - G_{t+1})\,(f(G_{t+1}) - G_{t+1})], \tag{93.2}$$

equation (93.1) becomes $u'(w_1 - f(G_t)) = \psi(G_t)/f(G_t)$.

Under log utility, $u'(c) = 1/c$, and this can be solved for saving in closed form:

$$\frac{1}{w_1 - f(G_t)} = \frac{\psi(G_t)}{f(G_t)}, \qquad \text{i.e.} \qquad f(G_t) = \frac{w_1\,\psi(G_t)}{1 + \psi(G_t)}.$$

So the whole problem reduces to finding the **conditional expectation** $\psi(G)$: once we have it, the saving rule follows in closed form.

That observation is the hinge of the entire lecture.

Every method below — parametric or not — is a way of estimating the one object $\psi(G)$.

Under log utility the random variable inside (93.2) is $y = (s' - G')/(w_2 + s' - G')$, where s' and G' are next period's saving and deficit.

We will call it the **regressand**, for reasons that will soon be clear.

```
w1, w2 = 20.0, 10.0

def s_from_psi(ψ):
    "Recover the saving rule from the conditional expectation ψ."
    return w1 * ψ / (1 + ψ)

def regressand(s, G):
    "u'(c_2) (s - G) under log utility, at saving s and deficit G."
    return (s - G) / (w2 + s - G)
```

93.2.1 The deficit process

We take $\log G_t$ to follow an AR(1), $\log G_{t+1} = (1-\rho)\log\bar{G} + \rho \log G_t + \sigma\varepsilon_{t+1}$.

To compute with it we replace it by a fine Markov chain, discretizing it on 201 grid points with the method of Tauchen [1986].

From here on that chain *is* the economy: the benchmark below is computed on it, and every learning economy is simulated from it.

Using one chain for both keeps the comparison honest.

If the learners lived in the AR(1) while the benchmark was computed on the chain, even a learner that solved its own economy perfectly would miss the benchmark, and the miss would be blamed on the learner.

With 201 states the chain is a close stand-in for the continuous process.

It is also exactly the case that defeats a state-by-state learner like those of *Adaptive Agents in an Overlapping Generations Monetary Economy*: such a learner would need 201 separate saving rates, and the rarest states are visited only about once every two thousand periods.

```
ρ, σ, G_bar = 0.7, 0.30, 0.6
n_states = 201

mc = qe.tauchen(n_states, ρ, σ, mu=np.log(G_bar) * (1 - ρ), n_std=2.5)
G, P = np.exp(mc.state_values), mc.P
ergodic = mc.stationary_distributions[0]      # where the deficit spends its time

def simulate_deficit(T, seed=0, P=P):
    "State indices of a simulated path of the deficit chain, started from its ergodic␣
 ↪distribution."
    rng = np.random.default_rng(seed)
    chain = qe.MarkovChain(P)
    init = rng.choice(len(P), p=chain.stationary_distributions[0])
    return chain.simulate_indices(T, init=init, random_state=rng)

G_perm = (np.sqrt(w1) - np.sqrt(w2))**2 / 2   # largest deficit that can be financed␣
 ↪forever

print(f"deficit grid: {n_states} points from {G.min():.3f} to {G.max():.3f}")
print(f"mean deficit E[G] under the ergodic distribution: {ergodic @ G:.3f}")
print(f"probability of the least-visited state: {ergodic.min():.1e}")
print(f"largest constant deficit with a monetary steady state: {G_perm:.3f}")
print(f"top of the grid relative to it: {G.max() / G_perm:.2f}")
print(f"share of time the deficit is above it: {ergodic[G > G_perm].sum():.2f}")
```

```
deficit grid: 201 points from 0.210 to 1.715
mean deficit E[G] under the ergodic distribution: 0.653
probability of the least-visited state: 4.4e-04
largest constant deficit with a monetary steady state: 0.858
top of the grid relative to it: 2.00
share of time the deficit is above it: 0.19
```

How large a deficit can this economy finance?

With a deficit held constant at G, a monetary steady state solves a quadratic (Exercise 93.8.2) that has real roots only if $G \leq (\sqrt{w_1} - \sqrt{w_2})^2/2 \approx 0.858$.

The top of our grid is twice that, and the deficit spends about a fifth of its time above it.

A monetary equilibrium nevertheless exists at every state, because high deficits are transitory.

With $\rho = 0.7$, a young agent in a high-deficit state expects the deficit, and with it the inflation tax on his saving, to fall back toward its mean.

93.3 A benchmark solution

To measure any learning scheme, we first need the true $f(G)$.

On the grid, (93.1) is a system of 201 equations, which we solve by **iterating the perceived-to-actual map**, precisely the T map of *A Peculiar Definition of Bounded Rationality*.

Guess a saving rule; use it on the right-hand side to compute the actual saving each state would call forth; repeat until the two agree.

On the chain the right-hand side is a matrix–vector product, $\psi = Py$ with $y_j = (s_j - G_j)/(w_2 + s_j - G_j)$, and the closed form then delivers the new saving rule.

This is a form of the time iteration of *Optimal Savings IV: Time Iteration*, and the damping weight on the new guess plays the role of the relaxation parameter λ of *A Peculiar Definition of Bounded Rationality*.

```
def T_map(s):
    "Actual saving rule called forth by a perceived rule s (one entry per state)."
    return s_from_psi(P @ regressand(s, G))

def solve_benchmark(damp=0.5, tol=1e-12, max_iter=5000):
    "Fixed point of the perceived-to-actual saving map on the deficit grid."
    s = np.full(n_states, (w1 - w2) / 2)
    for it in range(1, max_iter + 1):
        s_new = T_map(s)
        if np.max(np.abs(s_new - s)) < tol:
            return s_new, it
        s = damp * s_new + (1 - damp) * s
    warnings.warn("the benchmark iteration did not converge")
    return s, it

s_benchmark, iters = solve_benchmark()
print(f"converged in {iters} iterations")

def foc_residual(s_rule):
    "Max |first-order-condition error| of a saving rule under the true kernel P."
    return np.max(np.abs(1 / (w1 - s_rule) - (P @ regressand(s_rule, G)) / s_rule))

print(f"benchmark FOC residual: {foc_residual(s_benchmark):.2e}")
print(f"saving rule f(G) runs from {s_benchmark.max():.3f} (low deficit) "
      f"to {s_benchmark.min():.3f} (high deficit)")
```

```
converged in 223 iterations
benchmark FOC residual: 1.70e-14
saving rule f(G) runs from 4.471 (low deficit) to 2.840 (high deficit)
```

Here is the rule.

```
fig, ax = plt.subplots(figsize=(6.5, 4))

ax.set_xlabel("deficit $G$")
ax.set_ylabel("saving $f(G)$")
plt.show()
```

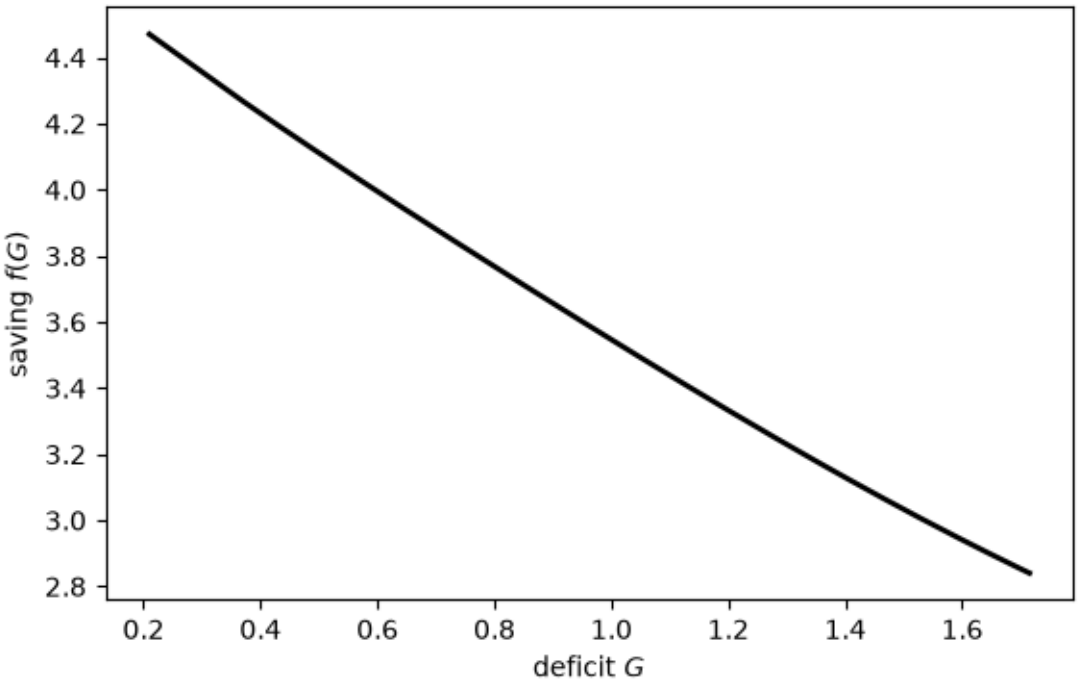

Fig. 93.1: Benchmark equilibrium saving rule

Saving falls as the deficit rises: a larger deficit means faster money creation, a poorer return on currency, and less saving.

The rule is gently curved, which will matter in a moment.

This $f(G)$ is the object no adaptive agent gets to see.

Everything below tries to recover it.

93.3.1 Which equilibrium?

Sargent [1993] notes that systems like (93.1) generally have more than one solution.

Our iteration started from $s = 5$, the saving rate of an economy with no deficit, and found a high-saving, low-inflation solution.

It would find the same solution from any nearby start, because the solution is **stable under the T map**: every eigenvalue of the map's Jacobian there is less than one.

```
def jacobian(f, x, eps=1e-6):
    "Numerical Jacobian of the map f at the point x."
    return np.column_stack([(f(x + eps * e) - f(x - eps * e)) / (2 * eps)
                            for e in np.eye(len(x))])

eig_benchmark = np.linalg.eigvals(jacobian(T_map, s_benchmark))
print(f"largest |imaginary part|: {np.abs(eig_benchmark.imag).max():.1e}")
print("largest eigenvalues of DT at the benchmark:",
      np.sort(eig_benchmark.real)[::-1][:4].round(3))
```

```
largest |imaginary part|: 3.0e-09
largest eigenvalues of DT at the benchmark: [0.773 0.542 0.353 0.208]
```

That is the E-stability condition of *One recursion, many learners*: the condition under which learners whose beliefs are pulled toward the T map's output settle on an equilibrium.

The economy with a constant deficit makes the point sharply.

It has two steady states, and at the high-inflation one the slope of the T map exceeds one (Exercise 93.8.2), so neither the iteration nor a learner can settle there.

That is the computational face of the stability reversal in *The stability reversal*, where least squares learners select the low-inflation steady state.

The largest eigenvalue printed above, about 0.77, will come back: it sets the speed of the algorithms below.

93.4 Parameterized expectations

Marcet's **method of parameterized expectations** [den Haan and Marcet, 1990, Marcet and Marshall, 1992] attacks (93.1) by putting a parametric form on the conditional expectation $\psi(G)$ from (93.2),

$$\psi(G) \approx \psi(G, \theta) = \phi(G)^\top \theta,$$

where $\phi(G)$ is a vector of basis functions and θ a short vector of coefficients.

The algorithm is a fixed-point iteration on θ:

1. Given θ, the saving rule is $f(G) = w_1 \psi(G, \theta)/(1 + \psi(G, \theta))$.
2. Simulate a long path of the deficit and compute the implied saving each period.
3. Form the *realized* value of the object inside (93.2), $y_t = u'(w_2 + s_{t+1} - G_{t+1})(s_{t+1} - G_{t+1})$, and **regress** it on $\phi(G_t)$ to get a new θ.
4. Iterate to convergence.

The regression in step 3 is doing the work of the conditional expectation: least squares projects the realized y_t onto functions of the current state, which is exactly what $\mathbb{E}_t[\cdot \mid G_t]$ is.

We use monomials in a rescaled $\log G$ as the basis, and vary the degree.

Every algorithm in this lecture starts from the same initial belief, $\psi = 1/3$, under which agents save $s = 5$, as they would if there were no deficit.

The functions take the deficit levels, the transition matrix, and the basis evaluated at each state as arguments, so that they can be reused on other economies.

Because the regressors do not change from one pass to the next, we evaluate the basis on the grid, and invert the regressor matrix, only once.

```
def basis(G_vals, degree):
    "Monomials in log-deficit rescaled to [-1, 1]."
    x = 2 * (np.log(G_vals) - np.log(G.min())) / (np.log(G.max()) - np.log(G.min())) -
↪ 1
    return np.vstack([x**k for k in range(degree + 1)]).T

ψ_init = 1 / 3                    # the belief under which agents save s = 5

def θ_init(k):
    "Initial coefficients: a constant ψ = ψ_init."
    θ = np.zeros(k)
    θ[0] = ψ_init
    return θ
```

(continues on next page)

(continued from previous page)

```
def rule(Φ, θ, G=G):
    "Saving rule at each state implied by coefficients θ, kept feasible."
    ψ = np.clip(Φ @ θ, 0.05, 50)
    return np.clip(s_from_psi(ψ), G + 0.05, w1 - 0.05)

def errors(s_rule):
    "Sup-norm and ergodic-weighted RMS distance from the benchmark."
    d = s_rule - s_benchmark
    return np.max(np.abs(d)), np.sqrt(ergodic @ d**2)

def parameterized_expectations(Φ, G=G, P=P, T=150_000, seed=0,
                               damp=0.6, tol=1e-11, max_iter=1000):
    """
    Batch parameterized expectations.  Φ holds the basis functions evaluated
    at each deficit state, one row per state.  Returns the implied saving rule
    at each state, the coefficients and the number of passes.
    """
    idx = simulate_deficit(T + 1, seed, P)
    X = Φ[idx[:-1]]                          # regressors ψ(G_t) along the history
    X_pinv = np.linalg.pinv(X)               # they never change, so invert once
    θ = θ_init(Φ.shape[1])
    for it in range(1, max_iter + 1):
        y = regressand(rule(Φ, θ, G), G)[idx[1:]]     # realized y_t
        θ_new = X_pinv @ y                            # regress y_t on ψ(G_t)
        if np.max(np.abs(θ_new - θ)) < tol:
            return rule(Φ, θ_new, G), θ_new, it
        θ = (1 - damp) * θ + damp * θ_new
    warnings.warn("parameterized expectations did not converge")
    return rule(Φ, θ, G), θ, it
```

93.4.1 Approximate versus exact equilibria

Now run it for families of increasing richness: a constant ψ (saving independent of the deficit), a linear one, and a quadratic one.

```
pea = {deg: parameterized_expectations(basis(G, deg)) for deg in (0, 1, 2)}
rules = {deg: pea[deg][0] for deg in pea}

fig, ax = plt.subplots(figsize=(7, 4.5))
ax.plot(G, s_benchmark, 'k-', lw=2.2, label="benchmark $f(G)$")
labels = {0: "degree 0 (constant)", 1: "degree 1 (linear)", 2: "degree 2 (quadratic)"}
for deg, colour in [(0, 'C0'), (1, 'C1'), (2, 'C2')]:
    ax.plot(G, rules[deg], '--', color=colour, lw=1.4, label=labels[deg])
ax.set_xlabel("deficit $G$")
ax.set_ylabel("saving $s$")
ax.legend(frameon=False)
plt.show()
```

The **constant** family cannot represent a saving rule that depends on the deficit at all, so the best it can do is a flat line through the middle of the data.

That flat line *is* an approximate equilibrium — a fixed point of the learning scheme — but it satisfies the first-order condition only on average, not state by state.

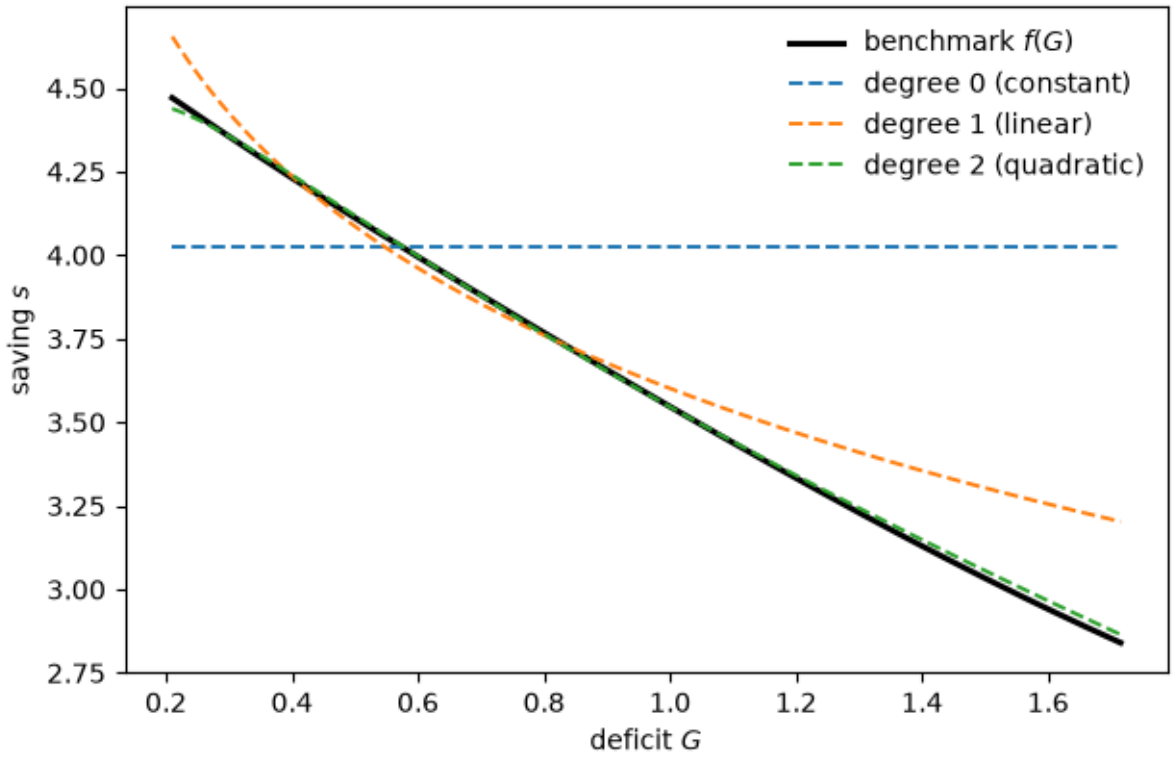

Fig. 93.2: Parameterized expectations rules of increasing degree

In the language of *Optimal Misspecified Beliefs* it is an equilibrium under forecast misspecification: the functional form is wrong, but the coefficient within it is the best that the data the agents themselves generate allow.

The **linear** family does much better, but it misses at the extremes: its rule lies above the benchmark at both ends of the deficit range and below it in the middle.

The **quadratic** family is almost indistinguishable from the benchmark: ψ is very nearly a quadratic function of $\log G$, the variable our basis is built on, so a three-parameter rule essentially nails it.

We can quantify "how close" two ways: by the distance to the benchmark, and by the residual in the first-order condition under the true kernel, the honest measure of how far an approximate equilibrium is from an exact one.

```
rows = []
for deg in (0, 1, 2):
    s_hat, _, passes = pea[deg]
    rows.append([labels[deg], *errors(s_hat), foc_residual(s_hat), passes])

pd.DataFrame(rows, columns=["family", "sup $|s - f|$", "ergodic RMS",
                            "FOC residual", "passes"]).set_index("family").round(4)
```

family	sup $\|s - f\|$	ergodic RMS	FOC residual	passes
degree 0 (constant)	1.1825	0.3212	0.0090	115
degree 1 (linear)	0.3626	0.0683	0.0039	135
degree 2 (quadratic)	0.0322	0.0073	0.0005	142

Every error column falls as the family grows richer.

The first-order-condition residual — the quantity that is exactly zero at a rational expectations equilibrium and positive

at an approximate one — drops by more than an order of magnitude from the constant family to the quadratic.

Marcet and Marshall [1992] give conditions under which this is no accident: as the family grows, the approximate equilibria computed by parameterized expectations converge to the rational expectations equilibrium.

The last column counts the passes the algorithm needed to converge: well over a hundred, for a reason we will come to.

Note

Richer is not *always* better with finite data.

The approximation error keeps falling as the degree rises, but the sampling error in the regression does not, and beyond the quadratic it takes over.

The extra terms then chase sampling noise in the tails of the deficit distribution, where observations are scarce: the ergodic-weighted error levels off, and the sup-norm error can tick back up, by an amount that depends on the simulated history.

That is the same phenomenon as the slowly-learned rare state in *Adaptive Agents in an Overlapping Generations Monetary Economy*, seen from the approximation side: a scheme fits well where the data is, and the cost of misfitting a rarely-visited region is small in terms of expected utility.

Exercise 93.8.1 separates the two sources of error.

93.5 Learning is equilibrium computation

So far parameterized expectations is an algorithm *we* run to compute an equilibrium.

Now comes the point of the whole lecture.

Write the same algorithm **recursively** — updating θ once per period as a single new observation arrives, rather than re-regressing a whole simulated history — and it becomes a model of *adaptive agents learning in real time*.

The recursive form is ordinary recursive least squares:

$$\begin{aligned} M_{t+1} &= M_t + \gamma_t(\phi(G_t)\phi(G_t)^\top - M_t), \\ \theta_{t+1} &= \theta_t + \gamma_t M_{t+1}^{-1}\phi(G_t)(y_t - \phi(G_t)^\top\theta_t), \end{aligned} \tag{93.3}$$

where y_t is the same realized regressand as before, M_t estimates the second-moment matrix of the regressors, and the gain γ_t declines like $1/t$.

In the code below, $\gamma_t = 1/(t+1)$, and M starts at a small multiple of the identity so that it can be inverted from the first period on.

This is a stochastic-approximation recursion with a decreasing gain, the same family as the Robbins–Monro learners of *Adaptive Agents in an Overlapping Generations Monetary Economy*, with M in the role of their curvature estimate.

It differs from their scheme in two ways, not one.

- **What is learned.** The agents of *Adaptive Agents in an Overlapping Generations Monetary Economy* learn a saving rate directly, taking Newton steps on *realized lifetime utility*. An agent's lifetime utility is known only when he is old, so the population there is split into odd and even classes that take turns. The agents here instead learn a *conditional expectation*, ψ, and solve their own Euler equation given it — what Sargent [1993] calls learning via model formation, as opposed to learning the hard way. Each period's realized regressand is known one period later, as soon as the next generation has saved, so no odd/even split is needed.
- **How far an observation reaches.** θ indexes a *parametric* rule, so a single observation updates the saving rule at every state at once, not just at the state that was visited.

Here is the learning economy.

```
def online_pea(Φ, G=G, P=P, T=500_000, seed=0, ridge=1e-3, a=1.0):
    """
    Recursive-least-squares parameterized expectations: the learning economy.

    The young at t save according to the current θ.  Their saving reveals the
    date t-1 realized regressand, and θ and the moment matrix M are updated
    once, with gain a / (t + a).  Returns the path of θ.
    """
    idx = simulate_deficit(T, seed, P)
    k = Φ.shape[1]
    θ, M = θ_init(k), ridge * np.eye(k)
    θ_path = np.empty((T, k))
    θ_path[0] = θ
    for t in range(1, T):
        g, x = G[idx[t]], Φ[idx[t - 1]]
        ψ = min(max(Φ[idx[t]] @ θ, 0.05), 50.0)
        s = min(max(s_from_psi(ψ), g + 0.05), w1 - 0.05)     # date-t saving
        y = regressand(s, g)                                  # date t-1's y, now known
        γ = a / (t + a)
        M += γ * (np.outer(x, x) - M)
        θ = θ + γ * np.linalg.solve(M, x * (y - x @ θ))
        θ_path[t] = θ
    return θ_path

Φ2 = basis(G, 2)
θ_path = online_pea(Φ2)
s_online = rule(Φ2, θ_path[-1])
print("online PEA after {:,} periods: sup error = {:.4f},  ergodic RMS = {:.4f}"
      .format(len(θ_path), *errors(s_online)))
```

```
online PEA after 500,000 periods: sup error = 0.0673,  ergodic RMS = 0.0224
```

How should we judge that?

The learner's target is not the benchmark but the approximate equilibrium of the quadratic family, the fixed point that the batch algorithm computes.

We can compute that target exactly, as a batch pass with infinitely much data would.

Let $T(\theta)$ be the coefficients of the population least squares projection of y_t on $\phi(G_t)$ when agents' beliefs are θ.

This is the T map of *A Peculiar Definition of Bounded Rationality* for beliefs confined to the family, and on the chain we can evaluate it exactly, using P for the conditional expectation and the ergodic distribution for the projection.

```
def T_pea(θ, Φ, G=G, P=P, π=ergodic):

plt.show()
```

The coefficients head for θ^*, but slowly: after half a million periods the online rule still lies visibly above the approximate equilibrium at high deficits, and it misses the benchmark by more than the batch rule does.

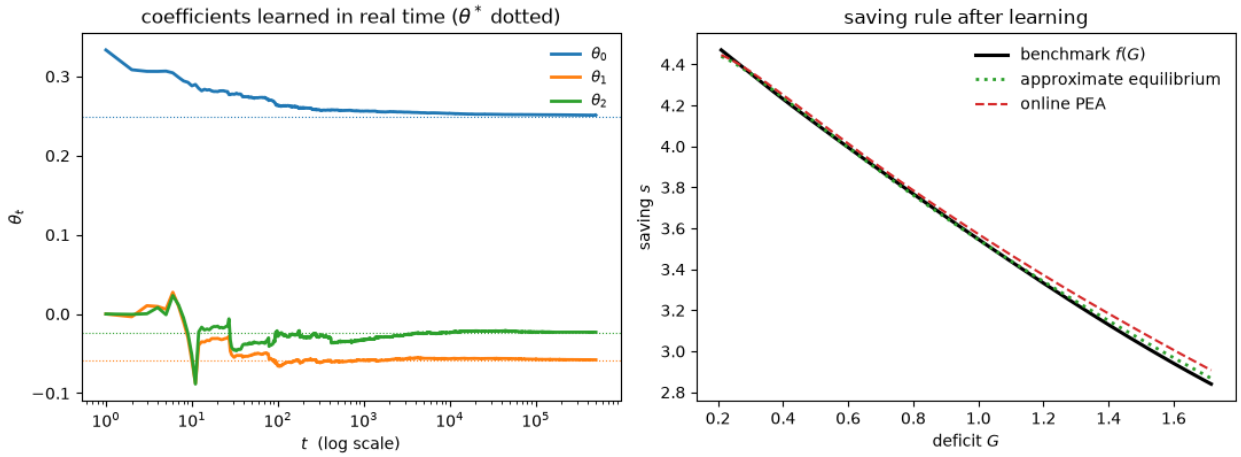

Fig. 93.3: Online learning of the saving rule

93.5.1 Same limit, different speeds

Why do the two algorithms share a limit, and why is the online one so slow?

A batch pass with damping $\delta = 0.6$ is $\theta_k = \theta_{k-1} + \delta\,[\hat{T}(\theta_{k-1}) - \theta_{k-1}]$, where $\hat{T}$ is the sample version of T.

That is the relaxation scheme of *A Peculiar Definition of Bounded Rationality*, with δ in the role of its relaxation parameter λ.

The online recursion (93.3) is a stochastic approximation algorithm.

The theory of such algorithms [Ljung, 1977, Marcet and Sargent, 1989, Woodford, 1990], later systematized and generalized by Evans and Honkapohja [2001], says that with a gain like $1/t$ the beliefs θ_t follow, on average, the ordinary differential equation

$$\frac{d\theta}{d\tau} = T(\theta) - \theta \tag{93.4}$$

in the rescaled time $\tau = \log t$, while M_t settles down to the second-moment matrix of the regressors.

One recursion, many learners sets out the general argument, and *Least Squares Learning in Self-Referential Models* works it through for linear models; Sargent [1993] illustrates it with the very economy of this lecture.

Three consequences follow.

- **Same fixed points.** The rest points of (93.4) are the fixed points of T, which the batch algorithm computes up to sampling error. Both schemes aim at the same approximate equilibrium θ^*.
- **Same stability condition.** Both converge to θ^* only if every eigenvalue of $DT(\theta^*)$ has real part below one, the E-stability condition. For the online algorithm this is the stability of (93.4). For the batch algorithm, the eigenvalues of its iteration matrix $I + \delta\,(DT - I)$ lie inside the unit circle only if this condition holds, and, for small enough δ, whenever it does.
- **Different speeds.** Near θ^*, a batch pass shrinks the error by the factor $1 - \delta(1 - \lambda_{\max})$, where $\lambda_{\max}$ is the largest eigenvalue of $DT(\theta^*)$. The differential equation shrinks it like $e^{-(1-\lambda_{\max})\tau}$, which is $t^{-(1-\lambda_{\max})}$ in calendar time.

```
δ = 0.6
print(f"largest eigenvalue of DT(θ*):          {λ_max:.3f}")
print(f"batch: error shrinks per pass by       {1 - δ * (1 - λ_max):.3f}")
print(f"online: error shrinks like             t^(-{1 - λ_max:.2f})")
print(f"500 times more data shrinks it by      {500**(1 - λ_max):.1f}")
```

```
largest eigenvalue of DT(θ*):          0.772
batch: error shrinks per pass by       0.863
online: error shrinks like             t^(-0.23)
500 times more data shrinks it by      4.1
```

So a batch pass cuts the error by only about 14 percent, which is why the batch algorithm needed well over a hundred passes.

The online error falls only like $t^{-0.23}$.

That is slower than the $t^{-1/2}$ rate at which sampling noise averages out, so it is the drift toward θ^*, not the noise, that dominates the error.

Sargent [1993], drawing on Benveniste *et al.* [1990], states the condition for the usual $\sqrt{t}$ rate: every eigenvalue of $DT - I$ must lie below $-1/2$, that is, $\lambda_{\max} < 1/2$, which fails here.

At that rate, multiplying the agents' experience by 500, from 1,000 to 500,000 periods, would cut their error only by a factor of about four.

Exercise 93.8.5 checks the rate.

The gap in speed measures the difference between an agent constrained to learn from experience as it arrives and a modeller free to re-use a whole simulated history at once.

But the limit is the same object.

Sargent's summary:

> Learning algorithms and equilibrium computation algorithms look like each other. Equilibrium computation algorithms often have interpretations as centralized learning algorithms whereby the model builder, acting in a role of 'social planner,' gropes for a set of pricing functions for markets and decision rules for agents that will satisfy all of the individual optimum conditions and market-clearing conditions. We have also seen that learning systems with boundedly rational agents sometimes have interpretations as decentralized equilibrium computation algorithms.

This is why, as Sargent [1993] remarks, it is understandable that Marcet arrived at parameterized expectations as a *computational* method by way of earlier work on the *dynamics of least squares learning* [Marcet and Sargent, 1989].

The two are not one recursion read in two directions.

They are two recursions that share their fixed points and, through (93.4), their stability condition; what separates them is speed, and what each asks of whoever runs it.

93.6 Learning without a functional form

The parametric route is fast but stakes everything on the family.

If no member of $\{f(\cdot, \theta)\}$ supports an equilibrium, the scheme converges to an approximate equilibrium and stops.

The **non-parametric** alternative imposes no functional form.

Following the recursive kernel estimators of Chen and White [1998], an agent estimates the conditional expectation $\psi(G)$ directly from a kernel-weighted average of past realized values, letting the data choose the shape.

The building block is the recursive kernel density estimator, itself a stochastic-approximation recursion,

$$\widehat{p}_t(x) = \widehat{p}_{t-1}(x) + \tfrac{1}{t}\left[h_t^{-d}\, K\!\left(\tfrac{x - x_t}{h_t}\right) - \widehat{p}_{t-1}(x)\right],$$

where $x \in \mathbb{R}^d$, K is a probability density such as the standard normal, and the bandwidth $h_t \searrow 0$.

The factor h_t^{-d} makes each term a density; without it, as the formula is printed in Sargent [1993], the estimate would shrink to zero along with the bandwidth.

Our agents need a conditional expectation rather than a density.

The ratio of two recursions of this kind gives the recursive **Nadaraya–Watson** estimator

$$\hat{\psi}_t(G) = \hat{\psi}_{t-1}(G) + \gamma_t(G)[y_t - \hat{\psi}_{t-1}(G)], \qquad \gamma_t(G) = \frac{K_{h_t}(\log G - \log G_t)}{\sum_{\tau \le t} K_{h_\tau}(\log G - \log G_\tau)}, \tag{93.5}$$

where $K_h(u) = h^{-1}K(u/h)$ and distance is measured in $\log G$.

It has the same shape as every other recursion in this lecture, now with a separate gain at each state: large when the deficit lands near G, and essentially zero when it lands far away.

Hold the bandwidth fixed at h and shrink it on a grid, and the gain becomes familiar.

As $h \to 0$, $K_h(\log G - \log G_t)/K_h(0)$ tends to one if $G_t = G$ and to zero otherwise.

The denominator then counts the visits to state G, and $\gamma_t(G) = 1/\tau_G$ when the deficit is at G, where τ_G is the number of visits so far, and zero otherwise.

That is the state-by-state $1/\tau$ clock of the Robbins–Monro learners of *Adaptive Agents in an Overlapping Generations Monetary Economy*, the book's "different clock for each event".

A positive bandwidth lets a visit to one state also advance the clocks of its neighbours: h measures how far the learner generalizes from the states it has seen to the states it has not.

What we implement below is the **batch** counterpart of (93.5): a Nadaraya–Watson estimate of $\psi(G)$ with a fixed bandwidth, formed as a kernel-weighted average of the realized regressand over a whole simulated history, and iterated to a fixed point.

With a fixed bandwidth and fixed data, the recursion reproduces the batch estimate exactly.

In a learning economy the data are not fixed, because the y_t depend on the rule being learned, so the recursive and batch versions are related as (93.3) is to the batch algorithm of *Parameterized expectations*: different recursions with the same fixed points.

Because the simulated deficit lives on the grid, the kernel-weighted sum over the history can be computed state by state, from how often each state was visited and the sum of the y_t that followed those visits.

The fixed-point iteration converges slowly, at a rate set by essentially the same eigenvalue as before, so we allow it many passes and warn if it has not converged.

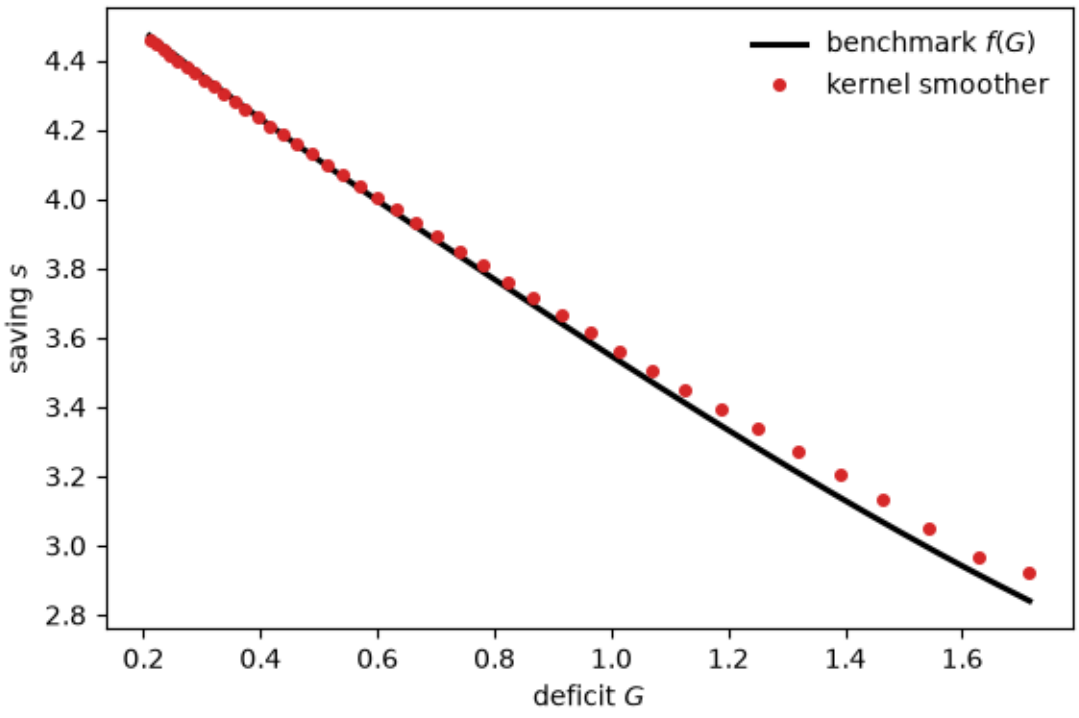

Fig. 93.4: Kernel smoother approximation to the saving rule

With no functional form imposed, the kernel learner recovers the benchmark well.

On this history it does less well than the quadratic rule fitted to the same data: both of its error measures are between two and three times as large.

The size of the gap varies from one simulated history to another, because a kernel estimate is noisier than a three-parameter fit, but much of the kernel's error here is systematic.

It grows toward the top of the deficit range, where the kernel overstates saving.

There the rule is steep, and most of the observations inside the kernel's window come from lower deficits, which are visited more often and call forth more saving; at the very top of the grid all of them do.

The quadratic family does so well because the true ψ *happens* to be almost exactly quadratic in $\log G$, so the parametric family we chose was very nearly correct.

Exercise 93.8.3 shows that a better choice of bandwidth closes most of the gap — but choosing it took knowledge of the benchmark, which no learner has.

When the family is not nearly correct, the two part ways, and the trade-off is the one familiar from econometrics:

- the **parametric** scheme learns fast and extrapolates gracefully, but is only as good as its family; a poorly chosen family delivers an approximate equilibrium and no warning;
- the **non-parametric** scheme cannot be led astray by a bad functional form, but pays for its flexibility with slower learning and with bias where the data is thin, at the edges of the deficit's range, where the kernel has few neighbours to average.

Both are recursions of the same shape.

Which one an adaptive agent should use is, once again, one of the modelling choices that the bounded-rationality program forces into the open and that rational expectations quietly made for us.

93.7 Concluding remarks

The overlapping generations model gave us a clean laboratory for a general lesson.

An adaptive agent in an environment with a large or continuous state cannot learn a separate response for every contingency.

It must **generalize**, imposing some structure that lets a finite amount of experience inform behavior across the whole state space.

Whether that structure is a low-order polynomial, a kernel bandwidth, or something else is a modelling choice with real consequences: it fixes whether the achievable limit is a rational expectations equilibrium or merely an approximation to one.

That same act of generalization is what makes learning and equilibrium computation two faces of one object.

Marcet's algorithm computes an equilibrium by parameterizing an expectation and regressing; an adaptive agent learns by parameterizing an expectation and regressing.

The two recursions are not identical, but they share their fixed points and their stability condition, and one eigenvalue of the T map sets how fast each of them converges.

The next lecture, *Exchange Rate Indeterminacy, Learning, and Experiments*, puts the two-currency economy of *A Peculiar Definition of Bounded Rationality* into this overlapping generations setting, where learners must cope with an exchange rate that rational expectations leaves undetermined.

The generalization problem in its sharpest form waits for *Networks, Genetic Algorithms, and Classifier Systems* and *Money as a Medium of Exchange among Artificially Intelligent Agents*.

There the state and action spaces are large enough that enumerating rules is out of the question, and agents must **discover** a compact set of good rules from scratch, using John Holland's genetic algorithm and classifier systems in place of the least squares and kernel machinery of this lecture.

93.8 Exercises

Exercise 93.8.1

The note above claimed that pushing the polynomial degree too high stops helping, because high-order terms chase sampling noise in the sparsely visited tails of the deficit distribution.

Check it, separating the two sources of error.

1. For degrees 0 through 5, compute the *population* approximate equilibrium, the fixed point of the family's T map with infinitely much data, as `approximate_equilibrium` does. Its distance from the benchmark is pure approximation error.
2. For the same degrees, run the batch parameterized-expectations algorithm on three simulated histories of length 150,000.

Report two error measures against the benchmark: the sup norm over the whole grid, and the RMS error weighted by the ergodic distribution of the deficit (i.e. weighted by where agents actually operate).

How does each measure behave as the degree rises, with and without sampling error?

Interpret.

Solution

```
seeds = (0, 1, 2)
sup_rows, rms_rows = [], []

```

With infinitely much data, both measures fall steadily as the degree rises: adding terms to a polynomial in $\log G$ shrinks the approximation error, which by degree 5 is tiny.

With 150,000 observations, the errors fall steeply up to the quadratic, as in the population.

Beyond it the sample errors stop tracking the population errors: the ergodic-weighted errors stay above the population values on every history, and from degree 4 on the gap is about as large as the remaining approximation error, or larger.

The ergodic-weighted error levels off, at a level that differs from one history to another.

The sup-norm error behaves less regularly: on one history it keeps falling, while on the other two it rises at degree 3 and stays above its degree-2 value.

The high-order polynomials fit the center well but are free to move at the ends of the grid, where the ergodic distribution puts little mass and the regression has few data to discipline them.

This is the approximation-side image of the rare-state problem from *Adaptive Agents in an Overlapping Generations Monetary Economy*.

A learning scheme allocates its accuracy to where the observations are.

Misfitting a rarely-visited region shows up starkly in the sup norm but costs almost nothing in expected utility, which is why the ergodic-weighted measure is the economically relevant one.

Exercise 93.8.2

The constant family (degree 0) delivers an *approximate* equilibrium: a single saving rate, independent of the deficit, that satisfies the first-order condition only on average.

There is a natural benchmark for it.

Compute the single saving rate $\bar{s}$ that a degree-0 parameterized-expectations agent converges to, and compare it with the saving rate of the economy in which the deficit is fixed forever at its mean $\mathbb{E}[G]$.

That fixed-deficit economy has two steady states.

Find both, compute the slope of its T map at each, and say which one belongs in the comparison.

Are $\bar{s}$ and the fixed-deficit saving rate the same?

Should they be?

Which is larger, and why?

Solution

With the deficit fixed at G, the T map is $s \mapsto w_1 x/(w_2 + 2x)$ with $x = s - G$, so its slope is $w_1 w_2/(w_2 + 2x)^2$, and the steady states solve $2x^2 - (w_1 - w_2 - 2G)x + w_2 G = 0$.

```
# the degree-0 approximate equilibrium
s_const = rules[0][0]                          # constant across states
G_mean = ergodic @ G

# the deterministic economy with G fixed at its mean
x_roots = np.roots([2, -(w1 - w2 - 2 * G_mean), w2 * G_mean])
s_steady = np.sort(x_roots + G_mean)[::-1]     # high saving (low inflation) first
slopes = w1 * w2 / (w2 + 2 * (s_steady - G_mean))**2

s_iter = (w1 - w2) / 2                         # iterate the T map from s = 5
for _ in range(1000):
    s_iter = 0.5 * s_iter + 0.5 * s_from_psi(regressand(s_iter, G_mean))

print(f"mean deficit  E[G]                              : {G_mean:.4f}")
print(f"steady states with G fixed at E[G]              : {s_steady.round(4)}")
print(f"slope of the T map at each                      : {slopes.round(3)}")
print(f"iterating the T map from s = 5 lands on         : {s_iter:.4f}")
print(f"degree-0 approximate-equilibrium saving rate    : {s_const:.4f}")
```

```
mean deficit  E[G]                              : 0.6531
steady states with G fixed at E[G]              : [4.0342 1.619 ]
slope of the T map at each                      : [0.712 1.405]
iterating the T map from s = 5 lands on         : 4.0342
degree-0 approximate-equilibrium saving rate    : 4.0226
```

The fixed-deficit economy has two steady states, as in Part 2 of *Adaptive Agents in an Overlapping Generations Monetary Economy*.

At the high-saving, low-inflation one the slope of the T map is about 0.71, below one; at the low-saving one it is about 1.4, above one.

Iterating the saving map from $s = 5$ lands on the first, and nothing that iterates on beliefs can settle at the second.

That is the computational face of the stability reversal of *The stability reversal*, and it is why the low-inflation steady state is the right comparison.

The two saving rates are close but not equal, and the sign of the gap is predictable.

A regression on a constant returns the sample mean of y_t, so $\bar{s}$ is the fixed point of the map that sends s to $w_1\psi/(1+\psi)$ with $\psi = \mathbb{E}[y(s, G)]$, the expectation taken over the ergodic distribution of the deficit.

The fixed-deficit economy uses $\psi = y(s, \mathbb{E}[G])$ instead.

For given s, $y(s, G) = 1 - w_2/(w_2 + s - G)$ is concave in G, so by Jensen's inequality $\mathbb{E}[y(s, G)] < y(s, \mathbb{E}[G])$: spreading the deficit out lowers the expected payoff to saving.

The degree-0 map therefore lies below the fixed-deficit map at every s.

Both maps cross the 45-degree line from above at their stable fixed points, so $\bar{s}$ is below the fixed-deficit saving rate, as the numbers confirm.

They would agree only if the deficit were deterministic to begin with.

The lesson is that an approximate equilibrium is not a naive "certainty-equivalent" object.

Even the crudest one-parameter learner is responding to the *whole* distribution of outcomes it experiences, not to a point forecast.

Exercise 93.8.3

The non-parametric kernel learner has one free tuning constant: the bandwidth h.

Explore its effect on a shorter history, $T = 40{,}000$, where sampling noise matters.

For bandwidths from 0.003 to 0.2, run the kernel learner on ten simulated histories.

Split its ergodic-weighted mean squared error into a squared bias (the error of the rule averaged across histories) and a variance (the dispersion of the rules across histories).

Explain the shape of the trade-off.

What does the smallest bandwidth correspond to?

How does the kernel learner at its best bandwidth compare with the quadratic parametric rule fitted to the same histories?

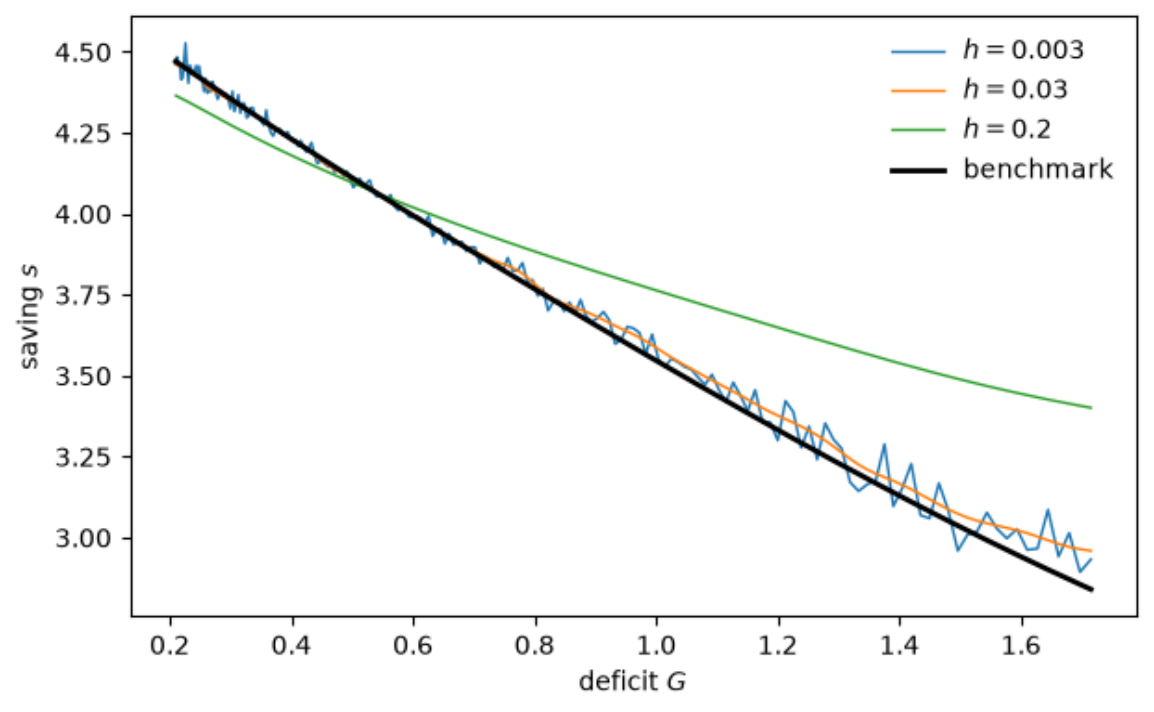
Solution

```
T_short, seeds = 40_000, range(10)
bandwidths = (0.003, 0.01, 0.02, 0.03, 0.05, 0.08, 0.12, 0.20)

rows = []
for h in bandwidths:
    S = np.array([kernel_smoother(T=T_short, seed=seed, h=h)[0] for seed in seeds])
    bias2 = ergodic @ (S.mean(axis=0) - s_benchmark)**2
    var = ergodic @ S.var(axis=0)
    rows.append([h, np.sqrt(bias2), np.sqrt(var), np.sqrt(bias2 + var)])

table = pd.DataFrame(rows, columns=["bandwidth $h$", "bias", "std. deviation",
                                    "RMS error"]).set_index("bandwidth $h$")

S_quad = np.array([parameterized_expectations(Φ2, T=T_short, seed=seed)[0] for␣
 ↪seed in seeds])
rms_quad = np.sqrt(ergodic @ ((S_quad - s_benchmark)**2).mean(axis=0))
step = np.diff(np.log(G))[0]



print(f"quadratic family on the same histories: RMS error {rms_quad:.4f}")
print(f"at h = 0.003 the weight on a neighbouring state is {np.exp(-0.5 * (step /␣
 ↪0.003)**2):.4f}")
table.round(4)
```

```
quadratic family on the same histories: RMS error 0.0133
at h = 0.003 the weight on a neighbouring state is 0.0022
```

```
                 bias  std. deviation  RMS error
bandwidth $h$
0.003          0.0088          0.0272     0.0286
0.010          0.0046          0.0178     0.0184
0.020          0.0027          0.0151     0.0153
0.030          0.0030          0.0138     0.0141
0.050          0.0110          0.0124     0.0166
0.080          0.0307          0.0110     0.0326
0.120          0.0636          0.0093     0.0643
0.200          0.1294          0.0075     0.1296
```

The rules themselves show the two failure modes.

```
fig, ax = plt.subplots(figsize=(7, 4.2))
for h, colour in [(0.003, 'C0'), (0.03, 'C1'), (0.20, 'C2')]:
    ax.plot(G, kernel_smoother(T=T_short, h=h)[0], '-', lw=1, color=colour, label=f
↪"$h = {h}$")
ax.plot(G, s_benchmark, 'k-', lw=2, label="benchmark")
ax.set_xlabel("deficit $G$")
ax.set_ylabel("saving $s$")
ax.legend(frameon=False)
plt.show()
```

The variance falls steadily as the bandwidth widens.

The bias is small up to about $h = 0.03$ and then rises steeply.

(At the smallest bandwidths the bias column mostly measures the noise in an average of ten noisy rules, about the standard deviation divided by $\sqrt{10}$.)

So the RMS error has an interior minimum, here near $h = 0.03$.

A **small** bandwidth averages over few neighbours, so the estimate is noisy: it wiggles around the benchmark, most of all toward the high-deficit end of the range.

This is the **variance** end of the trade-off.

At $h = 0.003$ the weight on even the nearest neighbouring state is negligible, so the learner is effectively the state-by-state learner of *Adaptive Agents in an Overlapping Generations Monetary Economy*, with one estimate per state: the $h \to 0$ limit of (93.5).

A **large** bandwidth averages over a wide window, smoothing the estimate but flattening it: the rule is pulled toward the saving of the middle of the range, below the benchmark at low deficits and above it at high ones.

This is the **bias** end.

At its best bandwidth the kernel learner is about as accurate as the quadratic family fitted to the same histories, but finding that bandwidth took the benchmark, which no learner has.

The bandwidth is the non-parametric counterpart of the polynomial degree in Exercise 93.8.1: both control how much structure the learner imposes, and both have a sweet spot that trades misfit-from-too-little-flexibility against noise-from-too-much.

The bounded-rationality program does not tell us where that spot is; it is one more choice that replaces the single discipline of rational expectations with a menu of plausible alternatives.

Exercise 93.8.4

Return to Economy 2 of *Adaptive Agents in an Overlapping Generations Monetary Economy*.

There the deficit is 0.8 in state 1 and 0 in state 2, the transition matrix is

$$\begin{bmatrix} 0.75 & 0.25 \\ 0.50 & 0.50 \end{bmatrix},$$

and the rational expectations saving rates are $(4.211, 4.364)$, which the Robbins–Monro learners of that lecture found state by state.

1. Run the batch parameterized-expectations algorithm on this economy with the basis $\phi(G) = (1, G)$. (The log-deficit basis of this lecture won't do, because $G = 0$ in state 2.) Show that it reproduces the rational expectations saving rates, and explain why it must.
2. Now use a constant basis, $\phi(G) = 1$. Run both the batch algorithm and the online learner (93.3), and compare their limits with each other and with the rational expectations equilibrium.

The functions `parameterized_expectations`, `online_pea` and `approximate_equilibrium` accept the deficit levels, the transition matrix and the basis evaluated at each state as arguments.

Solution

Here is part 1.

```
G_2 = np.array([0.8, 0.0])
P_2 = np.array([[0.75, 0.25],
                [0.50, 0.50]])
π_2 = qe.MarkovChain(P_2).stationary_distributions[0]
economy_2 = dict(G=G_2, P=P_2)

Φ_lin = np.column_stack([np.ones(2), G_2])
s_lin_batch = parameterized_expectations(Φ_lin, **economy_2)[0]
s_lin_pop = rule(Φ_lin, approximate_equilibrium(Φ_lin, π=π_2, **economy_2), G_2)
```

```
print(f"batch, ψ = (1, G), T = 150,000 : {s_lin_batch.round(4)}")
print(f"population fixed point         : {s_lin_pop.round(4)}")
print( "rational expectations          : [4.211 4.364]")
```

```
batch, ψ = (1, G), T = 150,000 : [4.2088 4.3629]
population fixed point         : [4.2111 4.3637]
rational expectations          : [4.211 4.364]
```

On a two-point state space every function of G is a linear function of G: two coefficients can match any two values.

So the linear family contains the rational expectations equilibria exactly, and every fixed point of the algorithm is one of them.

This economy also has a high-inflation equilibrium, with saving of about $(1.19, 1.63)$, but it is not E-stable, so the algorithm settles on the one shown.

The population fixed point matches it to every digit shown, and the batch version differs from it only by sampling error.

On two points the "parametric" family is non-parametric in disguise: it reaches the same equilibrium that the learners of *Adaptive Agents in an Overlapping Generations Monetary Economy* found state by state, but by model formation rather than the hard way.

Here is part 2, with the online learner run for 200,000 periods under both bases.

```
Φ_const = np.ones((2, 1))
s_const_batch = parameterized_expectations(Φ_const, **economy_2)[0]

linear   basis, online, t =  10,000: [4.251 4.392]
linear   basis, online, t = 100,000: [4.228  4.3789]
linear   basis, online, t = 199,999: [4.2235 4.3751]
```

The constant family cannot let saving depend on the state, so its fixed point is a single saving rate, between the two rational expectations rates: an approximate equilibrium.

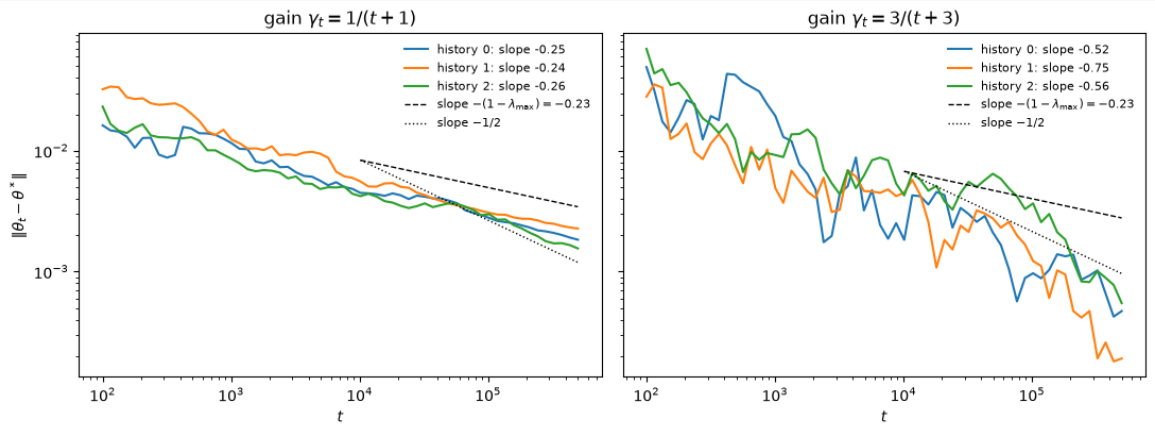
The batch algorithm and the online learner aim at that same rate, not at the rational expectations equilibrium.

The online learner approaches it slowly, from above, because it starts from $s = 5$.

With the linear basis the online learner instead heads for the rational expectations saving rates.

What a learner can reach is set by its family, not by whether it learns in batch or in real time.

Exercise 93.8.5



The text predicted that the online learner's distance from the approximate equilibrium θ^* shrinks like $t^{-(1-\lambda_{\max})}$, where $\lambda_{\max}$ is the largest eigenvalue of $DT(\theta^*)$.

1. Plot $\|\theta_t - \theta^*\|$ against t on log–log axes, for the path computed in the lecture and for two more simulated histories. Fit the slope over $t \geq 10{,}000$, and compare it with $-(1-\lambda_{\max})$ and with $-1/2$, the rate at which sampling noise averages out.
2. Repeat with the gain $\gamma_t = 3/(t+3)$ in place of $1/(t+1)$, which `online_pea` delivers with `a=3`. What changes, and why?

Solution

```
T_online = len(θ_path)
ts = np.unique(np.logspace(2, np.log10(T_online - 1), 60).astype(int))
late = ts >= 10_000

fig, axes = plt.subplots(1, 2, figsize=(11, 4.2), sharey=True)
for ax, a in zip(axes, (1, 3)):
    starts = []
    for seed in (0, 1, 2):
        path = θ_path if (a == 1 and seed == 0) else online_pea(Φ2, seed=seed, a=a)
        dist = np.linalg.norm(path[ts] - θ_star, axis=1)
        slope = np.polyfit(np.log(ts[late]), np.log(dist[late]), 1)[0]
        ax.loglog(ts, dist, lw=1.5, label=f"history {seed}: slope {slope:.2f}")
        starts.append(dist[late][0])
    t_rel = ts[late] / ts[late][0]                # reference lines start at t =␣
↪10,000
    anchor = 1.5 * max(starts)
    ax.loglog(ts[late], anchor * t_rel**(-(1 - λ_max)), 'k--', lw=1,
              label=rf"slope $-(1-\lambda_{{\max}}) = {-(1 - λ_max):.2f}$")
    ax.loglog(ts[late], anchor * t_rel**(-0.5), 'k:', lw=1, label="slope $-1/2$")
    ax.set_xlabel("$t$")
    ax.set_title(f"gain $\\gamma_t = {a}/(t + {a})$")
    ax.legend(frameon=False, fontsize=8)
axes[0].set_ylabel(r"$\|\theta_t - \theta^*\|$")
plt.tight_layout()
plt.show()
```

With the gain $1/(t+1)$ the fitted slopes are close to $-(1-\lambda_{\max}) \approx -0.23$ and far from $-1/2$.

In the rescaled time $\tau = \log t$, the mean dynamics (93.4) contract at the rates $1-\lambda_i$, the slowest of which is $1-\lambda_{\max}$, so the drift toward θ^* decays like $t^{-(1-\lambda_{\max})}$, while sampling noise averages out like $t^{-1/2}$.

The slower of the two dominates, and here it is the drift.

A gain of a/t runs the differential equation a times faster, so the drift decays like $t^{-a(1-\lambda_{\max})}$.

With $a = 3$ that is faster than $t^{-1/2}$, so in the long run sampling noise takes over and the error falls at the usual $\sqrt{t}$ rate.

The fitted slopes are now near $-1/2$ or steeper, and after half a million periods the error is several times smaller than with the gain $1/(t+1)$.

This is the sense in which the book's condition for $\sqrt{t}$ convergence is a condition on the gain as well as on DT.

Larger gains are not free: they make the early phase, far from θ^*, more violent, and a gain that never declines would leave beliefs fluctuating around θ^* forever, the constant-gain behaviour described in *One recursion, many learners*.

94.1 Overview

In *A Peculiar Definition of Bounded Rationality* we met a model in which rational expectations cannot pin down the exchange rate at all.

Two fiat currencies, perfect substitutes as long as their rates of return are equal, leave the exchange rate e *completely unrestricted*: if the equilibrium conditions have a solution for one e, they have a solution for every other, and the real allocation is identical across all of them.

This lecture, following Sargent [1993], expels the rational agents from that economy and puts adaptive ones in their place.

It is the hinge of the series.

Its first half uses the last of the series' econometric learners, a Newton–Raphson rule like the one in *Adaptive Agents in an Overlapping Generations Monetary Economy*.

Its second half uses the series' first genetic algorithm, a device that *Networks, Genetic Algorithms, and Classifier Systems* then sets out in general.

Two questions organize what follows.

First, does learning pin the exchange rate down?

An adaptive agent has beliefs, a rule for revising them, and initial conditions, and those initial conditions are exactly what the equilibrium conditions failed to determine.

We shall see that Newton–Raphson learners do converge to a constant exchange rate, but that learning does not *select* one.

Where they end up depends on where their portfolios and saving rates started, and also on how the learning algorithm is tuned.

Learning makes the exchange rate *history-dependent*: what Sargent calls the "dead hand of history" does the pinning that fundamentals refused to do.

Second, does a ghost of the indeterminacy survive?

It does.

The rest points of the learning algorithm reproduce the indeterminacy exactly: the condition that stops the algorithm is the same arbitrage condition that made the exchange rate free in the first place.

Sargent judges that an adaptive mechanism that selects the exchange rate path in this way "may seem a weak reed on which to base exchange rate determination."

Then we turn to evidence.

Arifovic [1996] ran this economy as a laboratory experiment with paying human subjects.

Their exchange rate did not settle down.

When she replaced the Newton–Raphson learners with a **genetic algorithm** — a population of binary-string agents bred by selection, crossover, and mutation — she got an economy whose exchange rate does not settle down either.

The genetic population learns to save at close to the rational expectations rate, but nothing pins down its portfolio share, which wanders along the continuum of equilibria.

The ghost of indeterminacy returns as volatility.

That contrast — a learning rule that converges versus one that generates permanent volatility — is where this lecture lands.

Let's start with some imports.

```
import numpy as np
import pandas as pd
import matplotlib.pyplot as plt
from typing import NamedTuple
```

94.2 The two-currency economy

We use the overlapping generations incarnation of the Kareken and Wallace [1981] indeterminacy.

At each date t, N two-period-lived agents are born, endowed with w_1 when young and w_2 when old, with $w_1 > w_2$.

(As in *Adaptive Agents in an Overlapping Generations Monetary Economy*, the endowments are w_1 and w_2; *A Peculiar Definition of Bounded Rationality* writes them as $2w_1$ and $2w_2$.)

There are two fiat currencies in fixed supplies H_1 and H_2.

A young agent makes two decisions: how much to save, s_t, and what fraction λ_t of that saving to hold in currency 1 (the rest going to currency 2).

The realized lifetime utility of an agent who chooses (s_t, λ_t) is

$$U(s_t, \lambda_t) = u(w_1 - s_t) + u\left(w_2 + \lambda_t s_t \frac{p_{1t}}{p_{1,t+1}} + (1-\lambda_t) s_t \frac{p_{2t}}{p_{2,t+1}}\right), \tag{94.1}$$

where p_{it} is the price level in currency i and $p_{it}/p_{i,t+1}$ is the gross return on holding currency i.

We take $u(c) = \ln c$ throughout.

Equating each currency's supply to the demand for it gives the price levels

$$p_{1t} = \frac{H_1}{\sum_i \lambda_{it} s_{it}}, \qquad p_{2t} = \frac{H_2}{\sum_i (1-\lambda_{it}) s_{it}}, \tag{94.2}$$

and the exchange rate is $e_t = p_{1t}/p_{2t}$.

94.2.1 The indeterminacy, recalled

Consider a stationary equilibrium with constant prices.

Then each currency returns $p_{it}/p_{i,t+1} = 1$, so both returns are equal, and the portfolio return in (94.1) is 1 regardless of λ.

The saving decision then solves $\max_s \ln(w_1 - s) + \ln(w_2 + s)$, giving

$$s^\star = \frac{w_1 - w_2}{2},$$

but the portfolio share λ is *completely undetermined*: utility does not depend on it when the two returns are equal.

And λ is what fixes the exchange rate.

From (94.2), with a common (s, λ),

$$e = \frac{p_1}{p_2} = \frac{H_1}{H_2} \cdot \frac{1-\lambda}{\lambda}.$$

Every $\lambda \in (0, 1)$ is an equilibrium, so every $e \in (0, \infty)$ is an equilibrium.

This is the indeterminacy of *A Peculiar Definition of Bounded Rationality*, now expressed through an undetermined portfolio choice.

This lecture runs two economies with different parameters.

The Newton–Raphson section uses Sargent's $(w_1, w_2, H_1, H_2) = (20, 15, 100, 120)$, whose currency supplies are those of the two-currency example in *A Peculiar Definition of Bounded Rationality*.

The laboratory and genetic-algorithm sections use Arifovic's $(11, 1, 10, 10)$.

So we carry the parameters in a container and pass them explicitly rather than leaving them lying about as globals.

```
class Params(NamedTuple):
    w1: float           # endowment when young
    w2: float           # endowment when old
    H1: float           # fixed supply of currency 1
    H2: float           # fixed supply of currency 2

    @property
    def s_star(self):
        "Rational expectations saving rate, when both currencies return 1."
        return (self.w1 - self.w2) / 2

kw = Params(w1=20.0, w2=15.0, H1=100.0, H2=120.0)

print(f"rational expectations saving rate s* = {kw.s_star}")
print(f"any portfolio share λ is an equilibrium, and e = (H1/H2)(1-λ)/λ is free")
```

```
rational expectations saving rate s* = 2.5
any portfolio share λ is an equilibrium, and e = (H1/H2)(1-λ)/λ is free
```

94.3 Newton–Raphson learning

Now expel the rational agents.

As in *Adaptive Agents in an Overlapping Generations Monetary Economy*, a cohort's lifetime utility cannot be evaluated until it is old, so the population is split into an "even" and an "odd" class.

Each class carries its own rule (s, λ), updated only from the experience of earlier agents of the same class.

An agent revises (s, λ) by a **Newton–Raphson** step against realized utility: move in the direction that a second-order expansion of (94.1) says would have raised utility, given the returns the agent actually experienced.

Writing ∇U_τ and $\nabla^2 U_\tau$ for the gradient and Hessian of realized utility and M for a running estimate of the (negative-definite) Hessian, the recursion is

$$\begin{aligned} M_{\tau+1} &= M_\tau + \gamma_\tau(\nabla^2 U_\tau - M_\tau), \\ \begin{bmatrix} s \\ \lambda \end{bmatrix}_{\tau+1} &= \begin{bmatrix} s \\ \lambda \end{bmatrix}_\tau - \gamma_\tau M_{\tau+1}^{-1} \nabla U_\tau, \end{aligned} \tag{94.3}$$

with γ_τ a gain.

This is the two-variable version of the Robbins–Monro rule of *Adaptive Agents in an Overlapping Generations Monetary Economy*.

We use a **constant gain**, $\gamma_\tau = \gamma = 0.3$, a variant that Sargent mentions in a footnote.

Because this economy has no shocks, a constant gain can still converge to a point.

Here are the gradient and Hessian of (94.1) in the returns $R_1 = p_{1t}/p_{1,t+1}$ and $R_2 = p_{2t}/p_{2,t+1}$.

```
def grad_hess(p, s, lam, R1, R2):
    "Gradient and Hessian of realized utility U(s, λ)."
    A = lam*R1 + (1 - lam)*R2               # portfolio gross return
    c2 = p.w2 + s*A                         # old-age consumption
    dR = R1 - R2
    g = np.array([-1/(p.w1 - s) + A/c2,
                  s*dR/c2])
    U_ss = -1/(p.w1 - s)**2 - A**2/c2**2
    U_ll = -s**2 * dR**2 / c2**2
    U_sl = dR/c2 - s*A*dR/c2**2
    return g, np.array([[U_ss, U_sl], [U_sl, U_ll]])
```

94.3.1 The indeterminacy shows up as a singular Hessian

Look at the λ block of the Hessian.

When the two returns are equal, $R_1 = R_2$, every λ-derivative vanishes: the gradient component $s(R_1 - R_2)/c_2$ is zero, and so is the curvature $-s^2(R_1 - R_2)^2/c_2^2$.

Utility is **flat in** λ at equal returns.

That is the indeterminacy, seen locally: there is no force pushing λ in any direction.

Near equal returns the curvature is of second order in $R_1 - R_2$ while the gradient is of first order, so an undamped Newton step in λ, which divides the gradient by the curvature, is enormous.

We therefore add a constant **ridge** $\kappa > 0$ to the curvature estimate in the λ direction: each period we feed (94.3) the matrix $\nabla^2 U_\tau - \text{diag}(0, \kappa)$ in place of $\nabla^2 U_\tau$.

This is a one-direction version of the Levenberg–Marquardt device of numerical optimization, and it is this lecture's addition, not the book's.

It is a *stabilizer*, not an enabler.

Without it the algorithm does not freeze; it explodes, as we check below.

With it, a λ step is roughly $\gamma\,|\partial U/\partial\lambda|/\kappa$, so a large κ makes portfolios adjust sluggishly.

```
def newton_learning(p, s0, lam0, T=400, gain=0.3, κ=0.5, w2_path=None):
    """
    Two-currency OLG with Newton-Raphson learning of (s, λ), one rule per class
    (even/odd).  κ is a ridge added to the curvature estimate M in the
    λ direction.  w2_path optionally gives the old-age endowment at each date.
    """
    s = np.array(s0, float)
    lam = np.array(lam0, float)
    M = [np.array([[-1.0, 0.0], [0.0, -κ]]) for _ in range(2)]   # initial curvature
    p1 = np.empty(T)
    p2 = np.empty(T)
    e = np.empty(T)
    s_hist = np.empty((T, 2))
    lam_hist = np.empty((T, 2))

    for t in range(T):
        j = t % 2                                        # class that is young at t
        p1[t] = p.H1 / (lam[j]*s[j])
        p2[t] = p.H2 / ((1 - lam[j])*s[j])
        e[t] = p1[t] / p2[t]
        if t >= 1:                                       # class young at t-1 is now old
            jp = 1 - j
            R1, R2 = p1[t-1]/p1[t], p2[t-1]/p2[t]
            q = p if w2_path is None else p._replace(w2=w2_path[t])
            g, h = grad_hess(q, s[jp], lam[jp], R1, R2)
            h[1, 1] -= κ                                 # the ridge
            M[jp] = M[jp] + gain*(h - M[jp])
            step = gain * np.linalg.solve(M[jp], g)
            s[jp] = np.clip(s[jp] - step[0], 0.1, p.w1 - 0.1)
            lam[jp] = np.clip(lam[jp] - step[1], 0.02, 0.98)
        s_hist[t] = s
        lam_hist[t] = lam

    return e, s_hist, lam_hist
```

94.3.2 Convergence to a history-dependent exchange rate

Run two experiments that are identical except for the initial saving rates and portfolio shares.

```
e1, s1, l1 = newton_learning(kw, [3.5, 2.0], [0.35, 0.40])
e2, s2, l2 = newton_learning(kw, [2.0, 3.5], [0.62, 0.58])

fig, axes = plt.subplots(1, 3, figsize=(14, 4))

axes[0].plot(np.log(e1), 'C0', lw=1.3, label="experiment 1")
axes[0].plot(np.log(e2), 'C1', lw=1.3, label="experiment 2")
axes[0].set_title("log exchange rate")
axes[0].set_xlabel("$t$")
axes[0].legend(frameon=False)

for s_h, c in [(s1, 'C0'), (s2, 'C1')]:
    axes[1].plot(s_h[:, 0], color=c, lw=1.0)
    axes[1].plot(s_h[:, 1], color=c, lw=1.0, ls=':')
axes[1].axhline(kw.s_star, color='k', lw=0.8, ls='--')
axes[1].set_title("saving  (solid = even, dotted = odd)")
axes[1].set_xlabel("$t$")

for l_h, c in [(l1, 'C0'), (l2, 'C1')]:
    axes[2].plot(l_h[:, 0], color=c, lw=1.0)
    axes[2].plot(l_h[:, 1], color=c, lw=1.0, ls=':')
axes[2].set_title(r"portfolio share $\lambda$")
axes[2].set_xlabel("$t$")
plt.tight_layout()
plt.show()
```

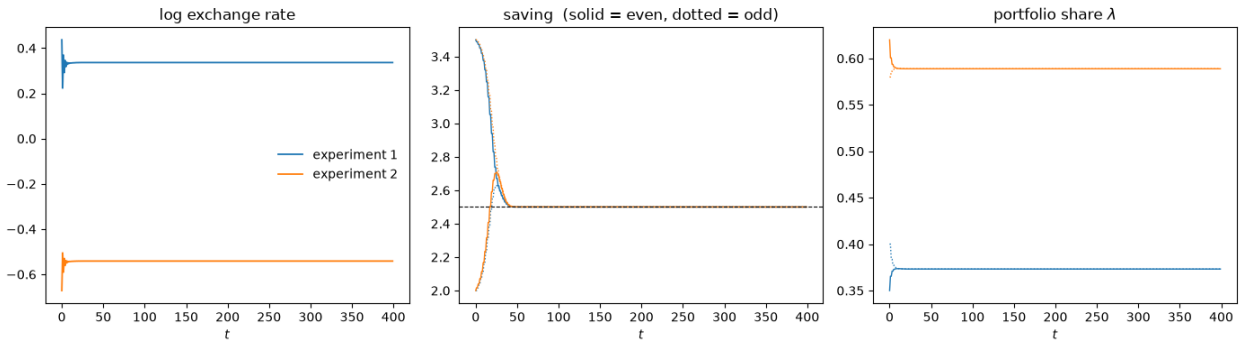

Fig. 94.1: Newton-Raphson learning from two initial conditions

Both economies converge.

Saving climbs or falls to the rational expectations rate $s^\star = 2.5$ from either side, and the two classes' portfolio shares merge to a common value.

But the two experiments converge to *different exchange rates*.

```
for name, e, s_h, l_h in [("experiment 1", e1, s1, l1), ("experiment 2", e2, s2, l2)]:
    still = np.abs(np.diff(l_h, axis=0)).max(axis=1) > 1e-6
    t_freeze = np.flatnonzero(still)[-1] + 2          # λ moves by < 1e-6 from here on
    print(f"{name}: e → {e[-1]:.4f} (log e → {np.log(e[-1]):.3f}),  s → {s_h[-1][0]:.
```

(continues on next page)

(continued from previous page)

```
↪3f},  "
          f"λ → {l_h[-1][0]:.4f},  λ frozen from t = {t_freeze}")
```

```
experiment 1: e → 1.3998 (log e → 0.336),  s → 2.500,  λ → 0.3732,  λ frozen from␣
↪t = 28
experiment 2: e → 0.5819 (log e → -0.541),  s → 2.500,  λ → 0.5888,  λ frozen from␣
↪t = 35
```

The saving rate is pinned down by fundamentals; the exchange rate is pinned down by history.

Experiment 1's limit is close to that of Sargent's experiment 1, whose λ settles near 0.37 and whose log exchange rate settles near 0.3.

Sargent's paths are still drifting after a few hundred periods, while with our constant gain λ stops moving within about 35 periods.

Before looking at how the limit depends on history, let's check what the ridge κ does.

Here is experiment 1 again with $\kappa = 0$.

```
e0, s0_h, l0_h = newton_learning(kw, [3.5, 2.0], [0.35, 0.40], κ=0.0)
print("last four exchange rates:", ", ".join(f"{x:.3f}" for x in e0[-4:]))
print(f"final λ (even, odd): {l0_h[-1]},  final s (even, odd): {s0_h[-1]}")
```

```
last four exchange rates: 40.833, 0.017, 40.833, 0.017
final λ (even, odd): [0.02 0.98],  final s (even, odd): [0.1 0.1]
```

Without the ridge the algorithm does not stand still.

The curvature estimate stays invertible, but its λ entry is tiny, so the λ steps are huge.

The portfolio shares crash into the bounds 0.02 and 0.98 that the code imposes, saving collapses to its lower bound, and from then on the exchange rate flips between two extreme values.

94.3.3 The dead hand of history

To see how history governs the outcome, sweep the initial portfolio shares and record the exchange rate each economy settles on.

The two classes must start with *different* portfolio shares.

If they start with the same λ_0, the exchange rate, which depends only on the young class's λ, is constant from the first period on.

Then $R_1 = R_2$ from the start, the λ-gradient is identically zero, and λ never moves, so the limit would be $(H_1/H_2)(1-\lambda_0)/\lambda_0$ by construction.

So we start the even and odd classes at $\bar\lambda_0 - 0.05$ and $\bar\lambda_0 + 0.05$, with experiment 1's saving rates, and plot each limit against the mean initial share $\bar\lambda_0$.

We compare the limits with the curve $(H_1/H_2)(1-\lambda)/\lambda$ evaluated at two points: the limiting share λ_∞, and the mean initial share $\bar\lambda_0$.

```
def e_of_λ(p, lam):
    "Exchange rate when every agent holds portfolio share λ."
    return (p.H1/p.H2) * (1 - lam) / lam

```

(continues on next page)

(continued from previous page)

```
λ_bar0 = np.linspace(0.15, 0.85, 15)
e_lim = np.empty_like(λ_bar0)
λ_lim = np.empty_like(λ_bar0)
for k, lb in enumerate(λ_bar0):
    e, s_h, l_h = newton_learning(kw, [3.5, 2.0], [lb - 0.05, lb + 0.05])
    e_lim[k], λ_lim[k] = e[-1], l_h[-1].mean()

fig, ax = plt.subplots(figsize=(7, 4.5))
ax.plot(λ_bar0, e_lim, 'C0o', ms=6, label="limiting $e$ from learning")
ax.plot(λ_bar0, e_of_λ(kw, λ_lim), 'C0-', lw=1,
        label=r"$(H_1/H_2)(1-\lambda_\infty)/\lambda_\infty$")
ax.plot(λ_bar0, e_of_λ(kw, λ_bar0), 'k--', lw=1,
        label=r"$(H_1/H_2)(1-\bar\lambda_0)/\bar\lambda_0$")
ax.set_yscale('log')
ax.set_xlabel(r"mean initial portfolio share $\bar\lambda_0$")
ax.set_ylabel("limiting exchange rate $e$")
ax.legend(frameon=False)
plt.show()
```

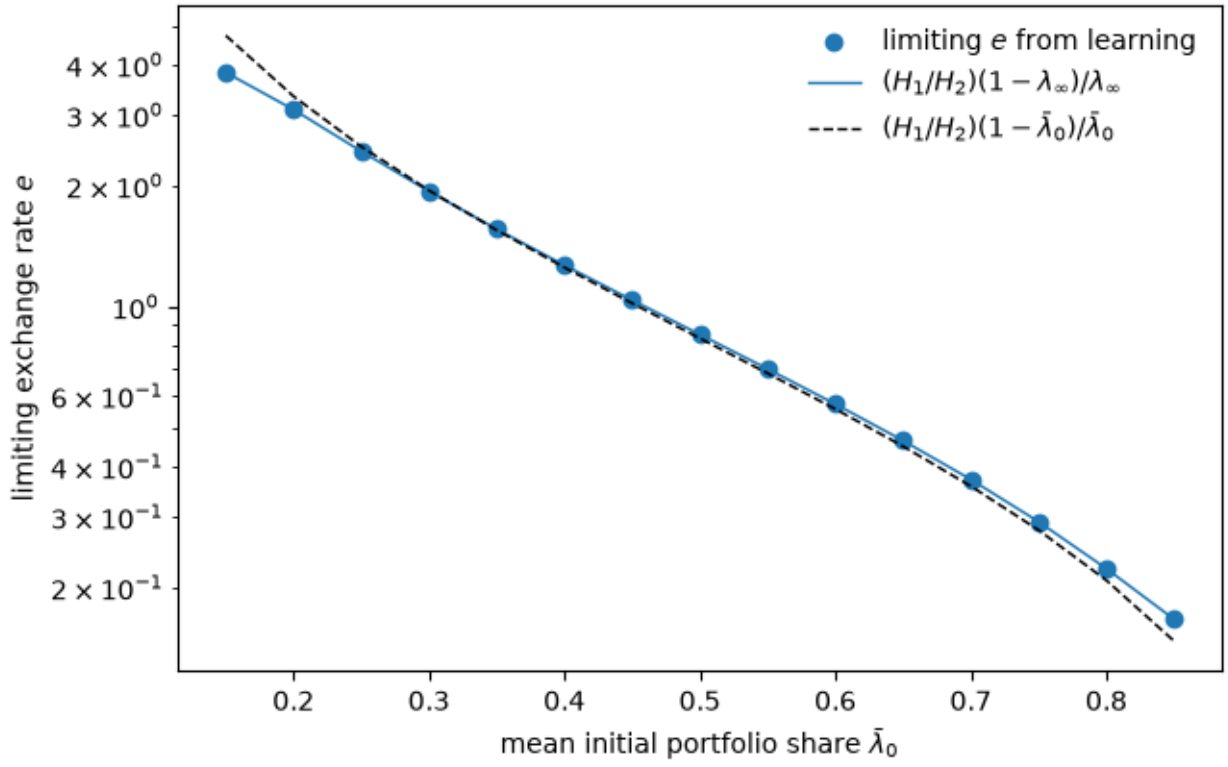

Fig. 94.2: Limiting exchange rate against the mean initial portfolio share

Here are the gaps between the limits and the two curves.

```
gap_lim = np.abs(e_lim / e_of_λ(kw, λ_lim) - 1)
gap_init = np.abs(e_lim / e_of_λ(kw, λ_bar0) - 1)
print(f"largest relative gap from the curve at λ∞:  {gap_lim.max():.1e}")
```

(continues on next page)

(continued from previous page)

```
print(f"relative gap from the curve at mean λ0:     "
      f"{gap_init.min():.3f} to {gap_init.max():.3f}")
```

```
largest relative gap from the curve at λ∞:  2.2e-16
relative gap from the curve at mean λ0:     0.005 to 0.191
```

Every limit lies exactly on the rational expectations continuum, evaluated at its own limiting λ: each one is an equilibrium.

The zero gap is close to automatic: in every period, transients included, the exchange rate is $(H_1/H_2)(1-\lambda)/\lambda$ at the young class's share, so all the gap confirms is that the two classes' shares have merged.

The informative comparison is with the dashed curve.

As $\bar{\lambda}_0$ sweeps from 0.15 to 0.85, the limits trace out a wide stretch of the continuum.

But the limit is not simply the equilibrium that the mean initial share implies.

While the two classes still differ, the two currencies' returns differ, and those transient return gaps push λ around before the arbitrage condition shuts the motion off.

The gaps from the dashed curve range from half a percent to almost twenty percent.

They are largest at the edges of the grid, where the classes' initial shares imply very different exchange rates.

This is what Sargent means by the dead hand of history:

> Our learning system renders the exchange rate path determinate by having the 'dead hand of history' put enough sluggishness into decisions. The exchange rate path can be said to be 'history-dependent' because the initial conditions assigned to (λ, s) assume an importance that does not vanish as time passes.

The relevant history is more than the initial portfolio shares.

The limit also depends on the initial saving rates and on the tuning of the algorithm, the ridge κ and the gain γ; Exercise 94.7.1 measures both.

Learning converts an *indeterminacy of levels* into a *dependence on history*.

It makes the exchange rate history-dependent; it does not select one.

94.3.4 The ghost of indeterminacy

Why does the exchange rate freeze rather than move to some particular value?

Because the algorithm comes to rest wherever the gradient vanishes, and the portfolio gradient $s(R_1 - R_2)/c_2$ vanishes precisely when $R_1 = R_2$, the **arbitrage condition** that made the exchange rate free under rational expectations.

Let's compute the returns and the gradient at the end of experiment 1, and the λ derivatives at other points of the continuum.

```
s_lim, lam_lim = s1[-1], l1[-1]                    # (even, odd) rules at the end
p1_lim = kw.H1 / (lam_lim*s_lim)                   # price levels when each class is␣
 ↪young
p2_lim = kw.H2 / ((1 - lam_lim)*s_lim)
R1, R2 = p1_lim[1]/p1_lim[0], p2_lim[1]/p2_lim[0]  # returns to an odd agent
g, h = grad_hess(kw, s_lim[1], lam_lim[1], R1, R2)
print(f"end of experiment 1: R1 = {R1:.6f}, R2 = {R2:.6f}, gradient = {g.round(8) + 0.
 ↪0}")

print("\nλ derivatives at other rest points (s = s*, R1 = R2 = 1):")
for lam in (0.2, 0.5, 0.8):
```

(continues on next page)

(continued from previous page)

```
    g, h = grad_hess(kw, kw.s_star, lam, 1.0, 1.0)
    print(f"  λ = {lam}:  ∂U/∂λ = {g[1] + 0.0:.1f},  ∂²U/∂λ² = {h[1, 1] + 0.0:.1f},  "
          f"e = {e_of_λ(kw, lam):.3f}")
```

```
end of experiment 1: R1 = 1.000000, R2 = 1.000000, gradient = [0. 0.]

λ derivatives at other rest points (s = s*, R1 = R2 = 1):
  λ = 0.2:  ∂U/∂λ = 0.0,  ∂²U/∂λ² = 0.0,  e = 3.333
  λ = 0.5:  ∂U/∂λ = 0.0,  ∂²U/∂λ² = 0.0,  e = 0.833
  λ = 0.8:  ∂U/∂λ = 0.0,  ∂²U/∂λ² = 0.0,  e = 0.208
```

The rest points of the learning dynamics *are* the rational expectations equilibria, exchange rate and all: a whole continuum of them.

One recursion, many learners explains how the limit of a learning recursion is governed by its linearization near a rest point: a rest point attracts when the linearized algorithm contracts in every direction.

A continuum of rest points rules that out in one direction, and shows up as an eigenvalue of exactly one.

Shift both classes' portfolio shares by the same amount and nothing pulls them back, because the shifted point is another rest point.

To see this, compute the Jacobian of two periods of the algorithm (one update of each class) at experiment 1's limit, by finite differences.

We hold the curvature estimate M at its limit, which loses nothing to first order, because the Newton step multiplies M^{-1} by a gradient that vanishes at the rest point.

```
def two_period_map(p, z, M, gain=0.3):
    "One update of each class's (s, λ), with the curvature estimate held at M."
    s, lam = z[:2].copy(), z[2:].copy()
    for jp in (1, 0):                                   # the odd class updates, then␣
↪the even
        j = 1 - jp
        R1 = lam[j]*s[j] / (lam[jp]*s[jp])              # p1 when jp was young / p1 now
        R2 = (1 - lam[j])*s[j] / ((1 - lam[jp])*s[jp])
        g, _ = grad_hess(p, s[jp], lam[jp], R1, R2)
        step = gain * np.linalg.solve(M, g)
        s[jp], lam[jp] = s[jp] - step[0], lam[jp] - step[1]
    return np.concatenate([s, lam])

def rest_point_jacobian(p, lam, κ=0.5, gain=0.3, ε=1e-6):
    "Jacobian of the two-period map at the rest point (s*, s*, λ, λ)."
    z = np.array([p.s_star, p.s_star, lam, lam])
    _, M = grad_hess(p, p.s_star, lam, 1.0, 1.0)      # Hessian at the rest point,
    M[1, 1] -= κ                                      # plus the ridge: the limit of M
    return np.column_stack([(two_period_map(p, z + ε*d, M, gain)
                             - two_period_map(p, z - ε*d, M, gain)) / (2*ε)
                            for d in np.eye(4)])

J = rest_point_jacobian(kw, lam_lim[0])
eigvals, eigvecs = np.linalg.eig(J)
order = np.argsort(-np.abs(eigvals))
labels = ["s even", "s odd", "λ even", "λ odd"]
print(pd.DataFrame(eigvecs[:, order].real, index=labels,
                   columns=[f"{v:.4f}" for v in eigvals[order].real]).round(3))
```

```
         1.0000  0.4014  0.2500  0.1600
s even    0.000   0.000   0.447   0.371
s odd     0.000   0.000   0.894   0.928
λ even    0.707  -0.535   0.000   0.000
λ odd     0.707   0.845   0.000   0.000
```

The columns are the eigenvectors, headed by their eigenvalues.

The eigenvalue of one belongs to the direction that moves both classes' λ together: the continuum.

The next eigenvalue belongs to a direction that moves the two classes' portfolio shares in opposite directions, and the two smallest belong to saving.

All three are below one, so saving returns to $s^\star$ and the classes' shares merge.

But the place on the continuum where they merge is whatever the stable directions left behind.

That is the dead hand of history, written as an eigenvalue.

The indeterminacy is not resolved; it is displaced into the initial conditions and the tuning of the algorithm.

Sargent's verdict is hedged but clear.

By tying down the expectations that the rational expectations equilibrium left free, he writes, the adaptive mechanism selects an exchange rate path, but

> This may seem a weak reed on which to base exchange rate determination.

A footnote adds:

> Put differently, a regime that allows the exchange rate to be history-dependent seems to be an ill-formed mechanism.

The ghost stays quiet here only because the Newton–Raphson learner stops experimenting once the returns are equal.

A learning rule that keeps experimenting can wake it, as the evidence below shows.

94.4 Evidence from the laboratory

Arifovic [1996] implemented this two-currency economy as an experiment with paying human subjects, using $w_1 = 11$, $w_2 = 1$, $H_1 = H_2 = 10$, so that $s^\star = 5$.

These are not the parameters of the Newton–Raphson section above; Exercise 94.7.4 runs the Newton–Raphson learner at Arifovic's parameters.

Each young subject chose a saving rate and a fraction to allocate between the two currencies; the experimenters cleared the two money markets against those choices, exactly as in (94.2).

Arifovic split her subjects into two groups of equal size, one young in odd periods and the other in even periods.

These alternating groups are the laboratory counterpart of the odd and even classes of our learners.

The experiment ended in a period that the subjects did not know in advance.

The money held by that last young generation was redeemed at the average of the previous two periods' price levels.

The result did not look like the Newton–Raphson simulations at all.

The exchange rate fluctuated persistently, roughly within a band from 0.5 to 2, and showed no sign of settling down.

If anything the amplitude grew between the second and third sessions.

The simple Newton–Raphson model, which at Sargent's parameters converges to a constant, does a poor job of matching that.

So Arifovic built a different model of the same economy, one in which the agents are a **population** bred by a genetic algorithm.

94.5 A genetic algorithm economy

Networks, Genetic Algorithms, and Classifier Systems sets out Holland's genetic algorithm in general; here we need only the version Arifovic used.

Now each class is a population of $N = 30$ agents, and each agent is a **binary string** of length 30: the first 20 bits encode its saving rate, the last 10 its portfolio share.

Every period the young population's strings are decoded into (s_i, λ_i) pairs, the two money markets clear against the aggregates via (94.2), and the exchange rate is read off.

A generation later, when the cohort is old, each string's realized utility (94.1) is its **fitness**, and the genetic algorithm breeds the next generation.

```
N, L_s, L_lam = 30, 20, 10          # population size; bits for saving and portfolio

arifovic = Params(w1=11.0, w2=1.0, H1=10.0, H2=10.0)

def decode(p, pop):
    "Binary strings → (s, λ), with s in (0, w1) and λ in [0.02, 0.98]."
    ints_s = pop[:, :L_s] @ (1 << np.arange(L_s)[::-1])
    ints_l = pop[:, L_s:] @ (1 << np.arange(L_lam)[::-1])
    s = 0.05 + (p.w1 - 0.10) * ints_s / (2**L_s - 1)
    lam = 0.02 + 0.96 * ints_l / (2**L_lam - 1)
    return s, lam

def fitness(p, pop, R1, R2):
    "Realized lifetime utility of each string given the returns it experienced."
    s, lam = decode(p, pop)
    c2 = p.w2 + s*(lam*R1 + (1 - lam)*R2)
    return np.log(p.w1 - s) + np.log(np.maximum(c2, 1e-9))
```

The genetic algorithm has the classic three operators — roulette-wheel **selection** of parents, single-point **crossover**, and bit-flip **mutation** — plus one that Arifovic introduced, the **election operator**: a child is admitted to the next generation only if it would have been fitter than its parent on the most recent returns, otherwise the parent survives.

Some details of our implementation are this lecture's own choices, not necessarily Arifovic's:

- a mutation probability of 0.033 per bit;
- crossover applied to every pair of parents;
- a roulette wheel whose weights are fitness minus the population's minimum fitness (a "windowed" wheel, needed because log utility can be negative);
- the decoding ranges for s and λ.

```
def genetic_step(p, pop, R1, R2, rng, p_mut=0.033, election=True):
    "Breed one new generation from the current one."
    fit = fitness(p, pop, R1, R2)
    weight = fit - fit.min() + 1e-6                  # windowed roulette wheel
    new = np.empty_like(pop)
```

(continues on next page)

(continued from previous page)

```
    for k in range(0, N, 2):
        i, j = np.searchsorted(np.cumsum(weight), rng.random(2) * weight.sum())
        parents = np.array([pop[i], pop[j]])
        cut = rng.integers(1, L_s + L_lam)           # single-point crossover
        kids = parents.copy()
        kids[0, cut:], kids[1, cut:] = parents[1, cut:], parents[0, cut:]
        for c in kids:                               # mutation
            c[rng.random(L_s + L_lam) < p_mut] ^= 1
        if election:                                 # Arifovic's election operator
            f_kids = fitness(p, kids, R1, R2)
            f_par = fitness(p, parents, R1, R2)
            for m in range(2):
                new[k + m] = kids[m] if f_kids[m] > f_par[m] else parents[m]
        else:
            new[k], new[k + 1] = kids
    return new

def genetic_economy(p, T=3000, seed=0, election=True):
    """
    Run the genetic-algorithm economy.  Returns the exchange rate e_t and, for
    the population that is young at t, the mean and standard deviation of s
    and of λ across its strings.
    """
    rng = np.random.default_rng(seed)
    pops = [rng.integers(0, 2, (N, L_s + L_lam)) for _ in range(2)]   # even, odd
    p1 = np.empty(T)
    p2 = np.empty(T)
    stats = np.empty((T, 4))                         # mean s, sd s, mean λ, sd λ
    for t in range(T):
        j = t % 2
        s, lam = decode(p, pops[j])
        p1[t], p2[t] = p.H1 / np.sum(lam*s), p.H2 / np.sum((1 - lam)*s)
        stats[t] = s.mean(), s.std(), lam.mean(), lam.std()
        if t >= 1:
            jp = 1 - j
            R1, R2 = p1[t-1]/p1[t], p2[t-1]/p2[t]
            pops[jp] = genetic_step(p, pops[jp], R1, R2, rng, election=election)
    return p1 / p2, stats
```

94.5.1 Volatility that does not die out

Let's run the economy for 4000 periods and drop the first 500 as a burn-in.

Because every string's λ lies in $[0.02, 0.98]$ and $H_1 = H_2$, the exchange rate is confined to $[1/49, 49]$, so $|\log e_t| \leq \ln 49 \approx 3.89$.

The dotted lines in the figure mark those bounds, and the shaded band marks the experimental range $[0.5, 2]$.

```
burn = 500
e_ga, stats_ga = genetic_economy(arifovic, T=4000, seed=1)
t_ga = np.arange(burn, len(e_ga))
log_e = np.log(e_ga[burn:])
bound = np.log(0.98 / 0.02)

fig, ax = plt.subplots(figsize=(10, 4))
```

(continues on next page)

(continued from previous page)

```
ax.plot(t_ga, log_e, lw=0.5)
ax.axhspan(np.log(0.5), np.log(2), color='C1', alpha=0.2, label="experimental range")
for b in (bound, -bound):
    ax.axhline(b, color='k', ls=':', lw=0.8)
ax.set_xlabel("$t$")
ax.set_ylabel(r"$\log e_t$")
ax.legend(frameon=False, loc='upper right')
plt.show()
```

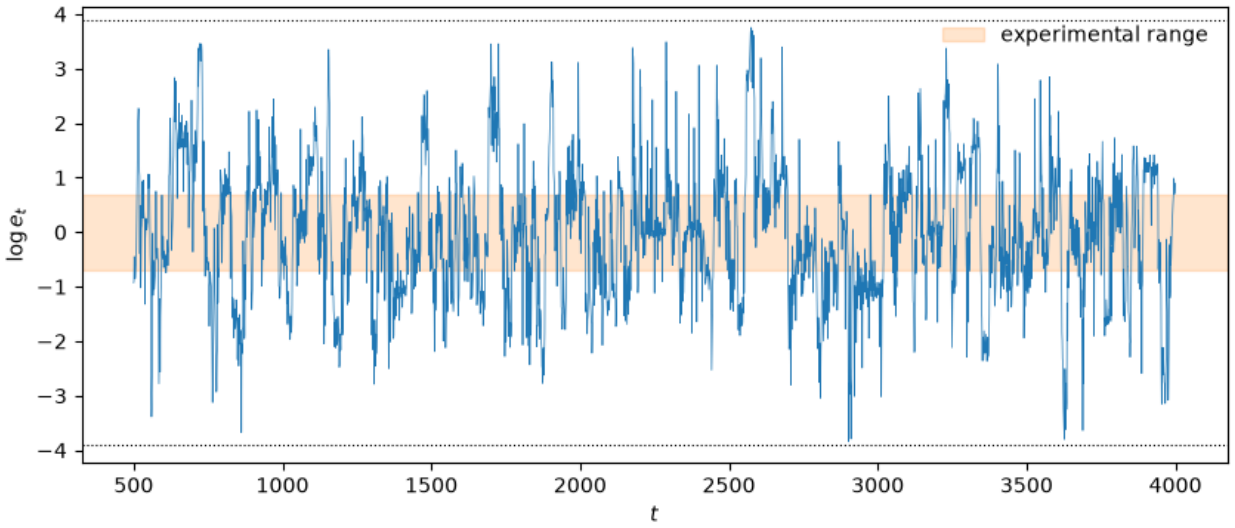

Fig. 94.3: Exchange rate in the genetic-algorithm economy

The exchange rate wanders and keeps wandering, and it does so far outside the experimental range.

```
in_band = np.mean((e_ga[burn:] > 0.5) & (e_ga[burn:] < 2))
print(f"e ranges from {e_ga[burn:].min():.3f} to {e_ga[burn:].max():.1f}; "
      f"share of periods in [0.5, 2]: {in_band:.2f}")
print(f"largest |log e| = {np.abs(log_e).max():.2f}, against the bound {bound:.2f}")
print(f"standard deviation of log e, t = 500-1499: {np.log(e_ga[500:1500]).std():.3f}
↪")
print(f"standard deviation of log e, t = 3000-3999: {np.log(e_ga[3000:]).std():.3f}")
```

```
e ranges from 0.021 to 42.8; share of periods in [0.5, 2]: 0.43
largest |log e| = 3.85, against the bound 3.89
standard deviation of log e, t = 500-1499: 1.279
standard deviation of log e, t = 3000-3999: 1.194
```

The volatility is a permanent feature, not a transient: it is about as large late in the run as early.

It is also bigger than in the laboratory.

Fewer than half the periods fall inside the experimental band, and the series comes close to the bounds that the encoding imposes.

Sargent noted the same thing about Arifovic's genetic economy, whose exchange rates were "more variable than those found in Arifovic's experiments."

94.5.2 What the population learns

Unlike the Newton–Raphson learner, the genetic population never settles down completely, since mutation keeps injecting new strings.

But it does learn, and what it learns and what it cannot learn line up with the stable and the neutral directions of *The ghost of indeterminacy*.

To see this, look at the young population's mean and spread of s and of λ over a stretch of the run.

```
window = np.arange(2000, 2300)
fig, axes = plt.subplots(2, 1, figsize=(10, 6), sharex=True)
for ax, (m, sd), name in zip(axes, [(0, 1), (2, 3)], ["saving $s$", r"portfolio share
↪$\lambda$"]):
    mean, spread = stats_ga[window, m], stats_ga[window, sd]
    ax.plot(window, mean, lw=1, label="population mean")
    ax.fill_between(window, mean - spread, mean + spread, alpha=0.3,
                    label="± within-population s.d.")
    ax.set_ylabel(name)
axes[0].axhline(arifovic.s_star, color='k', ls='--', lw=0.8, label="$s^\\star$")
axes[0].legend(frameon=False, ncol=3, loc='upper right')
axes[1].set_ylim(0, 1)
axes[1].set_xlabel("$t$")
plt.tight_layout()
plt.show()
```

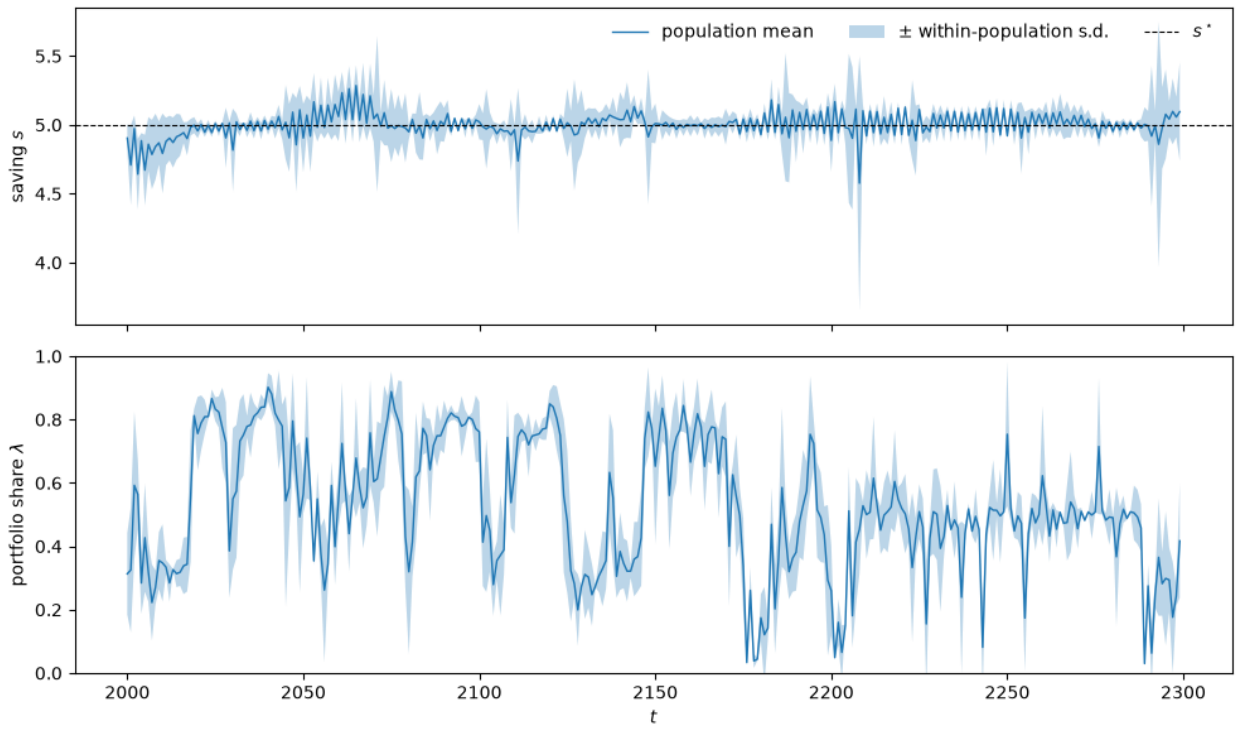

Fig. 94.4: Saving and portfolio shares inside the genetic population

Here are the same statistics averaged over the whole run after the burn-in.

```
S = stats_ga[burn:]
print(f"mean saving: {S[:, 0].mean():.3f}   (s* = {arifovic.s_star})")
print(f"within-population s.d. of s: {S[:, 1].mean():.3f}")
print(f"within-population s.d. of λ: {S[:, 3].mean():.3f}")
print(f"s.d. over time of the population's mean λ: {S[:, 2].std():.3f}  "
      f"(a uniform draw on [0.02, 0.98] has s.d. {0.96/np.sqrt(12):.3f})")
print(f"5th and 95th percentiles of the population's mean λ: "
      f"{np.percentile(S[:, 2], 5):.2f}, {np.percentile(S[:, 2], 95):.2f}")
```

```
mean saving: 4.990   (s* = 5.0)
within-population s.d. of s: 0.110
within-population s.d. of λ: 0.092
s.d. over time of the population's mean λ: 0.237  (a uniform draw on [0.02, 0.98]␣
↪has s.d. 0.277)
5th and 95th percentiles of the population's mean λ: 0.11, 0.88
```

The genetic economy settles in one direction and drifts in the other.

In the determinate direction, saving, the population learns: mean saving sits at $s^\star$ and the strings agree closely with one another.

The strings also agree fairly closely about λ at any moment.

But the population's common λ wanders over most of the range the encoding allows, and the exchange rate wanders with it.

The reason is the ghost of indeterminacy.

Nothing in the fundamentals favors one portfolio share over another: at equal returns every share is equally fit.

A share becomes fitter than another only when the two currencies' returns differ, and they differ only because one cohort's portfolio differs from the previous cohort's.

So fitness is neutral in λ apart from return gaps that the population creates itself, and nothing anchors the population's portfolio.

Mutation, crossover, and those self-generated return gaps push it along the continuum of equilibria, and nothing holds it in place.

The indeterminacy that the Newton–Raphson learner froze into a history-dependent constant returns here as volatility.

The election operator does much of the population's learning; Exercise 94.7.2 shows what happens without it.

94.5.3 The shape of the volatility

Sargent describes the exchange rate in Arifovic's genetic economy as close to a random walk — but with **mean reversion**, showing up as a dip at zero frequency in the spectrum of its first difference.

We plot the spectrum of the winsorized $\Delta \log e_t$ against frequency in radians on a log scale, as Sargent does, together with the autocorrelation of $\log e_t$.

```
def averaged_spectrum(x, n_seg=16):
    "Bartlett-averaged periodogram; frequencies in radians per period."
    x = x - x.mean()
    seg = len(x) // n_seg
    acc = np.zeros(seg // 2 + 1)
    for k in range(n_seg):
        acc += np.abs(np.fft.rfft(x[k*seg:(k+1)*seg]))**2 / seg
    return 2 * np.pi * np.fft.rfftfreq(seg), acc / n_seg
```

(continues on next page)

(continued from previous page)

```
d_log_e = np.diff(log_e)
d_log_e = np.clip(d_log_e, *np.percentile(d_log_e, [1, 99]))     # winsorize tails
freq, spec = averaged_spectrum(d_log_e)

def acf(x, K):
    x = x - x.mean()
    return np.array([np.sum(x[k:]*x[:len(x)-k]) / np.sum(x*x) for k in range(K)])

fig, axes = plt.subplots(1, 2, figsize=(12, 4))
axes[0].semilogy(freq[1:], spec[1:], lw=1.2)
axes[0].set_title(r"spectrum of $\Delta \log e$")
axes[0].set_xlabel("frequency (radians)")

axes[1].bar(range(25), acf(log_e, 25))
axes[1].set_title(r"autocorrelation of $\log e$")
axes[1].set_xlabel("lag")
plt.tight_layout()
plt.show()
```

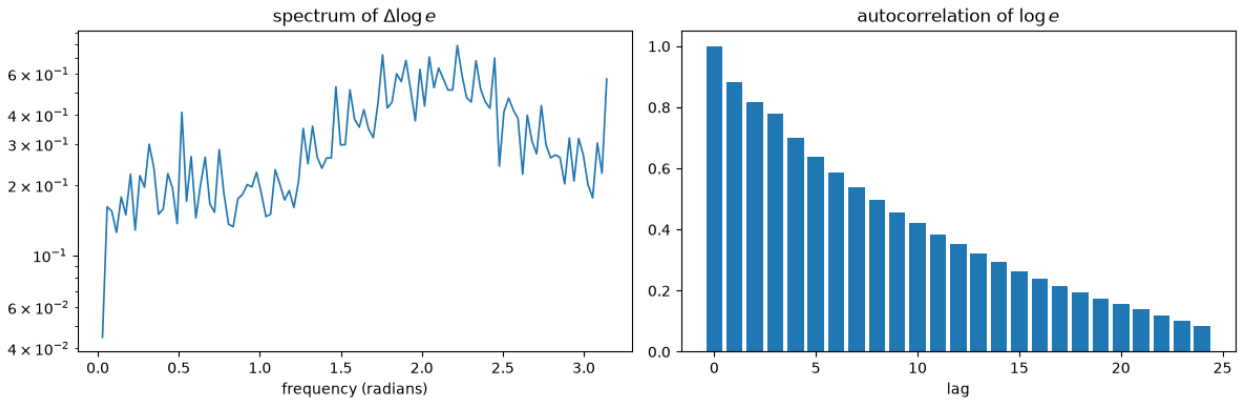

Fig. 94.5: Spectrum and autocorrelation of the exchange rate

The spectrum is hump-shaped.

It is low near zero frequency, rises to a peak at intermediate frequencies, and falls off toward π, much like the spectrum in Sargent's figure, which peaks near 1.5 radians.

The autocorrelation of the level falls to one half by about lag 8 and is close to zero by lag 25.

That is much faster than a near unit root would allow.

But the sample autocorrelation is only an informal guide, because a random walk's sample autocorrelation also decays in a finite sample.

A direct test is to regress $\log e_t$ on a constant and $\log e_{t-1}$ and compare the coefficient $\hat{\phi}$ with one.

The Dickey–Fuller statistic $(\hat{\phi} - 1)/\mathrm{se}(\hat{\phi})$ rejects a unit root at the 5% level when it is below about -2.86.

```
def ar1(x):
    "OLS of x_t on (1, x_{t-1}): returns ψ̂ and the Dickey-Fuller statistic."
    X = np.column_stack([np.ones(len(x) - 1), x[:-1]])
    b = np.linalg.lstsq(X, x[1:], rcond=None)[0]
    u = x[1:] - X @ b
    se = np.sqrt(u @ u / (len(u) - 2) * np.linalg.inv(X.T @ X)[1, 1])
    return b[1], (b[1] - 1) / se

band = slice(1, len(spec)//2)
ψ, df_stat = ar1(log_e)
print(f"spectrum of Δlog e at the lowest frequency / mean over (0, π/2): "
      f"{spec[1] / spec[band].mean():.2f}")
print(f"spectral peak at frequency {freq[1:][np.argmax(spec[1:])]:.2f} radians")
print(f"AR(1) coefficient ψ = {ψ:.3f},  half-life = {np.log(0.5)/np.log(ψ):.1f}␣
↪periods")
print(f"Dickey-Fuller statistic = {df_stat:.1f}   (5% critical value ≈ -2.86)")
```

```
spectrum of Δlog e at the lowest frequency / mean over (0, π/2): 0.21
spectral peak at frequency 2.22 radians
AR(1) coefficient ψ = 0.882,  half-life = 5.5 periods
Dickey-Fuller statistic = -14.8   (5% critical value ≈ -2.86)
```

The dip at zero frequency is pronounced.

The spectrum peaks near 2.2 radians, a cycle of about three periods.

The level is strongly mean-reverting, with a half-life of about five and a half periods, and the Dickey–Fuller test rejects a unit root decisively; Exercise 94.7.3 checks other seeds.

So in our implementation the genetic exchange rate is a stationary series, not a near random walk.

Part of the mean reversion is mechanical: the encoding's bounds on λ cap $|\log e_t|$, so the series cannot wander off for good.

Sargent's assessment is that real floating exchange rates for hard-currency pairs have spectra of log differences that look much like Arifovic's, except *without* the dip at zero frequency.

Actual exchange rates are even closer to pure random walks: it is hard to find a model that forecasts them better than "no change," a benchmark that the neural-network forecasts of Kuan and Liu [1995] set out to beat.

So the genetic economy matches the higher-frequency texture of floating rates but not their lowest frequencies.

That it gets that far with no fundamental shocks at all, from a population of adapting agents repricing two intrinsically identical currencies, is the striking part.

94.6 Concluding remarks

Two models of the same indeterminate economy gave two very different verdicts.

The Newton–Raphson learner **converges** — and in converging, exposes the indeterminacy rather than curing it.

Its rest points satisfy the arbitrage condition that leaves the exchange rate free.

They form a continuum, along which the algorithm has a unit eigenvalue.

So the limit is wherever the transient leaves the economy, and it depends on the initial portfolios and saving rates and on the tuning of the algorithm.

Learning makes the exchange rate history-dependent; it does not select one on any economic ground.

Sargent's hedged verdict is that such a mechanism "may seem a weak reed."

The genetic-algorithm economy **does not converge**, but not because it fails to learn.

With Arifovic's election operator, the population learns a saving rate close to $s^\star$ and becomes nearly homogeneous.

What it cannot learn is a portfolio share, because at equal returns no share is fitter than any other.

So the population's common λ wanders along the continuum of equilibria, and the exchange rate wanders with it.

The ghost of indeterminacy returns as volatility, in an economy with no fundamental disturbances whatsoever.

That volatility is an instance of one of the payoffs that *What the program is good for* lists for the bounded-rationality program: a new source of dynamics.

It resembles the higher-frequency texture of floating exchange rates but not their low frequencies, where the genetic economy's strong mean reversion has no counterpart in the data.

The two halves of the lecture also use different calibrations.

Exercise 94.7.4 runs the Newton–Raphson learner at Arifovic's, and finds that it converges there only if it is damped enough.

With this lecture's damping it sits on the edge of stability, and it generates recurrent bursts of volatility of its own.

Which learning model an economist reaches for, and how she tunes it, is one more of the choices that the bounded-rationality program forces into the open.

Networks, Genetic Algorithms, and Classifier Systems sets out Holland's genetic algorithm in general, together with its richer cousin, the classifier system.

Money as a Medium of Exchange among Artificially Intelligent Agents then puts populations of classifier systems to work: they must not merely tune a portfolio but *discover from scratch* which good will serve as money.

94.7 Exercises

Exercise 94.7.1

The main text varied the initial portfolio shares.

This exercise asks whether anything else matters for the limit.

1. Hold the initial portfolio shares fixed at $\lambda_0 = (0.30, 0.50)$ for the (even, odd) classes, and vary the initial saving rates s_0 over a few values. Confirm that the classes' shares merge and saving converges to $s^\star$. Does the limiting exchange rate change with s_0?
2. Start from experiment 1's initial condition and vary the ridge κ over $(0.1, 0.2, 0.5, 1, 2)$, holding $\gamma = 0.3$. Then vary the gain γ over $(0.05, 0.1, 0.3)$, holding $\kappa = 0.5$. Record the limiting exchange rate each time.

Is the limiting exchange rate a function of the initial portfolio shares alone?

Solution

Here is part 1.

```
rows = []
for s0 in ([3.0, 2.2], [2.2, 3.0], [4.0, 4.0], [1.0, 1.0], [6.0, 2.0]):
    e, s_h, l_h = newton_learning(kw, s0, [0.30, 0.50], T=800)
    rows.append([str(s0), l_h[-1][0], l_h[-1][1], s_h[-1].mean(), e[-1]])
```

```
pd.DataFrame(rows, columns=["initial s", "λ even (limit)", "λ odd (limit)",
                            "s (limit)", "e (limit)"]).round(4)
```

	initial s	λ even (limit)	λ odd (limit)	s (limit)	e (limit)
0	[3.0, 2.2]	0.4117	0.4117	2.5	1.1908
1	[2.2, 3.0]	0.4471	0.4471	2.5	1.0304
2	[4.0, 4.0]	0.4444	0.4444	2.5	1.0418
3	[1.0, 1.0]	0.4145	0.4145	2.5	1.1773
4	[6.0, 2.0]	0.3772	0.3772	2.5	1.3759

The two classes' shares merge (columns 2 and 3 agree), and saving converges to $s^\star = 2.5$.

But the limiting exchange rate changes with the initial saving rates, even though the initial portfolio shares are the same in every row.

The λ-gradient $s(R_1 - R_2)/c_2$ is proportional to saving, and the returns during the transient depend on both classes' saving.

So saving's path to $s^\star$ shapes how far λ moves before the arbitrage condition stops it.

Here is part 2.

```
rows = []
for κ in (0.1, 0.2, 0.5, 1.0, 2.0):
    e, s_h, l_h = newton_learning(kw, [3.5, 2.0], [0.35, 0.40], T=2000, κ=κ)
    rows.append([κ, 0.3, l_h[-1][0], e[-1]])
for gain in (0.05, 0.1, 0.3):
    e, s_h, l_h = newton_learning(kw, [3.5, 2.0], [0.35, 0.40], T=4000, gain=gain)
    rows.append([0.5, gain, l_h[-1][0], e[-1]])

pd.DataFrame(rows, columns=["κ", "gain γ", "λ (limit)", "e (limit)"]).round(4)
```

	κ	gain γ	λ (limit)	e (limit)
0	0.1	0.30	0.5445	0.6970
1	0.2	0.30	0.3859	1.3263
2	0.5	0.30	0.3732	1.3998
3	1.0	0.30	0.3709	1.4136
4	2.0	0.30	0.3707	1.4145
5	0.5	0.05	0.3694	1.4225
6	0.5	0.10	0.3701	1.4185
7	0.5	0.30	0.3732	1.3998

From the same initial condition, the limit moves with both κ and γ.

The ridge and the gain set how far λ travels in response to a given transient return gap, and so where on the continuum the motion stops.

The effect is modest for moderate values but large for small κ, where the λ steps are big and the transient is violent.

So the limiting exchange rate is not a function of the initial portfolio shares alone.

It depends on the whole initial condition and on the tuning of the algorithm, which makes the weak reed weaker still: two economists with identical data on initial beliefs, but different learning algorithms, would predict different exchange rates.

Exercise 94.7.2

Arifovic's **election operator** admits a child to the next generation only if it beats its parent on the latest returns.

Investigate what the operator does.

Run the genetic economy with and without it for several seeds, and report for each case:

- the standard deviation of $\log e_t$;
- the population's mean saving, compared with $s^\star$;
- the within-population standard deviations of s and of λ;
- the standard deviation over time of the population's mean λ.

Which way does the operator push exchange rate volatility, and why?

Solution

Here are the six seeds with and without the operator.

```
rows = []
for election in (True, False):
    for sd in range(6):
        e, st = genetic_economy(arifovic, T=2500, seed=sd, election=election)
        st = st[500:]
        rows.append([election, sd, np.log(e[500:]).std(), st[:, 0].mean(),
                     st[:, 1].mean(), st[:, 3].mean(), st[:, 2].std()])

table = pd.DataFrame(rows, columns=["election", "seed", "s.d. log e", "mean s",
                                    "within s.d. s", "within s.d. λ", "s.d. of␣
↪mean λ"])
table.drop(columns="seed").groupby("election").agg(["min", "max"]).T.round(3)
```

```
election             False  True
s.d. log e     min   0.473  1.081
               max   0.553  1.350
mean s         min   4.535  4.973
               max   5.399  5.286
within s.d. s  min   1.327  0.088
               max   1.358  0.110
within s.d. λ  min   0.229  0.083
               max   0.238  0.095
s.d. of mean λ min   0.111  0.214
               max   0.129  0.255
```

The table reports, for each statistic, its smallest and largest value across the six seeds.

The election operator **raises** exchange rate volatility, and the ranges across seeds do not overlap.

The other rows show why.

Without the operator the genetic algorithm learns much less.

Every child is admitted however unfit, so mutation and crossover keep the population a broad cloud.

Saving is spread widely within the population, and depending on the seed its mean lies anywhere between about 4.5 and 5.4, against $s^\star = 5$.

Portfolio shares are almost as dispersed as a uniform draw on $[0.02, 0.98]$, whose standard deviation is 0.277.

The aggregates in (94.2) average over that diverse population, so the aggregate portfolio share, and with it the exchange rate, moves comparatively little.

The lower volatility comes mainly from averaging over that cloud.

With the operator, selection works.

Mean saving stays within about six percent of $s^\star$ in every seed, and the population becomes nearly homogeneous in both s and λ.

But a homogeneous population whose fitness is flat in λ moves its portfolio share together, and nothing anchors where it goes.

So the population's mean λ wanders much more, and the exchange rate with it.

The operator that makes the population learn is the same one that makes the indeterminacy visible: learning the determinate part of the equilibrium exposes the indeterminate part.

Exercise 94.7.3

The lecture reported that the genetic economy's exchange rate is strongly mean-reverting.

Check that the finding does not depend on the seed, and check the diagnostic.

1. For six seeds, run the genetic economy for 4000 periods, drop 500 as a burn-in, and estimate ϕ in $\log e_t = \mu + \phi \log e_{t-1} + \varepsilon_t$. Report ϕ, the half-life $\ln(1/2)/\ln\phi$, and the Dickey–Fuller statistic. Is the series stationary?
2. Simulate a pure random walk of the same length and compute its sample autocorrelations at lags 1, 5, 10, and 25. Can a decaying sample autocorrelation distinguish a mean-reverting series from a random walk?

Solution

Here is part 1.

```
rows = []
for sd in range(6):
    le = np.log(genetic_economy(arifovic, T=4000, seed=sd)[0][500:])
    ψ_sd, df_sd = ar1(le)
    rows.append([sd, ψ_sd, np.log(0.5)/np.log(ψ_sd), df_sd])

pd.DataFrame(rows, columns=["seed", "ψ", "half-life", "Dickey-Fuller"]).round(3)
```

	seed	ψ	half-life	Dickey-Fuller
0	0	0.903	6.819	-13.316
1	1	0.882	5.530	-14.794
2	2	0.893	6.118	-14.071
3	3	0.876	5.244	-15.184
4	4	0.884	5.632	-14.658
5	5	0.896	6.337	-13.814

Across seeds ϕ is well below one, the half-life is a handful of periods, and the Dickey–Fuller statistic is far below the 5% critical value of about -2.86.

The series is stationary, and strongly mean-reverting.

Here is part 2.

```
rw = np.cumsum(np.random.default_rng(0).standard_normal(3500))
print("sample autocorrelation of a random walk at lags 1, 5, 10, 25:",
      acf(rw, 26)[[1, 5, 10, 25]].round(3))
print("sample autocorrelation of the GA log e at lags 1, 5, 10, 25:   ",
      acf(log_e, 26)[[1, 5, 10, 25]].round(3))
```

```
sample autocorrelation of a random walk at lags 1, 5, 10, 25: [0.999 0.995 0.
↪991 0.978]
sample autocorrelation of the GA log e at lags 1, 5, 10, 25:    [0.882 0.639 0.
↪42  0.067]
```

The random walk's sample autocorrelation decays too, because in a finite sample the autocorrelation is computed around the sample mean.

So "it decays" is not by itself evidence against a unit root.

What distinguishes the two series is *how fast* the autocorrelation decays, and the Dickey–Fuller statistic turns that into a formal test.

The genetic economy's autocorrelation falls nearly to zero within 25 lags, while the random walk's barely moves.

Exercise 94.7.4

The Newton–Raphson section used Sargent's parameters $(w_1, w_2, H_1, H_2) = (20, 15, 100, 120)$, while the genetic-algorithm section used Arifovic's $(11, 1, 10, 10)$.

To compare like with like, run the Newton–Raphson learner at Arifovic's parameters.

1. With the lecture's tuning ($\kappa = 0.5$, $\gamma = 0.3$), run it for 3000 periods from $s_0 = (6, 4)$, $\lambda_0 = (0.45, 0.55)$. Does it converge?
2. Linearize around a rest point $(s^\star, s^\star, \lambda, \lambda)$. Show that each update multiplies the difference between the two classes' portfolio shares by $1 - a$, where

$$a = \frac{\gamma\, s^\star}{\kappa\, c_2^\star\, \lambda(1-\lambda)}, \qquad c_2^\star = w_2 + s^\star.$$

   Hint: the portfolio return $A = \lambda R_1 + (1-\lambda) R_2$ does not depend on the portfolio shares at all, and near a rest point $R_1 - R_2 \approx (\lambda_{\text{young}} - \lambda_{\text{old}})/(\lambda(1-\lambda))$. Compute a at both calibrations, and check the result against `rest_point_jacobian`.
3. How large must κ be for some rest points to be stable at Arifovic's parameters? Rerun part 1 with $\kappa = 2$.

Solution

Here is part 1.

```
ea, sa, la = newton_learning(arifovic, [6.0, 4.0], [0.45, 0.55], T=3000)
eb, sb, lb = newton_learning(arifovic, [6.0, 4.0], [0.45, 0.55], T=3000, κ=2.0)

fig, axes = plt.subplots(2, 1, figsize=(10, 6), sharex=True)
axes[0].plot(np.log(ea), lw=0.6, label=r"$\kappa = 0.5$")
axes[0].plot(np.log(eb), lw=1.2, label=r"$\kappa = 2$")
axes[0].set_ylabel(r"$\log e_t$")
axes[0].legend(frameon=False)
axes[1].plot(la[:, 0] - la[:, 1], lw=0.6)
axes[1].plot(lb[:, 0] - lb[:, 1], lw=1.2)
axes[1].set_ylabel(r"$\lambda_{\mathrm{even}} - \lambda_{\mathrm{odd}}$")
axes[1].set_xlabel("$t$")
plt.tight_layout()
plt.show()
```

With the lecture's tuning the learner does not converge.

The two classes' portfolio shares nearly merge, saving reaches $s^\star = 5$, and the exchange rate rests for a while.

Then the gap between the classes' shares grows in an alternating pattern until it explodes.

The exchange rate shoots to the bounds and comes back to rest somewhere else, again and again.

For part 2, let δ be the young class's share minus the old class's.

The portfolio return is $A = \lambda_{\text{old}} R_1 + (1 - \lambda_{\text{old}}) R_2 = s_{\text{young}} / s_{\text{old}}$, which does not involve the shares.

So the saving equations do not involve λ at all.

Near a rest point, the cross term $\partial^2 U / \partial s \partial \lambda$ is proportional to $R_1 - R_2$ and vanishes.

The curvature estimate's λ entry is then $-\kappa$, and the old class's update is

$$\lambda_{\text{old}} \leftarrow \lambda_{\text{old}} + \frac{\gamma}{\kappa} \frac{s^\star}{c_2^\star} (R_1 - R_2) \approx \lambda_{\text{old}} + a\,\delta.$$

Next period the classes swap roles, so the new young-minus-old difference is $-(1 - a)\delta$.

Measured as even minus odd, the gap is multiplied by $1 - a$ at each update, and by $(1 - a)^2$ over two periods.

That is the eigenvalue we met in *The ghost of indeterminacy*.

The gap dies out if $0 < a < 2$ and explodes if $a > 2$.

```
def a_coef(p, lam, κ=0.5, gain=0.3):
    return gain * p.s_star / (κ * (p.w2 + p.s_star) * lam * (1 - lam))

for p, name in [(kw, "Sargent"), (arifovic, "Arifovic")]:
    for lam in (0.3, 0.5, 0.7):
        a = a_coef(p, lam)
        ev = np.sort(np.abs(np.linalg.eigvals(rest_point_jacobian(p, lam))))[::-1]
        print(f"{name:8s} λ = {lam}:  a = {a:.3f},  (1-a)² = {(1 - a)**2:.3f},  "
              f"|eigenvalues| = {ev.round(3)}")
```

```
Sargent  λ = 0.3:  a = 0.408,  (1-a)² = 0.350,  |eigenvalues| = [1.   0.35 0.25␣
↪0.16]
Sargent  λ = 0.5:  a = 0.343,  (1-a)² = 0.432,  |eigenvalues| = [1.    0.432 0.
↪25  0.16 ]
Sargent  λ = 0.7:  a = 0.408,  (1-a)² = 0.350,  |eigenvalues| = [1.   0.35 0.25␣
↪0.16]
Arifovic λ = 0.3:  a = 2.381,  (1-a)² = 1.907,  |eigenvalues| = [1.907 1.    0.
↪695 0.646]
Arifovic λ = 0.5:  a = 2.000,  (1-a)² = 1.000,  |eigenvalues| = [1.    1.    0.
↪695 0.646]
Arifovic λ = 0.7:  a = 2.381,  (1-a)² = 1.907,  |eigenvalues| = [1.907 1.    0.
↪695 0.646]
```

The formula matches the numerical Jacobian.

At Sargent's parameters a is far below 2 unless λ is below about 0.05 or above about 0.95, so the rest points are stable apart from the unit eigenvalue along the continuum.

At Arifovic's parameters the λ-gradient is much steeper, because the ratio $s^\star/c_2^\star$ is $5/6$ instead of $1/7$.

With $\kappa = 0.5$ and $\gamma = 0.3$, then, $a = 0.5/(\lambda(1-\lambda)) \geq 2$ at *every* rest point.

The rest point at $\lambda = 1/2$ is exactly on the edge, and all the others are unstable.

That is why the learner keeps escaping.

For part 3, $\lambda(1-\lambda) \leq 1/4$, so some rest points are stable if and only if $\kappa > 2\gamma s^\star/c_2^\star = 0.5$ at Arifovic's parameters.

The lecture's κ sits exactly on that boundary.

With $\kappa = 2$ the rest points with $\lambda(1-\lambda) > 1/16$, that is, with λ between about 0.07 and 0.93, are stable, and the figure shows the learner converging to a constant.

```
print(f"κ = 2: e → {eb[-1]:.4f},  s → {sb[-1].round(3)},  λ → {lb[-1].round(4)}")
print(f"largest |Δ log e| over the last 500 periods: "
      f"{np.abs(np.diff(np.log(eb[-500:]))).max():.1e}")
```

```
κ = 2: e → 0.9475,  s → [5. 5.],  λ → [0.5135 0.5135]
largest |Δ log e| over the last 500 periods: 0.0e+00
```

So the gap between the two halves of the lecture is about the adaptive machinery, not the calibration.

A Newton–Raphson learner that is damped enough converges at Arifovic's parameters too, to a history-dependent constant.

But how much damping is "enough" depends on the economy: with the same tuning, one calibration converges and the other bursts.

Exercise 94.7.5

In a footnote, Sargent distinguishes *history* dependence from *path* dependence.

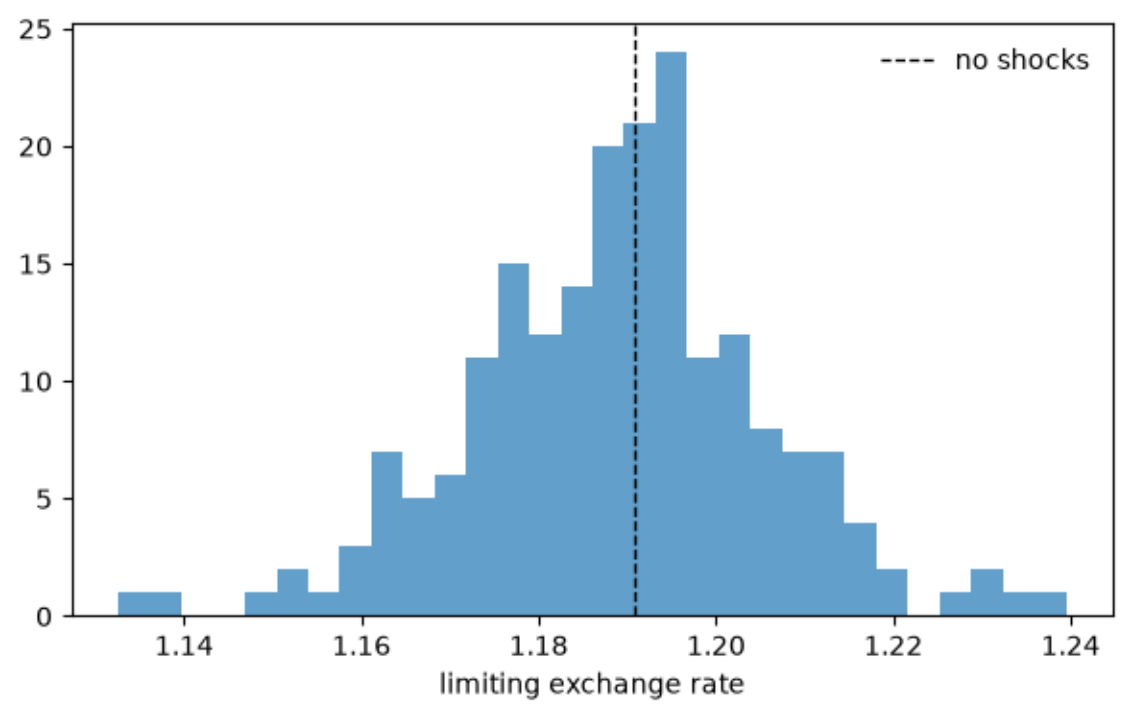
In a stochastic version of the model, realizations that start from identical initial conditions can converge to different exchange rates, because different shocks hit the transient dynamics.

Add IID shocks to the old-age endowment, $w_{2t} = w_2 + \sigma\varepsilon_t$ with $\varepsilon_t \sim N(0,1)$ and $\sigma = 1$, at Sargent's parameters.

(The `w2_path` argument of `newton_learning` does this.)

1. Start 200 economies at the same initial condition, $s_0 = (3.0, 2.2)$ and $\lambda_0 = (0.30, 0.50)$, with different shock sequences, and run each for 600 periods. Does the exchange rate converge in each run? Does saving?

2. Plot a histogram of the limiting exchange rates, and mark the limit without shocks.
3. Why do the shocks stop affecting the exchange rate after a while, even though they never stop hitting the economy?



Solution

Here are parts 1 and 2.

```
T, σ = 600, 1.0
e_det = newton_learning(kw, [3.0, 2.2], [0.30, 0.50], T=T)[0][-1]

limits, last_move, s_spread = [], [], []
for seed in range(200):
    shocks = σ * np.random.default_rng(seed).standard_normal(T)
    e, s_h, l_h = newton_learning(kw, [3.0, 2.2], [0.30, 0.50], T=T,
                                  w2_path=kw.w2 + shocks)
    limits.append(e[-1])
    last_move.append(np.abs(np.diff(np.log(e[-300:]))).max())
    s_spread.append(s_h[-300:, 0].std())

fig, ax = plt.subplots(figsize=(7, 4))
ax.hist(limits, bins=30, alpha=0.7)
ax.axvline(e_det, color='k', ls='--', lw=1, label="no shocks")
ax.set_xlabel("limiting exchange rate")
ax.legend(frameon=False)
plt.show()
```

Here is a summary of the runs.

```
limits = np.array(limits)
print(f"limit without shocks: {e_det:.4f}")
print(f"limits with shocks: {limits.min():.4f} to {limits.max():.4f}, s.d. {limits.
 ↪std():.4f}")
print(f"largest |Δ log e| over the last 300 periods, across all runs: {max(last_
 ↪move):.1e}")
print(f"s.d. of even-class saving over the last 300 periods: "
      f"{min(s_spread):.3f} to {max(s_spread):.3f}")
```

```
limit without shocks: 1.1908
limits with shocks: 1.1326 to 1.2395, s.d. 0.0169
largest |Δ log e| over the last 300 periods, across all runs: 7.8e-16
s.d. of even-class saving over the last 300 periods: 0.193 to 0.274
```

Every exchange rate path converges: over the last 300 periods it does not move at all, up to rounding.

Saving does not converge; with a constant gain and shocks that never stop, it keeps fluctuating around $s^\star$.

Yet the economies, which differ only in their shocks, settle on different exchange rates.

That is path dependence in Sargent's sense.

Sargent [1993] quotes Evans and Honkapohja's description of how adaptive learning resolves indeterminacy:

> models with multiple solutions are converted into models with path dependence in which the trajectory of the economy, and the [rational expectations equilibrium] attained in the limit, are determined through a learning rule by initial forecasts and by the sequence of exogenous shocks.

The shocks matter only during the transient, because the exchange rate depends only on the young class's λ.

Once the two classes' shares merge, $R_1 = R_2$ whatever saving does, so the λ-gradient $s(R_1 - R_2)/c_2$ is zero whatever the endowment.

From then on, shocks to w_2 move saving but cannot move the portfolio share, and the exchange rate stays wherever the transient left it.

Because the shocks have only the brief transient in which to act, the spread of limits around the no-shock value is narrow.

95.1 Overview

The lectures so far gave adaptive agents a fairly econometric brain.

In *Adaptive Agents in an Overlapping Generations Monetary Economy* they ran stochastic approximation and recursive least squares, in *Learning, Approximation, and Equilibrium Computation* they fitted conditional expectations, and in *Exchange Rate Indeterminacy, Learning, and Experiments* they took Newton steps against realized utility.

Each of those learners was told what to estimate (a saving rate, a conditional expectation, a portfolio) and updated its estimate by a recursion of the kind described in *One recursion, many learners*.

Exchange Rate Indeterminacy, Learning, and Experiments also gave a first look at a learner of another kind: Arifovic's genetic-algorithm economy (*A genetic algorithm economy*), whose exchange rate never settles down.

This lecture sets out that algorithm and its relatives in general.

They make up the toolbox that Sargent [1993] draws from John Holland's work on adaptive systems [Holland, 1975, Holland *et al.*, 1986] and from the connectionist literature on neural networks.

Sargent's framing is that the bounded-rationality program asks us to populate models with agents who "behave like econometricians," and that the artificial-intelligence literature is a catalogue of candidate brains for them:

> It is from the store of methods built up in these literatures that we shall select the 'brains' to give our boundedly rational agents.

We tour four of them:

1. the **perceptron**, the simplest neural network, which turns out to be a linear discriminant function, a direct link to the "agents as econometricians" reading;
2. the **Hopfield network**, an associative memory that recovers stored patterns from corrupted inputs by rolling downhill on an energy function;
3. the **genetic algorithm**, Holland's population-based search, which we set loose on Axelrod's iterated prisoner's dilemma;
4. the **classifier system**, Holland's "brain as a competitive economy" of if-then rules, whose simplest instance, a two-armed bandit, already exposes a subtle limitation, and whose **bucket brigade** passes credit back along chains of decisions.

The first two are bridges from what came before.

The perceptron is a parametric rule that an econometrician recognizes on sight, and the Hopfield network is a memory rather than a rule.

The last two do something new: instead of tuning the coefficients of a fixed rule, they **discover rules**, searching a large space of possibilities with experience as the only guide.

We close with **evolutionary programming**: the idea that a population of adaptive agents, plodding toward an equilibrium, can be used to *compute* equilibria that we cannot solve for directly.

That is the idea *Money as a Medium of Exchange among Artificially Intelligent Agents* carries out in full, and this lecture builds the machinery it uses.

Let's start with some imports.

```
import numpy as np
import matplotlib.pyplot as plt
```

95.2 The perceptron: an agent as a discriminant function

The simplest neural network is a single **perceptron**: k inputs x_i, weights w_i, and one output

$$y = S\left(\sum_{i=1}^{k} w_i x_i\right) = S(w^\top x),$$

where S is a "squasher" mapping $\mathbb{R}$ onto $[0, 1]$: a step function, or the sigmoid $S(z) = 1/(1 + e^{-z})$, or any cumulative distribution function.

For fixed weights the perceptron is a **classifier**: it fires ($y = 1$) when $w^\top x > 0$ and stays quiet otherwise, so the boundary $w^\top x = 0$ is a hyperplane separating two classes.

Training the perceptron, that is, choosing w to minimize $\sum_t (y_t - S(w^\top x_t))^2$, is a nonlinear least squares problem, solved by the stochastic-gradient recursion

$$w_t = w_{t-1} + \gamma_t \nabla S(w_{t-1}, x_t)\,(y_t - S(w_{t-1}^\top x_t)),$$

where $\nabla S(w, x)$ is the gradient of $S(w^\top x)$ with respect to w, equal to $S(w^\top x)(1 - S(w^\top x))\,x$ for the sigmoid.

This has the form $\theta_t = \theta_{t-1} + \gamma_t Q(\theta_{t-1}, x_t)$ shared by every learner in this series (*One recursion, many learners*).

The book suggests a simple scheme: set γ_t to a small constant and run the sample through the recursion repeatedly until the weights settle.

Take the book's example: separate football players from economists on two features, weight and salary (synthetic data, in arbitrary units).

```
rng = np.random.default_rng(0)
n = 100
economists = rng.multivariate_normal([-1.0, -0.3], [[0.5, 0.1], [0.1, 0.5]], n)
players    = rng.multivariate_normal([1.2,  0.8], [[0.6, 0.0], [0.0, 0.6]], n)
X = np.vstack([economists, players])
y = np.r_[np.zeros(n), np.ones(n)]
X_aug = np.column_stack([np.ones(len(X)), X])          # prepend an intercept

def sigmoid(z):
    return 1 / (1 + np.exp(-z))

def train_perceptron(X_aug, y, y=0.1, passes=200, nls=True, seed=1):
    "Constant-gain stochastic gradient, run repeatedly through the sample."
    rng = np.random.default_rng(seed)
    w = np.zeros(X_aug.shape[1])
    for _ in range(passes):
        for t in rng.permutation(len(y)):
            S = sigmoid(X_aug[t] @ w)
            grad = S * (1 - S) * X_aug[t] if nls else X_aug[t]
            w += y * grad * (y[t] - S)
    return w

w = train_perceptron(X_aug, y)                         # the recursion displayed above
print(f"training accuracy: {np.mean((sigmoid(X_aug @ w) > 0.5) == y):.3f}")
```

```
training accuracy: 0.945
```

The `nls=False` branch drops the factor $S(1-S)$; we use it in a moment.

The point Sargent [1993] stresses is that this is nothing exotic to an econometrician: the perceptron's decision boundary is essentially a **linear discriminant function**.

Compare the perceptron's boundary normal to Fisher's linear discriminant direction.

```
def unit(v):
    return v / np.linalg.norm(v)

def angle(u, v):
    "Angle in degrees between two directions, ignoring sign."
    return np.degrees(np.arccos(min(1.0, abs(unit(u) @ unit(v)))))

m0, m1 = X[y == 0].mean(0), X[y == 1].mean(0)
S_within = np.cov(X[y == 0].T) * n + np.cov(X[y == 1].T) * n
lda_direction = unit(np.linalg.solve(S_within, m1 - m0))
perceptron_direction = unit(w[1:])

print(f"perceptron boundary normal   : {perceptron_direction.round(3)}")
print(f"Fisher discriminant direction: {lda_direction.round(3)}")
print(f"cosine similarity: {abs(perceptron_direction @ lda_direction):.4f}, "
      f"angle {angle(w[1:], lda_direction):.1f} degrees")
```

```
perceptron boundary normal   : [0.982 0.188]
Fisher discriminant direction: [0.925 0.38 ]
cosine similarity: 0.9798, angle 11.5 degrees
```

Dropping the factor $S(1-S)$ from the recursion turns it into stochastic-gradient ascent on the logistic log-likelihood, that is, into **logistic regression**.

```
w_logit = train_perceptron(X_aug, y, nls=False)
print(f"logistic regression: cosine {abs(unit(w_logit[1:]) @ lda_direction):.4f}, "
      f"angle {angle(w_logit[1:], lda_direction):.1f} degrees")
```

```
logistic regression: cosine 0.9978, angle 3.8 degrees
```

Here is the perceptron's boundary.

```
fig, ax = plt.subplots(figsize=(6.5, 5))
ax.scatter(*economists.T, s=18, c='C0', label="economists ($y=0$)")
ax.scatter(*players.T, s=18, c='C1', label="football players ($y=1$)")
xs = np.linspace(X[:, 0].min(), X[:, 0].max(), 2)
ax.plot(xs, -(w[0] + w[1]*xs) / w[2], 'k-', lw=1.5, label="perceptron boundary")
ax.set_ylim(X[:, 1].min() - 0.5, X[:, 1].max() + 0.5)
ax.set_xlabel("weight")
ax.set_ylabel("salary")
ax.legend(frameon=False)
plt.show()
```

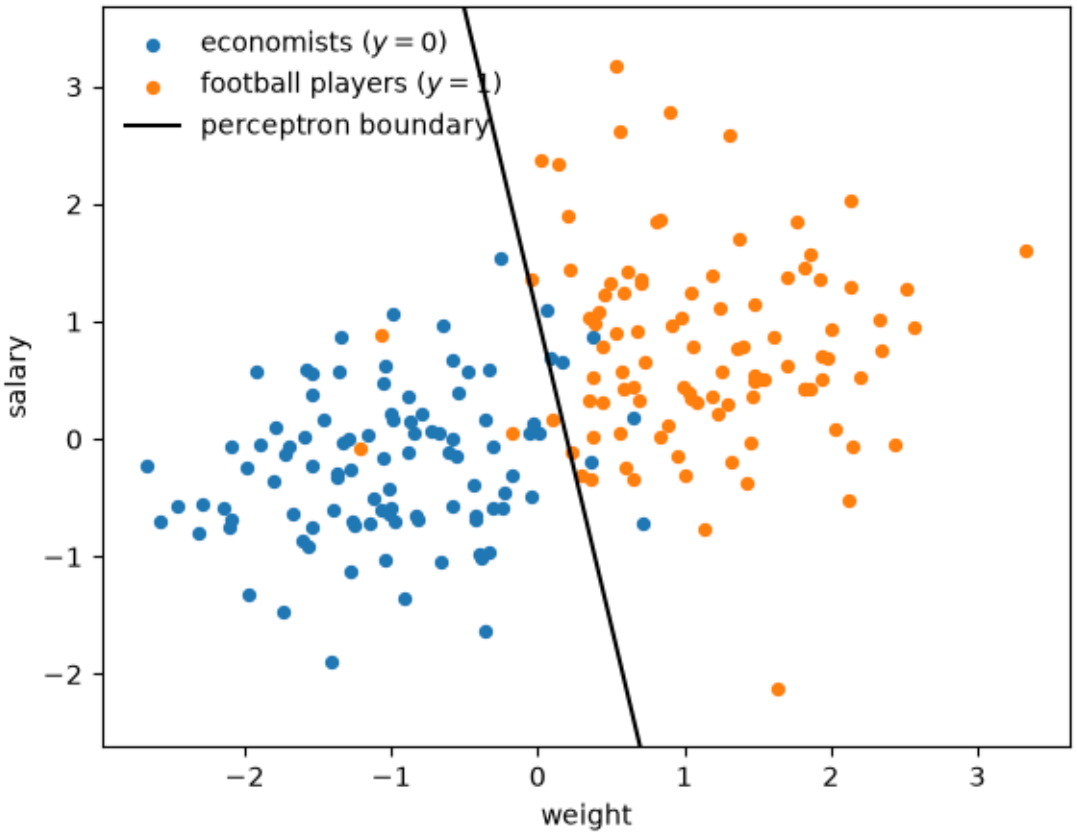

Fig. 95.1: Perceptron boundary separating the two groups

Both boundaries point close to Fisher's direction: the perceptron's is about 11.5 degrees away and logistic regression's about 4.

The closeness is no accident.

If the two classes are Gaussian with a common covariance matrix Σ, then $\Pr(y = 1 \mid x)$ is exactly a sigmoid in x whose slope is $\Sigma^{-1}(\mu_1 - \mu_0)$, Fisher's direction, so both recursions aim at it.

Here the two covariance matrices differ a little and the sample is finite, and the least squares criterion weights the observations differently from the likelihood, so the directions differ.

Minsky and Papert's famous critique [Minsky and Papert, 1969] was precisely that a single perceptron can represent *only* a linear discriminant, and so cannot separate classes that a line cannot.

The revival of the field came with the recognition that **layering** perceptrons, feeding their outputs into further perceptrons, approximates any nonlinear discriminant, the subject of *Introduction to Artificial Neural Networks*.

For our purposes the perceptron is the entry in the catalogue closest to what the previous lectures already did: a parametric rule, trained by a stochastic-gradient recursion, that an econometrician would recognize on sight.

The Hopfield network is a bridge of another kind, and the last two brains are stranger still.

95.3 Associative memory: the Hopfield network

The second device stores patterns and recalls them from corrupted fragments.

Represent a pattern as a vector of ± 1 of length N.

We want to store p patterns $\sigma^1, \dots, \sigma^p$, the columns of an $N \times p$ matrix σ, so that each is a fixed point of a dynamical system, and so that feeding in a corrupted version converges quickly to the nearest stored pattern.

The **Hopfield network** [Hopfield, 1982] does this with the dynamics

$$s(t+1) = \operatorname{sgn}(w\, s(t)),$$

and a weight matrix built from the patterns themselves.

When the patterns are orthogonal, Hebb's rule $w = \frac{1}{N}\sigma\sigma^\top$ suffices; for merely linearly independent (correlated) patterns one uses the projection rule $w = \frac{1}{N}\sigma V^{-1}\sigma^\top$ with $V = \frac{1}{N}\sigma^\top\sigma$.

Both make each stored pattern an exact fixed point.

The projection rule has a simple geometry: $w = \sigma(\sigma^\top\sigma)^{-1}\sigma^\top$ is the orthogonal projection onto the span of the stored patterns.

So the energy $E(s) = -\frac{1}{2}s^\top w s$ equals $-\frac{1}{2}\|ws\|^2$, which is at least $-\frac{1}{2}\|s\|^2 = -N/2$, with equality exactly when s lies in that span.

The stored patterns are therefore *global* minima of the energy.

We store five letters on a 5×5 pixel grid, and because letters share many pixels, they are correlated, so the projection rule is the right one.

(The code stores the patterns as the rows of σ, the transpose of the matrix in the formulas.)

```
PATTERNS = {
    'A': ["01110", "10001", "11111", "10001", "10001"],
    'E': ["11111", "10000", "11110", "10000", "11111"],
    'I': ["11111", "00100", "00100", "00100", "11111"],
    'O': ["01110", "10001", "10001", "10001", "01110"],
    'T': ["11111", "00100", "00100", "00100", "00100"],
}

def to_vector(rows):
    return np.array([1 if c == '1' else -1 for r in rows for c in r])
```

(continues on next page)

(continued from previous page)

```
letters = list(PATTERNS)
σ = np.array([to_vector(PATTERNS[c]) for c in letters])      # (p, N): one pattern␣
↪per row

def projection_rule(patterns):
    "Weight matrix making each (correlated) pattern an exact fixed point."
    N = patterns.shape[1]
    Σ = patterns.T                                           # (N, p)
    V = Σ.T @ Σ / N
    return Σ @ np.linalg.inv(V) @ Σ.T / N

def energy(w, s):
    "Hopfield energy; stored patterns are global minima."
    return -0.5 * s @ w @ s

def recall(w, s0, max_iter=30):
    "Iterate sgn(w s) to a fixed point."
    s = s0.copy()
    for _ in range(max_iter):
        s_new = np.sign(w @ s)
        s_new[s_new == 0] = 1
        if np.array_equal(s_new, s):
            break
        s = s_new
    return s

w_hop = projection_rule(σ)
fixed = all(np.array_equal(np.sign(w_hop @ σ[i]), σ[i]) for i in range(len(letters)))
print(f"all stored letters are fixed points: {fixed}")
print(f"energy of each stored letter: {[round(energy(w_hop, σ[i]), 1) for i in␣
↪range(len(letters))]}")
```

```
all stored letters are fixed points: True
energy of each stored letter: [np.float64(-12.5), np.float64(-12.5), np.float64(-
↪12.5), np.float64(-12.5), np.float64(-12.5)]
```

Every stored letter sits at the same energy $-N/2$ and is a fixed point.

Now corrupt a few pixels and let the network fall back to the nearest memory.

```
rng = np.random.default_rng(3)
show = ['E', 'O', 'T']

fig, axes = plt.subplots(len(show), 3, figsize=(6, 6))
for row, letter in enumerate(show):
    i = letters.index(letter)
    corrupt = σ[i].copy()
    corrupt[rng.choice(25, 4, replace=False)] *= -1             # flip 4 pixels
    recovered = recall(w_hop, corrupt)
    for col, (img, title) in enumerate([(σ[i], "stored"),
                                        (corrupt, "corrupted"),
                                        (recovered, "recovered")]):
        axes[row, col].imshow(img.reshape(5, 5), cmap='binary', vmin=-1, vmax=1)
        axes[row, col].set_xticks([])
        axes[row, col].set_yticks([])
        if row == 0:
```

(continues on next page)

(continued from previous page)

```
            axes[row, col].set_title(title)
plt.tight_layout()
plt.show()
```

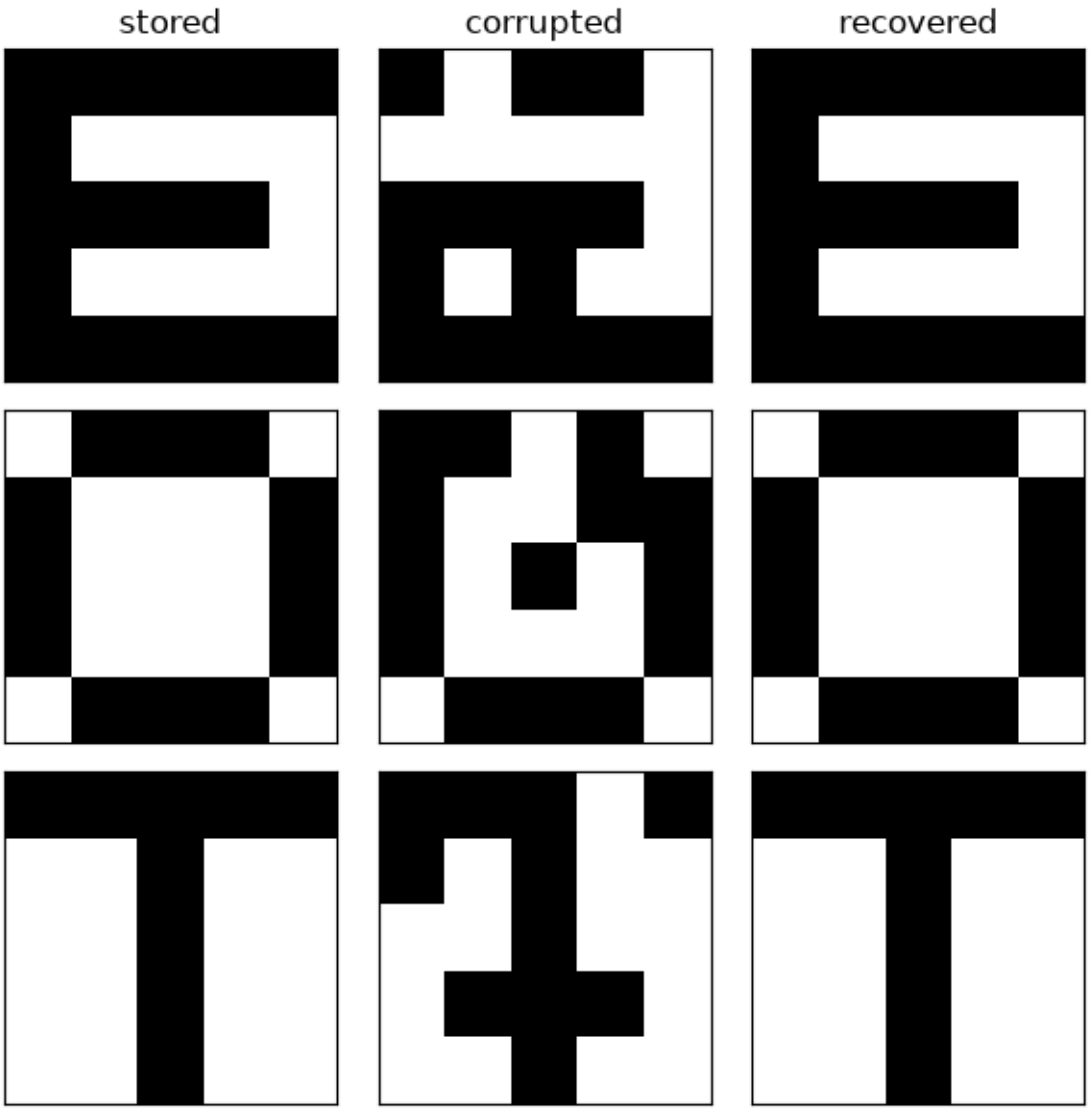

Fig. 95.2: Hopfield recall of letters from corrupted inputs

The corrupted letters snap back to their originals.

How reliably depends on how much is corrupted and on how correlated the patterns are.

A corrupted letter can occasionally land in a *different* letter's basin, or in a spurious mixture the designer never stored.

```
for n_flip in (3, 5, 7):
    correct = 0
    for i in range(len(letters)):
```

(continues on next page)

(continued from previous page)

```
        for _ in range(40):
            corrupt = σ[i].copy()
            corrupt[rng.choice(25, n_flip, replace=False)] *= -1
            if np.array_equal(recall(w_hop, corrupt), σ[i]):
                correct += 1
    print(f"{n_flip} pixels flipped: recovered exactly {correct}/{len(letters)*40}")
```

```
3 pixels flipped: recovered exactly 179/200
5 pixels flipped: recovered exactly 138/200
7 pixels flipped: recovered exactly 77/200
```

Five patterns on 25 pixels is a heavy load ($p/N = 0.2$), and the letters overlap a lot: I and T differ in only 4 of the 25 pixels.

That is why even 3-pixel corruptions fail about one time in ten.

The book's analysis of recall assumes many fewer patterns than pixels, $p \ll N$.

The mechanism is worth naming because it recurs throughout this program.

Recall is **descent on an energy function** whose minima include the stored patterns.

Feeding in a corrupted pattern places the system on the energy surface near the right minimum, and the dynamics roll it down.

This is exactly the geometry behind **simulated annealing**, the method the book invokes for escaping *unwanted* local minima: add a controlled amount of random "shaking," large at first and declining over time, so the system can hop out of shallow spurious basins before settling into a deep one.

Annealing and stochastic Newton methods modify Newton's method to improve its global behavior without giving up its good local behavior.

The same principle, to experiment a lot early and less later, governs the classifier systems of *Money as a Medium of Exchange among Artificially Intelligent Agents*, whose genetic algorithm fires with a probability that declines like $1/\sqrt{t}$, and the softmax auction of Exercise 95.8.3, whose "temperature" $1/\beta$ plays the role of the shaking.

95.4 The genetic algorithm

The third brain departs from Newton's method more fundamentally: it does not descend a smooth surface at all.

Holland's **genetic algorithm** [Goldberg, 1989, Holland, 1975] searches "rugged landscapes" that lack the smoothness Newton's method needs, by evolving a *population* of candidate solutions encoded as binary strings.

The two approaches can be combined.

Ellen McGrattan applied genetic algorithms to estimate nonlinear rational expectations models: she first used a genetic algorithm to search for the vicinity of a maximum, then switched to a Newton method [Sargent, 1993].

The algorithm is handed two things: a nonnegative fitness function f to maximize, and an *encoding* that maps each binary string of length S to a candidate solution x.

Given a population of N strings, one generation applies four operators:

1. **Evaluation**: compute each string's fitness $f(x_i)$.
2. **Reproduction**: copy strings into the next generation, string i with probability $f(x_i)/\sum_j f(x_j)$, proportional to fitness (a "biased roulette wheel").

3. **Crossover**: pair strings up and swap their tails at a random cut point, forming children that recombine their parents' segments.
4. **Mutation**: flip each bit independently with a small probability p_m.

The parameters of the algorithm are N, S and p_m.

Our code below uses a common variant of reproduction called *windowing*: it subtracts the generation's lowest fitness before spinning the wheel.

When all fitnesses lie close together, as they will below, plain proportional selection barely discriminates among strings; windowing sharpens it, and gives the worst string essentially no chance to reproduce.

Reproduction concentrates the population on what already works; crossover and mutation inject new candidates.

Holland's account of why crossover helps is in terms of **schemata**.

A schema H is a template in $\{0, 1, *\}^S$, where $*$ matches either bit: `1**0*` is the set of strings of length 5 with a 1 in the first position and a 0 in the fourth.

Its *order* $o(H)$ is the number of fixed positions, and its *defining length* $\delta(H)$ is the distance between the first and the last of them.

Holland's **schema theorem** says that with fitness-proportional reproduction, single-point crossover applied to every pair, and mutation at rate p_m, the expected number of strings in H satisfies

$$\mathbb{E}\, m(H, t+1) \;\geq\; m(H, t)\, \frac{f(H)}{\bar{f}} \left[1 - \frac{\delta(H)}{S-1} - o(H)\, p_m \right],$$

where $f(H)$ is the average fitness of the strings in H and $\bar{f}$ that of the whole population (with windowing, read f as the windowed fitness).

Short, low-order schemata with above-average fitness therefore tend to multiply.

The bound covers one generation only.

The "building-block hypothesis," that the algorithm works by assembling short, fit schemata into better strings, is a heuristic rather than a theorem.

Whether it applies depends, in the book's words, "precisely on how a given problem has been encoded": on whether bits that work well together sit near one another.

The $*$ of a schema reappears as the $\#$ of a classifier's condition below.

Crucially, the individual strings do not learn: each lives one generation and dies.

Only the *society*, the sequence of populations, learns.

(Arifovic's election operator in *Exchange Rate Indeterminacy, Learning, and Experiments* softens this: a parent survives unless its child would have done better, so a good string can live for many generations.)

That is what makes the genetic algorithm awkward as a model of one brain, and a better fit as a model of a population or a market, a point that matters when we reach *Money as a Medium of Exchange among Artificially Intelligent Agents*.

95.4.1 Axelrod's iterated prisoner's dilemma

Axelrod [1987] used the genetic algorithm to evolve strategies for the **iterated prisoner's dilemma**, the game whose round-robin computer tournament, famously, was won by tit-for-tat.

He bred strategies against eight strategies representative of those submitted to his second tournament; we use a smaller panel.

Two players each choose to Cooperate or Defect; the payoffs reward defection against a cooperator but punish mutual defection.

```
# 1 = Cooperate, 0 = Defect;  T > R > P > S is the prisoner's dilemma ranking
T_pay, R_pay, P_pay, S_pay = 5, 3, 1, 0
PAYOFF = np.array([[P_pay, T_pay],       # row: my move (D, C); column: opponent's (D,
 ↪ C)
                   [S_pay, R_pay]])
```

Following Axelrod, a strategy is a **70-bit string**: a strategy conditions on the outcomes of the last three rounds.

Each round is one of four outcomes (my move, opponent's move), so three rounds give $4^3 = 64$ possible histories, and 64 bits specify the action in each.

The remaining 6 bits encode a presumed pre-game history to get the first moves going.

Our `play` function plays a whole population of strings at once, one row per string.

```
POW = 2 ** np.arange(5, -1, -1)          # reads 6 history bits as an integer 0..63

def play(pop, opponent, n_rounds=150):
    "Play every 70-bit string in pop against opponent; return average payoffs."
    pop = np.atleast_2d(pop)
    N = len(pop)
    action = pop[:, :64]
    idx = pop[:, 64:] @ POW                      # the presumed pre-game history
    mine = np.zeros((N, n_rounds), int)
    theirs = np.zeros((N, n_rounds), int)
    my_total, opp_total = np.zeros(N), np.zeros(N)
    for t in range(n_rounds):
        a = action[np.arange(N), idx]            # my move from the lookup table
        b = opponent(mine[:, :t], theirs[:, :t], t)
        my_total += PAYOFF[a, b]
        opp_total += PAYOFF[b, a]
        mine[:, t], theirs[:, t] = a, b
        idx = 32 * a + 16 * b + (idx >> 2)       # newest round in, oldest round out
    return my_total / n_rounds, opp_total / n_rounds
```

The strategy is bred to do well against a fixed panel of opponents.

Each panel member is a function of the histories *as that member sees them*: its first argument is what its opponent has played and its second is what it has played itself.

The Random member flips a fair coin each round.

To make comparisons fair, each generation draws one sequence of coin flips, and every string in the population faces that same sequence.

This device, **common random numbers**, makes differences in fitness within a generation reflect differences in strategy rather than luck of the draw.

```
def all_cooperate(opp_moves, own_moves, t): return np.ones(len(opp_moves), int)
def all_defect(opp_moves, own_moves, t):    return np.zeros(len(opp_moves), int)

def tit_for_tat(opp_moves, own_moves, t):
    return opp_moves[:, -1] if t > 0 else np.ones(len(opp_moves), int)

def grudger(opp_moves, own_moves, t):
    return opp_moves.all(axis=1).astype(int)     # cooperate until the first defection

def random_opponent(flips):
    "An opponent who plays coin flips drawn in advance: row k of flips in game k."
    return lambda opp_moves, own_moves, t: flips[:, t]

PANEL = {'AllC': all_cooperate, 'AllD': all_defect,
         'TFT': tit_for_tat, 'Grudger': grudger}

def fitness(pop, flips):
    "Average payoff of each string against the panel, Random included."
    opponents = list(PANEL.values()) + [random_opponent(flips)]
    return np.mean([play(pop, opp)[0] for opp in opponents], axis=0)
```

Tit-for-tat copies what its opponent last did, and the grudger defects forever once its opponent has defected once.

Both are themselves 70-bit strings.

Tit-for-tat's table copies the opponent's most recent move.

The grudger's table cooperates only after three rounds of mutual cooperation, which, starting from a cooperative pre-game history, is the same as never having seen a defection.

We use these two strings as benchmarks, and score any string by its payoff against each panel member, averaging over 400 fresh Random games (the same 400 for every string we compare).

```
TFT_GENE = np.r_[(np.arange(64) >> 4) & 1, np.ones(6, int)]
GRUDGER_GENE = np.r_[(np.arange(64) == 63).astype(int), np.ones(6, int)]

def panel_scores(gene, reps=400, seed=1):
    "Payoff against each panel member; Random is averaged over reps fresh games."
    flips = np.random.default_rng(seed).integers(0, 2, (reps, 150))
    scores = {name: play(gene, opp)[0][0] for name, opp in PANEL.items()}
    scores['Random'] = play(np.tile(gene, (reps, 1)), random_opponent(flips))[0].
 ↪mean()
    return scores

def panel_fitness(gene):
    return np.mean(list(panel_scores(gene).values()))

def first_move(gene):
    return 'C' if gene[:64][gene[64:] @ POW] else 'D'
```

Now evolve.

We display one run, with seed 16, chosen because its champion's fitness is close to the median of the twenty runs examined below.

```
def evolve(N=60, generations=80, p_mut=0.01, seed=0):
    rng = np.random.default_rng(seed)
    pop = rng.integers(0, 2, (N, 70))
    best_hist, mean_hist = [], []
```

(continues on next page)

(continued from previous page)

```
    for _ in range(generations):
        flips = rng.integers(0, 2, (1, 150))           # one coin sequence for␣
↪everyone
        fit = fitness(pop, flips)
        best_hist.append(fit.max())
        mean_hist.append(fit.mean())
        weight = fit - fit.min() + 1e-6                # windowing
        cum = np.cumsum(weight)
        parents = pop[np.searchsorted(cum, rng.random(N) * cum[-1])]
        mom, dad = parents[0::2], parents[1::2]
        left = np.arange(70) < rng.integers(1, 70, (N // 2, 1))   # single-point cuts
        pop = np.vstack([np.where(left, mom, dad), np.where(left, dad, mom)])
        pop[rng.random(pop.shape) < p_mut] ^= 1        # mutation
    fit = fitness(pop, rng.integers(0, 2, (1, 150)))
    return pop[fit.argmax()], np.array(best_hist), np.array(mean_hist)

champion, best_hist, mean_hist = evolve(seed=16)
print(f"generation 0:  best {best_hist[0]:.3f}, mean {mean_hist[0]:.3f}")
print(f"generation {len(best_hist)-1}: best {best_hist[-1]:.3f}, mean {mean_hist[-1]:.
↪3f}")
```

```
generation 0:  best 2.429, mean 1.941
generation 79: best 2.608, mean 2.397
```

The figure tracks the best and the mean fitness within each generation.

```
fig, ax = plt.subplots(figsize=(7.5, 4))
ax.plot(best_hist, label="best in population", lw=2)
ax.plot(mean_hist, label="population mean", lw=2)
ax.set_xlabel("generation")
ax.set_ylabel("panel fitness")
ax.legend(frameon=False)
plt.show()
```

The population mean climbs quickly for about a dozen generations and then fluctuates around 2.4, held down by the crossover and mutation that keep creating weaker strings.

The best string's fitness jumps around and drifts up slowly, to about 2.6 by the end.

It jumps around because each generation faces a new sequence of coin flips from Random, and because nothing guarantees that the best string survives reproduction, crossover, and mutation.

What kind of strategy did evolution find?

```
strategies = {'champion': champion, 'TFT': TFT_GENE, 'Grudger': GRUDGER_GENE}
table = {name: panel_scores(gene) for name, gene in strategies.items()}

print(f"{'payoff vs':>10}" + "".join(f"{name:>10}" for name in strategies))
for opp in table['champion']:
    print(f"{opp:>10}" + "".join(f"{table[name][opp]:>10.3f}" for name in strategies))
print(f"{'panel avg':>10}" + "".join(f"{np.mean(list(table[name].values())):>10.3f}"
                                     for name in strategies))
print(f"champion's first move: {first_move(champion)}")
```

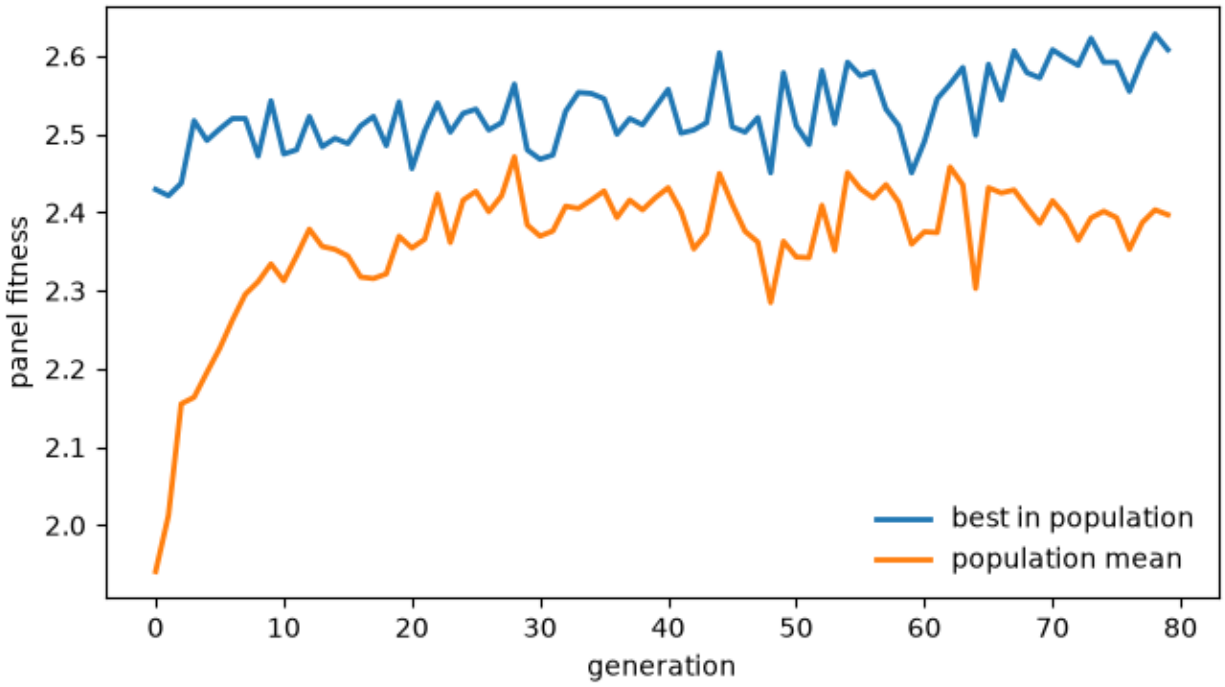

Fig. 95.3: Population fitness across generations

```
 payoff vs  champion       TFT   Grudger
      AllC     3.000     3.000     3.000
      AllD     0.987     0.993     0.993
       TFT     3.000     3.000     3.000
   Grudger     3.000     3.000     3.000
    Random     2.881     2.239     2.971
 panel avg     2.573     2.446     2.593
champion's first move: C
```

The evolved strategy is *nice*, in Axelrod's language: it is never the first to defect against AllC, TFT, or the grudger, and so earns the mutual-cooperation payoff of 3 against all three.

It refuses to be suckered by AllD after its first two rounds, and it defects against Random often enough to earn much more than tit-for-tat does.

Against this panel it beats tit-for-tat, and the margin comes almost entirely from Random.

It does not beat the grudger, a member of the panel, which does slightly better still.

Is this run typical?

The next cell repeats the experiment with twenty seeds.

```
results = []
for seed in range(20):
    sc = panel_scores(evolve(seed=seed)[0])
    nice = all(sc[k] == 3.0 for k in ('AllC', 'TFT', 'Grudger'))
    results.append((np.mean(list(sc.values())), nice))
fits = np.array([r[0] for r in results])
nice = np.array([r[1] for r in results])
tft_fit, grudger_fit = panel_fitness(TFT_GENE), panel_fitness(GRUDGER_GENE)
```

(continues on next page)

(continued from previous page)

```
print(f"nice champions: {nice.sum()} of 20")
print(f"champion fitness: median {np.median(fits):.3f}, "
      f"range [{fits.min():.3f}, {fits.max():.3f}]")
print(f"  nice ones: mean {fits[nice].mean():.3f};  others: mean {fits[~nice].mean():.
 ↪3f}")
print(f"beat TFT ({tft_fit:.3f}): {np.sum(fits > tft_fit)} of 20")
print(f"within 0.01 of Grudger ({grudger_fit:.3f}): {np.sum(fits > grudger_fit - 0.
 ↪01)} of 20;"
      f"  above it: {np.sum(fits > grudger_fit)}")
```

```
nice champions: 15 of 20
champion fitness: median 2.576, range [2.481, 2.594]
  nice ones: mean 2.550;  others: mean 2.556
beat TFT (2.446): 20 of 20
within 0.01 of Grudger (2.593): 7 of 20;  above it: 1
```

Most champions are nice, but not all.

The rest are *probe-and-exploit* strategies: at some point they defect unprovoked, which wins 5 a round forever against AllC and plunges them into mutual defection with the grudger.

The panel makes the two families almost exactly equal.

AllC and the grudger behave identically until someone defects, so a strategy cannot tell them apart without probing.

A probe gains 2 a round against AllC and loses 2 a round against the grudger, so the two families tie on that pair of opponents.

Which family the algorithm lands on is a matter of the seed: a small instance of a rugged landscape with two peaks of almost equal height.

The panel also has a ceiling.

No strategy can average more than 1 against AllD, more than 3 against Random (against a coin, defection is better whatever the coin shows), more than about 3 against tit-for-tat, or more than about 6 against AllC and the grudger together.

So panel fitness cannot exceed about $13/5 = 2.6$, and the grudger is already within 0.01 of that ceiling.

Every champion beats tit-for-tat, but none beats the grudger by more than a rounding error.

Axelrod's own genetic algorithm, as Sargent [1993] summarizes it, "produced a strategy that would have won the tournament, and in particular would have outplayed the 'tit-for-tat' strategy that won the tournament."

Our toy version reproduces the second half of that sentence, and shows where the edge comes from.

It is not extra memory: the grudger needs only one bit of memory, and does as well as any champion.

It is refusing to forgive: against Random, tit-for-tat keeps returning to cooperation and gets suckered, while the grudger and the best champions settle into defection.

And, as Sargent notes, such comparisons flatter the genetic algorithm, because it "got to practice against" its opponents, while the strategies submitted to a tournament could only guess what they would face.

95.5 Classifier systems

The genetic algorithm evolves a population in which no individual learns.

Holland's **classifier system** puts the same evolutionary machinery *inside a single agent*, as a model of one brain [Holland *et al.*, 1986].

Sargent describes it as Holland's vision of the mind as a **competitive economy**:

> The statements compete with one another for the opportunity to decide. The classifier system incorporates elements of the genetic algorithm with other aspects in a way that represents a brain in terms that Holland describes as a competitive economy.

A classifier system has five parts:

- **Classifiers**, if-then rules encoded as strings over the trinary alphabet $\{0, 1, \#\}$, with a condition part that is matched against the state and an action part that prescribes a move.
- **A decoder** that, given the current state, finds which classifiers' conditions match.
- **An auction** that selects one matching classifier to act.
- **An accounting system** that updates each classifier's **strength** from the payoffs that follow its decisions and, in sequential problems, passes payoffs *backward* along the chain of rules that produced them.
- **A device for creating new classifiers**, so that the system's very vocabulary evolves:
  - when no classifier matches the state, one is created whose condition matches it and whose action is random;
  - now and then new rules replace weak ones, so that untried actions get tried;
  - rules are *generalized* (0's and 1's replaced by #'s) or *specialized* (#'s replaced by 0's and 1's), often by genetic operators.

We take the decoder and the auction first, then the accounting system, through two examples: the bandit and the bucket brigade.

95.5.1 Matching, specificity, and bids

A state matches a condition if they agree in every position where the condition does not have a #, the "I don't care" symbol.

The condition `1#0` matches the states `100` and `110` and nothing else.

A rule with many #'s is *general*: its condition is met often.

A rule with few is *specific*.

Marimon *et al.* [1990] measure the specificity of a classifier e by $\sigma_e = 1/(1 + \text{number of } \#\text{'s in } e)$.

```
def matches(condition, state):
    "A state matches if it agrees with every position that is not '#'."
    return all(c in ('#', s) for c, s in zip(condition, state))

def specificity(condition):
    return 1 / (1 + condition.count('#'))

state = '110'
for condition in ('110', '1#0', '##0', '###', '0##'):
    print(f"condition {condition}: matches {state}? {str(matches(condition, state)):5}
 ↪  "
          f"specificity {specificity(condition):.2f}")
```

```
condition 110: matches 110? True   specificity 1.00
condition 1#0: matches 110? True   specificity 0.50
condition ##0: matches 110? True   specificity 0.33
condition ###: matches 110? True   specificity 0.25
condition 0##: matches 110? False  specificity 0.33
```

Several rules usually match at once, and they may disagree about what to do.

Each matched rule e bids a fraction $b(e)$ of its strength S_e, a fraction that rises with its specificity:

$$B_e = b(e)\, S_e, \qquad b(e) = b_{11} + b_{12}\, \sigma_e,$$

where, in the notation of Marimon *et al.* [1990], b_{11} and b_{12} are positive constants that sum to less than one.

When a general rule and a specific one are equally strong, the specific one outbids it, so an auction on bids favors it.

This is how a classifier system handles the trade-off that the book calls *generality versus discrimination*.

General rules are tested often, because their conditions are often met, but they prescribe the same action across many states.

Specific rules can fit the action to the state, but they need long histories before their strengths mean much.

The trade-off resembles the one between parametric and non-parametric estimation (*Learning without a functional form*).

With a specificity premium, a specific rule can carve out an exception to a general one, and the balance between generality and specificity can itself evolve as rules are generalized and specialized.

95.5.2 The auction

The auction turns bids into a decision.

The book lists two principles: the highest bidder wins, or each matched rule wins with probability equal to its relative strength.

Both belong to one family, the **softmax**:

$$\Pr(e \text{ wins}) = \frac{\exp(\beta B_e)}{\sum_{e' \in M} \exp(\beta B_{e'})},$$

where M is the set of matched rules.

As $\beta \to \infty$ the softmax puts all its weight on the highest bid, so the **argmax auction** is its limit.

Applied to the logarithms of strengths with $\beta = 1$, it gives the relative-strength rule, since $\exp(\ln S_e) / \sum_{e'} \exp(\ln S_{e'}) = S_e / \sum_{e'} S_{e'}$.

The parameter β sets how much the system experiments.

The argmax auction never lets a rule that looks worse act, so it can never discover that the rule is in fact better; with a finite β, the system always might.

Money as a Medium of Exchange among Artificially Intelligent Agents uses an argmax auction applied to strengths rather than bids: there the strongest matched rule acts, bids only set the payments of the bucket brigade, and all experimentation is left to the operators for creating rules.

95.5.3 A two-armed bandit

The simplest classifier system is an example of Brian Arthur and Carl Simon, who presented it independently at the Santa Fe Institute in 1989 (see also Arthur [1991]).

Arm i pays a random reward with mean $\mu_i > 0$, with $\mu_1 > \mu_2$, and the player knows neither distribution.

The classifier system holds two rules, `#1` ("whatever the history, pull arm 1") and `#0` ("pull arm 2"), whose conditions are always met.

Arthur's accounting sets the strength of rule i to the average payoff its arm has delivered,

$$S_{i,\tau_i} = S_{i,\tau_i - 1} + \frac{1}{\tau_i}\left(x_{i,\tau_i} - S_{i,\tau_i - 1}\right),$$

where τ_i counts the times arm i has been pulled, and the auction picks rule i with probability $S_i/(S_1 + S_2)$.

The two rules start with **equal** strengths: the system is told nothing about either arm and must build its estimates out of the rewards it experiences.

```
def two_armed_bandit(μ, noise_sd=0.5, T=20_000, seed=0):
    "Strength = running average of an arm's payoff; pull ∝ strength."
    rng = np.random.default_rng(seed)
    S = np.ones(2)                              # equal strengths: no prior knowledge
    τ = np.array([1, 1])                        # pull counters
    pulls = np.empty(T, int)
    for t in range(T):
        w = np.maximum(S, 1e-9)                 # guard against a dip below zero
        i = 0 if rng.random() < w[0] / w.sum() else 1
        reward = μ[i] + noise_sd * rng.standard_normal()
        τ[i] += 1
        S[i] += (reward - S[i]) / τ[i]          # running average
        pulls[t] = i
    return pulls

pulls = two_armed_bandit([3.0, 1.0])
frac_best = np.cumsum(pulls == 0) / np.arange(1, len(pulls) + 1)

fig, ax = plt.subplots(figsize=(7.5, 4))
ax.plot(frac_best, lw=1)
ax.axhline(0.75, color='k', ls='--', label="probability match  $\\mu_1/(\\mu_1+\\mu_2)
↪$")
ax.axhline(1.0, color='C3', ls=':', label="optimal (always best arm)")
ax.set_xlabel("$t$")
ax.set_ylabel("fraction of pulls on the best arm")
ax.set_ylim(0.5, 1.05)
ax.legend(frameon=False)
plt.show()
```

The fraction of pulls on the better arm converges, but **not to one**.

It converges to $\mu_1/(\mu_1 + \mu_2)$, the arm's share of total expected reward.

```
for μ in ([1.0, 0.5], [2.0, 1.0], [3.0, 1.0]):
    frac = np.mean(two_armed_bandit(μ)[-5000:] == 0)
    print(f"μ = {μ}: fraction on best arm = {frac:.3f}, "
          f"probability match = {μ[0]/(μ[0]+μ[1]):.3f}  (optimal = 1.0)")
```

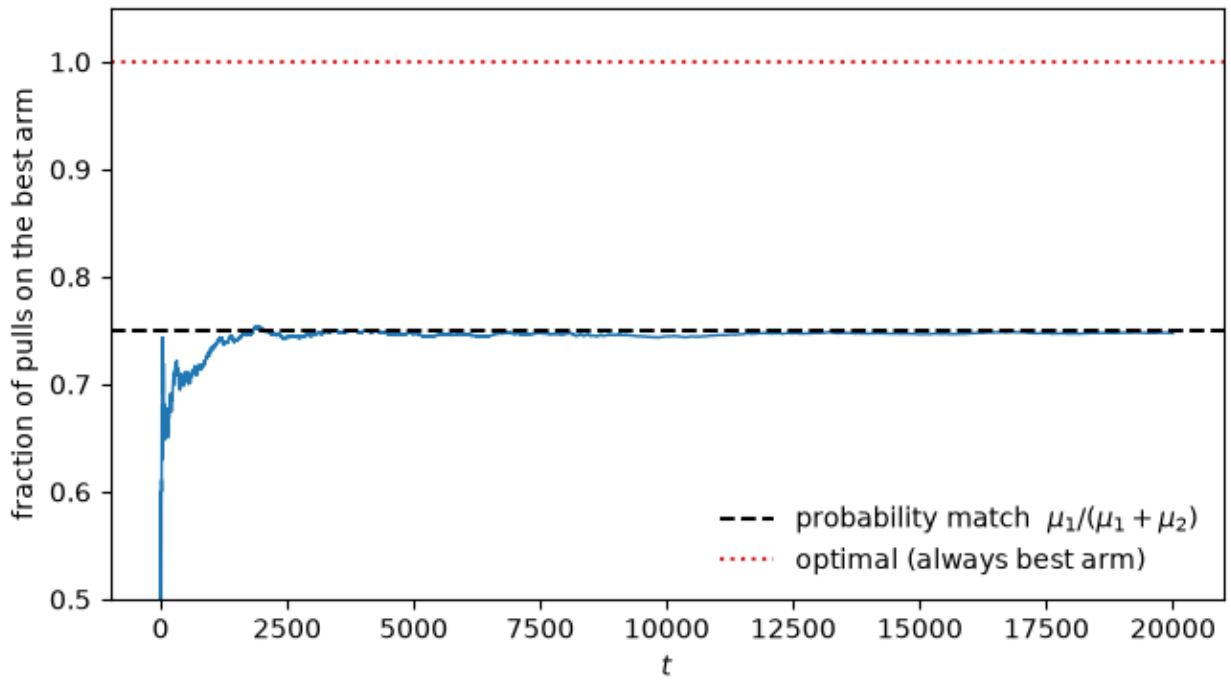

Fig. 95.4: The classifier bandit converges to probability matching

```
μ = [1.0, 0.5]: fraction on best arm = 0.655, probability match = 0.667  (optimal␣
↪= 1.0)
μ = [2.0, 1.0]: fraction on best arm = 0.659, probability match = 0.667  (optimal␣
↪= 1.0)
μ = [3.0, 1.0]: fraction on best arm = 0.750, probability match = 0.750  (optimal␣
↪= 1.0)
```

Arthur showed, by the methods of stochastic approximation, that the strength-proportional classifier **probability-matches**.

The argument is short.

As long as the strengths stay positive, which needs $\mu_i > 0$, each arm keeps a positive probability of being pulled, and so is pulled infinitely often.

Each strength is the sample mean of its arm's payoffs, so it converges to μ_i by the strong law of large numbers.

The auction's probabilities therefore converge to $\mu_1/(\mu_1 + \mu_2)$, and so does the fraction of pulls on arm 1.

The classifier plays the arms in proportion to their expected rewards rather than concentrating on the best one, so it leaves reward on the table forever.

With $\mu = (3, 1)$ it earns $0.75 \times 3 + 0.25 \times 1 = 2.5$ a pull, against 3 for always pulling arm 1.

The proportional rule also cares only about the ratio μ_1/μ_2: $\mu = (1, 0.5)$ and $\mu = (2, 1)$ produce the same shares.

Notice where the trouble lies.

The accounting is fine: each strength converges to the right number, its arm's mean payoff.

The trouble is the **auction**, which turns correct strengths into choice probabilities proportional to them.

Exercise 95.8.3 cures probability matching by changing the auction alone.

That separates two jobs.

The auction governs the balance between exploring and exploiting.

The accounting governs *credit assignment*, which is trivial in the bandit, where each payoff belongs to the arm that produced it, but hard in sequential problems.

95.5.4 The bucket brigade

In a sequential problem, a rule's decision may pay off only later, through a chain of further decisions.

The accounting must then reward a rule for merely *setting up* a profitable future decision.

Holland's device for this is the **bucket brigade**: each rule that wins an auction pays its bid to the rule that acted just before it, the one that moved the system into the state where the current rule could act.

A rule's receipts are the payoff it collects from the environment plus the bid paid to it by its successor.

Take the shortest chain.

A *setup* rule s acts first and moves the system into a state where a *payoff* rule p acts and collects R.

Rule p pays its bid bS_p back to s; to keep things simple, every rule bids the same fraction b of its strength.

Holland kept strengths as **cumulative balances**: a rule that acts pays out its bid and takes in its receipts, like a bank account, so that $S \leftarrow S - bS + \text{receipts}$.

Arthur, in the bandit, and Marimon *et al.* [1990], in the economy of the next lecture, **average** instead:

$$S_\tau = S_{\tau-1} + \frac{1}{\tau}\left[\text{receipts}_\tau - (1+b)\, S_{\tau-1}\right],$$

where τ counts the times the rule has acted, so that strength is a running average of receipts net of the bid.

With $b = 0$ this is the bandit's running average.

The code runs both accountings on the chain, starting from zero strengths, with $R = 1$ and $b = 0.1$.

```
def bucket_brigade(R=1.0, b=0.1, passes=10_000, accounting='average'):
    "Two-link chain: the setup rule acts, then the payoff rule acts and earns R."
    S = np.zeros(2)                                  # strengths of [setup, payoff]
    path = []
    for τ in range(1, passes + 1):
        receipts = np.array([b * S[1], R])           # the payoff rule pays its bid back
        if accounting == 'average':                  # Arthur; Marimon-McGrattan-Sargent
            S = S + (receipts - (1 + b) * S) / τ
        else:                                        # Holland's cumulative balance
            S = S - b * S + receipts
        path.append(S.copy())
    return np.array(path)

for accounting in ('balance', 'average'):
    path = bucket_brigade(accounting=accounting)
    print(f"{accounting}: [setup, payoff] after passes 1, 2, 3: "
          f"{path[0].round(3)}, {path[1].round(3)}, {path[2].round(3)};  "
          f"limit {path[-1].round(3)}")
```

```
balance: [setup, payoff] after passes 1, 2, 3: [0. 1.], [0.1 1.9], [0.28 2.71]; ␣
↪limit [10. 10.]
average: [setup, payoff] after passes 1, 2, 3: [0. 1.], [0.05 0.95], [0.063 0.935];
↪  limit [0.083 0.909]
```

Two things stand out.

First, credit moves back **one link per pass**.

In the first pass the payoff rule collects R but the setup rule receives nothing, because the payoff rule's strength, and hence its bid, was still zero when it paid.

In a chain of k links, the payoff takes $k-1$ passes to reach the first rule.

Second, the two accountings disagree about what the setup rule is worth.

Cumulative balances come to rest where receipts equal the bid, $bS_p = R$ and $bS_s = bS_p$, so $S_s = S_p = R/b$: the setup rule ends up exactly as strong as the payoff rule.

Averages come to rest where $(1+b)S_p = R$ and $(1+b)S_s = bS_p$, so

$$S_p = \frac{R}{1+b}, \qquad S_s = \frac{b}{1+b}\, S_p.$$

Each link back along the chain scales strength by $b/(1+b)$, about 0.09 when $b = 0.1$.

The averaging accounting values a setup rule as if it discounted the future very heavily, a fact with large consequences in *Money as a Medium of Exchange among Artificially Intelligent Agents* (*The bucket brigade's discount factor*).

Exercise 95.8.5 asks when a setup rule can beat a rule that pays off at once.

Why average, then?

Holland's balance with bids proportional to strength can be written $S \leftarrow S + b\,(\text{receipts}/b - S)$, a *constant-gain* average of receipts$/b$, which keeps fluctuating as long as the receipts are random.

The $1/\tau$ gain turns it into a decreasing-gain stochastic approximation of the kind studied in *One recursion, many learners*.

Its limit is a rest point of the mean dynamics $dS/d\tau = \mathbb{E}[\text{receipts}] - (1+b)S$, which is what makes strengths converge and lets the next lecture characterize their limits.

The bucket brigade is also an ancestor of **temporal-difference learning** [Sutton and Barto, 2018].

A rule's strength is moved toward what it earns now plus a fraction of the strength of the rule it hands the system to.

The Q-learning of *Job Search X: Search with Q-Learning* and *Inventory Management via Q-Learning* moves the value of a state-action pair toward the current reward plus the discounted value of the next state in the same way, with the successor's bid playing the role of that discounted value.

Designing that backward flow is the central craft of building a classifier system, and it is exactly what *Money as a Medium of Exchange among Artificially Intelligent Agents* must get right to make agents learn to accept money today for the sake of a trade tomorrow.

95.6 Evolutionary programming

We have surveyed four brains.

The last idea is about what to *do* with them.

Many of the systems of adaptive agents in this series, however plodding, find their way to an equilibrium.

The least squares learners of *Adaptive Agents in an Overlapping Generations Monetary Economy* converge to a stationary equilibrium, and the learners of *Learning, Approximation, and Equilibrium Computation* to the best approximate equilibrium their functional form allows.

At Sargent's calibration, the Newton learners of *Exchange Rate Indeterminacy, Learning, and Experiments* converge to one of a continuum of equilibria, picked out by history.

Not all of them do.

The same Newton learners fail to converge at Arifovic's calibration.

And the genetic-algorithm economy of *Exchange Rate Indeterminacy, Learning, and Experiments* never settles down (*A genetic algorithm economy*): its saving rate settles near the equilibrium value, but mutation keeps injecting new strings, and its exchange rate keeps fluctuating with a volatility that does not die out.

Evolutionary programming turns the tendency to converge into a tool.

If a population of adaptive agents reliably converges to an equilibrium, we can run the population as a *method for computing* the equilibrium, especially in models too complicated to solve by hand.

The genetic-algorithm economy is a reminder that the reliability has to be designed in: the experimentation must die away, as annealing's shaking does, if the population is to come to rest.

Sargent is careful about what is and isn't going on:

> The adaptive agents are 'teaching' the economist in the same sense that any numerical algorithm for solving nonlinear equations 'teaches' a mathematician. When these agents can 'teach' us something, it is because we designed them to do so.

This is the same duality that ran through *Learning, Approximation, and Equilibrium Computation*: a learning economy is a decentralized equilibrium computation, and an equilibrium computation is a centralized learning algorithm.

The genetic algorithm and the classifier system are simply richer computational engines than recursive least squares, able to search rugged landscapes and to discover the structure of a good rule, not just tune the coefficients of a fixed one.

The showcase is Kiyotaki and Wright [1989]'s search-theoretic model of money, in which the medium of exchange is not assumed but must **emerge** from how agents choose to trade.

The equilibrium is a set of trading strategies and matching probabilities, and for enriched versions of the model it is hard to characterize analytically.

Marimon *et al.* [1990] put populations of Holland classifier systems into that environment and watched them converge to an equilibrium, then built a five-good version, with no known analytical solution, and let the classifier systems suggest what the equilibrium looked like.

95.7 Concluding remarks

The four brains in this catalogue differ in what they take as given.

The perceptron is handed a functional form and asked only for its coefficients, which is why an econometrician recognizes it immediately.

The Hopfield network is handed the patterns themselves and asked only to recall them.

The genetic algorithm is handed an encoding and a fitness function and must search a space in which it cannot compute a gradient.

The classifier system is handed a vocabulary in which rules can be written and must discover which rules are worth holding.

Moving down that list, we hand the agent less and ask it to find more, which is precisely the direction the bounded-rationality program pushes us.

Three cautions emerged along the way, and all three return in the next lecture.

The genetic algorithm's individuals do not learn: only the population does, which makes it a model of a society rather than of a mind, and a population that never stops experimenting, as in *Exchange Rate Indeterminacy, Learning, and Experiments*, need not settle down.

The bandit showed that a classifier system's behavior is decided by its auction and its accounting rather than by the fact of having classifiers at all: the auction decides how much it experiments, and the accounting how it assigns credit.

And the bucket brigade showed that the accounting builds in a valuation of the future: with averaged strengths, a rule that sets up a payoff one link away is worth only a fraction $b/(1+b)$ of the rule that collects it.

Money as a Medium of Exchange among Artificially Intelligent Agents assembles this machinery into agents who must learn, from scratch, which good to use as money.

Their rules have conditions over $\{0, 1, \#\}$ and bid in proportion to strength with a specificity premium; an argmax auction on strength picks among them; a bucket brigade links each trade to the consumption it makes possible; and a genetic algorithm whose activity dies away over time refreshes them.

All three cautions bear directly on what those agents turn out to be able to learn.

95.8 Exercises

Exercise 95.8.1

The Hopfield network's recall is descent on the energy $E(s) = -\frac{1}{2} s^\top w s$.

Verify the descent directly.

Take a stored letter, corrupt several pixels, and record the energy at each step of the recall dynamics.

Confirm that energy never increases, and that a recall that ends at a stored letter ends at energy $-N/2$, the lowest energy any state can have.

Then prove that energy cannot increase under the synchronous update $s' = \operatorname{sgn}(ws)$ when w is the projection-rule matrix.

Finally, corrupt patterns more heavily and classify the failures: does recall land on a *different* stored letter, or on a *spurious* state that was never stored?

Compare the energies in each case, and use them to explain why the error happens.

Solution

Here is a version of `recall` that records the energy at every step.

```
def recall_with_energy(w, s0, max_iter=30):
    s = s0.copy()
    trace = [energy(w, s)]
    for _ in range(max_iter):
        s_new = np.sign(w @ s)
        s_new[s_new == 0] = 1
        trace.append(energy(w, s_new))
        if np.array_equal(s_new, s):
            break
        s = s_new
    return s, trace

rng = np.random.default_rng(1)
i = letters.index('E')
corrupt = σ[i].copy()
corrupt[rng.choice(25, 5, replace=False)] *= -1
final, trace = recall_with_energy(w_hop, corrupt)
```

```
print(f"energy along the recall path: {[round(e, 2) for e in trace]}")
print(f"monotonically non-increasing: {all(np.diff(trace) <= 1e-9)}")
print(f"recovered the intended letter 'E': {np.array_equal(final, σ[i])}")
```

```
energy along the recall path: [np.float64(-6.38), np.float64(-12.5), np.
↪float64(-12.5)]
monotonically non-increasing: True
recovered the intended letter 'E': True
```

The energy falls from its corrupted value to $-N/2 = -12.5$ and stays there.

Here is why it cannot rise.

Let $s' = \text{sgn}(ws)$ and $d = s' - s$.

Expanding the quadratic form, and using the symmetry of w,

$$E(s') - E(s) = -d^\top ws - \tfrac{1}{2}\, d^\top w d.$$

Each nonzero entry of d is $d_i = 2s'_i = 2\,\text{sgn}((ws)_i)$, so the first term is $-2\sum_i |(ws)_i|$, summed over the flipped pixels, and is never positive.

The second term is never positive either, because the projection matrix w is positive semidefinite.

So the energy never rises, and it falls strictly whenever a pixel flips against a nonzero field.

Since there are finitely many states, recall cannot cycle and must halt at a fixed point.

(Ties are broken toward $+1$, as in the code, so a pixel can only flip from $+1$ to -1 against a strictly negative field, and that strict fall rules out cycles.)

The argument uses positive semidefiniteness, which the projection rule has.

The usual Hebb rule with its diagonal set to zero does not have it, and with such weights, updating all pixels at once can cycle between two states.

Hopfield's own energy argument [Hopfield, 1982] is for updating one pixel at a time.

Now corrupt more heavily and sort the outcomes into three kinds: the intended letter, a *different* stored letter, and a spurious state that is a fixed point but was never taught.

The code also checks monotonicity on every one of the 1000 recall paths, and looks at the spurious states that sit at the lowest possible energy.

```
def classify_outcome(final, i):
    if np.array_equal(final, σ[i]):
        return "intended"
    if any(np.array_equal(final, σ[k]) for k in range(len(letters))):
        return "wrong letter"
    return "spurious"

counts = {"intended": 0, "wrong letter": 0, "spurious": 0}
wrong_energy, spurious_energy, deepest = [], [], []
always_downhill = True
for i in range(len(letters)):
    for seed in range(200):
        r = np.random.default_rng(1000*i + seed)
        corrupt = σ[i].copy()
        corrupt[r.choice(25, 7, replace=False)] *= -1
        final, trace = recall_with_energy(w_hop, corrupt)
        always_downhill &= all(np.diff(trace) <= 1e-9)
        kind = classify_outcome(final, i)
```

```
        counts[kind] += 1
        if kind == "wrong letter":
            wrong_energy.append(energy(w_hop, final))
        elif kind == "spurious":
            spurious_energy.append(energy(w_hop, final))
            if np.isclose(energy(w_hop, final), -12.5):
                deepest.append(final)

negatives = sum(any(np.array_equal(s, -σ[k]) for k in range(len(letters))) for s␣
↪in deepest)
print(f"7-pixel corruptions ({sum(counts.values())} trials): {counts}")
print(f"energy non-increasing on every path: {always_downhill}")

↪energy):.1f}]")
print(f"spurious results:     energy in [{min(spurious_energy):.1f}, {max(spurious_
↪energy):.1f}]")
print(f"spurious results at energy -N/2: {len(deepest)}, "
      f"of which sign-reversed letters: {negatives}")
```

```
7-pixel corruptions (1000 trials): {'intended': 404, 'wrong letter': 62,
↪'spurious': 534}
energy non-increasing on every path: True
stored patterns all have energy -12.5
wrong-letter results: energy in [-12.5, -12.5]
spurious results:     energy in [-12.5, -10.4]
spurious results at energy -N/2: 41, of which sign-reversed letters: 3
```

Both failure modes occur, and at this level of corruption spurious states outnumber wrong letters by almost nine to one.

A **wrong-letter** result sits at exactly the stored energy $-N/2$: the corruption pushed the starting point clear across a basin boundary, into the domain of attraction of a *different* stored memory that is just as deep.

Energy descent converges to *a* minimum but cannot guarantee the *nearest* one when correlated patterns have interlocking basins.

A **spurious** result is a fixed point the designer never intended, created as an artifact of the storage rule.

Most spurious results are shallower than the stored patterns: they are fixed points outside the span of the letters, most of them local minima.

A minority sit at exactly $-N/2$, which requires them to lie in that span.

Some of those are photographic negatives of letters: because $\operatorname{sgn}(w(-s)) = -\operatorname{sgn}(ws)$, the vector $-\sigma$ is a fixed point whenever σ is.

Most are signed mixtures of letters that happen to be ± 1 vectors, such as $E - I + T$ and $A - E + I$.

Depth alone therefore does not identify a memory as one we asked for.

Because all of these are fixed points of the update, the dynamics cannot escape any of them.

That is why **simulated annealing** matters: adding declining random shaking lets the system hop out of a shallow spurious basin, or across a basin boundary, before settling, something pure energy descent can never do.

Exercise 95.8.2

The genetic algorithm's exploration comes from two operators, crossover and mutation.

The book argues that crossover "lies at the heart of the algorithm," while mutation alone "is a poor mechanism for injecting diversity."

Test the claim on Axelrod's game.

Write a mutation-only variant (each child is a mutated copy of one selected parent, with no crossover) and compare the fitness it reaches against the full algorithm.

Score each run by its champion's `panel_fitness`, so that every strategy faces the same Random games, and use several seeds.

The book is careful to say *when* mutation alone is weak: "when the mutation rate is set to a very low value, mutation alone is a poor mechanism for injecting diversity."

So run the comparison at a **low** mutation rate, $p_m = 0.002$, where crossover has to carry the exploration, and then at a higher one, $p_m = 0.02$.

Solution

The mutation-only variant keeps the windowed roulette wheel and drops crossover.

```
def evolve_mutation_only(N=60, generations=60, p_mut=0.002, seed=0):
    "Each child is a mutated copy of one roulette-selected parent."
    rng = np.random.default_rng(seed)
    pop = rng.integers(0, 2, (N, 70))
    for _ in range(generations):
        fit = fitness(pop, rng.integers(0, 2, (1, 150)))
        weight = fit - fit.min() + 1e-6
        cum = np.cumsum(weight)
        pop = pop[np.searchsorted(cum, rng.random(N) * cum[-1])]
        pop[rng.random(pop.shape) < p_mut] ^= 1
    fit = fitness(pop, rng.integers(0, 2, (1, 150)))
    return pop[fit.argmax()]

n_seeds = 12
for p_mut in (0.002, 0.02):
    gaps = []
    for seed in range(n_seeds):
        with_x = panel_fitness(evolve(generations=60, p_mut=p_mut, seed=seed)[0])
        without_x = panel_fitness(evolve_mutation_only(p_mut=p_mut, seed=seed))
        gaps.append(with_x - without_x)
    gaps = np.array(gaps)
    print(f"p_mut = {p_mut}: crossover minus mutation-only = {gaps.mean():.3f} "
          f"(standard error {gaps.std(ddof=1) / np.sqrt(n_seeds):.3f}); "
          f"crossover ahead in {np.sum(gaps > 0)} of {n_seeds} seeds")
```

```
p_mut = 0.002: crossover minus mutation-only = 0.070 (standard error 0.017);␣
↪crossover ahead in 11 of 12 seeds
p_mut = 0.02: crossover minus mutation-only = -0.010 (standard error 0.020);␣
↪crossover ahead in 6 of 12 seeds
```

At the low mutation rate crossover clearly wins: its champion is fitter in almost every seed.

At the higher rate the advantage shrinks to near zero: in these seeds the average gap is within one standard error of zero, and crossover is ahead in only about half of them.

The reason is the one the book gives.

With little mutation, a mutation-only population can only inch forward one rare bit-flip at a time, and it quickly loses

diversity as selection copies its few best strings.

Crossover instead recombines segments of strings that have already proved useful.

In this encoding a block of 16 consecutive table entries is a set of histories that share the most recent round's outcome, so crossover splices one string's responses to some recent outcomes onto another string's responses to others.

That is the schema story, though the schema theorem guarantees only that short, fit blocks tend to survive, not that splicing them improves the string.

When mutation generates plenty of diversity on its own, crossover's contribution is no longer pivotal, which is the book's qualification: it is at a very low mutation rate that mutation alone is weak.

Exercise 95.8.3

The two-armed bandit classifier probability-matches, which is suboptimal: it keeps pulling the worse arm a fixed fraction of the time forever.

A natural fix is to make the auction **greedier**.

Replace the strength-proportional choice rule with a softmax,

$$\pi_1 = \frac{e^{\beta S_1}}{e^{\beta S_1} + e^{\beta S_2}},$$

where β controls greediness ($\beta \to \infty$ always picks the stronger arm).

1. Implement it and show how the long-run fraction on the best arm depends on β, for $\mu = (3, 1)$.
2. How large must β be for the softmax to beat probability matching?
3. Now make the arms hard to tell apart: $\mu = (1.2, 1.0)$ with reward noise of standard deviation 2. Compare $\beta = 2$ with a very greedy $\beta = 32$ across 40 seeds. What does greed cost?

Solution

The softmax bandit changes only the line that chooses the arm.

```
def bandit_softmax(μ, β, noise_sd=0.5, T=20_000, seed=0):
    "Share of the last 5000 pulls on arm 1 under a softmax auction."
    rng = np.random.default_rng(seed)
    S = np.ones(2)                              # equal strengths, as before
    τ = np.array([1, 1])
    pulls = np.empty(T, int)
    for t in range(T):
        p1 = 1 / (1 + np.exp(-β * (S[0] - S[1])))
        i = 0 if rng.random() < p1 else 1
        reward = μ[i] + noise_sd * rng.standard_normal()
        τ[i] += 1
        S[i] += (reward - S[i]) / τ[i]
        pulls[t] = i
    return np.mean(pulls[-5000:] == 0)

μ = [3.0, 1.0]
β_star = np.log(μ[0] / μ[1]) / (μ[0] - μ[1])
print(f"probability match target = {μ[0]/(μ[0]+μ[1]):.3f},  optimal = 1.000,  "
      f"break-even β = {β_star:.3f}\n")
```

```
for β in (0.5, 1.0, 2.0, 4.0, 8.0):
    theory = 1 / (1 + np.exp(-β * (μ[0] - μ[1])))
    print(f"β = {β:>4}: fraction on best arm = {bandit_softmax(μ, β):.3f}  "
          f"(limit {theory:.3f})")
```

```
probability match target = 0.750,  optimal = 1.000,  break-even β = 0.549

β =  0.5: fraction on best arm = 0.732  (limit 0.731)
β =  1.0: fraction on best arm = 0.888  (limit 0.881)
β =  2.0: fraction on best arm = 0.980  (limit 0.982)
β =  4.0: fraction on best arm = 1.000  (limit 1.000)
β =  8.0: fraction on best arm = 1.000  (limit 1.000)
```

The softmax keeps every arm's probability bounded away from zero, so each arm is pulled infinitely often and its strength converges to μ_i, as in the proportional case.

The long-run share on arm 1 is therefore $1/(1+e^{-\beta(\mu_1-\mu_2)})$, the "limit" column, which the simulations match.

It beats the probability-matching share $\mu_1/(\mu_1+\mu_2)$ exactly when $e^{-\beta(\mu_1-\mu_2)} < \mu_2/\mu_1$, that is, when

$$\beta > \frac{\ln(\mu_1/\mu_2)}{\mu_1-\mu_2} = \frac{\ln 3}{2} \approx 0.55.$$

So $\beta = 0.5$ does slightly *worse* than probability matching, and from $\beta = 1$ on the softmax does better, approaching the optimal policy as β rises.

Unlike the proportional rule, the softmax depends on the difference $\mu_1 - \mu_2$, not the ratio, so the threshold depends on the units of the payoffs.

Greed has a cost when the arms are hard to tell apart.

```
for β in (2.0, 32.0):
    shares = np.array([bandit_softmax([1.2, 1.0], β, noise_sd=2.0, seed=s)
                       for s in range(40)])
    print(f"β = {β:>4}: mean share on the better arm {shares.mean():.3f}; "
          f"runs ending mostly on the worse arm: {np.sum(shares < 0.5)} of 40")
```

```
β =  2.0: mean share on the better arm 0.597; runs ending mostly on the worse␣
↪arm: 0 of 40
β = 32.0: mean share on the better arm 0.675; runs ending mostly on the worse␣
↪arm: 13 of 40
```

With $\beta = 32$ the auction concentrates quickly, and in these 40 runs that raises the average share on the better arm above that of $\beta = 2$.

The gain is not robust, though: over 400 seeds the two averages are 0.63 and 0.60, about one standard error apart.

And in about a third of the runs the auction concentrates on the *worse* arm.

A few unlucky early payoffs make the better arm look worse, after which it is almost never pulled, so its strength is almost never corrected: the system **locks in**.

With $\beta = 2$ the system never locks onto the worse arm, but it never concentrates either.

The softmax is the Boltzmann distribution of statistical mechanics with temperature $1/\beta$.

Getting both benefits requires starting hot and cooling slowly, letting $\beta_t \to \infty$ over time, which is simulated annealing again.

The argmax auction of *Money as a Medium of Exchange among Artificially Intelligent Agents* is the $\beta = \infty$ limit, which locks in whenever it is wrong; that is why its classifier systems need separate operators for experimentation, whose activity is made to decline over time.

So the exercise makes concrete why the *auction* and the *accounting*, and not just the fact of having classifiers, determine how well a classifier system performs.

Exercise 95.8.4

Return to Bray's market (*From relaxation to learning: Bray's market*, *Least Squares Learning in Self-Referential Models*), in which the price is

$$p_t = a + b\,\bar{\beta}_t + u_t,$$

where $\bar{\beta}_t$ is the average forecast of p_t and u_t is IID $N(0, \sigma_u^2)$.

Least squares learners converge to the rational expectations price $a/(1-b)$ when $b < 1$ and do not when $b > 1$ [Bray, 1982].

Replace Bray's representative least squares learner by a population of $N = 60$ forecasters, each a 16-bit string decoded into a forecast in $[0, 20]$.

Each period:

- the price is set by the population's average forecast;
- each forecaster's fitness is minus its squared forecast error;
- the population breeds next period's forecasters by this lecture's genetic algorithm (windowed roulette, single-point crossover, mutation at rate 0.01), followed by the election operator of *Exchange Rate Indeterminacy, Learning, and Experiments*: a child replaces its parent only if it would have forecast this period's price better.

Set $a = (1-b)p^*$, so that the rational expectations price is $p^* = 10$ whatever b is, and take $\sigma_u = 0.1$.

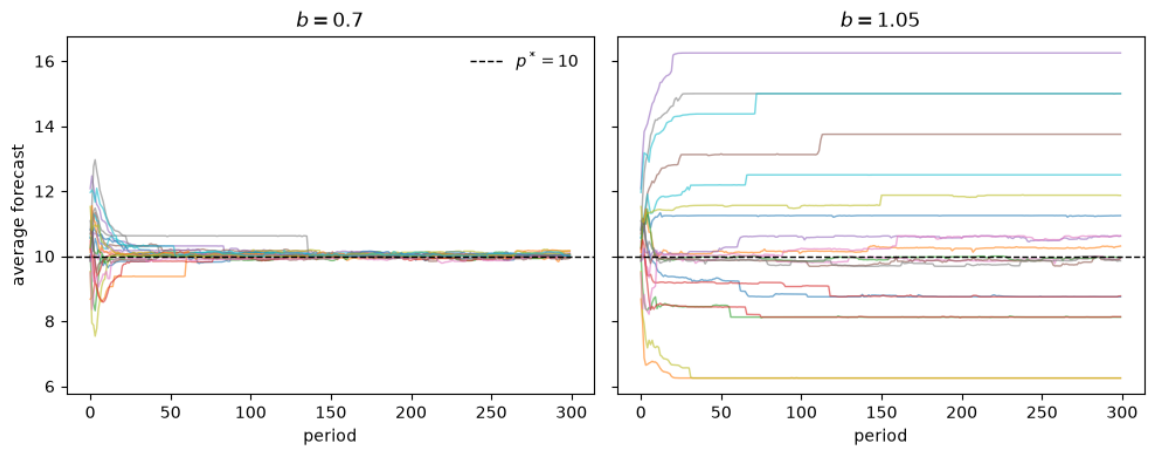
1. With $b = 0.7$, show that across 20 seeds the average forecast settles at the rational expectations price within 300 periods.
2. Try $b = 1.05$, slightly above Bray's bound. What happens, and why?
3. Sargent's book reports that, in her 1991 thesis, Jasmina Arifovic found that a population of this kind "can sometimes learn its way to a rational expectations equilibrium even when Bray's necessary condition $b < 1$ is violated" [Sargent, 1993]. In what sense does your experiment agree? (Arifovic [1994] studies genetic-algorithm learning in the cobweb model.)

Solution

Here is the population of forecasters.

```
def decode(pop, lo=0.0, hi=20.0):
    "Read each row of bits as a binary number and map it into [lo, hi]."
    L = pop.shape[1]
    return lo + (hi - lo) * (pop @ 2.0 ** np.arange(L - 1, -1, -1)) / (2**L - 1)

def ga_forecasters(b, p_star=10.0, σ_u=0.1, N=60, L=16, T=300, p_mut=0.01, seed=0):
    "Path of the average forecast in Bray's market with a GA population."
    rng = np.random.default_rng(seed)
    a = (1 - b) * p_star
    pop = rng.integers(0, 2, (N, L))
    path = np.empty(T)
    for t in range(T):
        β = decode(pop)
```



```
        path[t] = β.mean()
        p = a + b * β.mean() + σ_u * rng.standard_normal()
        fit = -(p - β)**2
        weight = fit - fit.min() + 1e-6
        cum = np.cumsum(weight)
        parents = pop[np.searchsorted(cum, rng.random(N) * cum[-1])]
        mom, dad = parents[0::2], parents[1::2]
        left = np.arange(L) < rng.integers(1, L, (N // 2, 1))
        kids = np.vstack([np.where(left, mom, dad), np.where(left, dad, mom)])
        kids[rng.random(kids.shape) < p_mut] ^= 1
        parents = np.vstack([mom, dad])
        better = (p - decode(kids))**2 < (p - decode(parents))**2    # election
        pop = np.where(better[:, None], kids, parents)
    return path

paths = {b: np.array([ga_forecasters(b, seed=s) for s in range(20)]) for b in (0.7,
 ↪ 1.05)}
for b, P in paths.items():
    gap = np.abs(P - 10)
    print(f"b = {b}: median |average forecast - p*| at t = 10, 100, 299: "
          f"{np.median(gap[:, 10]):.3f}, {np.median(gap[:, 100]):.3f}, "
          f"{np.median(gap[:, -1]):.3f};  runs within 0.25 of p* at the end: "
          f"{np.sum(gap[:, -1] < 0.25)} of 20")
```

```
b = 0.7: median |average forecast - p*| at t = 10, 100, 299: 0.347, 0.055, 0.
 ↪046;  runs within 0.25 of p* at the end: 20 of 20
b = 1.05: median |average forecast - p*| at t = 10, 100, 299: 1.313, 1.398, 1.
 ↪557;  runs within 0.25 of p* at the end: 4 of 20
```

The figure shows all forty paths.

```
fig, axes = plt.subplots(1, 2, figsize=(10, 4), sharey=True)
for ax, (b, P) in zip(axes, paths.items()):
    ax.plot(P.T, lw=1, alpha=0.6)
    ax.axhline(10, color='k', ls='--', lw=1, label="$p^* = 10$")
    ax.set_title(f"$b = {b}$")
    ax.set_xlabel("period")
axes[0].set_ylabel("average forecast")
axes[0].legend(frameon=False)
plt.tight_layout()
plt.show()
```

At $b = 0.7$ every one of these runs settles at the rational expectations price.

At $b = 1.05$ only a few runs end near it.

The others are pushed away in the first few periods, while the population is still diverse.

They then stall, apart from occasional jumps, at a forecast that is wrong in the same direction every period.

The T-map of *One recursion, many learners* explains the direction.

A population whose average forecast is $\bar{\beta}$ induces the price $T(\bar{\beta}) = a + b\bar{\beta}$ on average, and selection and election favor forecasts near the realized price.

Since $T(\bar{\beta}) - \bar{\beta} = (b - 1)(\bar{\beta} - p^*)$, the favored forecasts lie on the side of p^* when $b < 1$ and on the far side when $b > 1$.

The genetic algorithm lies outside the theory of stochastic approximation, but here it moves in the direction that the theory's mean dynamics would predict.

Why does it stall rather than run off to the edge of $[0, 20]$?

Because b is close to 1, the push is weak: a population 1.5 away from p^* makes systematic forecast errors of only $0.05 \times 1.5 = 0.075$ a period, less than the noise.

And once the strings are nearly identical, crossover creates nothing new, and many small moves of the forecast require several bits to flip at once (a "Hamming cliff" of binary encoding), so the population can freeze.

So the experiment agrees with the book in a weak sense.

When $b > 1$ the population ends near the rational expectations price only in runs that happened to stall near it.

The equilibrium does not attract it, and it does not attract least squares either, which diverges when $b > 1$, though very slowly when b is this close to 1 (*Least Squares Learning in Self-Referential Models*).

The election operator matters even when $b = 0.7$.

Remove it, and the population keeps its children however badly they forecast, and it settles much less tightly on p^*: as in *Exchange Rate Indeterminacy, Learning, and Experiments*, election is what lets a genetic population learn, by making it homogeneous.

Exercise 95.8.5

Extend the two-link chain of *The bucket brigade* by giving the system a choice at the first stage.

A *myopic* rule m collects $r_m = 1$ at once and ends the episode.

The setup rule s collects nothing but moves the system to a second stage, where the payoff rule p collects R.

To separate the accounting from the auction, choose m or s at random with equal probability in every episode, and use the averaging accounting with $b = 0.1$.

1. Suppose there are no backward payments: the payoff rule's bid is paid to no one. What happens to the setup rule's strength?
2. With the payoff rule paying its bid to the setup rule, find the stationary strengths of m and s, and the smallest ratio R/r_m at which an argmax auction would choose the setup rule. Check your answer by simulation.
3. Repeat part 2 with Holland's cumulative balances. Which accounting is more patient?

Solution

Here is the chain with a choice at its first stage.

```
def two_stage(R, r_m=1.0, b=0.1, T=20_000, accounting='average', backward=True,␣
↪seed=0):
    "Strengths of [myopic, setup, payoff] when the first-stage rule is chosen at␣
↪random."
    rng = np.random.default_rng(seed)
    S, τ = np.zeros(3), np.zeros(3)
    for _ in range(T):
        if rng.random() < 0.5:
            acts = [(0, r_m)]                                    # myopic: paid at␣
↪once
        else:
            acts = [(1, b * S[2] if backward else 0.0),          # setup: paid the␣
↪next bid
                    (2, R)]                                      # payoff: paid by␣
↪the world
        for k, receipts in acts:
            τ[k] += 1
            if accounting == 'average':
                S[k] += (receipts - (1 + b) * S[k]) / τ[k]
            else:
                S[k] += receipts - b * S[k]
    return S

b = 0.1
print(f"predicted threshold R / r_m = (1 + b) / b = {(1 + b) / b:.1f}\n")
for R in (5.0, 10.0, 12.0, 20.0):
    rows = {'no backward payment': two_stage(R, backward=False),
            'average': two_stage(R),
            'balance': two_stage(R, accounting='balance')}
    for name, S in rows.items():
        winner = 'setup' if S[1] > S[0] else 'myopic'
        print(f"R = {R:>4}, {name:>19}: S_m = {S[0]:7.3f}, S_s = {S[1]:7.3f}  ->
↪{winner}")
    print()
```

R =  5.0,             average: S_m =   0.909, S_s =   0.413  -> myopic
R =  5.0,             balance: S_m =  10.000, S_s =  50.000  -> setup
R = 10.0, no backward payment: S_m =   0.909, S_s =   0.000  -> myopic
R = 10.0,             average: S_m =   0.909, S_s =   0.826  -> myopic
R = 10.0,             balance: S_m =  10.000, S_s = 100.000  -> setup

R = 12.0, no backward payment: S_m =   0.909, S_s =   0.000  -> myopic
R = 12.0,             average: S_m =   0.909, S_s =   0.992  -> setup
R = 12.0,             balance: S_m =  10.000, S_s = 120.000  -> setup
R = 20.0, no backward payment: S_m =   0.909, S_s =   0.000  -> myopic
R = 20.0,             average: S_m =   0.909, S_s =   1.653  -> setup
R = 20.0,             balance: S_m =  10.000, S_s = 200.000  -> setup
```

Part 1. Without backward payments the setup rule's receipts are always zero, so its strength never rises above zero, however large R is.

No auction based on strength would ever choose it.

Part 2. With averaging, the stationary strengths solve $(1+b)S_m = r_m$, $(1+b)S_p = R$ and $(1+b)S_s = bS_p$, so

$$S_m = \frac{r_m}{1+b}, \qquad S_s = \frac{b}{(1+b)^2}\,R.$$

The setup rule wins exactly when $R/r_m > (1+b)/b = 11$.

The simulation confirms it: the setup rule loses at $R = 10$ and wins at $R = 12$.

Part 3. With cumulative balances, $S_m = r_m/b$ and $S_s = S_p = R/b$, so the setup rule wins whenever $R > r_m$.

Holland's accounting is patient; the averaging accounting is very impatient.

A classifier system that averages its strengths with $b = 0.1$ prefers 1 now to 10 one step later.

The bucket brigade's discount factor shows how the same arithmetic, applied to the chain that links trading to consuming, makes the agents of *Money as a Medium of Exchange among Artificially Intelligent Agents* effectively very impatient.

96.1 Overview

Kiyotaki and Wright [Kiyotaki and Wright, 1989] studied an economy in which there is no double coincidence of wants.

Trade can occur only if some good is accepted not because it is wanted, but because it can be passed along later.

A good that plays that role is a **medium of exchange**.

Kiyotaki and Wright characterized *stationary Nash equilibria* of such an economy under the assumption that agents are fully rational: agents know the distribution of goods across their trading partners and best-respond to it.

Marimon, McGrattan and Sargent [Marimon *et al.*, 1990] asked a different question.

Suppose we drop rationality altogether and put in its place a collection of **artificially intelligent agents** who begin with arbitrary, even random, rules of thumb, and who adapt those rules only by keeping score of what has paid off in the past.

Will such agents *learn* to use a medium of exchange?

And when the economy has two equilibria, or when its only equilibrium asks agents to be patient, what will they settle on?

These are instances of the question that *A Peculiar Definition of Bounded Rationality* asked of rational expectations (*The knowledge that rational expectations imputes*): can adaptive agents find an equilibrium, and which one?

The learning device that Marimon, McGrattan and Sargent used is John Holland's **classifier system** [Holland, 1975, Holland *et al.*, 1986].

Networks, Genetic Algorithms, and Classifier Systems introduced classifier systems and the bucket brigade in the abstract; here they are assembled into agents.

Each type of agent gets a population of if-then rules, an auction that decides which rule acts, and an accounting system that credits rules that lead to good outcomes and debits rules that lead to bad ones.

When the rules are generated at random, a **genetic algorithm** breeds new rules and retires old ones.

This lecture rebuilds their computational experiments and runs each of them for many random seeds, so that we can say how often each outcome occurs.

The main findings are:

1. With a complete list of rules, agents in Economy A1 learn its unique stationary equilibrium in every run: good 1, the cheapest good to store, circulates as money. Starting from random rules they get most of the way, as in the paper.
2. In Economy A2, where patient agents would *speculate* by accepting an expensive good, the artificial agents never do. Most runs settle on the fundamental pattern of trade, which is not an equilibrium of that economy, some only after thousands of periods stuck in a pattern with too little trade, and a few stay stuck for good. We show why: the bucket brigade makes the agents behave as if they discounted the future at a factor of about 0.016.
3. In Economy B, which has a fundamental and a speculative equilibrium, the agents select the fundamental one in most runs and the speculative one in none.
4. In nearly every run, an intrinsically worthless, costlessly stored object – **fiat money** – is accepted in trade by agents who have to discover its usefulness for themselves.
5. In an economy with five goods and five types, for which the authors had no analytical characterization of equilibrium, the algorithm proposes a pattern of trade, with qualifications that we describe.

Let's start with some imports.

```
import numpy as np
import pandas as pd
import matplotlib.pyplot as plt
from dataclasses import dataclass, replace
from typing import NamedTuple
from numba import njit
```

96.2 The Kiyotaki-Wright environment

There are three types of agents, indexed by $i = 1, 2, 3$, and three goods, indexed by $k = 1, 2, 3$.

A type i agent derives utility only from consuming good i.

He has a technology for producing good i^*, where $i^* \neq i$.

In Kiyotaki and Wright's *model A*, the production pattern is the "Wicksell triangle"

type i	produces i^*	consumes
1	2	1
2	3	2
3	1	3

so there is no double coincidence of wants: the agent who has what you want never wants what you have.

All goods are indivisible and each agent can store exactly one unit of exactly one good from one period to the next.

Storing good k for one period costs s_k, with

$$s_3 > s_2 > s_1 > 0.$$

There are equal numbers A_i of agents of each type, so $A = 3A_i$ in total.

Each period every agent is randomly matched with exactly one other agent, without regard to type.

Write x_{at} for the good that agent a carries into date t and $\rho_t(a)$ for the agent with whom a is matched.

The **pre-trade state** of agent a is the pair

$$z_{at} = (x_{at},\ x_{\rho_t(a)t}).$$

Each period each agent makes two decisions in sequence.

First, having seen z_{at}, he decides whether to propose a trade,

$$\lambda_{at} = \begin{cases} 1 & \text{propose to trade } x_{at} \text{ for } x_{\rho_t(a)t} \\ 0 & \text{refuse} \end{cases}$$

Trade occurs if and only if $\lambda_{at}\lambda_{\rho_t(a)t} = 1$, so post-trade holdings are

$$x^+_{at} = (1 - \lambda_{at}\lambda_{\rho_t(a)t})x_{at} + \lambda_{at}\lambda_{\rho_t(a)t}x_{\rho_t(a)t}. \tag{96.1}$$

Second, he decides whether to consume what he is left holding,

$$\gamma_{at} = \begin{cases} 1 & \text{consume } x^+_{at} \\ 0 & \text{carry } x^+_{at} \text{ into } t+1 \end{cases}$$

If he consumes he immediately produces good $f(a) = i^*$ and carries that into $t + 1$.

Hence

$$x_{a,t+1} = \gamma_{at} f(a) + (1 - \gamma_{at})x^+_{at}. \tag{96.2}$$

The one-period net payoff is

$$U_a(\gamma_{at}) = \gamma_{at}[u_i(x^+_{at}) - s(f(a))] - (1 - \gamma_{at})\, s(x^+_{at}), \tag{96.3}$$

where $u_i(k) = u_i > 0$ if $k = i$ and $u_i(k) = 0$ otherwise.

Note that an agent is *permitted* to consume a good he does not want; he simply gets zero utility from it while still producing and paying to store $f(a)$.

This "consume anything" feature has a consequence worth stating once.

An agent who swaps his own production good for some other good and then eats it ends the period exactly where refusing to trade would have left him: holding his production good and paying its storage cost.

Such trades are payoff-neutral, so nothing in the accounting system described below pushes them out, and they will turn up in several of our economies.

Note

Kiyotaki and Wright ranked payoff streams by expected discounted utility.

Marimon, McGrattan and Sargent instead assume that each agent cares about his **long-run average** utility, and they build the accounting system inside a classifier system out of running averages for that reason.

We shall see in *The bucket brigade's discount factor* that the agents this accounting system produces nevertheless behave as if they discounted the future very heavily.

96.2.1 Two equilibria

Since agents' payoffs depend on what other agents do, the model can have more than one stationary equilibrium.

Kiyotaki and Wright characterize equilibria by a set of probabilities, of which the most useful for us is

$$\pi_{it}^h(k) = \text{probability that a type } i \text{ agent holds good } k \text{ at } t.$$

In the **fundamental equilibrium**, good 1 – the cheapest to store – is the general medium of exchange:

- type 1 agents always hold good 2 (which they produce) and trade it for good 1;
- type 3 agents always hold good 1 and trade it for good 3;
- type 2 agents hold good 1 half the time and good 3 half the time.

So the equilibrium holding probabilities are

	$k=1$	$k=2$	$k=3$
$i=1$	0	1	0
$i=2$	0.5	0	0.5
$i=3$	1	0	0

Type 2 agents accept good 1 even though they never consume it: they use it as money.

In the **speculative equilibrium**, type 1 agents additionally accept good 3 – the *most* expensive good to store – because they expect to trade it away quickly for good 1.

The reason is that a type 1 agent holding good 2 can get good 1 only from a type 2 agent, whereas a type 1 agent holding good 3 can get it from a type 3 agent, who wants good 3 and holds good 1.

Each partner type is met with probability $1/3$, so holding good 3 instead of good 2 raises the chance of acquiring good 1 each period by $(\pi_3^h(1) - \pi_2^h(1))/3$, at an extra storage cost of $s_3 - s_2$.

Kiyotaki and Wright show that, in the limit as the discount rate goes to zero, the fundamental equilibrium is the unique stationary equilibrium if

$$s_3 - s_2 > (\pi_3^h(1) - \pi_2^h(1))\tfrac{1}{3}u_1, \tag{96.4}$$

evaluated at fundamental holdings, and that the speculative equilibrium is the unique one when the inequality is reversed at speculative holdings.

Footnote 7 of the paper prints $\pi_1^h(3) - \pi_1^h(2)$, which transposes the indices: with type 1's own holdings the right side would be $-u_1/3$ and the inequality could never fail.

At the fundamental equilibrium $\pi_3^h(1) = 1$ and $\pi_2^h(1) = 1/2$, and at the speculative equilibrium (tabulated below) $\pi_2^h(1) = 0.586$.

The following function solves (96.4) for u_1; the argument β will be used in *The bucket brigade's discount factor*.

```
s_A = np.array([0.1, 1.0, 20.0])           # storage costs in Economy A

def speculation_threshold(s, π31, π21, β=1.0):
    "The u_1 above which a type 1 agent with discount factor β prefers good 3."
    return 3 * (s[2] - s[1]) / (β * (π31 - π21))

u_fund = speculation_threshold(s_A, π31=1.0, π21=0.5)     # at fundamental holdings
u_spec = speculation_threshold(s_A, π31=1.0, π21=0.586)   # at speculative holdings
print(f"fundamental equilibrium requires u_1 < {u_fund:.1f}")
print(f"speculative equilibrium requires u_1 > {u_spec:.1f}")
```

```
fundamental equilibrium requires u_1 < 114.0
speculative equilibrium requires u_1 > 137.7
```

Economy A1 has $u_1 = 100$, which satisfies the fundamental condition, though the cutoff is only 14 percent above it.

Economy A2 has $u_1 = 500$, which violates it, so for patient agents the unique stationary equilibrium of A2 is the speculative one.

Each of these economies thus has one stationary equilibrium for patient agents, and the question it poses is whether that equilibrium is learnable.

Economy B below has two, and poses the question of selection.

96.2.2 The economies

The following table, modeled on the paper's Table 4, lists the economies we simulate.

All have fifty agents of each type and equal utilities $u_i = u$ for every type.

economy	type i produces	storage costs	u	bids $b_{11}, b_{12}, b_{21}, b_{22}$	initial rules	equilibrium for patient agents
A1.1	2, 3, 1	0.1, 1, 20	100	0.025, 0.025, 0.25, 0.25	all 72 + 12	fundamental
A2.1	2, 3, 1	0.1, 1, 20	500	0.025, 0.025, 0.25, 0.25	all 72 + 12	speculative
B.1	3, 1, 2	1, 4, 9	100	0.25, 0.25, 0.25, 0.25	all 72 + 12	fundamental and speculative
A1.2	2, 3, 1	0.1, 1, 20	100	0.025, 0.025, 0.25, 0.25	72 + 12 random	fundamental
A2.2	2, 3, 1	0.1, 1, 20	500	0.025, 0.025, 0.25, 0.25	72 + 12 random	speculative
B.2	3, 1, 2	1, 4, 9	100	0.025, 0.025, 0.25, 0.25	72 + 12 random	fundamental and speculative
C	2, 3, 1	9, 14, 29; fiat 0	100	0.025, 0.025, 0.025, 0.25	150 + 20 random	fundamental
D	3, 4, 5, 1, 2	1, 4, 9, 20, 30	200	0.025, 0.025, 0.25, 0.25	180 + 20 random	not characterized

The bids are explained below; "all 72 + 12" means a complete enumeration of exchange and consumption rules.

A2.2 and B.2 appear in the exercises.

The paper's Table 4 lists Economy C's storage costs as 0.1, 20 and 70, but its Table 15, which reports the simulation, lists 9, 14 and 29, and we use those.

96.3 Classifier systems for the Kiyotaki-Wright environment

Networks, Genetic Algorithms, and Classifier Systems set out the general machinery in *Classifier systems*: the alphabet $\{0, 1, \#\}$, matching, specificity, and auctions among rules with strengths.

Its *The bucket brigade* showed how a rule that sets up a later reward gets paid for it.

Here we record only what is specific to Marimon, McGrattan and Sargent: how goods are encoded, the two decisions each agent makes every period, and the two strength equations that link them.

96.3.1 Encoding

Each type has two classifier systems, one for exchange decisions and one for consumption decisions.

The paper's Table 1 encodes goods with three positions each: a one-hot code for "good k" and a code with a 0 in position k for "not good k".

```
WILD = -1                                   # the "don't care" symbol #

def table1(n_goods):
    "The paper's Table 1: one-hot codes for 'good k', then codes for 'not good k'."
    good = np.eye(n_goods, dtype=np.int8)
    not_good = np.full((n_goods, n_goods), WILD, dtype=np.int8)
    np.fill_diagonal(not_good, 0)
    return np.vstack([good, not_good])
```

(continues on next page)

(continued from previous page)

```
def code_string(c):
    return ''.join('#' if b == WILD else str(int(b)) for b in c)

def rule_string(cond, action, n_goods):
    "Print a classifier the way the paper does, for example '010 100 -> 1'."
    s = code_string(cond)
    if len(cond) == 2 * n_goods:
        s = s[:n_goods] + ' ' + s[n_goods:]
    return f"{s} -> {int(action)}"

pd.DataFrame({'code': [code_string(c) for c in table1(3)],
              'meaning': [f'good {k}' for k in (1, 2, 3)]
                         + [f'not good {k}' for k in (1, 2, 3)]})
```

	code	meaning
0	100	good 1
1	010	good 2
2	001	good 3
3	0##	not good 1
4	#0#	not good 2
5	##0	not good 3

An **exchange classifier** is a string of length 7: three positions for the agent's own holding, three for the partner's holding, and a binary action (1 = propose trade, 0 = refuse).

The paper's two examples are

```
100 001 -> 1     "if I hold good 1 and my partner holds good 3, propose to trade"
100 ##0 -> 0     "if I hold good 1 and my partner does not hold good 3, refuse"
```

A **consumption classifier** is a string of length 4: three positions for the post-trade holding x_{at}^{+} and one action digit (1 = consume).

A *complete enumeration* pairs every condition in Table 1 with both actions.

That gives $6 \times 6 \times 2 = 72$ exchange classifiers and $6 \times 2 = 12$ consumption classifiers, enough to express every Markov strategy.

Table 1 has no condition meaning "any good", so the enumeration contains no rule such as "eat whatever you hold".

When rules are drawn at random, each position is 0, 1 or # with equal probability.

There are then $3^6 \times 2 = 1458$ possible exchange strings and $3^3 \times 2 = 54$ consumption strings, and many of them match no state at all: `110`, for instance, is no good's code.

With four objects (Economy C) or five goods (Economy D) the codes are one-hot strings of length four or five.

For C that gives the paper's count of $3^8 \times 2 = 13{,}122$ possible exchange strings.

The paper does not say how it encoded the goods of Economy D, so the five-position code is our choice.

A rule's **specificity** is $\sigma = 1/(1 + \text{number of } \#\text{'s})$.

An exchange rule about two particular goods has $\sigma = 1$, a rule like `100 ##0` has $\sigma = 1/3$, and a rule about two "not" conditions has $\sigma = 1/5$.

96.3.2 The auction

Attached to classifier e at date t is a **strength** $S_e^a(t)$.

Given the state z_{at}, let $M_e(z_{at})$ be the set of exchange classifiers whose conditions z_{at} satisfies.

The classifier that acts is the strongest matched one,

$$e_t(z_{at}) = \arg\max \{S_e^a(t) : e \in M_e(z_{at})\}, \tag{96.5}$$

and the consumption classifier is chosen the same way from the classifiers that match x_{at}^+.

This is the paper's equation (6); we break ties at random, a detail the paper does not specify.

Each matched classifier also has a **bid**, a fraction of its strength,

$$b_1(e) = b_{11} + b_{12}\sigma_e \qquad \text{and} \qquad b_2(c) = b_{21} + b_{22}\sigma_c$$

for exchange and consumption classifiers, respectively.

Under (96.5) the bid plays no role in deciding who wins: it only determines the payments described below.

The paper's verbal description calls the winner "the highest bidder" and says that bids that rise with specificity "favor specific rules over more general rules".

That would be true of an auction on $b \cdot S$ among rules of positive strength, but under (96.5) a larger bid fraction pulls a rule's strength at a rest point *toward zero*, as the note below shows.

So among rules whose downstream payments are positive, higher bids lower stationary strength and favor general rules; only among rules whose downstream payments are negative do they favor specific rules, as the paper says.

The argmax auction is the greedy limit of the softmax auction in *Networks, Genetic Algorithms, and Classifier Systems*'s two-armed bandit exercise (Exercise **??**), in which matched rule r wins with probability proportional to $e^{\eta S_r}$ and $\eta \to \infty$ gives the argmax; that lecture calls the intensity β, a letter we reserve here for discount factors.

The paper's footnote 5 mentions such a stochastic auction as an alternative.

A greedy auction avoids probability matching, but it leaves all experimentation to the initial strengths and to the operators that create new rules, a choice that will matter in Economy A2.

96.3.3 The bucket brigade

Strengths are updated by a system of internal payments that Holland calls a *bucket brigade*.

Only the classifier that wins an auction changes its strength, so each classifier carries a counter $\tau_e^a(t)$ recording the number of auctions it has won, initialized at 1.

Payments flow as follows.

- The external payoff $U_a(\gamma_t)$ goes to the winning **consumption** classifier at t.
- The winning consumption classifier at t pays its bid to the winning **exchange** classifier at t, which created the state that gave it a chance to act.
- The winning exchange classifier at t pays its bid to the winning **consumption** classifier at $t-1$, which set up the state z_{at}.

The resulting laws of motion are the paper's equations (12) and (13),

$$S^a_{c,\tau_c(t)} = S^a_{c,\tau_c(t)-1} - \frac{1}{\tau_c(t)-1}\Big[(1+b_2(c))S^a_{c,\tau_c(t)-1} - \sum_e I_e^a(t) b_1(e) S^a_{e,\tau_e(t)} - U_a(\gamma_{ct})\Big] \tag{96.6}$$

$$S^a_{e,\tau_e(t)+1} = S^a_{e,\tau_e(t)} - \frac{1}{\tau_e(t)}\Big[(1+b_1(e))S^a_{e,\tau_e(t)} - \sum_c I^a_c(t) b_2(c) S^a_{c,\tau_c(t)}\Big] \tag{96.7}$$

where $I^a_e(t)$ and $I^a_c(t)$ are indicators for winning the auction at t.

So the consumption classifier updated at date t is the one that won at $t-1$, and each bid travels one step back along the chain

$$\cdots \to c_{t-1} \to e_t \to c_t \to e_{t+1} \to \cdots$$

An exchange classifier that proposes a trade which is *not* reciprocated is not charged, its counter does not advance, and it pays nothing backward: the agent learns nothing from an offer that was refused.

All agents of a given type share one classifier system, as in the paper.

The paper runs (96.6)-(96.7) in "synthetic time", counting matches rather than periods, so read literally a consumption classifier is paid by the next exchange classifier of its *type* to act, which usually belongs to a different agent.

We instead link each agent's own consecutive decisions, which is what the equations describe for a single agent, and the reading under which a decision is credited with its own consequences.

Note

Equations (96.6)-(96.7) make strength a running **average** of past net receipts rather than a cumulative total, which is what Holland's original specification used; the paper's footnote 8 says the averaging was chosen so that strengths could converge.

With $1/\tau$ gains these are stochastic approximation recursions, the same decreasing-gain recursion that drives the learners of *Adaptive Agents in an Overlapping Generations Monetary Economy* and *Learning, Approximation, and Equilibrium Computation* (*One recursion, many learners*).

So any limit point must satisfy the paper's equation (17),

$$\mathbb{E}\Big[(1+b_2(c))S_c - \sum_e I_e b_1(e) S_e - U(\gamma_c)\Big] = 0, \qquad \mathbb{E}\Big[(1+b_1(e))S_e - \sum_c I_c b_2(c) S_c\Big] = 0.$$

Marimon, McGrattan and Sargent call strengths solving these equations *stationary*, and say a stationary Nash equilibrium is *supported* when the rules that win auctions at stationary strengths are exactly the rules that implement equilibrium behavior.

The second equation gives $S_e = \mathbb{E}[b_2(c)S_c]/(1+b_1(e))$, so a larger bid fraction $b_1(e)$ shrinks a rule's stationary strength toward zero: it lowers S_e when $\mathbb{E}[b_2(c)S_c] > 0$ and raises it when $\mathbb{E}[b_2(c)S_c] < 0$.

One more feature of the system drives much of what follows.

All strengths start at zero, while nearly every net payoff an agent experiences is negative, because storage is costly.

So an untried rule beats every rule whose experience so far has been net costly, and under the argmax auction an agent sweeps through its untried rules early on.

This *optimistic initialization* is the main way an agent experiments when it starts from a complete enumeration.

It has a failure mode.

A rule that has never acted, or whose offers were all refused so that it learned nothing, keeps its strength of zero, and it loses every auction to a rival whose strength happens to sit slightly above zero, for as long as that rival's average stays there.

96.4 Implementation

The state spaces are tiny, so for every rule we precompute the set of states it matches and store it as the bits of an integer: state (x, y) of an exchange rule is bit $xG + y$, where G is the number of goods.

The simulation loops run under Numba's `njit`.

Classifier systems are stored as parallel arrays indexed by type and rule.

```
class Rules(NamedTuple):
    "Classifier systems for all types, stored as arrays indexed [type, rule]."
    cond: np.ndarray        # condition part, entries in {0, 1, WILD}
    action: np.ndarray      # action part: 1 = trade (or consume), 0 = refuse
    strength: np.ndarray    # S, a running average of net receipts
    used: np.ndarray        # the counter tau, initialized at 1
    match: np.ndarray       # bit s is set if the rule matches state s
    sigma: np.ndarray       # specificity, 1 / (1 + number of #'s)
    born: np.ndarray        # a stamp that changes whenever the rule is replaced

@njit
def goods_matched(field):
    "Bitmask of the goods whose one-hot code satisfies a condition field."
    n_goods = field.shape[0]
    mask = 0
    for g in range(n_goods):

The auction (96.5) follows.

For the exercises it also offers the softmax auction with intensity η.

Several operators below must delete a "weak" rule, and the paper measures weakness "in terms of a combination of strength and cumulated number of times the classifier has won the bidding in the past".

Our combination adds the two, each rescaled to $[0, 1]$ across the candidates.

```

Three of the four operators that the paper adds for random rules (its Section 6) act inside an auction, so we implement them here.

Creation fires when no rule matches the state: the weakest rule is replaced by one whose condition is exactly the state, with a random action.

Diversification fires when every matched rule calls for the same action: the weakest *other* matched rule is replaced by a rule for exactly this state with the opposite action and the winner's strength, which then ties with the winner.

Specialization is switched on in period t with probability $f_s(t) = 1/(2\sqrt{t})$.

When it is on, each # in the winner's condition is replaced, with probability $p_s = 0.01$, by the bit that matches the current state, and the sharpened copy replaces a weak matched rule.

Under a complete enumeration every state is matched and every condition appears with both actions, so creation and diversification never fire, as the paper notes; specialization is used only with random rules.

```

The next cell defines helpers that put the output into the format of the paper's tables (which report ten-period moving averages) and figures.

`winners` lists, for each state, the rule that would win the auction there, and `contenders` lists every rule competing in a state.

`across_seeds` reruns an economy for twenty seeds.

96.5 Economy A1.1: does a medium of exchange emerge?

Our first economy is the Wicksell triangle with

$$s_1 = 0.1, \quad s_2 = 1, \quad s_3 = 20, \quad u_i = 100,$$

fifty agents of each type, and a complete enumeration of the 72 exchange and 12 consumption classifiers, all with strength zero.

Every economy we display is run with seed 0, and its typicality is then checked across 20 seeds (10 for Economy D).

```
economy_a11 = Economy(
    name='A1.1',

print(f"max |simulated - paper's table|           = "
      f"{distance(holdings(sim_a11).to_numpy(), paper_a11):.3f}")
```

```
holdings at t = 500
         good 1  good 2  good 3
type 1   0.000     1.0   0.000
type 2   0.428     0.0   0.572
type 3   1.000     0.0   0.000

holdings at t = 1000
         good 1  good 2  good 3
type 1   0.000     1.0   0.000
type 2   0.494     0.0   0.506
type 3   1.000     0.0   0.000

max |simulated - fundamental equilibrium| = 0.006
max |simulated - paper's table|           = 0.012
```

By $t = 500$ type 1 holds good 2, type 3 holds good 1, and type 2 splits its time between goods 1 and 3, as in the fundamental equilibrium tabulated above.

The time paths show how quickly types 1 and 3 settle down, and a pause in type 2's learning.

```
plot_holdings(sim_a11)
```

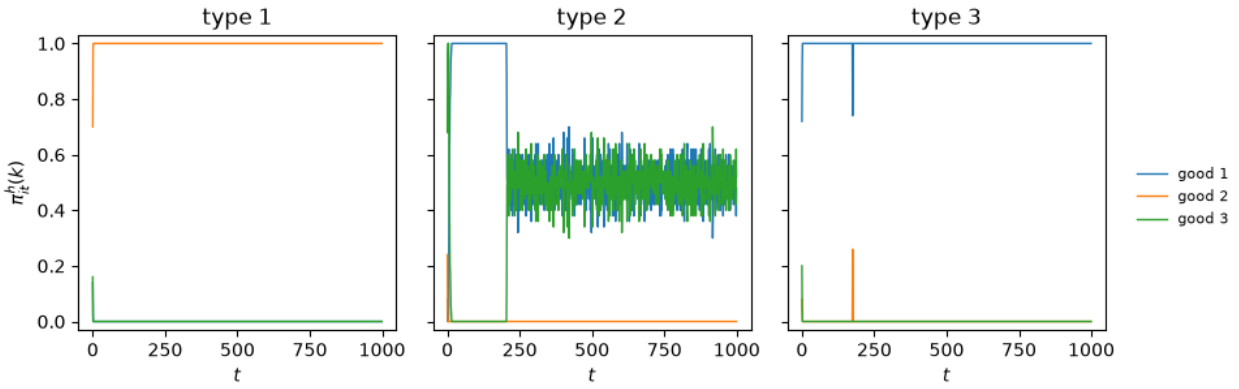

Fig. 96.1: Holdings in Economy A1.1

For roughly the first two hundred periods type 2 agents hold good 1 and nothing else: they have acquired money but do not yet spend it.

The rule that buys good 2 with good 1 has not yet been given a chance, for a reason we explain in *Economy A2.1: when theory predicts speculation*, and once it wins its first auctions type 2 enters the cycle "acquire money, spend money".

From then on type 2's holdings fluctuate, because which good a type 2 agent holds depends on where it is in that cycle.

The next figure shows the trades themselves, averaged over the last hundred periods.

```
plot_flows(sim_a11)
```

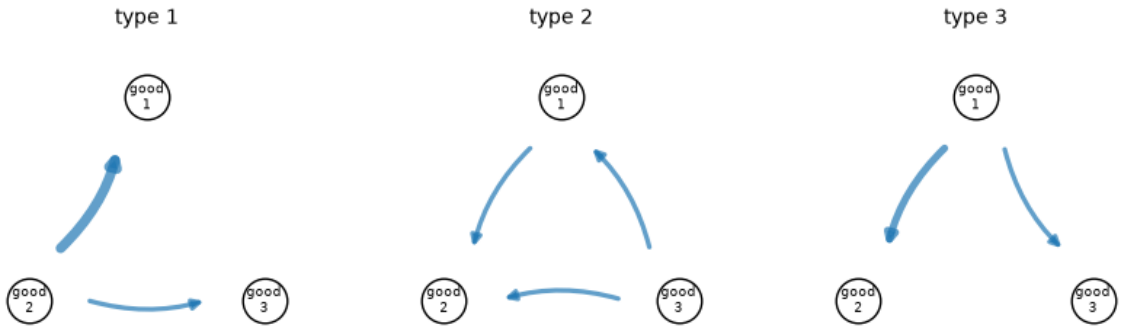

Fig. 96.2: Exchange pattern discovered in Economy A1.1

The fundamental equilibrium triangle is there: type 1 gives up good 2 for good 1, type 3 gives up good 1 for good 3, and type 2 runs both legs, giving up good 3 for good 1 and later good 1 for good 2.

Good 1 circulates as money.

The picture also has arrows that the fundamental equilibrium does not, and they are not thin: type 3 gives up good 1 for good 2 about twice as often as it gives up good 1 for good 3, and type 1 gives up good 2 for good 3 about as often as type 2 runs either of its equilibrium legs.

Each is a payoff-neutral trade of the kind described above, in which the agent eats what it receives and produces its own

good again; the partner gains, because type 1 now gets good 1 from type 3 as well as from type 2, and type 2 gets good 2 for its good 3 directly.

The paper's run had none of these trades, but nothing in the accounting rules them out.

We can also look inside type 1's classifier systems and read off the rule that wins in each state, first for exchange and then for consumption.

```
pd.concat([winners(sim_a11, 0), winners(sim_a11, 0, exchange=False)])
```

```
                winning rule  strength  times used
state
good 1, good 1  ##0 100 -> 1     32.09       22404
good 1, good 2  #0# 0## -> 1      7.93           5
good 1, good 3  #0# 0## -> 1      7.93           5
good 2, good 1  ##0 100 -> 1     32.09       22404
good 2, good 2  010 0## -> 1     -0.14        9320
good 2, good 3  010 001 -> 1     -0.10        6370
good 3, good 1  001 #0# -> 1     40.69           2
good 3, good 2  #0# 0## -> 1      7.93           5
good 3, good 3  001 #0# -> 1     40.69           2
good 1              100 -> 1     66.35       22389
good 2              010 -> 1     -0.33       18730
good 3              #0# -> 1     -0.34        6556
```

The rule that does the work, `##0 100 -> 1`, says "if I hold anything but good 3 and my partner holds good 1, trade": a general rule.

In the state (good 2, good 3) the winning rule *accepts* good 3, but a type 1 agent who acquires good 3 eats it at once and produces good 2 again, which leaves him exactly where refusing would have.

That is the payoff-neutral trade described above, and it is why we read the outcome from holdings, which never show type 1 holding good 3, rather than from the winning actions.

The paper's run (its Table 6) had type 1 refusing good 3 instead, which leads to the same holdings.

Is seed 0 typical?

```
sims_a11 = across_seeds(economy_a11, 1000)
H_a11 = final_holdings(sims_a11)
F_a11 = np.array([trade_rates(sim) for sim in sims_a11])
d, n = distance(H_a11, fundamental), len(sims_a11)
print(f"runs within 0.1 of the fundamental equilibrium: {np.sum(d < 0.1)} of {n}")
print(f"largest distance in any run: {d.max():.3f}")
print(f"runs in which type 3 gives good 1 for good 2:   {np.sum(F_a11[:, 2, 0, 1] > 0.
↪02)} of {n}")
print(f"runs in which type 1 gives good 2 for good 3:   {np.sum(F_a11[:, 0, 1, 2] > 0.
↪02)} of {n}")
```

```
runs within 0.1 of the fundamental equilibrium: 20 of 20
largest distance in any run: 0.060
runs in which type 3 gives good 1 for good 2:   17 of 20
runs in which type 1 gives good 2 for good 3:   15 of 20
```

In every run the holdings settle on the unique stationary equilibrium, and in most runs the payoff-neutral trades appear alongside it.

The medium of exchange is learnable.

96.6 Economy A2.1: when theory predicts speculation

Economy A2 differs from A1 only in that $u_i = 500$ instead of 100.

That is enough to violate the Kiyotaki-Wright inequality (96.4), so for patient agents the unique stationary equilibrium is now the **speculative** one, in which type 1 agents accept good 3 in the expectation of trading it for good 1.

Do our adaptive agents find it?

```
economy_a21 = replace(economy_a11, name='A2.1', u=500.0)

sim_a21 = Simulation(economy_a21, seed=0)
sim_a21.run(1000)

speculative = pd.DataFrame([[0, 0.707, 0.293],        # the paper's Table 8b
                            [0.586, 0, 0.414],
                            [1, 0, 0]],
                           index=type_names(economy_a21),
                           columns=good_names(economy_a21))
print("simulated holdings at t = 1000\n", holdings(sim_a21), "\n")
print("speculative equilibrium\n", speculative)
```

```
simulated holdings at t = 1000
        good 1  good 2  good 3
type 1   0.000     1.0   0.000
type 2   0.524     0.0   0.476
type 3   1.000     0.0   0.000

speculative equilibrium
         good 1  good 2  good 3
type 1   0.000   0.707   0.293
type 2   0.586   0.000   0.414
type 3   1.000   0.000   0.000
```

The answer is no.

The simulated holdings are those of the *fundamental* pattern: type 1 agents hold good 2 and never good 3, whereas speculation requires them to hold good 3 nearly thirty percent of the time.

Here is what happens across seeds.

```
sims_a21 = across_seeds(economy_a21, 1000)
H_a21 = final_holdings(sims_a21)
n = len(sims_a21)
print(f"type 1 holds good 3 more than 5% of the time:  {np.sum(H_a21[:, 0, 2] > 0.05)}
 ↪ of {n}")
print(f"within 0.1 of the fundamental pattern:         "
      f"{np.sum(distance(H_a21, fundamental) < 0.1)} of {n}")
print(f"type 2 holds good 1 less than 10% of the time: {np.sum(H_a21[:, 1, 0] < 0.1)}␣
 ↪of {n}")
print(f"type 2 holds good 1 more than 90% of the time: {np.sum(H_a21[:, 1, 0] > 0.9)}␣
 ↪of {n}")
```

```
type 1 holds good 3 more than 5% of the time:  0 of 20
within 0.1 of the fundamental pattern:         10 of 20
type 2 holds good 1 less than 10% of the time: 9 of 20
type 2 holds good 1 more than 90% of the time: 1 of 20
```

Type 1 never speculates.

Half the runs are near the fundamental pattern at $t = 1000$.

In nearly all the others type 2 almost never holds good 1: types 2 and 3 have stopped trading with each other, so type 2 never acquires the money it needs to buy good 2.

In one run type 2 holds good 1 all the time: it has money but never spends it, as in the first two hundred periods of our A1.1 run.

Here is the first run of the more common kind, seen through the exchange rules of type 3 agents who hold good 1 and meet a type 2 agent holding good 3.

```
locked = int(np.flatnonzero(H_a21[:, 1, 0] < 0.1)[0])
sim_locked = sims_a21[locked]
print(f"seed {locked}\n", holdings(sim_locked), "\n")
c = contenders(sim_locked, 2, 0, 2)          # type 3 holds good 1, meets good 3
pd.concat([c.head(2), c[c['rule'] == '100 001 -> 1']])
```

```
seed 2

         good 1  good 2  good 3
type 1      0.0     1.0     0.0
type 2      0.0     0.0     1.0
type 3      1.0     0.0     0.0
```

```
           rule  strength  times used
0  ##0 001 -> 0       0.1       16714
1  100 001 -> 0       0.0           1
2  100 001 -> 1       0.0           0
```

The type 3 agent wants good 3, which is worth 500 to it, yet the winning rule `##0 001 -> 0` refuses to trade.

Its strength is only 0.1, but it is positive, while the specific rule that would trade, `100 001 -> 1`, has never been used and still has its initial strength of zero.

The refusal rule earned a large payment in the first periods, when a general consumption rule that also covered good 3 followed it.

With $1/\tau$ averaging, the average remembers that windfall for thousands of uses.

This is optimistic initialization's failure mode, and the greedy auction never gives the trade rule a chance until the refusal rule's average sinks below zero.

That does happen eventually, so runs locked in this way are slow rather than stuck for good.

We continue the runs that were not near the fundamental pattern for another 5,000 periods.

```
slow = [sim for sim, h in zip(sims_a21, H_a21) if distance(h, fundamental) >= 0.1]
for sim in slow:
    sim.run(5000)
H_slow = final_holdings(slow)
print(f"runs not near the fundamental pattern at t = 1000: {len(slow)}")
print(f"of these, within 0.1 of it at t = 6000:            "
      f"{np.sum(distance(H_slow, fundamental) < 0.1)}")
print(f"of these, type 1 holds good 3 more than 5%:        {np.sum(H_slow[:, 0, 2] >␣
↪0.05)}")
```

```
runs not near the fundamental pattern at t = 1000: 10
of these, within 0.1 of it at t = 6000:            10
of these, type 1 holds good 3 more than 5%:        0
```

All of these runs reach the fundamental pattern by $t = 6000$, and type 1 still never speculates.

Lock-in is more frequent here than in Economy A1.1, plausibly because u_1 is five times larger, and so are the early windfalls that the averages must forget.

Not every lock-in wears off, though.

Other seeds turn up a second failure mode, and seed 24 shows it.

```
sim_24 = Simulation(economy_a21, seed=24)
sim_24.run(6000)
print(holdings(sim_24), "\n")
winners(sim_24, 1, exchange=False)
```

```
        good 1  good 2  good 3
type 1     0.0     1.0     0.0
type 2     0.0     0.0     1.0
type 3     1.0     0.0     0.0
```

```
       winning rule  strength  times used
state
good 1     ##0 -> 1    146.86      123378
good 2     ##0 -> 1    146.86      123378
good 3     001 -> 0    -12.61      175852
```

This time type 3 does accept good 3; the trouble is with type 2.

It trades good 3 for good 1, as in the fundamental pattern, but then eats the good 1 instead of keeping it to buy good 2 from type 1, so it ends every period holding good 3 again.

The rule responsible is the general consumption rule `##0 -> 1`, which says "eat" whether type 2 holds good 1 or good 2.

Eating good 2 is right and earns type 2 its utility of consumption, which keeps the rule's strength high; eating good 1 is wrong, but the same rule decides that state too.

The specific rule that would keep good 1, `100 -> 0`, was tried only a few times and sits far below the general rule's strength, an average that includes every meal of good 2, so under the argmax auction it never wins again.

So this run is stuck for good: seed 24, and seed 26 in the same way, are still in this pattern at $t = 24{,}000$.

Optimistic initialization lets a rule that was once lucky shut out an untried rival; this second lock-in is the work of an overgeneral consumption rule, one that earns well in one state and shuts out the specific rule that would act correctly in another.

Type 1 still never speculates: across seeds 20 to 59 it holds good 3 no more than 5 percent of the time in every run.

So the agents do not find A2's equilibrium.

For patient agents the speculative equilibrium is the *unique* stationary equilibrium of this economy, so this is not learning selecting among equilibria.

It is convergence to an outcome that is not an equilibrium of the economy the agents live in.

The paper reached the same verdict from a single run, and its diagnosis is worth quoting in full:

> *Patience requires experience.* The transfer system inside the classifier system is designed to converge to a set of long-run average strengths. In the limit, the artificially intelligent agents should behave as long-run average payoff maximizers, since the steady-state strengths weight payoffs by their relative frequencies. It takes time, however, for optimal rules to achieve the desired strengths. The behavior of our artificially intelligent agents can be very myopic at the beginning. In economies, such as Economy A2, in which the nature of the equilibrium changes with the discount rate, this early myopia might have a perverse effect in diverting

> the economy towards a low discount-factor stationary equilibrium, such as the fundamental equilibrium. The underlying algorithm has to provide enough experimentation to avoid an early 'lock in'. The present algorithm seems defective in that it has too little experimentation to support the speculative equilibrium even in the long simulations we have run.

The paper's footnote 14 adds that a fundamental equilibrium exists in A2 only if the discount factor is sufficiently low.

Its footnote 15 reports a telling contrast: in experiments by Marimon and Miller with a genetic algorithm that breeds whole trading strategies (the approach the paper's footnotes 1 and 3 describe), 25 of 30 runs of Economy A2 converged to the speculative equilibrium.

Their agents had no bucket brigade to credit: each strategy was judged as a whole.

The paper also points to a second culprit.

In its run, type 1's winning exchange rule *accepted* good 3 (its Table 9d), but type 1's winning consumption rules were "too general (have too many # signs) to distinguish among goods stored", so type 1 ate good 3 rather than carrying it to a type 3 agent.

Accepting good 3 and then eating it is payoff-equivalent to refusing it, which is why the holdings looked fundamental.

Our seed 0 shows the same thing.

```
pd.concat([winners(sim_a21, 0).loc[['good 2, good 1', 'good 2, good 3']],
           winners(sim_a21, 0, exchange=False).loc[['good 1', 'good 3']]])
```

```
                winning rule  strength  times used
state
good 2, good 1  0## ##0 -> 1     96.82       29260
good 2, good 3  010 0## -> 1      0.30       10707
good 1              100 -> 1    334.29       17421
good 3              #0# -> 1      1.08        5983
```

Type 1's winning exchange rule in the state (good 2, good 3), `010 0## -> 1`, accepts good 3, and the consumption rule that wins when type 1 holds good 3 is the general rule `#0# -> 1`, "if I do not hold good 2, eat".

So far this is the paper's Table 9d.

But generality is not what makes type 1 eat good 3 here.

Here are all of type 1's consumption rules that match good 3.

```
c = sim_a21.C
rows = [r for r in range(c.cond.shape[1]) if (c.match[0, r] >> 2) & 1]
pd.DataFrame({'rule': [rule_string(c.cond[0, r], c.action[0, r], 3) for r in rows],
              'strength': c.strength[0, rows].round(2),
              'times used': c.used[0, rows] - 1})
```

```
       rule  strength  times used
0  001 -> 0    -11.59           1
1  001 -> 1     -0.48          13
2  0## -> 0     -9.32           6
3  0## -> 1     -0.68         141
4  #0# -> 0    -13.09           5
5  #0# -> 1      1.08        5983
```

The specific rule that eats good 3 has a strength near zero, while the specific rule that carries it, tried only once, has a strength near -12.

Carrying good 3 costs 20 this period, against 1 for eating it, and the reward for carrying it, a chance to trade it for good 1 next period, reaches the carrying rule only through the bucket brigade, heavily discounted.

Type 1 therefore never carries good 3 into the next period, and the holdings are fundamental.

Three mechanisms are therefore at work in A2:

1. **Impatience.** Even at rest, the bucket brigade values the future at a tiny discount factor, which the next section derives.
2. **Greedy lock-in.** The argmax auction stops experimenting once untried rules are used up, as in the trapped runs above.
3. **Overconsumption by general consumption rules**, which makes accepting good 3 pointless, as in the paper's Table 9, and in seed 24 keeps type 2 from holding money.

Exercise 96.14.3, Exercise 96.14.4 and Exercise 96.14.5 take them apart one at a time.

96.7 The bucket brigade's discount factor

The paper hoped that strengths built from long-run averages would make the agents behave like long-run average payoff maximizers once the strengths settled down.

The stationarity conditions say otherwise.

Take an agent whose exchange rule e' at $t+1$ follows a consumption rule c at t, and whose consumption rule c' at $t+1$ follows e'.

From the second stationarity condition, $(1+b_1(e'))S_{e'} = \mathbb{E}[b_2(c')S_{c'}]$.

Substituting it into the first gives

$$(1+b_2(c))S_c = \mathbb{E}[U(\gamma_c)] + \mathbb{E}\Big[\beta_{\text{eff}}\,(1+b_2(c'))S_{c'}\Big], \qquad \beta_{\text{eff}} = \frac{b_1(e')\,b_2(c')}{(1+b_1(e'))(1+b_2(c'))}. \tag{96.8}$$

So the scaled strengths $V_c = (1+b_2(c))S_c$ satisfy a Bellman equation for the agent's current policy, $V_c = \mathbb{E}[U] + \mathbb{E}[\beta_{\text{eff}}V_{c'}]$, with discount factor β_{eff}.

The exchange strengths inherit the ranking: among exchange rules of equal specificity, S_e is proportional to the expected value of the consumption rule that follows e.

When an offer is refused, e' pays nothing backward, which lowers the effective discount factor further.

```
def beta_eff(b1, b2):
    "Effective discount factor of the bucket brigade for bid fractions b1, b2."
    return b1 * b2 / ((1 + b1) * (1 + b2))

b11, b12, b21, b22 = 0.025, 0.025, 0.25, 0.25            # Economy A's bids
β_A = beta_eff(b11 + b12, b21 + b22)                     # fully specific rules
print(f"β_eff with A's bids, specific rules:   {β_A:.4f}")
print(f"β_eff with A's bids, general rules:    {beta_eff(b11 + b12 / 5, b21 + b22 /␣
↪3):.4f}")
print(f"β_eff with B.1's bids, specific rules: {beta_eff(0.5, 0.5):.4f}")
print(f"β_eff as both bid fractions approach 1: {beta_eff(1, 1):.4f}")
```

```
β_eff with A's bids, specific rules:   0.0159
β_eff with A's bids, general rules:    0.0073
β_eff with B.1's bids, specific rules: 0.1111
β_eff as both bid fractions approach 1: 0.2500
```

With the paper's bids the agents behave, at rest, as if they discounted the future at a factor of about 0.016 per period, and the most general rules, which bid less, at about 0.007.

Because $b/(1+b) < 1/2$ for any bid fraction below one, β_{eff} can never reach $1/4$.

The source is the averaging itself: a rule's own bid enters the average it keeps, so each link of the chain passes back only the fraction $b/(1+b)$ of the value it receives.

What does an agent with discount factor β do in Economy A?

Redoing the argument behind (96.4) for an agent who discounts each period's payoffs by β, a type 1 agent facing given holdings of the other types prefers to hold good 3 if and only if

$$s_3 - s_2 < \beta(\pi_3^h(1) - \pi_2^h(1))\tfrac{1}{3}u_1,$$

so lowering β scales up the threshold for u_1 by $1/\beta$.

```
for label, β in [("patient agents, β = 1", 1.0), ("bucket brigade, β = β_eff", β_A)]:
    print(f"{label}: fundamental for u_1 < "
          f"{speculation_threshold(s_A, 1.0, 0.5, β):,.0f}, speculative for u_1 > "
          f"{speculation_threshold(s_A, 1.0, 0.586, β):,.0f}")
print(f"A2's u_1 = 500 supports speculation only if β > "
      f"{speculation_threshold(s_A, 1.0, 0.586) / 500:.3f}")
```

```
patient agents, β = 1: fundamental for u_1 < 114, speculative for u_1 > 138
bucket brigade, β = β_eff: fundamental for u_1 < 7,182, speculative for u_1 > 8,674
A2's u_1 = 500 supports speculation only if β > 0.275
```

For an agent with $\beta = \beta_{\text{eff}}$, A2's $u_1 = 500$ is far inside the region where the fundamental pattern is the unique equilibrium.

The figure plots the two thresholds against β.

```
βs = np.logspace(-2.5, 0, 200)
fig, ax = plt.subplots(figsize=(7, 4))
ax.loglog(βs, speculation_threshold(s_A, 1.0, 0.5, βs),
          label="fundamental equilibrium exists below")
ax.loglog(βs, speculation_threshold(s_A, 1.0, 0.586, βs), '--',

```

Economy A2 supports speculation only for β above 0.275, beyond the reach of any bid fractions, so at rest the bucket brigade cannot support A2's equilibrium with fully specific rules, whatever its bids.

This sharpens the paper's diagnosis.

Early myopia is real, but it is not only early: the stationary strengths themselves are impatient.

The fundamental pattern – accept a good only if you eat it or it is cheaper to store – is exactly what an impatient agent does, which is the paper's "low discount-factor stationary equilibrium".

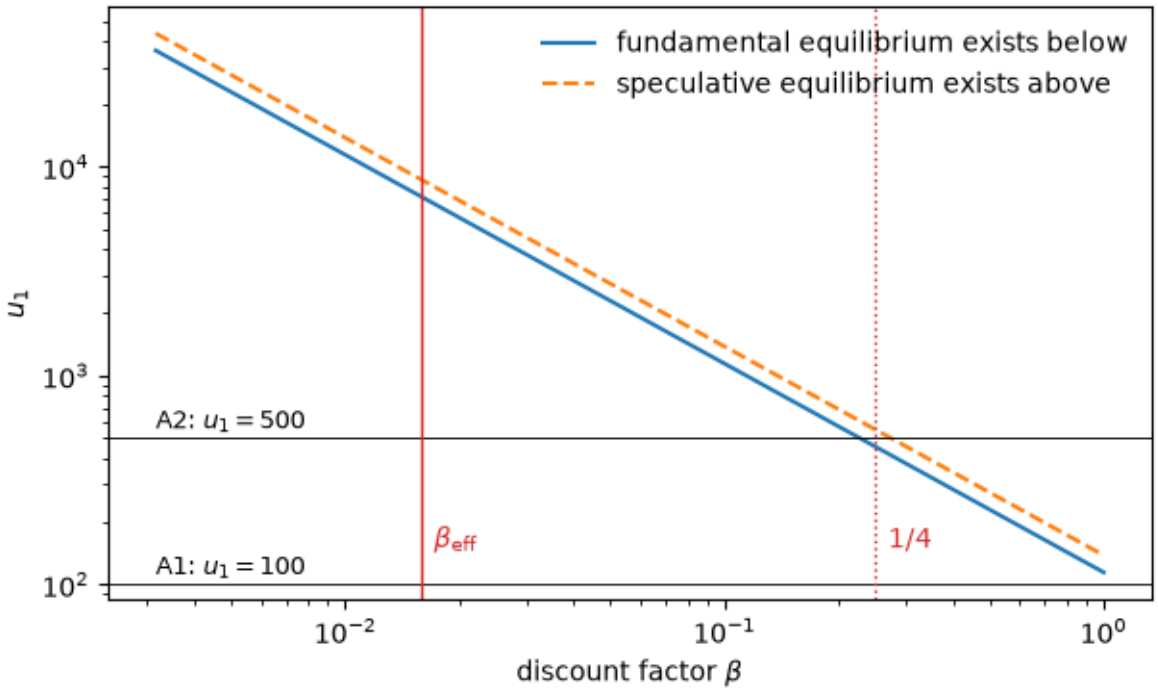

Fig. 96.3: Speculation thresholds for u_1 against the discount factor

The same is true of the patterns the classifier systems find in every other economy of this lecture: the fundamental equilibrium of Economy B, the acceptance of fiat money in Economy C (fiat costs nothing to store), and the "lower storage cost" pattern the paper reports for Economy D.

Equation (96.8) is a familiar object.

The scaled strengths are evaluated like the temporal-difference value estimates of reinforcement learning [Sutton and Barto, 2018], which *Job Search X: Search with Q-Learning* and *Inventory Management via Q-Learning* apply to a job seeker and to a firm.

The difference is that here the discount factor is not chosen to match the agent's preferences: it is a by-product of the bid fractions.

The bucket brigade finds the same factor $b/(1+b)$ per link in a two-link chain, and shows that Holland's cumulative balances, which do not average, pass a payoff back undiminished but need not converge.

One recursion, many learners explains why, with $1/\tau$ averaging, the rest points of (96.6)-(96.7) are the objects to study.

Exercise 96.14.5 checks the threshold by simulation.

96.8 Economy B.1: selecting between two equilibria

Economy B changes the production pattern – type 1 produces good 3, type 2 produces good 1, type 3 produces good 2 – and compresses storage costs to $s = (1, 4, 9)$, with $u_i = 100$.

Now there are two stationary equilibria for patient agents: in the fundamental one goods 1 and 2 serve as media of exchange, and in the speculative one goods 2 and 3 do.

B.1 also uses exchange bids ten times A's, $b_{11} = b_{12} = 0.25$, as in the paper's Table 12, which raises β_{eff} to about 0.11.

```
economy_b1 = Economy(
    name='B.1',
    produces=np.array([2, 0, 1]),               # type 1 -> good 3, type 2 -> good 1,␣
 ↪...
    storage_costs=np.array([1.0, 4.0, 9.0]),
    u=100.0,
    b_trade=(0.25, 0.25),
)

sim_b1 = Simulation(economy_b1, seed=0)
sim_b1.run(1000)

fundamental_b = np.array([[0, 0.293, 0.707],     # the paper's Table 10b
                          [1, 0, 0],
                          [0.586, 0.414, 0]])
speculative_b = np.array([[0, 0.586, 0.414],     # the paper's Table 11b
                          [0.707, 0, 0.293],
                          [0, 1, 0]])
paper_b1 = np.array([[0.0, 0.28, 0.72],          # the paper's Table 12b, t = 1000
                     [0.994, 0.0, 0.006],
                     [0.526, 0.474, 0.0]])

```

The run ends near the fundamental equilibrium of Economy B, closer to it than the paper's own run.

```
plot_holdings(sim_b1)
```

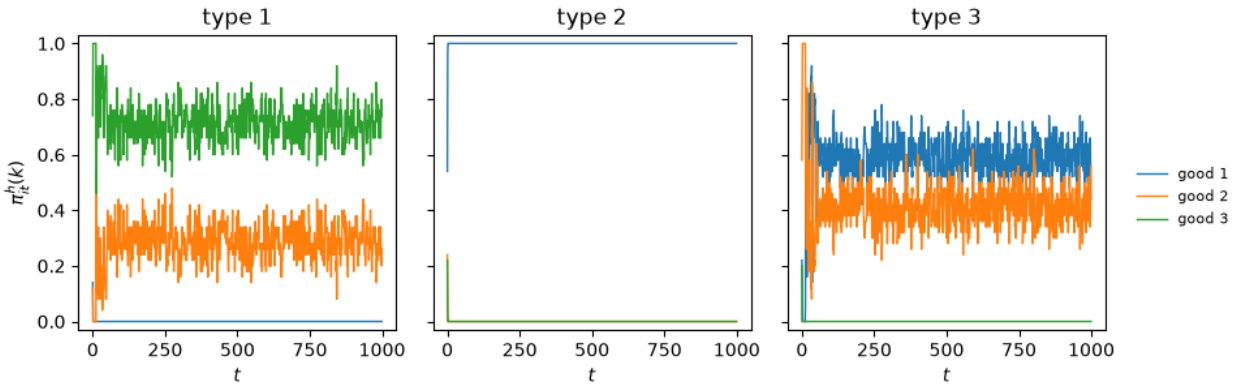

Fig. 96.4: Holdings in Economy B.1

Across seeds:

```
H_b1 = final_holdings(across_seeds(economy_b1, 1000))
d_f, d_s = distance(H_b1, fundamental_b), distance(H_b1, speculative_b)
print(f"within 0.1 of the fundamental equilibrium: {np.sum(d_f < 0.1)} of {len(H_b1)}
 ↪")
print(f"within 0.1 of the speculative equilibrium: {np.sum(d_s < 0.1)} of {len(H_b1)}
 ↪")
print(f"smallest distance from the speculative equilibrium: {d_s.min():.2f}")
print("holdings in the runs farther than 0.1 from the fundamental equilibrium:")
print(H_b1[d_f >= 0.1].round(2))
```

```
within 0.1 of the fundamental equilibrium: 18 of 20
within 0.1 of the speculative equilibrium: 0 of 20
smallest distance from the speculative equilibrium: 0.29
holdings in the runs farther than 0.1 from the fundamental equilibrium:
[[[0.   0.49 0.51]
  [1.   0.   0.  ]
  [0.   1.   0.  ]]

 [[0.   0.27 0.73]
  [1.   0.   0.  ]
  [0.47 0.53 0.  ]]]
```

In 18 of the 20 runs the holdings end within 0.1 of the fundamental equilibrium, and no run comes within 0.29 of the speculative one.

Of the other two runs, one is just outside the 0.1 band, and in the other type 3 agents never trade their good 2 for good 1.

Here learning does select between two equilibria, and it selects the fundamental one.

The paper reports one more feature that our run does not reproduce: at $t = 500$ its B.1 looked speculative, and only by $t = 1000$ had it "practically converged to the fundamental equilibrium".

The paper read that movement as evidence that the selection was not "the result of myopic behavior".

In our run there is no speculative phase beyond the first few periods, which are dominated by the random initial holdings, so the movement is not something we can confirm.

And *The bucket brigade's discount factor* suggests a different reading: the fundamental equilibrium of Economy B is also the one an impatient agent plays, and the bucket brigade is impatient at rest, not just early on.

96.9 The genetic algorithm

Complete enumeration is feasible only because the Kiyotaki-Wright state space is tiny.

In larger problems an agent must work with a limited population of rules that is continually revised.

The paper starts such agents from randomly generated rules and adds four operators: the three we have already met inside the auction, and **generalization**, a genetic algorithm.

Generalization is called with probability $f_g(t) = 1/(2\sqrt{t})$ in period t.

When it is called, it works as follows (the paper's Section 6 and Table 7):

- **Potential exterminants** are rules that are both weak and seldom used: strength below $\bar{S} = 0$ *and* a counter below $p_3 = 0.2$ times the largest counter.
- **Potential parents** are a fraction $p_2 = 0.7$ of the rules, chosen randomly "in accordance with strength and frequency"; we draw them with probabilities proportional to their counters and then select pairs within them by a roulette wheel on strength.
- Pairs mate until a fraction $p_1 = 0.2$ of the population has been replaced.
- **Generalizing crossover** (the paper's Fig. 4): the pair draws two cut points and focuses on the positions inside them, or, with probability one half, outside them; wherever the parents carry different specific bits in the focus, both children get a $\#$. Children therefore match everything their parents matched, and more.
- Each child gets the average of its parents' strengths and replaces the potential exterminant it most resembles, by **crowding**: $N = 8$ times (4 for consumption rules) a sample of half the potential exterminants is drawn, the weakest member of each sample is scored by the number of positions it shares with the child plus one if its action differs, and the highest score loses its place.

The paper's footnote 12 says that more standard Holland algorithms "were first tried without much success, prompting us to produce the modified algorithm described in section 6".

We therefore use the generalizing crossover in every economy with random rules, and, since the paper's Table 7 lists no mutation rate, no mutation.

Where the paper is silent we have made the following choices:

- ties in the auction are broken at random;
- generalization is drawn independently for each type's exchange and consumption systems;
- new rules, including children, start with a counter of 1, so after their first experience the strength they were born with survives only through the bid they paid out of it;
- creation gives the new rule strength zero;
- "weakness" outside the genetic algorithm is the score in `weakest`;
- specialization, when switched on in a period, applies to every auction in that period;
- each agent's own decisions form a bucket-brigade chain, as discussed above;
- the goods of Economy D get a five-position one-hot code.

```

96.10 Economy A1.2: learning from random rules

Economy A1.2 has the same parameters as A1.1, but agents begin with 72 exchange rules and 12 consumption rules drawn *at random* from the 1,458 and 54 possible strings.

Most of these rules are nonsense, and there is no guarantee that the population contains the rules needed to support an equilibrium.

The operators must manufacture them.

```
economy_a12 = replace(economy_a11, name='A1.2', random_rules=True)

sim_a12 = Simulation(economy_a12, seed=0)
sim_a12.run(2000)

```

Here are the time paths.

```
plot_holdings(sim_a12)
```

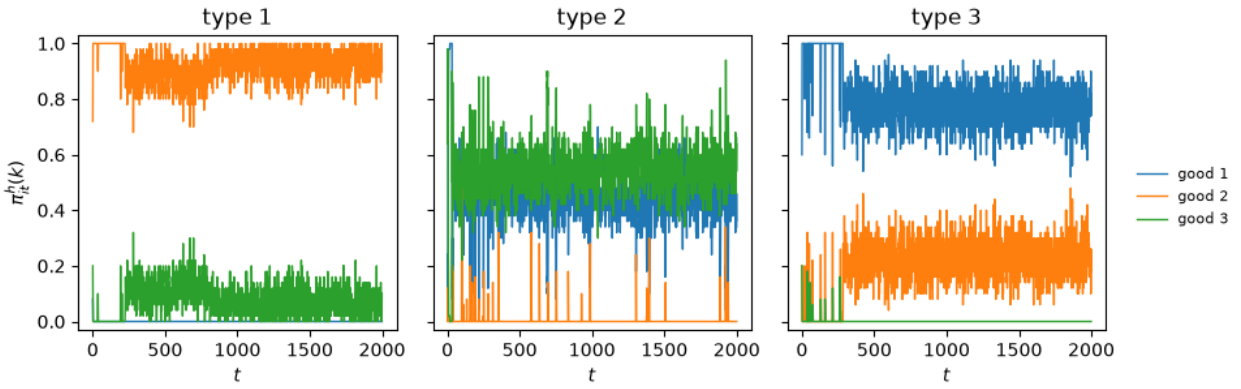

Fig. 96.5: Holdings in Economy A1.2

The fundamental pattern emerges again, though less cleanly than under complete enumeration.

Type 1 mostly holds good 2, type 2 holds only goods 1 and 3, and type 3 mostly holds good 1.

But types 1 and 3 also hold goods that the fundamental equilibrium excludes: in this run type 1 holds good 3 about 5 percent of the time and type 3 holds good 2 about a fifth of the time.

The paper's run was cleaner for types 1 and 3 but not for type 2: at $t = 2000$ its type 2 agents held good 1 only 32 percent of the time, and its Table 7e shows type 2 eating good 1 – its money – with probability 0.45 at $t = 1000$ and 0.23 at $t = 2000$.

The paper calls this overeating "a minor problem in several of our economies", associated with states the classifier system visits too rarely to learn about.

Here are the eating frequencies over the last 200 periods of our run.

```
eating_rates(sim_a12)
```

```
         good 1  good 2  good 3
type 1     1.00    0.50    0.53
type 2     0.02    0.98    0.97
type 3     0.56    0.46    1.00
```

In this run type 2 hardly ever eats its money, which is why its holdings are close to the equilibrium's even split.

Types 1 and 3 eat "wrong" goods about half the time, which costs them nothing when the good is their own production good (good 2 for type 1, good 1 for type 3).

But type 1 also carries good 3 into the next period about half the times it gets it, at a cost of 20 rather than 1, and type 3 carries good 2 about half the time: these are the rarely visited states the paper blames.

Across seeds:

```
sims_a12 = across_seeds(economy_a12, 2000)
H_a12 = final_holdings(sims_a12)
eat_money = np.array([eating_rates(sim).iloc[1, 0] for sim in sims_a12])
n = len(H_a12)
print(f"type 1 holds good 2 at least 90% of the time: {np.sum(H_a12[:, 0, 1] >= 0.9)}␣
↪of {n}")
print(f"type 3 holds good 1 at least 90% of the time: {np.sum(H_a12[:, 2, 0] >= 0.9)}␣
↪of {n}")
print(f"type 2 holds only goods 1 and 3:              {np.sum(H_a12[:, 1, 1] < 0.05)}␣
```

(continues on next page)

(continued from previous page)

```
 ↪of {n}")
print(f"type 2's share of good 1: median {np.median(H_a12[:, 1, 0]):.2f}, "
      f"range {H_a12[:, 1, 0].min():.2f} to {H_a12[:, 1, 0].max():.2f}")
print(f"within 0.1 of the fundamental equilibrium:    "
      f"{np.sum(distance(H_a12, fundamental) < 0.1)} of {n}")
print(f"type 2 eats good 1 at least 40% of the time:  {np.sum(eat_money >= 0.4)} of
 ↪{n}")
```

```
type 1 holds good 2 at least 90% of the time: 16 of 20
type 3 holds good 1 at least 90% of the time: 13 of 20
type 2 holds only goods 1 and 3:              20 of 20
type 2's share of good 1: median 0.19, range 0.09 to 0.50
within 0.1 of the fundamental equilibrium:    5 of 20
type 2 eats good 1 at least 40% of the time:  11 of 20
```

Seed 0 is one of the better runs.

In every run type 2 holds only goods 1 and 3, and in most runs types 1 and 3 hold their equilibrium goods at least 90 percent of the time.

But type 2's median share of good 1 is only 0.19, and in about half the runs type 2 eats good 1 at least 40 percent of the time, the overeating of the paper's run.

Only a quarter of the runs end within 0.1 of the fundamental equilibrium; the paper's own run was 0.18 away.

General rules survive the genetic algorithm.

```
share = lambda R: np.mean(R.cond == WILD)
print(f"share of # in exchange rules:    {share(sim_a12.E):.2f}")
print(f"share of # in consumption rules: {share(sim_a12.C):.2f}")
```

```
share of # in exchange rules:    0.32
share of # in consumption rules: 0.16
```

A random string has a # in a third of its positions, and generalizing crossover keeps adding them while specialization slowly removes them.

96.11 Economy C: fiat money

Now add a fourth object, fiat money, which the paper calls good 0.

It

- costs nothing to store, $s_0 = 0$;
- yields no utility to anybody; and
- cannot be consumed.

It is intrinsically worthless.

It is introduced by handing 48 units of it to 48 randomly chosen agents at $t = 0$, and commodity storage costs are raised to $s = (9, 14, 29)$ so that no commodity is nearly as cheap to store as money.

The paper's footnote 17 reports that a version with Economy A's storage costs did not converge, "probably because the low cost of storing good 1 (0.1) made this good too good a substitute for fiat money".

Agents start from 150 random exchange rules and 20 random consumption rules each, out of 13,122 and 162 possible strings.

```
economy_c = Economy(
    name='C',
    produces=np.array([1, 2, 0]),
    storage_costs=np.array([9.0, 14.0, 29.0, 0.0]),    # fiat money is the last good
    u=100.0,
    random_rules=True,
    n_trade_rules=150,
    n_consume_rules=20,
    b_consume=(0.025, 0.25),
    n_fiat=48,
)

max |simulated - paper's table|           = 0.158
```

Every type holds fiat money roughly 30 percent of the time, close to the theoretical fundamental equilibrium (the paper's Table 14b); the paper's own run (its Table 15b) has type 1 holding fiat money more often, 46 percent of the time.

The largest discrepancy from the theory is type 2's holding of good 1, about 0.10 in our run against 0.26 in theory and 0.18 in the paper's run: our type 2 agents rely on fiat money rather than good 1 as their medium of exchange more than the theory says.

```
plot_holdings(sim_c)
```

The exchange pattern shows money changing hands.

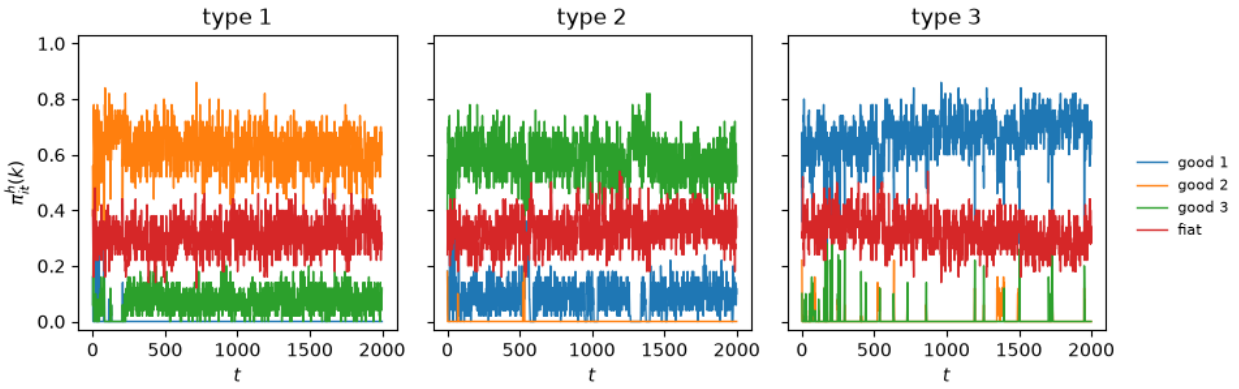

Fig. 96.6: Holdings in Economy C

```
plot_flows(sim_c)
```

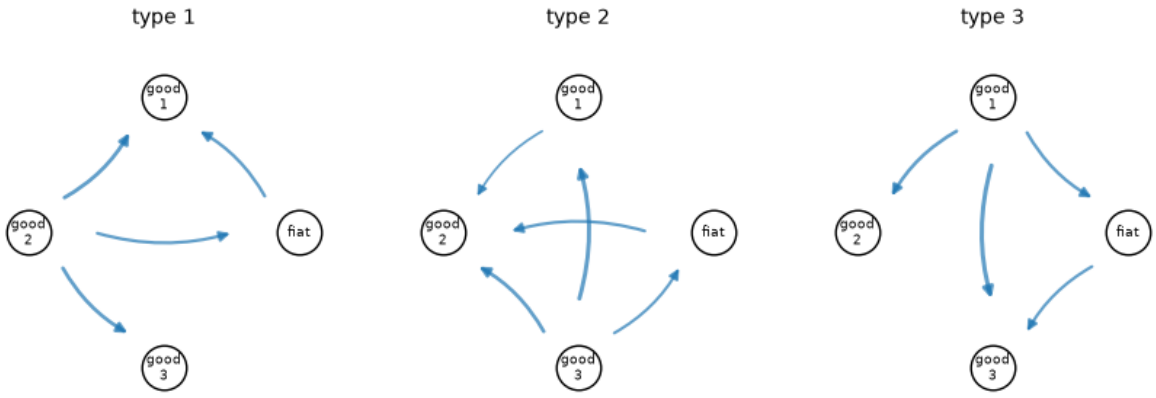

Fig. 96.7: Exchange pattern discovered in Economy C

The arrows into and out of the fiat node show money changing hands in both directions for every type: agents give up their production good to acquire it, and give it up to acquire the good they consume.

Good 1 still serves as a second money for type 2, which gives up good 3 for good 1 and good 1 for good 2.

The payoff-neutral trades of Economy A1.1 appear again: type 1 gives up good 2 for good 3, and type 3 gives up good 1 for good 2.

Across seeds:

```
H_c = final_holdings(across_seeds(economy_c, 1250))
n = len(H_c)
print(f"every type holds fiat at least 10% of the time: "
      f"{np.sum(H_c[:, :, 3].min(axis=1) >= 0.1)} of {n}")
print("holdings averaged over runs:")
print(pd.DataFrame(H_c.mean(axis=0), index=type_names(economy_c),
                   columns=good_names(economy_c)).round(2))
print(f"within 0.1 of the fundamental equilibrium:      "
```

(continues on next page)

(continued from previous page)

```
      f"{np.sum(distance(H_c, fundamental_c) < 0.1)} of {n}")
print(f"within 0.2 of the fundamental equilibrium:      "
      f"{np.sum(distance(H_c, fundamental_c) < 0.2)} of {n}")
print("holdings in runs where some type holds fiat less than 10% of the time:")
print(H_c[H_c[:, :, 3].min(axis=1) < 0.1].round(2))
```

```
every type holds fiat at least 10% of the time: 18 of 20
holdings averaged over runs:
        good 1  good 2  good 3  fiat
type 1    0.00    0.60    0.05  0.35
type 2    0.16    0.00    0.54  0.30
type 3    0.63    0.06    0.00  0.31
within 0.1 of the fundamental equilibrium:      2 of 20
within 0.2 of the fundamental equilibrium:      14 of 20
holdings in runs where some type holds fiat less than 10% of the time:
[[[0.   0.04 0.   0.96]
  [0.96 0.   0.04 0.  ]
  [0.98 0.01 0.01 0.  ]]

 [[0.   0.49 0.   0.51]
  [0.17 0.06 0.67 0.1 ]
  [0.52 0.13 0.   0.36]]]
```

In 18 of the 20 runs every type holds fiat money at least 10 percent of the time.

In one of the other two, type 1 agents hoard fiat money while types 2 and 3 hold almost none; in the other, type 2's share of fiat money is just under 10 percent.

On average across runs the holdings are within about 0.15 of the theoretical equilibrium: type 1 holds more fiat money and less good 2 than in theory, and type 2 less good 1 and more good 3, as in seed 0.

Those gaps are why only 2 runs come within 0.1 of the equilibrium, while 14 come within 0.2.

Nothing in the environment told the agents to do this.

Each agent discovered only that rules which end up holding the costless object earn more than rules that do not, and, because everyone was discovering this at once, the belief became self-confirming.

The discovery asks little of the agents: fiat money is the cheapest object to store, so even an impatient agent accepts it, provided others will take it in turn.

96.12 Economy D: five goods, five types

The last economy has five types and five goods, with production

type i	produces	consumes
1	good 3	good 1
2	good 4	good 2
3	good 5	good 3
4	good 1	good 4
5	good 2	good 5

storage costs $s = (1, 4, 9, 20, 30)$ from the paper's Table 4, and $u_i = 200$.

Each agent carries 180 exchange rules and 20 consumption rules.

The authors emphasize that they had *no analytical characterization of equilibrium* for this economy, and used the simulation to suggest what an equilibrium might look like.

```
economy_d = Economy(
    name='D',
    produces=np.array([2, 3, 4, 0, 1]),          # type 1 -> good 3, type 2 -> good 4,␣
 ↪...
    storage_costs=np.array([1.0, 4.0, 9.0, 20.0, 30.0]),
    u=200.0,
    random_rules=True,
    n_trade_rules=180,
    n_consume_rules=20,
)

sim_d = Simulation(economy_d, seed=0)
sim_d.run(2000)
holdings(sim_d)
```

	good 1	good 2	good 3	good 4	good 5
type 1	0.000	0.114	0.886	0.000	0.000
type 2	0.032	0.000	0.112	0.814	0.042
type 3	0.046	0.052	0.000	0.028	0.874
type 4	0.832	0.018	0.094	0.000	0.056
type 5	0.208	0.546	0.246	0.000	0.000

The time paths show how the holdings got there.

```
plot_holdings(sim_d)
```

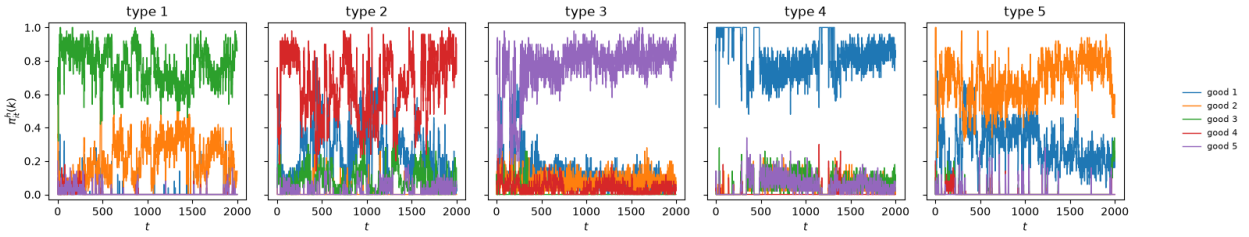

Fig. 96.8: Holdings in Economy D

Two features stand out.

First, the diagonal is zero: no type ends a period holding the good it consumes, because it eats it.

Second, every type holds mostly the good it produces; at the end of this run only type 5 holds other goods much of the time, and type 1 holds the cheaper good 2 about a tenth of the time.

The time paths have not fully settled; type 2's holdings in particular swing between goods 4 and 1 for much of the run.

The paper's run looks different in its details: at $t = 1750$ its type 1 agents held the cheaper good 2 83 percent of the time, and its type 3 agents split their holdings between good 2 and good 5.

Let us classify the trades that actually take place by what the agent acquires.

```
def trade_composition(sim, window=200):
    """
```

(continues on next page)

(continued from previous page)

```
    Shares of realized trades in which the agent acquires its own consumption
    good, a good cheaper to store than the one given up, or neither; and the
    share of 'neither' trades that give up the agent's own production good
    and are then eaten (payoff-neutral).
    """
    econ = sim.econ
    f = np.array(sim.exch_hist)[-window:].sum(axis=0)
    c = np.array(sim.cons_hist[-window:]).sum(axis=0)
    eat = c[:, :, 1] / np.maximum(c[:, :, 0], 1)
    s = econ.storage_costs
    out = {'own consumption good': 0.0, 'a cheaper good': 0.0, 'neither': 0.0}
    neutral = 0.0
    for i in range(econ.n_types):
        for j in range(econ.n_goods):
            for k in range(econ.n_goods):
                if j == k:
                    continue
                key = ('own consumption good' if k == i else
                       'a cheaper good' if s[k] < s[j] else 'neither')
                out[key] += f[i, j, k]
                if key == 'neither' and j == econ.produces[i]:
                    neutral += f[i, j, k] * eat[i, k]
    total = sum(out.values())
    out = {k: v / total for k, v in out.items()}
    out['  of which payoff-neutral'] = neutral / total
    return pd.Series(out, name='share of realized trades').round(3)

trade_composition(sim_d)
```

```
own consumption good         0.339
a cheaper good               0.307
neither                      0.354
  of which payoff-neutral    0.183
Name: share of realized trades, dtype: float64
```

About two thirds of realized trades acquire either the agent's own consumption good or a good that is cheaper to store, which is the pattern the paper describes.

About half of the remaining third are payoff-neutral: the agent gives up its own production good for a dearer good, eats it, and produces its own good again.

The rest, about a sixth of all trades, fit neither description.

Here are the same statistics for ten seeds, together with the number of times per period an agent of each type eats its own good.

```
sims_d = across_seeds(economy_d, 2000, seeds=range(10))
comp = pd.DataFrame([trade_composition(sim) for sim in sims_d])
print(comp.describe().loc[['mean', 'min', 'max']].round(2), "\n")
own = np.array([[np.array(sim.cons_hist[-200:]).sum(axis=0)[i, i, 1] / (200 * 50)
                 for i in range(5)] for sim in sims_d])
print("own-good consumption per agent per period, smallest over runs:",
      own.min(axis=0).round(3))
```

```
      own consumption good  a cheaper good  neither    of which payoff-neutral
mean                  0.33            0.31     0.37                       0.18
```

(continues on next page)

(continued from previous page)

```

↪0.059 0.07 ]
```

The shares change little from run to run, and every type eats its own good in every run.

The paper summarizes its own run this way:

> From the simulation results, we can see that the trading patterns nearly seem to describe a fundamental equilibrium in which agents are only willing to trade for commodities of lower cost than the one currently in storage, except that they always accept the commodity of their type. Some speculative moves can be detected.

Our runs share the first part of that description, with two qualifications: a third of the trades fit neither pattern, half of them because the "consume anything" rule makes them payoff-neutral, and in our displayed run the holdings have not settled down.

The paper's example of a speculative move – type 2 agents accepting good 3 from type 1 in exchange for good 1, in order to trade it to type 3 for good 2 – comes from its own run.

What the simulation delivers is a candidate pattern of trade, which would still have to be checked against the equilibrium conditions, as the authors note.

96.13 Concluding remarks

Marimon, McGrattan and Sargent's agents know very little.

They do not know their own utility functions, they do not know storage costs, they do not know the distribution of goods across the population, and they certainly do not solve dynamic programs.

They recognize utility when they experience it and costs when they bear them, and they keep running averages.

Out of this the following emerges.

- **A medium of exchange is learnable.** With a complete list of rules, Economy A1 reaches its unique stationary equilibrium in every run; from random rules the agents get most of the way, overeating money as the paper's agents did.
- **Selection, and its limits.** In Economy B, with two equilibria, the classifier systems select the fundamental one in most runs and the speculative one in none. In Economy A2, whose only equilibrium for patient agents is speculative, they never speculate: most runs converge, sometimes very slowly, to an outcome that is not an equilibrium of that economy, and a few lock into a pattern with even less trade.
- **Why: the agents are impatient.** At stationary strengths the bucket brigade values the future with a discount factor $b_1 b_2/((1+b_1)(1+b_2))$, about 0.016 with the paper's bids and below $1/4$ for any bids, and the patterns the agents find are those of impatient agents. The greedy auction and overgeneral consumption rules add to the effect.
- **Institutions can be discovered.** In nearly every run, Economy C's agents built a fiat monetary system out of nothing but their own experience of storage costs.
- **The method proposes candidates.** Economy D produced a pattern of trade in a model its authors had not solved, though not one that has been verified to be an equilibrium.

The paper is candid about what is missing.

There are no convergence theorems, only a sketch of how stochastic approximation arguments might supply them, and the authors judge their algorithm to provide "too little experimentation".

Experimentation is part of the story, but the stationary strengths show that more of it would not be enough: an agent built this way values a payoff one period ahead at less than a quarter of its worth, whatever its bids.

1993 Prospects for Bounded Rationality in Macroeconomics takes stock of what the series has delivered, and enters Economy A2 on the debit side of the ledger.

96.14 Exercises

Exercise 96.14.1

Economy A2.2 is Economy A2 – with $u_i = 500$ – but started from randomly generated rules and evolved with the genetic algorithm, exactly as A1.2 relates to A1.1.

The paper's summary table lists its equilibrium type as speculative, and the authors report that after 1000 iterations the economy had not converged, with trading patterns closer to the fundamental equilibrium than to the speculative one in period 1000 – "(The reverse was true in period 500.)"

Simulate it for 2000 periods and report holdings at $t = 500$, $t = 1000$ and $t = 2000$.

Then repeat for 20 seeds.

Does the extra experimentation supplied by the genetic algorithm produce speculation at any of these dates?

Solution

```
economy_a22 = replace(economy_a21, name='A2.2', random_rules=True)

sim_a22 = Simulation(economy_a22, seed=0)
sim_a22.run(2000)
for t in (500, 1000, 2000):
    print(f"t = {t}\n", holdings(sim_a22, t=t), "\n")
```

```
t = 500
          good 1  good 2  good 3
type 1   0.000   1.000   0.000
type 2   0.438   0.000   0.562
type 3   0.788   0.212   0.000

t = 1000
          good 1  good 2  good 3
type 1   0.000   1.000   0.000
type 2   0.428   0.000   0.572
type 3   0.722   0.278   0.000

t = 2000
          good 1  good 2  good 3
type 1   0.000   1.000   0.000
type 2   0.404   0.000   0.596
type 3   0.732   0.268   0.000
```

Now the same experiment for 20 seeds, recording holdings at each date.

```
sims_a22 = across_seeds(economy_a22, 2000)
for t in (500, 1000, 2000):
    H = final_holdings(sims_a22, t)
    closer = distance(H, speculative.to_numpy()) < distance(H, fundamental)
    print(f"t = {t}: type 1 holds good 3 > 5% in {np.sum(H[:, 0, 2] > 0.05)} runs "
          f"(at most {H[:, 0, 2].max():.2f} of the time); closer to speculative "
          f"than to fundamental in {np.sum(closer)} runs")
```

```
t = 500: type 1 holds good 3 > 5% in 2 runs (at most 0.16 of the time); closer␣
↪to speculative than to fundamental in 0 runs
t = 1000: type 1 holds good 3 > 5% in 1 runs (at most 0.12 of the time); closer␣
↪to speculative than to fundamental in 0 runs
t = 2000: type 1 holds good 3 > 5% in 3 runs (at most 0.15 of the time); closer␣
↪to speculative than to fundamental in 1 runs
```

No.

In this run type 1 never holds good 3 at any of the three dates.

Across 20 runs, at each date type 1 holds good 3 more than 5 percent of the time in at most three runs, and never as often as the speculative equilibrium's 29 percent.

Only one run, at $t = 2000$, is even marginally closer to the speculative holdings than to the fundamental ones, and our runs do not reproduce the paper's report that its run looked more speculative at $t = 500$.

Randomizing the initial rules and adding the genetic algorithm can manufacture rules that accept good 3, but it does not change the discount factor at which the bucket brigade values holding it (*The bucket brigade's discount factor*).

Exercise 96.14.2

Economy B.2 is Economy B started from random rules, with the genetic algorithm and A's bids.

The paper reports that it "had not converged after 2000 periods" but was "moving towards the fundamental equilibrium", with holdings at $t = 2000$ of $(0, 0.354, 0.646)$ for type 1, $(0.996, 0, 0.004)$ for type 2 and $(0.268, 0.732, 0)$ for type 3.

Simulate it, compare its holdings with the two equilibria of Economy B and with the paper's run, and compare its distance from the fundamental equilibrium with B.1's across 20 seeds.

Solution

```
economy_b2 = replace(economy_b1, name='B.2', random_rules=True,
                     b_trade=(0.025, 0.025))
sim_b2 = Simulation(economy_b2, seed=0)
sim_b2.run(2000)

paper_b2 = np.array([[0, 0.354, 0.646], [0.996, 0, 0.004], [0.268, 0.732, 0]])
rows = {'B.2 simulated, t = 2000': holdings(sim_b2).to_numpy(),
        'fundamental equilibrium': fundamental_b,
        'speculative equilibrium': speculative_b,
        "paper's B.2, t = 2000": paper_b2}
pd.concat({k: pd.DataFrame(v, index=type_names(economy_b2),
                           columns=good_names(economy_b2)).round(3)
           for k, v in rows.items()})
```

```
                                  good 1  good 2  good 3
B.2 simulated, t = 2000 type 1     0.000   0.100   0.900
                        type 2     0.856   0.000   0.144
                        type 3     0.112   0.888   0.000
fundamental equilibrium type 1     0.000   0.293   0.707
                        type 2     1.000   0.000   0.000
                        type 3     0.586   0.414   0.000
speculative equilibrium type 1     0.000   0.586   0.414
                        type 2     0.707   0.000   0.293
                        type 3     0.000   1.000   0.000
paper's B.2, t = 2000   type 1     0.000   0.354   0.646
                        type 2     0.996   0.000   0.004
                        type 3     0.268   0.732   0.000
```

Now compare B.2 with B.1 across seeds.

```
H_b2 = final_holdings(across_seeds(economy_b2, 2000))
for name, H in [("B.1", H_b1), ("B.2", H_b2)]:
    print(f"{name}: median distance to fundamental "
          f"{np.median(distance(H, fundamental_b)):.2f}, to speculative "
          f"{np.median(distance(H, speculative_b)):.2f}; "
          f"median share of good 1 for type 3 {np.median(H[:, 2, 0]):.2f}")
```

```
B.1: median distance to fundamental 0.06, to speculative 0.56; median share of␣
↪good 1 for type 3 0.56
B.2: median distance to fundamental 0.25, to speculative 0.52; median share of␣
↪good 1 for type 3 0.35
```

This run of B.2 is not near either equilibrium: type 3 holds good 1 only 11 percent of the time (59 percent in the fundamental equilibrium, 27 percent in the paper's run), and type 1 holds good 2 only 10 percent of the time (29 percent in the fundamental equilibrium, 59 in the speculative one).

Across seeds, B.2's median distance from the fundamental equilibrium is 0.25, against 0.06 for B.1, while both stay about 0.5 from the speculative one.

The typical type 3 agent in B.2 holds good 1 about a third of the time, between the paper's 27 percent and the equilibrium's 59.

Like the paper's run, B.2 ends much closer to the fundamental equilibrium than to the speculative one without reaching it in 2000 periods: building the needed rules from random material takes time that the enumerated economy never had to spend.

Exercise 96.14.3

Kiyotaki and Wright's agents cannot consume goods they do not value.

Impose that restriction on Economy A2.1 by setting `no_eat=True`, which removes the overconsumption mechanism of *Economy A2.1: when theory predicts speculation*.

Across 20 seeds, how often does type 1 hold good 3?

In the runs where it does, which rule of type 1's wins in the state (good 2, good 3), and what else does that rule cover?

Solution

```
economy_noeat = replace(economy_a21, name='A2.1, no eating', no_eat=True)
```

```
rows = []
for seed in range(20):
    sim = Simulation(economy_noeat, seed)
    sim.run(1000)
    h = holdings(sim, window=100).to_numpy()
    w = strongest(sim.E, 0, 1 * 3 + 2)
    f = trade_rates(sim)[0]
    rows.append({'seed': seed, 'type 1 holds good 3': h[0, 2],
                 'type 1 trades 2 for 3': f[1, 2], 'type 1 trades 3 for 1': f[2,␣
 ↪0],
                 'winning rule in (good 2, good 3)': rule_string(sim.E.cond[0, w],
                                                                 sim.E.action[0,␣
 ↪w], 3)})
noeat = pd.DataFrame(rows).set_index('seed').round(3)
noeat[noeat['type 1 holds good 3'] > 0.05]
```

```
      type 1 holds good 3  type 1 trades 2 for 3  type 1 trades 3 for 1  \
seed
3                   0.239                 0.179                 0.119
5                   0.360                 0.000                 0.000
6                   0.380                 0.000                 0.000
8                   0.278                 0.165                 0.101
10                  0.273                 0.164                 0.095
11                  0.363                 0.199                 0.089
12                  0.480                 0.000                 0.000
13                  0.600                 0.000                 0.000
18                  0.480                 0.000                 0.000

     winning rule in (good 2, good 3)
seed
3                          0## #0# -> 1

10                         ##0 #0# -> 1
11                         ##0 #0# -> 1
12                         ##0 001 -> 0
13                         ##0 #0# -> 0
18                         ##0 #0# -> 0
```

Type 1 holds good 3 more than 5 percent of the time in 9 of the 20 runs, but for two different reasons.

In four runs (seeds 3, 8, 10 and 11) type 1 trades good 2 for good 3 and good 3 for good 1, and its holdings look like the speculative equilibrium's.

But the rule that accepts good 3 is general, a version of "trade if my partner does not hold good 2", which also covers the state in which the partner holds good 1.

Its strength is earned in that state, where trading leads to eating good 1, and carried over to good 3: speculation by generality, not by the bucket brigade crediting the patience it requires.

In the other five runs type 1 holds good 3 but never trades it.

These agents acquired good 3 early on, cannot eat it, and meet type 3 agents who have locked into refusing it.

So removing overconsumption does not make the agents speculate for the right reason, and generality cuts both ways: it can carry rewards from one state to another, which here mimics speculation, and it produces the overconsumption of *Economy A2.1: when theory predicts speculation*.

This is the tradeoff between generality and discrimination that Sargent [1993] emphasizes in his discussion of classifier systems.

Exercise 96.14.4

Replace the argmax auction of Economy A2.1 by a softmax auction with intensity $\eta = 0.5$ (set `eta=0.5`), in the spirit of Exercise **??** and the paper's footnote 5, leaving everything else unchanged.

Across 20 seeds, how often does type 1's winning exchange rule in the state (good 2, good 3) accept good 3, and how often does type 1 actually hold good 3?

Compare your answer with the paper's Table 9d.

Solution

```
economy_soft = replace(economy_a21, name='A2.1, softmax', eta=0.5)

rows = []
for seed in range(20):
    sim = Simulation(economy_soft, seed)
    sim.run(1000)
    w, c = strongest(sim.E, 0, 1 * 3 + 2), strongest(sim.C, 0, 2)
    rows.append({'accepts good 3': sim.E.action[0, w] == 1,
                 'type 1 holds good 3': holdings(sim, window=100).iloc[0, 2],
                 'consumption rule for good 3': rule_string(sim.C.cond[0, c],
                                                            sim.C.action[0, c], 3)}
 ↪)
soft = pd.DataFrame(rows)
print(f"winning rule accepts good 3: {soft['accepts good 3'].sum()} of 20")
print(f"largest share of time type 1 holds good 3: {soft['type 1 holds good 3'].
 ↪max():.3f}")
soft['consumption rule for good 3'][soft['accepts good 3']].value_counts()
```

```
winning rule accepts good 3: 14 of 20
largest share of time type 1 holds good 3: 0.008
```

```
consumption rule for good 3
#0# -> 1    11
0## -> 1     3
Name: count, dtype: int64
```

With exploration, the rule that accepts good 3 wins in 14 of the 20 runs, yet type 1 almost never holds good 3.

In every run in which it accepts good 3, the winning consumption rule for good 3 is a general eating rule: either "eat if I do not hold good 2", which also covers good 1, or "eat if I do not hold good 1", which also covers good 2, where eating does no harm.

This is the paper's Table 9d pattern: the speculative exchange rule wins, and the general consumption rule eats good 3 at once.

A softmax auction keeps experimenting, so no rule is shut out for good by an early windfall, but it leaves the other two mechanisms in place.

Exercise 96.14.5

The bucket brigade's discount factor predicts that a type 1 agent whose rules are all fully specific will not speculate in Economy A2 unless u_1 exceeds roughly $6(s_3 - s_2)/\beta_{\text{eff}}$.

Test the prediction by simulation.

Give the agents only fully specific rules (`specific_only=True`), let them explore with a softmax auction ($\eta = 0.5$), forbid eating unwanted goods, and vary u_1.

For six seeds at each u_1, record whether type 1's winning rule in the state (good 2, good 3) accepts good 3.

At what u_1 does speculation start to win?

Solution

```
print(f"predicted thresholds: {speculation_threshold(s_A, 1, 0.5, β_A):,.0f} "
      f"(fundamental holdings), {speculation_threshold(s_A, 1, 0.586, β_A):,.0f} "
      f"(speculative holdings)\n")

for u in (500, 4_000, 8_000, 12_000, 20_000, 40_000):
    econ = replace(economy_a21, u=float(u), specific_only=True, eta=0.5,
                   no_eat=True)
    accept, share = 0, []
    for seed in range(6):
        sim = Simulation(econ, seed)
        sim.run(2000)
        accept += sim.E.action[0, strongest(sim.E, 0, 1 * 3 + 2)] == 1
        share.append(holdings(sim, window=200).iloc[0, 2])
    print(f"u_1 = {u:>6,}: accepts good 3 in {accept} of 6 runs; "
          f"type 1 holds good 3 {np.mean(share):.2f} of the time")
```

```
predicted thresholds: 7,182 (fundamental holdings), 8,674 (speculative holdings)
u_1 =    500: accepts good 3 in 0 of 6 runs; type 1 holds good 3 0.03 of the␣
 ↪time
u_1 =  4,000: accepts good 3 in 0 of 6 runs; type 1 holds good 3 0.03 of the␣
 ↪time
u_1 =  8,000: accepts good 3 in 0 of 6 runs; type 1 holds good 3 0.03 of the␣
 ↪time
u_1 = 12,000: accepts good 3 in 0 of 6 runs; type 1 holds good 3 0.05 of the␣
 ↪time
u_1 = 20,000: accepts good 3 in 2 of 6 runs; type 1 holds good 3 0.11 of the␣
 ↪time
u_1 = 40,000: accepts good 3 in 4 of 6 runs; type 1 holds good 3 0.32 of the␣
 ↪time
```

In these six runs, at A2's $u_1 = 500$ and at every u_1 up to 12,000, the rule that accepts good 3 never wins.

It starts to win between 12,000 and 20,000, and at 40,000 type 1 holds good 3 about as often as in the speculative equilibrium.

The prediction gets the order of magnitude right: speculation needs a utility tens of times larger than A2's, against a threshold of 138 for patient agents.

These six runs need somewhat more than the prediction, plausibly because the auction compares noisy strengths in runs of finite length; on other seeds the accepting rule already wins occasionally at 12,000.

97.1 Overview

This is the closing lecture of the series, and it is different in kind from the others.

It carries no new model.

Instead it gathers the judgments that Sargent [1993] recorded in 1993 — the opinions, reservations, and hopes with which he ended *Bounded Rationality in Macroeconomics* — and loops them back to the quest that opened the book, and that opened *A Peculiar Definition of Bounded Rationality*, the first lecture here.

That quest had a destination: a theory of **transition dynamics**, the out-of-equilibrium adjustment that the Eastern European reformers of 1989 had to manage with no map.

The route was to expel the rational agents from our models and replace them with "artificially intelligent" agents who behave like **econometricians**, who gather data, form theories, estimate, and adapt.

We can now ask how far that route carried us, by 1993, toward the destination.

Sargent's own answer is a ledger, with entries on both sides.

On the credit side: adaptive dynamics as a device for **selecting** among equilibria, as a tool — evolutionary programming — for **computing** them, and as a source of new tools for econometricians.

On the debit side: the original prize, a theory of transition dynamics, is largely unclaimed; the agents must be heavily prompted; and a striking asymmetry has emerged.

The program set out to make the agents in our models behave more like econometricians.

The econometricians, Sargent observes, have not returned the compliment.

This lecture explains that asymmetry, gives it a concrete numerical face, and asks when it fails.

It then settles, one by one, the four payoffs that *A Peculiar Definition of Bounded Rationality* promised, including one, new sources of dynamics, that the series delivers but Sargent's closing ledger leaves out.

The lecture closes with a postscript on what became of the program after 1993.

Let's start with some imports.

```
import numpy as np
import matplotlib.pyplot as plt
```

97.2 The quest, restated

The knowledge that rational expectations imputes set out the argument against which everything below is measured.

Rational expectations imposes two requirements, individual rationality and mutual consistency of perceptions, and when a rational expectations model is taken to data it imputes to the agents inside it far more knowledge than the econometrician studying them has.

The bounded rationality program proposes to close that gap from the other side, by making the agents learn the distributions from data, as the econometrician must.

The hope was a description of the system *while it is still adjusting*, before beliefs and outcomes have settled into mutual consistency: a theory of transition dynamics.

What the program is good for listed four payoffs the program might deliver: equilibrium selection, computation, transition dynamics and the analysis of regime changes, and new sources of dynamics.

We take stock following Sargent [1993]'s own accounting: first the debits, then the central asymmetry, then the credits; and then we settle each of the four payoffs.

97.3 The debit side: how much we must hard-wire

The first reservation is about **arbitrariness**.

Bounded rationality is most easily defined by what it is *not* — rational expectations — and that very malleability is a liability.

Once we stop insisting that agents know the equilibrium, we must decide, case by case, exactly what they *do* know and how they learn it.

Do they know their own utility and profit functions, or must they learn those too?

Do they know calculus and dynamic programming, or only trial and error?

Do they learn from their own experience alone, or from others'?

To what class of approximating functions do we confine what they learn about?

Every model in this series answered these questions by **hard-wiring**, by prompting the agents heavily, with an eye on the outcome we hoped they would reach.

The series descended a gradient of prompting, telling its agents a little less at each step.

Bray's least squares learners (*From relaxation to learning: Bray's market*; see also *Least Squares Learning in Self-Referential Models*), who reappear below, know the correct supply curve and need only estimate one conditional expectation to plug into it.

The Marcet–Sargent agents of the book's investment example (see *Least Squares Learning in Self-Referential Models*) know dynamic programming, know their return function, and know the parametric form of the law of motion — they lack only its coefficients, which they update by vector autoregression.

The Robbins–Monro agents of *Adaptive Agents in an Overlapping Generations Monetary Economy* know their utility function but not the distributions they face; the agents of *Learning, Approximation, and Equilibrium Computation* must in addition choose a functional form; the Newton–Raphson learners of *Exchange Rate Indeterminacy, Learning, and Experiments* know the gradient of their own payoff.

Even the least prompted agents — the genetic-algorithm strings of *Exchange Rate Indeterminacy, Learning, and Experiments* and the classifier systems of *Networks, Genetic Algorithms, and Classifier Systems* and *Money as a Medium of Exchange among Artificially Intelligent Agents*, which see only a payoff signal and recognize utility only when they experience it — are still told *when* to choose and *what* information to condition on, and the entire apparatus of their accounting system and genetic operators is designed by hand, with the Kiyotaki–Wright equilibrium in view.

Sargent named the consequence: "a concomitant sensitivity of outcomes to details of adaptive algorithms."

Economy A2 of *Money as a Medium of Exchange among Artificially Intelligent Agents* is the sharpest case in the series (*Economy A2.1: when theory predicts speculation*).

For patient agents, the speculative equilibrium is the *unique* stationary equilibrium of that economy, yet the classifier agents settle on the fundamental pattern of trade.

That is not learning selecting among equilibria, since there is nothing to select among.

It is convergence to an outcome that is not an equilibrium of the economy the agents live in.

Marimon *et al.* [1990] suspected early myopia of "diverting the economy towards a low discount-factor stationary equilibrium, such as the fundamental equilibrium", and *The bucket brigade's discount factor* shows why: the bucket brigade makes the agents effectively very impatient.

The outcome is a property of how the agents were built, and the paper itself reports (its footnote 15) that a genetic algorithm studied by Marimon and Miller reached the speculative equilibrium in 25 of 30 runs.

The second reservation is about **simplicity**.

The learning tasks we set our agents are trivial next to those in a first econometrics course, let alone those that real firms and households are implicitly solving.

We ask an agent to learn a single time-invariant decision rule, or a fixed collection of conditional expectations.

We do not ask it to learn the parameters of a simultaneous-equations system, or to infer a mapping from policy regimes to distributions, the tasks that make econometrics hard.

Even the choice of what to learn is a prompt.

Agents in *Learning, Approximation, and Equilibrium Computation* who are confined to a low-order polynomial converge to an approximate equilibrium, a fixed point of the restricted problem rather than the rational expectations equilibrium, and the modeller's choice of family decides how close they come.

Put together, these reservations bear directly on the original prize.

The environments into which we have cast our adaptive agents are far more stable and hospitable than the transitions we actually care about.

Convergence-rate results are scarce, and tractability forces us to restrict the distribution of agents' beliefs severely.

So the literature on adaptive processes, Sargent judged in 1993, falls well short of a secure foundation for a theory of real-time transition dynamics, the very thing the quest set out to find.

He declines to end on that failure, though, and the baseball metaphor he reaches for is deliberately modest:

> It would not be wise or fair to end this essay by dwelling on the failure of adaptive methods so far to have 'hit a home run' by giving us a good theory of transition dynamics. The problem of transition dynamics is difficult and long-standing. So maybe it should count as a single, or at least a sacrifice fly, that these methods have sharpened our appreciation of the problem.

97.4 Why the econometricians have not returned the compliment

Here is the asymmetry that gives this lecture its theme.

The bounded rationality program is, at bottom, a movement to make the agents in our models behave more like the econometricians who build and estimate those models.

Imitation is the sincerest form of flattery.

We might therefore have expected macroeconometricians to rush to fit these models to data.

There was no rush.

Chung [1990] estimated the Sims policy-maker model (*A government learning the Phillips curve*), in which a government runs a Kalman filter (*A First Look at the Kalman Filter*) on a Phillips curve whose coefficients it believes drift as random walks.

Along with the structural parameters, Chung estimated the variances of the drift and the prior mean that started the government's filter.

Sargent called this "the only econometrically serious macroeconomic implementation of bounded rationality of which I know."

Why the reluctance?

The reasons are worth spelling out, because they are not about taste.

The governing dictum among applied econometricians is Lucas's: *beware of theorists bearing free parameters*.

Replacing a rational agent with a boundedly rational one **adds** parameters: parameters describing beliefs and how beliefs move.

Take the simplest case, Bray's model.

Relative to its rational expectations version, the adaptive version adds at least the initial belief and a parameter setting the gain sequence, and one might want more parameters to describe the gain's shape.

That would already give Lucas's warning something to bite on.

But there is a deeper problem, and it is the reason the added parameters are not just unwelcome but genuinely hard to estimate.

Because Bray's adaptive system **converges** to the rational expectations equilibrium, which in her model is unique, the extra parameters influence only the *transient*.

The asymptotic distribution of the data contains no information about them.

Let us see this directly.

97.4.1 The nuisance parameter, made concrete

Bray's cobweb economy [Bray, 1982] sets the market price by

$$p_t = a + b\,\beta_t + u_t,$$

where β_t is the price agents expect, formed by averaging past prices,

$$\beta_t = \beta_{t-1} + \gamma_t\,(p_{t-1} - \beta_{t-1}), \qquad \gamma_t = \frac{1}{t + t_0},$$

and u_t is an IID standard normal shock.

The constant t_0 is the weight the agents attach to the belief they start with, measured in observations: with $t_0 = 50$ they treat β_0 as though it summarized fifty prior prices, so that after t periods β_0 still carries weight $t_0/(t + t_0)$.

Some such weight is needed for the exercise to have any content.

With $t_0 = 0$ the first gain is $\gamma_1 = 1$, so $\beta_1 = p_0$ exactly and the initial belief is erased after a single period — there would be no transient left for the econometrician to try to estimate.

When $b < 1$ the belief converges to the rational expectations value $\beta^\star = a/(1 - b)$, whatever value it started from.

That is Bray's result, and it is the E-stability condition of *One recursion, many learners*: the associated differential equation $d\beta/d\tau = T(\beta) - \beta = a + (b - 1)\beta$ is stable exactly when $b < 1$.

```
a, b = 5.0, 0.7
t0 = 50                                          # weight on the initial belief
β_star = a / (1 - b)                             # rational expectations belief

def simulate(β0, u):
    "Bray's cobweb under least squares learning, given a shock path u."
    T = len(u)
    β = np.empty(T)
    p = np.empty(T)
    β[0] = β0
    for t in range(T):
        p[t] = a + b * β[t] + u[t]
        if t + 1 < T:
            β[t + 1] = β[t] + (1 / (t + 1 + t0)) * (p[t] - β[t])
    return p, β

print(f"rational expectations belief β* = {β_star:.3f}")
```

```
rational expectations belief β* = 16.667
```

The initial belief β_0 is the extra "bounded rationality" parameter.

Watch three economies with very different initial beliefs head toward $\beta^\star$.

```
rng = np.random.default_rng(0)
u = rng.standard_normal(400)

fig, ax = plt.subplots(figsize=(7.5, 4))
for β0, colour in [(2.0, 'C0'), (16.667, 'C1'), (40.0, 'C2')]:
    _, β = simulate(β0, u)
    ax.plot(β, color=colour, lw=1.3, label=fr"$\beta_0 = {β0}$")
ax.axhline(β_star, color='k', ls='--', lw=0.8, label=r"$\beta^\star$")
ax.set_xlabel("$t$")
```

(continues on next page)

(continued from previous page)

```
ax.set_ylabel(r"belief $\beta_t$")
ax.legend(frameon=False)
plt.show()
```

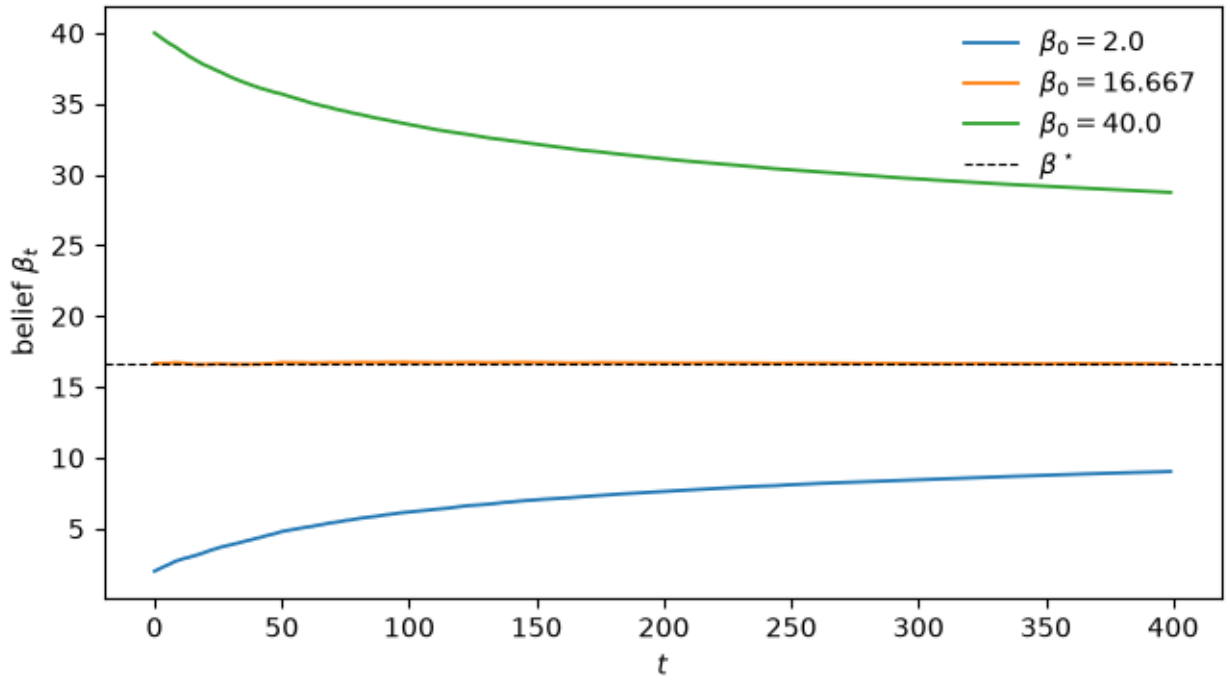

Fig. 97.1: Beliefs drift toward the rational expectations value, slowly

All three head toward $\beta^\star$, but slowly.

Each period the learning recursion closes the gap $\beta_t - \beta^\star$ by the factor $1-(1-b)/(t+t_0)$ on average, so after t periods roughly $(t_0/(t+t_0))^{1-b}$ of it remains.

```
for β0 in (2.0, 40.0):
    _, β = simulate(β0, u)
    share = (β[-1] - β_star) / (β0 - β_star)
    print(f"β0 = {β0:4.1f}: share of the initial gap left after {len(u)} periods =
 ↪{share:.2f}")
print(f"approximation (t0 / (t + t0))^(1 - b) = {(t0 / (len(u) - 1 + t0)) ** (1 - b):.
 ↪2f}")
```

```
β0 =  2.0: share of the initial gap left after 400 periods = 0.52
β0 = 40.0: share of the initial gap left after 400 periods = 0.52
approximation (t0 / (t + t0))^(1 - b) = 0.52
```

About half the initial gap is still there after 400 periods.

That is slower than the $1/\sqrt{t}$ rate at which an ordinary estimator settles down, as the book's chapter 5 warns: least squares learning converges at the $\sqrt{T}$ rate only when the slope of the associated differential equation, here $b-1$, is below $-1/2$.

Slow forgetting by the *economy*, however, is not the same thing as information for the *econometrician*.

Now put on the econometrician's hat.

Given a sample of prices and the structural parameters (a, b), the model implies a shock $\hat{u}_t = p_t - a - b\,\beta_t(\beta_0)$ for any candidate initial belief β_0, because the belief path is pinned down by β_0 and the observed prices.

The sum of squared implied shocks measures how well a given β_0 fits the data.

```
def belief_path(β0, p):
    "Belief sequence implied by an initial belief and an observed price path."
    T = len(p)
    β = np.empty(T)
    β[0] = β0
    for t in range(1, T):
        β[t] = β[t - 1] + (1 / (t + t0)) * (p[t - 1] - β[t - 1])
    return β

def ssr(β0, p):
    "Sum of squared implied shocks, as a function of the belief parameter β0."
    β = belief_path(β0, p)
    return np.sum((p - a - b * β) ** 2)
```

Whether the data can pin β_0 down is a question of how fast *information* about it accumulates as the sample grows.

The natural way to read that off is the **excess** sum of squares — how much worse a wrong β_0 fits than the best one.

For an ordinary, well-identified parameter every new observation adds to the penalty for being wrong, so the excess grows in proportion to T and the confidence interval shrinks like $1/\sqrt{T}$.

Because the shocks have unit variance, the excess is also a likelihood-ratio statistic, so a penalty above 3.84 rejects the wrong value at the 5 percent level.

Watch what happens here.

```
grid = np.linspace(2, 40, 80)

def excess_curve(T, seed=1):
    "SSR(β₀) − min SSR across the β₀ grid, for a sample of length T."
    u = np.random.default_rng(seed).standard_normal(T)
    p, _ = simulate(β_star, u)
    curve = np.array([ssr(b0, p) for b0 in grid])
    return curve - curve.min()

fig, ax = plt.subplots(figsize=(7.5, 4))
for T, colour in zip((50, 500, 5000), ('C0', 'C1', 'C2')):
    ax.plot(grid, excess_curve(T), color=colour, lw=1.5, label=f"$T = {T}$")
ax.axvline(β_star, color='k', ls='--', lw=0.8)
ax.set_xlabel(r"belief parameter $\beta_0$")
ax.set_ylabel("excess sum of squares")
ax.legend(frameon=False)
plt.show()
```

The curve for $T = 50$ is lower, but beyond a few hundred observations the curves lie nearly on top of one another instead of getting steeper.

To see that this is not an artifact of the range plotted, compare the penalty for a wrong β_0 with the penalty for a wrong *slope* b, estimated from the same data.

We compute the slope penalty twice: once holding the intercept a at its true value, and once re-estimating a along with b, and we average each penalty over 20 samples.

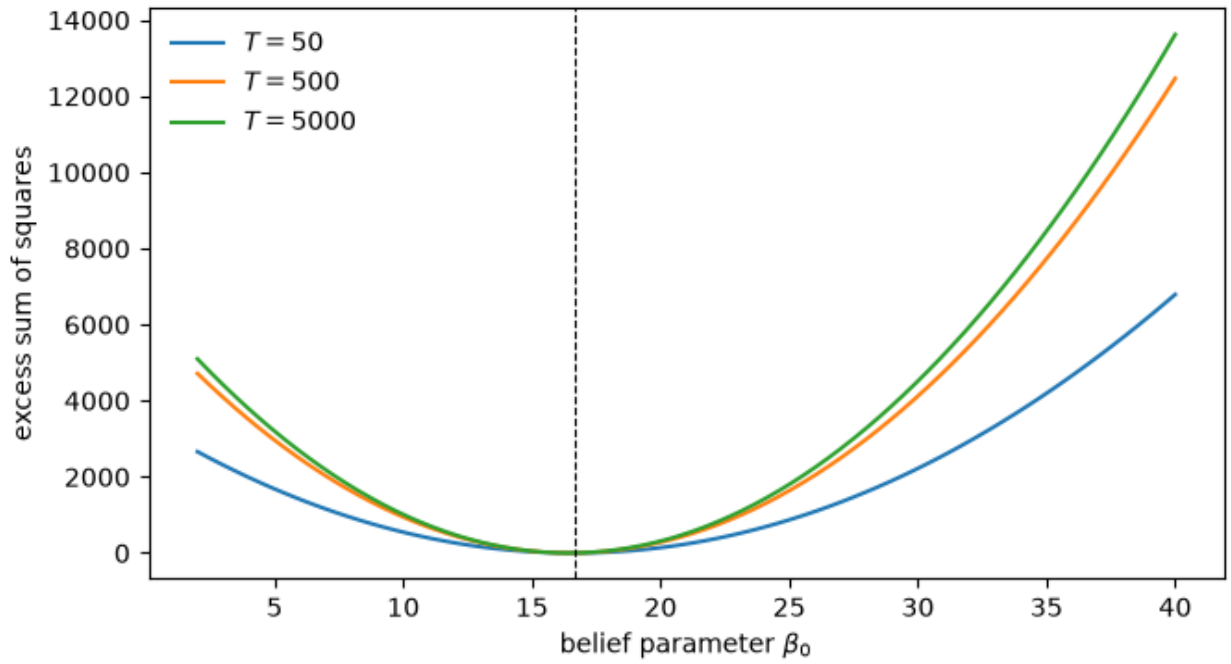

Fig. 97.2: Information about the belief parameter stops accumulating

```
def ssr_a_free(r):
    "Sum of squared residuals after re-estimating the intercept (removing the mean)."
    return np.sum((r - r.mean()) ** 2)

print(f"{'':>6}   {'β₀ = 2':>8}   {'b = 0.75':>10}   {'b = 0.75':>14}   {'b = 0.75, a␣
↪re-est.':>19}")
print(f"{'T':>6}   {'':>8}   {'a known':>10}   {'a re-estimated':>14}   {'largest of␣
↪20':>19}")
for T in (50, 500, 5_000, 50_000):
    pen_β0, pen_b_known, pen_b_free = [], [], []
    for seed in range(20):
        u = np.random.default_rng(seed).standard_normal(T)
        p, _ = simulate(β_star, u)
        β = belief_path(β_star, p)              # belief path at the true β0
        pen_β0.append(ssr(2.0, p) - ssr(β_star, p))
        pen_b_known.append(np.sum((p - a - 0.75 * β) ** 2)
                           - np.sum((p - a - b * β) ** 2))
        pen_b_free.append(ssr_a_free(p - 0.75 * β) - ssr_a_free(p - b * β))
    print(f"{T:>6}   {np.mean(pen_β0):8.1f}   {np.mean(pen_b_known):10.1f}   "

```

The columns behave completely differently.

The penalty for getting the initial belief wrong stops growing.

Past a few thousand observations it is pinned near a constant, and every further observation is uninformative about β_0.

The confidence interval for β_0 never shrinks; the parameter is not consistently estimable at all.

The reason is visible in the belief recursion.

Given the observed prices, the econometrician's reconstructed belief at t depends on β_0 only through the weight $t_0/(t+t_0)$, and the squares of those weights have a finite sum.

The rest of β_0's long shadow on the economy is carried by the observed prices themselves.

The penalty for a wrong slope with a held at its true value grows in proportion to the sample: a hundredfold more data makes a hundredfold stronger case against the wrong value, which is what identification looks like.

But this identification is borrowed.

With a held fixed, a wrong b shifts the predicted mean price, and the mean price $a/(1-b)$ is something the rational expectations version of the model identifies too.

What a learning model adds is the possibility of separating a from b, and for that the data have to see beliefs move.

The third column shows how little they see.

With a re-estimated, the penalty is a fraction of one and creeps up by a tenth or less with each tenfold increase in the sample; in none of the 20 samples does it come near 3.84, even with 50,000 observations.

Under a $1/t$ gain belief motion dies out, so the learning transient is the only thing that separates a from b: the weakness that makes β_0 unidentifiable afflicts the slope too, in milder form.

This is the technical heart of the matter.

The parameters that bounded rationality adds live in the transient, and under a decreasing gain so does the information that would separate the old parameters from one another.

A transient contributes only a limited amount of information no matter how long we watch the economy afterwards, so those parameters become a **nuisance to estimate** — they enter the likelihood, and the data have little to say about them.

Sargent adds one more reason for the econometricians' cool response, with a characteristic "maybe".

Many applied macroeconometricians are in the market for methods that *reduce* the number of parameters needed to explain the data.

A reduction is precisely what bounded rationality does not offer.

It offers more parameters, most of them weakly identified.

So the flattery ran one way.

The theorists remade their agents in the econometrician's image; the econometricians, offered models full of extra, poorly-identified parameters, and warned by Lucas against exactly that, declined the gift.

97.4.2 When the equilibrium is not unique

The argument assumed that learning converges to a unique, E-stable equilibrium, as it does in Bray's model with $b < 1$.

Then initial beliefs, and the shape of the gain, can only affect the transient.

Under multiplicity that premise can fail.

In *Adaptive Agents in an Overlapping Generations Monetary Economy* the initial belief decides whether the economy settles at the low-inflation steady state or collapses (*The stability reversal*).

In *Exchange Rate Indeterminacy, Learning, and Experiments*, at the calibration where the Newton–Raphson learner converges, the initial saving rates and portfolio shares fix the limiting exchange rate forever (*The dead hand of history*).

Where initial beliefs select among a continuum of limits, as in the exchange-rate economy, their effect is permanent, and a permanent effect is one that every new observation helps to measure.

In a deterministic economy like that one, observed with error, the data measure the effect of the initial beliefs at the usual rate, as they would a structural parameter.

Exercise 97.8.2 shows this, and also shows that permanence is not always enough.

When beliefs are driven by observed prices, as in Bray's model, the econometrician can reconstruct them from the data, and the initial belief's weight in that reconstruction dies away whatever the equilibrium structure.

Shocks blur the picture in the exchange-rate economy too: once they enter, even identical starting points converge to different exchange rates (Exercise **??**), so the limit no longer reflects the initial beliefs alone.

97.5 The credit side: selection, computation, and a returned gift

The ledger is not one-sided.

Set against those debits, Sargent lists three successes, and the last of them quietly undoes some of the asymmetry just described.

In his opening chapter he also counts as a credit the models' "success in inspiring useful tests of equilibrium selection", meaning laboratory experiments.

Equilibrium selection.

Where a rational expectations model has many equilibria, a system of adaptive agents often converges to a *particular* one, turning learning into a device for selecting among them.

The clearest case in the series is the economy of *Adaptive Agents in an Overlapping Generations Monetary Economy*, where least squares learners select the low-inflation steady state that the rational expectations dynamics reject (*The stability reversal*), and where the laboratory subjects of Marimon and Sunder [1993] went the same way.

With no deficit, the same learners kill the bubbles of *A Peculiar Definition of Bounded Rationality* and select its bubbleless equilibrium (Exercise **??**).

In *Money as a Medium of Exchange among Artificially Intelligent Agents*, Economy B has both a fundamental and a speculative equilibrium, and the classifier systems select the fundamental one; in Economy A1, where the fundamental equilibrium is the only one, they find it.

The exchange rate of *Exchange Rate Indeterminacy, Learning, and Experiments* earns credit only in a weaker sense: learning determines the exchange rate only by remembering where it started, and the limit also moves with the tuning of the algorithm, its stabilizer κ and its gain (*The dead hand of history*).

Even that much holds only where the Newton–Raphson learner converges; at Arifovic's calibration, with the same tuning, it does not converge at all.

The book granted that this "may seem a weak reed on which to base exchange rate determination".

Economy A2 belongs on the debit side, as we saw above.

Nor is selection a welfare theorem.

In the book's example in the spirit of Brock, which *Adaptive Agents in an Overlapping Generations Monetary Economy* recalls as a warning, least squares selects a stationary equilibrium that every nonstationary equilibrium Pareto-dominates.

Sargent is candid that his affection for this use sits in some tension with his doubts about the dynamics that perform the selection:

> I know that it is inconsistent to doubt the real-time dynamics but keep the equilibria selected by them. I confess that my affection for the selection performed in the monetary models described in Chapter 6 is partly driven by my prior conviction that the selected equilibria seem sensible to me.

Chapter 6 of the book is its chapter on laboratory experiments: Marimon and Sunder's with the one-currency economy of *Adaptive Agents in an Overlapping Generations Monetary Economy*, and Arifovic's with the two-currency economy of *Exchange Rate Indeterminacy, Learning, and Experiments*.

The selection Sargent has in mind is the low-inflation one, on which least squares learning and Marimon and Sunder's subjects agreed.

Evolutionary programming.

If a population of adaptive agents reliably converges to an equilibrium, we can run the population as a *method of computing* the equilibrium, especially in models too complicated to solve by hand (*Evolutionary programming*).

The procedure is guess-and-verify: the adaptive system supplies the guess, and the economist checks that it satisfies the equilibrium conditions.

That is what Marimon *et al.* [1990] proposed for a five-good Kiyotaki–Wright economy, for which no analytical characterization was in hand (*Money as a Medium of Exchange among Artificially Intelligent Agents*): their classifier economy settled down to trading strategies and holding probabilities that suggested an equilibrium ("we could then presumably verify whether it is an equilibrium"), although the paper itself reports only that the patterns "nearly seem to describe" a fundamental equilibrium.

The cleanest instance in the series is *Learning, Approximation, and Equilibrium Computation*.

There Marcet's method of parameterized expectations, a tool for computing equilibria, has a learning counterpart in which agents update their forecasting rule as data arrive, and the two share their fixed points and, through the associated differential equation, their stability condition (*Parameterized expectations*).

The book had already remarked that Marcet's method "has many aspects of a learning or adaptation algorithm".

Used this way, the dynamics need not be credible as dynamics.

The book's chapter 7 describes how Randall Wright, computing a Kiyotaki–Wright equilibrium with endogenous shares of types, told his evolving population the theoretical payoffs it could have learned only from very long histories: hopeless as a model of real time, harmless as a computation.

That division of labor is how one can doubt the dynamics and still compute with them.

Sargent expected this use to be applied often.

New tools for the econometrician.

Here the asymmetry bends back on itself.

The literatures on parallel and genetic algorithms have handed econometricians new computational gadgets — genetic algorithms and stochastic Gauss–Newton procedures among them — for solving their *own* estimation and optimization problems.

Ellen McGrattan, for instance, applied genetic algorithms to estimate nonlinear rational expectations models, using them to search for the vicinity of a maximum before switching to a Newton method, a use noted in *Networks, Genetic Algorithms, and Classifier Systems*.

So the econometricians took up the adaptive algorithms after all, not as *models* of the agents they study, but as *tools* in their own hands.

The compliment was returned, but through a side door: the algorithms crossed over, the models did not.

New sources of dynamics.

The book's second chapter listed one more payoff: adaptive agents might generate behavior that rational expectations models find hard to produce, such as the trading volume that the no-trade theorem rules out.

Sargent's closing ledger does not post it, but the series delivers two instances.

Arifovic's genetic-algorithm economy in *Exchange Rate Indeterminacy, Learning, and Experiments* produces an exchange rate that never settles down, even though saving settles near its equilibrium value (*A genetic algorithm economy*), and even though every equilibrium of that economy in which both currencies are valued has a constant exchange rate.

And the constant-gain government of *Adaptive Agents in an Overlapping Generations Monetary Economy* produces a recurrent sawtooth of escapes from the self-confirming inflation rate toward zero inflation (*A government learning the Phillips curve*), dynamics that the model's unique self-confirming equilibrium does not have.

97.6 Reading the ledger against the quest

Line the two columns up against the destination we set out for, and against the four payoffs of *What the program is good for*.

payoff	verdict	where the series shows it
equilibrium selection	credit, qualified	*Adaptive Agents in an Overlapping Generations Monetary Economy* (low inflation); *Money as a Medium of Exchange among Artificially Intelligent Agents* (Economy B); only in a weaker sense in *Exchange Rate Indeterminacy, Learning, and Experiments*; Economy A2 is a debit
computation	credit	*Learning, Approximation, and Equilibrium Computation*; *Networks, Genetic Algorithms, and Classifier Systems*; *Money as a Medium of Exchange among Artificially Intelligent Agents* (the five-good economy); tools for econometricians
transition dynamics and regime changes	debit in 1993, partly paid since	escape dynamics in *Adaptive Agents in an Overlapping Generations Monetary Economy*, characterized in *Escaping Nash Inflation*
new sources of dynamics	credit, absent from the 1993 ledger	*Exchange Rate Indeterminacy, Learning, and Experiments* (genetic-algorithm volatility); *Adaptive Agents in an Overlapping Generations Monetary Economy* (the escape sawtooth)

The **debit** column holds the prize itself.

Sargent had argued in his second chapter that comparing rational expectations equilibria across policy regimes is itself inconsistent with rational expectations, and a theory of how adaptive agents move from one regime to another was supposed to repair that.

A theory of real-time transition dynamics — the map the Eastern European reformers lacked — remained, in 1993, largely unclaimed, blocked by arbitrariness, prompting, over-simple learning tasks, and a shortage of empirical traction.

The **credit** column holds what the journey delivered along the way: a way to select among multiple equilibria where the selection does not hinge on the details of the algorithm, a practical way to compute equilibria that resist analysis, new sources of dynamics, and a transfer of computational technique into econometrics itself.

The organizing image of the whole book is the gap between the econometrician and the agents inside the model.

Rational expectations closes that gap by lifting the agents up to a knowledge the econometrician lacks.

Bounded rationality proposed to close it from the other side, by bringing the agents down to the econometrician's level and making them learn.

By 1993 the program had not, on Sargent's own accounting, delivered the transition dynamics that motivated it, and the econometricians it sought to imitate had kept the models at arm's length — for the sound reason that those models add parameters the data identify only weakly, and not consistently, when what the econometrician wants is fewer.

But it had sharpened the questions, selected equilibria, computed them, and lent its tools to the very econometricians who declined its models.

That was the state of the prospects for bounded rationality in macroeconomics, as they stood in 1993.

97.7 Postscript: what became of the program

Three decades is long enough to see which of the 1993 worries were permanent and which were about a field that had not yet found its footing.

97.7.1 The arbitrariness was disciplined

The first reservation was that once we stop insisting agents know the equilibrium, nothing tells us what to put in its place.

The discipline that matured is **expectational stability**.

Its core was already in the 1993 book.

A footnote to the book's chapter 5 writes the limiting dynamics of Bray's belief as the differential equation $d\beta/d\tau = T(\beta) - \beta = a + (b-1)\beta$, where T maps the perceived forecast into the optimal one.

The same footnote credits DeCanio [1979] and Evans [1985], Evans [1989] with using T to define expectational stability, and credits Marcet and Sargent [1989] with showing, by the differential-equation methods of Ljung [1977], that $T(\beta)-\beta$ governs the convergence of least squares learning in a class of models.

Woodford [1990] used the same methods to study learning of sunspot equilibria, and the book's chapter 5 closes with a section on the associated differential equation.

One recursion, many learners sets out this thread for the whole series.

What came after 1993 was systematization.

Evans and Honkapohja [2001] generalized these results and organized them into a theory of learnability that is now the standard test of whether a rational expectations equilibrium is a plausible outcome of adaptive behavior.

For least squares and related decreasing-gain estimators near a rational expectations equilibrium, E-stability is the right condition, and one can check which equilibria satisfy it without simulating anything.

That narrows the arbitrariness: the selection that least squares performs is not an artifact of the particular recursion the modeller happened to write down.

The condition has limits, and those were mapped too.

It is not a theorem about every algorithm.

Stochastic-gradient learners can fail to learn equilibria that are E-stable [Giannitsarou, 2005].

Population algorithms lie outside the theory altogether: drawing on Arifovic's 1991 dissertation, the book reports that a genetic-algorithm population can sometimes learn its way to the equilibrium of Bray's model even when $b > 1$, where least squares cannot (Sargent [1993], chapter 5), and the classifier agents of Economy A2 converge to something that is not an equilibrium at all.

Within those limits the condition does its job, and the stability reversal of *Adaptive Agents in an Overlapping Generations Monetary Economy* is a case in point.

Marcet and Sargent's differential equation already accounted for it in 1993.

In the language of E-stability, it says that $T'(2) = 1/2 < 1$ at the low-inflation steady state and $T'(3) = 2 > 1$ at the high one (*The stability reversal*), and the ranking is a theorem about the model rather than about these parameters (Exercise **??**).

That is why Bruno and Fischer [1990], using adaptive expectations instead of least squares, found the same reversal: rules that move beliefs toward realized inflation inherit the same stability condition.

The verdict does not even need small gains: with the timing of *Adaptive Agents in an Overlapping Generations Monetary Economy*, the low steady state is locally stable for every constant gain below 2 and the high one for none (*The stability reversal*, Exercise 97.8.1).

Bullard and Duffy [1993] supplied the warning against generalizing too far: in economies whose agents live four or more periods, least squares learning can fail to converge locally to a rational expectations equilibrium.

97.7.2 The transition dynamics arrived, in a narrower form than hoped

The prize was a theory of out-of-equilibrium adjustment.

What the program delivered instead was a theory of *departures from* equilibrium: escape dynamics.

In 1993, the escapes of Sims's government were known only from simulation, which the book presented as formalizations of a story and a counter-story about postwar inflation.

The recurrent sawtooth simulated in *A government learning the Phillips curve* comes from the constant-gain version of the model that Sargent [1999] studied after 1993.

Cho *et al.* [2002] characterized its escapes analytically with large-deviations theory, computing the most likely escape path and the rate at which escapes occur, and Williams [2019] extended the characterization considerably.

Sargent and Williams [2005] then explained why the simulated economies of Sims and Chung escape and *stay* near the Ramsey outcome while Sargent's are pulled back again and again: the difference lies in how much variance the government attributes to its regression error.

The QuantEcon lectures *Escaping Nash Inflation* and *Priors, Escapes, and Learning Cycles* work through both.

This is less than the original quest asked for.

It describes recurrent excursions away from a self-confirming equilibrium, not the arrival of a market economy in a country that never had one.

But it is a genuine theory of a system that does not settle down, derived rather than simulated, and in 1993 there was none.

97.7.3 The econometricians did return the compliment

Here the 1993 assessment was largely overtaken.

The obstacle, we saw above, was that the added parameters live in a vanishing transient.

But that argument applies to a learning scheme whose gain goes to zero, so that beliefs converge and then stop moving.

With a gain that does not vanish, beliefs never settle.

Their motion is part of the stationary distribution of the data, and the parameters that govern it are identified the way ordinary structural parameters are, from the whole sample.

The 1993 book already had the exception in view.

It noted that its transients came from algorithms that eventually settle down, adding that "the exceptions are the constant-gain algorithms".

And Chung's government, the one serious empirical case, ran a Kalman filter on coefficients it believed drift: for given drift variances its gain does not go to zero, which is why those variances could be estimated from the whole sample.

Let us check the claim on Bray's market, giving the econometrician the harder problem of re-estimating a and b along with the gain.

We hold the initial belief at its true value; under a constant gain its influence dies out geometrically.

```
def simulate_constant_gain(β0, gain, u):

```

Both penalties now keep growing with the sample, and in the largest samples they grow in proportion to it: each roughly quadruples between 50,000 and 200,000 observations.

Contrast the slope penalty with a re-estimated under the $1/t$ gain, which never got past a fraction of one.

Persistent belief motion supplies the identifying variation that a vanishing gain withholds.

The information per observation is small, though.

With 500 observations a gain of 0.08 cannot be told from 0.05: the average penalty is about zero and no sample rejects

the wrong gain at the 5 percent level.

With 5,000 observations a majority of samples reject it, and with 50,000 all do.

The gain is identified at the usual rate, but weakly per observation; Exercise 97.8.4 shows how the information shrinks with the size of the gain, and Exercise **??** poses the same question for the Phillips-curve government of *Adaptive Agents in an Overlapping Generations Monetary Economy*.

Later work built on Chung's foundation.

Sargent [1999] made a constant-gain government the center of an account of postwar U.S. inflation, and Sargent and Williams [2005] showed how the government's prior about drifting coefficients, encoded in a drift covariance V, shapes its learning dynamics (*Priors, Escapes, and Learning Cycles*).

Sargent *et al.* [2006] estimated a model in which the government runs a Kalman filter on drifting coefficients, the Sims–Chung specification, using postwar U.S. data to estimate the drift covariance V that sets its non-vanishing gain.

Primiceri [2006] estimated a model in which policy makers learn about the natural rate of unemployment and the persistence of inflation.

The estimates revived a version of the 1993 worry.

To fit the data, SWZ needed a large V, and critics, including Sargent [2008] himself, objected that the implied beliefs were implausibly volatile (*Priors, Escapes, and Learning Cycles*).

The response was to bring in direct evidence on beliefs.

Survey data. Carboni and Ellison [2009] required the model's beliefs to reproduce the forecasts in the Federal Reserve's Greenbook, which shrank the estimated drift variance of the constant by a factor of about fifty while keeping the account of the rise and fall of inflation.

Cohorts. Malmendier and Nagel [2016] found that people's inflation expectations in survey data weight the inflation they have lived through, with gains that decline with age.

In an economy of overlapping cohorts someone is always young, so the aggregate never finishes its transient, and parameters that would be transient for a single agent become parameters of the stationary distribution (Exercise 97.8.3).

Experiments. Laboratory experiments, which the book counted as a credit, offer a third route: there the experimenter knows the environment and observes choices, and sometimes forecasts, directly, as in Marimon and Sunder [1993] and Arifovic [1996].

The econometricians also adopted the agents' apparatus outright.

Cogley and Sargent [2005], whom *Drifts and Volatilities* follows, fit a vector autoregression whose coefficients drift as random walks, the very specification Sims and Chung had handed their government, and asked whether the Great Inflation was bad policy or bad luck.

So the flattery did run both ways in the end.

The learning technology that made the models estimable was already present in Chung's 1990 model.

What changed after 1993 was that a gain that never vanishes moved from exception to standard specification.

It was adopted largely for reasons of economics, since an agent who suspects that its world is changing should keep discounting old data, and it turned out to pay an econometric dividend.

97.7.4 A second retreat, made differently

The program in this book keeps individual rationality and gives up mutual consistency: agents optimize, but against beliefs they are still estimating.

A parallel literature retreats along a different axis.

In the **robustness** work of Hansen and Sargent [Hansen and Sargent, 2008], agents share an approximating model with the econometrician, a model that can be estimated, but they distrust it.

They optimize against the worst case among nearby models that the data could not easily distinguish from it, and the size of that set can be calibrated with detection-error probabilities (*Robust Permanent Income and Pricing*).

Where bounded rationality changes the agents' beliefs, robustness keeps a model common to agents and econometrician and changes the agents' preferences, toward caution.

The two are complements rather than rivals, and both are answers to the question that opens *A Peculiar Definition of Bounded Rationality*: what do we do about the knowledge that rational expectations imputes?

One answer is that agents should learn what the econometrician is learning.

The other is that they should act well while doubting what they have learned.

A third answer, which the book set aside for lack of space, keeps rationality whole: Bayesian agents learning inside a rational expectations equilibrium, as in *Rational Learning and Rational Expectations*.

97.7.5 The algorithms kept crossing over

The 1993 ledger noted that econometricians had adopted the adaptive algorithms as computational tools even while declining the models.

That traffic increased, and reversed direction again.

Holland's bucket brigade (*The bucket brigade*) — pay part of your reward backward to whatever set you up — is a precursor of *temporal-difference learning*, which became an organizing idea of modern reinforcement learning [Sutton and Barto, 2018]; *Job Search X: Search with Q-Learning* applies temporal-difference learning to a McCall worker.

The resemblance runs deep enough to be useful: *The bucket brigade's discount factor* reads the strengths of the bucket brigade in *Money as a Medium of Exchange among Artificially Intelligent Agents* as values computed with a very low discount factor, which helps explain Economy A2.

The classifier systems of *Money as a Medium of Exchange among Artificially Intelligent Agents* are recognizable, in retrospect, as reinforcement learners with a hand-built function approximator; and the perceptrons of *Networks, Genetic Algorithms, and Classifier Systems* are ancestors of the deep networks of *Introduction to Artificial Neural Networks*, which now serve as the function approximators.

Sargent said in 1993 that he would select the "brains" of his agents from the store of methods built up in statistics, econometrics, and artificial intelligence.

Those methods turned out to be early versions of what that last field went on to build.

97.7.6 Reading the ledger again

The 1993 debits have not all been paid.

The choices remain many, the learning tasks we set our agents remain simple next to the ones real firms solve, and no one has produced the theory of transition dynamics that the Eastern European reforms called for.

But the entries have moved.

Selection's theory, sketched in 1993, was systematized and its limits mapped; non-convergence acquired an analytical characterization instead of a simulation; and the econometricians, offered models whose gains never vanish, together with survey, cohort, and laboratory evidence on beliefs themselves, took them up.

The gap between the econometrician and the agents inside the model is still there.

It is narrower, and we now know a good deal about its width.

The next lecture, *The Rise and Fall of U.S. Inflation*, opens a suite built on *The Conquest of American Inflation* [Sargent, 1999], in which a government that keeps re-estimating its Phillips curve — the policy maker of Sims and Chung, grown up — is asked to explain the rise and fall of U.S. inflation.

97.8 Exercises

Exercise 97.8.1

This exercise checks the E-stability account of the stability reversal in *Adaptive Agents in an Overlapping Generations Monetary Economy* numerically, and extends that lecture's linearization (*The stability reversal*), which covers gains between 0 and 1, to find exactly how large the gain can be.

In the constant-deficit economy, a young agent who expects gross inflation β saves $s(\beta) = (w_1 - w_2\beta)/2$, and the government finances a real deficit G per young person by printing money.

If everyone expects the same constant β, realized inflation is constant at

$$T(\beta) = \frac{s(\beta)}{s(\beta) - G}.$$

Use Marimon and Sunder's Economy 7C, $w_1 = 6$, $w_2 = 1$, $G = 1$.

1. Find the fixed points of T and compute T' at each, analytically and numerically. Which steady states are E-stable? Compare with the slopes of the perfect-foresight map $g(\pi) = A_1 - A_2/\pi$, with $A_1 = (w_1 + w_2 - 2G)/w_2$ and $A_2 = w_1/w_2$, at the same points.
2. Replace least squares with Cagan's adaptive expectations, $\beta_{t+1} = \beta_t + \lambda(\pi_t - \beta_t)$, where realized inflation is $\pi_t = s(\beta_{t-1})/(s(\beta_t) - G)$ and $\beta_{-1} = \beta_0$. Simulate for $\lambda \in \{0.1, 0.5, 1, 1.5\}$ from initial beliefs $1.5, 2.5, 2.9, 2.99$ and 3.01, stopping if $s(\beta_t) \leq G$ (no positive price level). Where do the paths go?
3. Linearize the system in part 2 around each steady state and find, analytically, all the values of $\lambda > 0$ for which it is locally stable. Compare with the condition $|1 + \lambda(T' - 1)| < 1$ that a version of the recursion without the lag in realized inflation would give.

Solution

Here $s(\beta) = (6 - \beta)/2$, so $T(\beta) = (6 - \beta)/(4 - \beta)$.

Its fixed points solve $\beta^2 - 5\beta + 6 = 0$, so they are $\beta = 2$ and $\beta = 3$, the two steady states, and $T'(\beta) = 2/(4-\beta)^2$ gives $T'(2) = 1/2$ and $T'(3) = 2$.

```
w1, w2, G = 6.0, 1.0, 1.0

def s(β):
    return (w1 - w2 * β) / 2

def T_map(β):
    return s(β) / (s(β) - G)

A1, A2 = (w1 + w2 - 2 * G) / w2, w1 / w2
steady_states = np.sort(np.roots([1, -A1, A2]).real)

h = 1e-6
for β in steady_states:
    T_prime = (T_map(β + h) - T_map(β - h)) / (2 * h)
    g_prime = A2 / β**2
    print(f"β = {β:.0f}:  T(β) = {T_map(β):.4f}   T'(β) = {T_prime:.4f}   "
          f"g'(β) = {g_prime:.4f}   E-stable: {T_prime < 1}")
```

```
β = 2:  T(β) = 2.0000   T'(β) = 0.5000   g'(β) = 1.5000   E-stable: True
β = 3:  T(β) = 3.0000   T'(β) = 2.0000   g'(β) = 0.6667   E-stable: False
```

Only the low-inflation steady state is E-stable.

Under perfect foresight the ranking is reversed: $g'(2) = 3/2 > 1$ and $g'(3) = 2/3 < 1$.

At both steady states $T' - 1$ and $g' - 1$ have opposite signs, which is the reversal; Exercise **??** proves that this holds for all parameters.

Now the adaptive-expectations version.

```
def adaptive_path(β0, lam, n=2000):
    "Cagan adaptive expectations with the timing of olg_adaptive_money."
    β_prev, β = β0, β0
    for t in range(n):
        if s(β) <= G:
            return β, False                          # no positive price level
        π = s(β_prev) / (s(β) - G)                   # realized inflation
        β_prev, β = β, β + lam * (π - β)
    return β, True

starts = (1.5, 2.5, 2.9, 2.99, 3.01)
print("λ      " + "".join(f"β0 = {β0:<9}" for β0 in starts))
for lam in (0.1, 0.5, 1.0, 1.5):
    cells = []
    for β0 in starts:
        β_end, alive = adaptive_path(β0, lam)
        cells.append(f"{β_end:.4f}" if alive else "collapse")
    print(f"{lam:<6} " + "".join(f"{c:<14}" for c in cells))
```

```
λ      β0 = 1.5      β0 = 2.5      β0 = 2.9      β0 = 2.99     β0 = 3.01
0.1    2.0000        2.0000        2.0000        2.0000        collapse
0.5    2.0000        2.0000        2.0000        2.0000        collapse
1.0    2.0000        2.0000        2.0000        2.0000        collapse
1.5    2.0000        2.0000        2.0000        2.0000        collapse
```

Every path that starts below 3 converges to the low-inflation steady state, and the path that starts just above 3 collapses: the reversal survives Cagan's adaptive expectations, as Bruno and Fischer [1990] found.

For the linearization, write $\delta_t = \beta_t - \beta^\star$.

Realized inflation responds to the current and lagged belief with coefficients $c_0 = -s^\star s'/(s^\star - G)^2$ and $c_1 = s'/(s^\star - G)$, where $s' = -w_2/2$ and $s^\star = s(\beta^\star)$, and $c_0 + c_1 = T'(\beta^\star)$.

So $\delta_{t+1} = (1 + \lambda(c_0 - 1))\,\delta_t + \lambda c_1\,\delta_{t-1}$.

```
def spectral_radius(β_ss, lam):
    "Largest root modulus of the linearized adaptive-expectations system."
    s_ss, s_prime = s(β_ss), -w2 / 2
    c0 = -s_ss * s_prime / (s_ss - G)**2
    c1 = s_prime / (s_ss - G)
    A = np.array([[1 + lam * (c0 - 1), lam * c1],
                  [1.0, 0.0]])
    return np.max(np.abs(np.linalg.eigvals(A)))

for β_ss in steady_states:
    radii = [spectral_radius(β_ss, lam) for lam in (0.5, 1.0, 1.9, 2.0, 2.1)]
    print(f"β* = {β_ss:.0f}: spectral radius at λ = 0.5, 1, 1.9, 2, 2.1:",
          np.round(radii, 3))
```

```
β* = 2: spectral radius at λ = 0.5, 1, 1.9, 2, 2.1: [0.5   0.707 0.975 1.    1.
↪025]
β* = 3: spectral radius at λ = 0.5, 1, 1.9, 2, 2.1: [1.707 2.618 4.365 4.562 4.
↪759]
```

At $\beta^\star = 2$, $c_0 = 1$ and $c_1 = -1/2$, so the characteristic polynomial is $z^2 - z + \lambda/2$; the product of its roots is $\lambda/2$, and the system is stable exactly when $0 < \lambda < 2$.

At $\beta^\star = 3$, $c_0 = 3$ and $c_1 = -1$, so the polynomial is $z^2 - (1 + 2\lambda)z + \lambda$, which is negative at $z = 1$; there is always a root above one, and the high steady state is unstable for every $\lambda > 0$.

Without the lag the multiplier would be $1 + \lambda(T' - 1)$: $1 - \lambda/2$ at the low steady state, stable for $\lambda < 4$, and $1 + \lambda$ at the high one, never stable.

The lag in realized inflation halves the admissible range of λ but does not touch the ranking, which is fixed by the sign of $T' - 1$.

The admissible range includes every gain in $(0, 1]$, and so the effective gain of about 0.75 at which least squares operates near the low steady state (*The stability reversal*).

For small λ any rule that moves beliefs gradually toward realized inflation inherits the E-stability condition $T' < 1$, which is the logic of *One recursion, many learners*; here the condition survives gains far from small.

Exercise 97.8.2

This exercise asks when initial beliefs can be identified under multiplicity.

Set $a = 0$ and $b = 1$ in Bray's market.

Then every constant belief is self-fulfilling: $T(\beta) = \beta$, so $T' = 1$, the unit eigenvalue of the indeterminate direction in *Exchange Rate Indeterminacy, Learning, and Experiments*.

Keep the gain $1/(t + t_0)$ with $t_0 = 50$.

1. Simulate the learning economy for 20,000 periods from $\beta_0 \in \{5, 10, 15\}$, with five shock sequences each, and report the final beliefs. Do the same for $a = 5$, $b = 0.7$.
2. Make the economy deterministic, like the economies of *Adaptive Agents in an Overlapping Generations Monetary Economy* and *Exchange Rate Indeterminacy, Learning, and Experiments*: agents see $p_t = a + b\beta_t$, and the econometrician, who knows a, b and t_0, observes $y_t = p_t + e_t$ with e_t IID standard normal. Compute the expected penalty for $\beta_0 = 12$ when the truth is $\beta_0 = 10$, for $T = 10^2, 10^3, 10^4, 10^5$, and for $b = 0.3$ and

$b = 0.7$ (with $a = 5$) and $b = 1$ (with $a = 0$). Hint: the expected penalty is $\sum_t d_t^2$, where d_t is the difference between the two implied price paths. Explain the three growth rates.

3. Return to Bray's setting, where the shock u_t enters the market and moves beliefs, and the econometrician observes p_t. Compute the average penalty for $\beta_0 = 12$ against the truth $\beta_0 = 10$ for $b = 0.7$ (with $a = 5$) and $b = 1$ (with $a = 0$), for $T = 10^2, 10^3, 10^4$. Why is it bounded even when $b = 1$, where β_0 shifts the limit permanently?

Solution

We need a version of the economy and of the belief reconstruction that takes (a, b) as arguments.

```
t0_ex = 50

def bray(a_, b_, β0, u):
    "Bray's market with gain 1/(t + t0) and shocks u that move beliefs."
    T = len(u)
    β, p = np.empty(T), np.empty(T)
    β[0] = β0
    for t in range(T):
        p[t] = a_ + b_ * β[t] + u[t]
        if t + 1 < T:
            β[t + 1] = β[t] + (p[t] - β[t]) / (t + 1 + t0_ex)
    return p, β

print("final beliefs after 20,000 periods, five shock sequences each")
for a_, b_ in ((0.0, 1.0), (5.0, 0.7)):
    for β0 in (5.0, 10.0, 15.0):
        finals = [bray(a_, b_, β0, np.random.default_rng(seed).standard_normal(20_
↪000))[1][-1]
                  for seed in range(5)]
        print(f"a = {a_}, b = {b_}, β0 = {β0:4.1f}:", np.round(finals, 2))
```

```
final beliefs after 20,000 periods, five shock sequences each
a = 0.0, b = 1.0, β0 =  5.0: [4.97 4.82 4.93 5.08 5.05]
a = 0.0, b = 1.0, β0 = 10.0: [ 9.97  9.82  9.93 10.08 10.05]
a = 0.0, b = 1.0, β0 = 15.0: [14.97 14.82 14.93 15.08 15.05]
a = 5.0, b = 0.7, β0 =  5.0: [14.72 14.67 14.72 14.76 14.76]
a = 5.0, b = 0.7, β0 = 10.0: [15.55 15.5  15.55 15.59 15.59]
a = 5.0, b = 0.7, β0 = 15.0: [16.38 16.33 16.38 16.42 16.42]
```

With $b = 1$ the limit stays close to where the economy started, and it also differs across shock sequences: the outcome is path dependent, in the sense of the book's footnote on the exchange-rate model, which Exercise **??** demonstrates in that economy.

With $b = 0.7$ every economy heads toward $\beta^\star = 16.67$, slowly, whatever β_0.

For part 2 the economy is deterministic, so the expected penalty can be computed without simulating the measurement errors.

```
def deterministic_prices(a_, b_, β0, T):
    "Prices in Bray's market with no shocks in the market itself."
    β, p = β0, np.empty(T)
    for t in range(T):
        p[t] = a_ + b_ * β
        β = β + (p[t] - β) / (t + 1 + t0_ex)
    return p

Ts = (100, 1_000, 10_000, 100_000)
for a_, b_ in ((5.0, 0.3), (5.0, 0.7), (0.0, 1.0)):
    d = deterministic_prices(a_, b_, 12.0, Ts[-1]) - deterministic_prices(a_, b_,␣
↪10.0, Ts[-1])
    expected = [np.sum(d[:T] ** 2) for T in Ts]
    print(f"b = {b_}: expected penalty at T = 1e2, 1e3, 1e4, 1e5:", np.
↪round(expected, 1))
```

```
b = 0.3: expected penalty at T = 1e2, 1e3, 1e4, 1e5: [16.2 31.9 39.9 43.2]
b = 0.7: expected penalty at T = 1e2, 1e3, 1e4, 1e5: [ 135.9  585.7 1806.7 4900.
↪5]
b = 1.0: expected penalty at T = 1e2, 1e3, 1e4, 1e5: [   400.   4000.  40000.␣
↪400000.]
```

In the deterministic economy, the effect of β_0 on the price at t decays like $(t_0/(t+t_0))^{1-b}$, so the expected penalty is roughly a sum of terms of order $t^{-2(1-b)}$.

With $b = 0.3$ that sum converges, and the penalty levels off: the effect dies too fast to be measured well.

With $b = 0.7$ the effect dies slowly, and the penalty keeps growing, but far more slowly than T (eventually like $T^{2b-1} = T^{0.4}$).

With $b = 1$ the effect never dies: the price stays at β_0 forever, and the penalty is exactly $(12-10)^2 T = 4T$.

Here the multiplicity makes the initial belief permanent, and the data identify it at the usual rate, as they would a structural parameter.

Now part 3, with shocks that move beliefs.

```
def reconstructed_beliefs(β0, p):
    "Beliefs the econometrician reconstructs from observed prices and a candidate␣
↪β0."
    T = len(p)
    β = np.empty(T)
    β[0] = β0
    for t in range(1, T):
        β[t] = β[t - 1] + (p[t - 1] - β[t - 1]) / (t + t0_ex)
    return β

for a_, b_ in ((5.0, 0.7), (0.0, 1.0)):
    rows = []
    for T in (100, 1_000, 10_000):
        pens = []
        for seed in range(20):
            p, _ = bray(a_, b_, 10.0, np.random.default_rng(seed).standard_
↪normal(T))
            resid_wrong = p - a_ - b_ * reconstructed_beliefs(12.0, p)
            resid_true = p - a_ - b_ * reconstructed_beliefs(10.0, p)
            pens.append(np.sum(resid_wrong**2) - np.sum(resid_true**2))
        rows.append(np.mean(pens))
    print(f"b = {b_}: average penalty at T = 1e2, 1e3, 1e4:", np.round(rows, 1))
```

```
b = 0.7: average penalty at T = 1e2, 1e3, 1e4: [ 70.2 101.1 103.8]
b = 1.0: average penalty at T = 1e2, 1e3, 1e4: [140.8 202.1 208.6]
```

The penalty is bounded in both cases.

With gain $1/(t+t_0)$ the reconstructed belief is $\beta_t = (t_0\beta_0 + \sum_{s<t} p_s)/(t+t_0)$, so a wrong β_0 shifts it by $(\beta_0' - \beta_0)\, t_0/(t+t_0)$, whatever b is.

The expected penalty is therefore about $b^2(\beta_0' - \beta_0)^2 t_0$, which is close to $0.49 \times 4 \times 50 = 98$ for $b = 0.7$ and $4 \times 50 = 200$ for $b = 1$.

When $b = 1$, β_0 does shift the limit permanently, but so do the early shocks, and the observed prices tell the econometrician where the economy is without telling him how much of its position is due to the initial belief.

Permanence is necessary for identification at the usual rate, but not sufficient: the initial belief must leave a mark that the econometrician cannot attribute to anything he observes.

Exercise 97.8.3

Malmendier and Nagel [2016] find that people form inflation expectations from the inflation they have lived through, with gains that decline with age.

Put such cohorts into Bray's market with $a = 5$ and $b = 0.7$.

At each date $L = 40$ cohorts are alive; a cohort of age $k = 0, 1, \ldots, L-1$ updates its belief with gain $1/(k+1+t_0)$ with $t_0 = 5$; each newborn cohort starts from the prior $\beta_0 = 10$; and the market expectation is the average belief across living cohorts.

1. Simulate 50,000 periods and compare the average price after the first 1,000 periods with $\beta^\star = a/(1-b)$. Why does the economy never reach the rational expectations equilibrium?
2. An econometrician knows b, β_0 and the cohort structure, and re-estimates a. Compute the penalty for $t_0 = 10$ when the truth is $t_0 = 5$, for $T = 500, 5000, 50000$, averaged over 8 samples. Do the same for a single, infinitely lived learner with gain $1/(t+1+t_0)$, the same β_0 and the same t_0.
3. Explain the difference, and relate it to the postscript.

Solution

We carry the cohorts' beliefs in an array ordered by age; each period the oldest cohort dies and a newborn enters at the prior.

```
L = 40

def cohort_beliefs(β0, t0_c, p):
    "Average belief of the living cohorts implied by an observed price path."
    gains = 1 / (np.arange(L) + 1 + t0_c)
    B = np.full(L, β0)
    β_bar = np.empty(len(p))
    for t in range(len(p)):
        β_bar[t] = B.mean()
        B = B + gains * (p[t] - B)
        B[1:] = B[:-1].copy()                    # everyone ages; the oldest dies
        B[0] = β0                                # a newborn enters at the prior
    return β_bar
```

```
def cohort_economy(β0, t0_c, u):
    "Bray's market when the expectation is the average over overlapping cohorts."
    gains = 1 / (np.arange(L) + 1 + t0_c)
    B = np.full(L, β0)
    p = np.empty(len(u))
    for t in range(len(u)):
        p[t] = a + b * B.mean() + u[t]
        B = B + gains * (p[t] - B)
        B[1:] = B[:-1].copy()
        B[0] = β0
    return p

def single_beliefs(β0, t0_c, p):
    "A single infinitely lived learner with gain 1/(t + 1 + t0)."
    β = np.empty(len(p))
    β[0] = β0
    for t in range(1, len(p)):
        β[t] = β[t - 1] + (p[t - 1] - β[t - 1]) / (t + t0_c)
    return β

def single_economy(β0, t0_c, u):
    p = np.empty(len(u))
    β = β0
    for t in range(len(u)):
        p[t] = a + b * β + u[t]
        β = β + (p[t] - β) / (t + 1 + t0_c)
    return p

def penalty_a_free(p, β_wrong, β_true, Ts):
    "Excess SSR (intercept re-estimated) on the first T observations, for each T."
    r_w, r_t = p - b * β_wrong, p - b * β_true
    return np.array([ssr_a_free(r_w[:T]) - ssr_a_free(r_t[:T]) for T in Ts])

Ts = (500, 5_000, 20_000, 50_000)
pen_cohort, pen_single, mean_price = [], [], []
for seed in range(8):
    u = np.random.default_rng(seed).standard_normal(Ts[-1])
    p = cohort_economy(10.0, 5.0, u)
    mean_price.append(p[1_000:].mean())
    pen_cohort.append(penalty_a_free(p, cohort_beliefs(10.0, 10.0, p),
                                     cohort_beliefs(10.0, 5.0, p), Ts))
    p = single_economy(10.0, 5.0, u)
    pen_single.append(penalty_a_free(p, single_beliefs(10.0, 10.0, p),
                                     single_beliefs(10.0, 5.0, p), Ts))

print(f"cohort economy: average price {np.mean(mean_price):.2f}, β* = {β_star:.2f}
 ↪")
print("penalty for t0 = 10, at T = 500, 5000, 20000, 50000")
print("   cohorts:      ", np.round(np.mean(pen_cohort, axis=0), 2))
print("   single agent: ", np.round(np.mean(pen_single, axis=0), 2))
```

```
cohort economy: average price 14.00, β* = 16.67
penalty for t0 = 10, at T = 500, 5000, 20000, 50000
   cohorts:       [ 1.99  6.11 19.42 41.23]
   single agent:  [1.22 1.57 2.76 3.52]
```

The cohort economy's average price stays well below $\beta^\star$.

Every period a newborn cohort arrives believing $\beta_0 = 10$, and the young weight their own short experience heavily, so the average belief is permanently pulled toward the prior: the transient never ends in the aggregate.

The penalty for a wrong t_0 stays bounded for the single learner, whose t_0 matters only while its belief is young: the reconstructed belief is $(t_0\beta_0 + \sum_{s<t} p_s)/(t + t_0)$, so t_0's influence on it dies out like $1/t$.

In the cohort economy the penalty keeps growing, roughly in proportion to T beyond a few thousand observations, even though re-estimating a absorbs the permanent shift in the mean.

The information comes from the dynamics: t_0 governs how strongly the young respond to recent prices, and there are always young cohorts responding.

This is the identification route that Malmendier and Nagel [2016] took with survey data on the expectations of different cohorts: in an economy of overlapping generations, parameters that would be transient for one agent become parameters of the stationary distribution.

Exercise 97.8.4

The constant-gain demonstration in the postscript showed that a gain is identified at the usual rate, but weakly per observation.

This exercise asks how the information depends on the size of the gain.

Use Bray's market with $a = 5$, $b = 0.7$, initial belief $\beta^\star$, and constant gain g.

1. For $g \in \{0.005, 0.01, 0.02, 0.05, 0.1, 0.2\}$, with a and b re-estimated, compute the penalty for the wrong gain $1.6g$ at $T = 20{,}000$, averaged over 20 samples, and divide it by T. How does the information per observation depend on g?
2. At $T = 200$, roughly the length of the postwar record in quarterly data, in what share of the samples does the penalty exceed 3.84?
3. What do the answers imply for the $1/t$ learner, and for the debate over the large drift covariance estimated by Sargent *et al.* [2006]?

Solution

We reuse `simulate_constant_gain`, `belief_path_cg` and `ssr_ab_free` from the postscript.

```
print(f"{'g':>6}   {'penalty / T, T = 20000':>22}   {'share > 3.84, T = 20000':>23}
↪    "
      f"{'share > 3.84, T = 200':>21}")
for g in (0.005, 0.01, 0.02, 0.05, 0.1, 0.2):
    results = {}
    for T in (200, 20_000):
        pens = []
        for seed in range(20):
            u = np.random.default_rng(seed).standard_normal(T)
            p, β = simulate_constant_gain(β_star, g, u)
            pens.append(ssr_ab_free(p, belief_path_cg(β_star, 1.6 * g, p))
                        - ssr_ab_free(p, β))
        results[T] = np.array(pens)
    big = results[20_000]
    print(f"{g:>6}   {big.mean() / 20_000:22.5f}   {np.mean(big > 3.84):23.0%}   "
          f"{np.mean(results[200] > 3.84):21.0%}")
```

```
    g   penalty / T, T = 20000   share > 3.84, T = 20000   share > 3.84, T =␣
↪200
0.005                  0.00010                       25%                       0
↪%
 0.01                  0.00025                       55%                       0
↪%
 0.02                  0.00052                       70%                       0
↪%
 0.05                  0.00152                       95%                       0

↪%
  0.2                  0.00839                      100%                      10
↪%
```

The information per observation rises with the gain, roughly in proportion to it or a little faster.

The identifying variation is the motion of beliefs, and for small gains the stationary variance of beliefs around $\beta^\star$ is roughly proportional to the gain.

With 20,000 observations the wrong value of the largest gains is rejected in every sample, while that of the smallest is rejected in only a quarter of them; with 200 observations the data say almost nothing about any of the gains.

As $g \to 0$ the constant-gain learner approaches the $1/t$ learner, whose belief motion dies out and whose learning parameters are not consistently estimable: the two cases are the ends of a continuum.

In a sample as short as the postwar record, the data are informative about learning only when beliefs move a lot.

That is one way to read the large drift covariance that Sargent *et al.* [2006] estimated, and the objection that the implied beliefs were implausibly volatile.

Direct evidence on beliefs, such as the Greenbook forecasts that Carboni and Ellison [2009] used, supplies information that outcome data of that length cannot.

98.1 Overview

1993 Prospects for Bounded Rationality in Macroeconomics closed the Bounded Rationality suite by handing on a government that keeps re-estimating its Phillips curve: the policy maker of Sims and Chung, grown up.

This lecture opens a suite that asks that government to explain the history of U.S. inflation.

The suite is based on Thomas Sargent's *The Conquest of American Inflation* [Sargent, 1999], and this first lecture combines chapters 1 and 2 of that book, with a preview of its concluding chapter.

Readers arriving from the Bounded Rationality suite have already met a condensed version of the model.

A government learning the Phillips curve studies a constant-gain government with the calibration of the static model in *Escaping Nash Inflation*, *One recursion, many learners* sets out the stochastic-approximation and E-stability tools that we use to analyze such governments, and *The econometricians did return the compliment* tells how econometricians came to estimate them.

The suite asks a question about post-war U.S. macroeconomic history:

> If we take for granted that inflation is under the control of the Federal Reserve, how can we explain the rise of U.S. inflation into the 1970s and its abrupt fall under Paul Volcker in the early 1980s?

The essay evaluates two interpretations, both based on policy makers' *beliefs* about the Phillips curve.

In both stories, the Federal Reserve learns the natural-rate-of-unemployment theory from a combination of experience and *a priori* reasoning.

The stories differ in how that theory is cast:

- **The triumph of natural-rate theory.** Academic economists discovered the natural-rate hypothesis, taught that any inflation-unemployment tradeoff is temporary, and eventually persuaded policy makers to pursue low inflation.
- **The vindication of econometric policy evaluation.** Policy makers never abandoned the methods that Robert Lucas criticized in his famous Critique.
  - Recurrently re-estimating a Phillips curve and using it to choose a target, they were led toward lower inflation by the *data itself*, an adversely shifting empirical Phillips curve.

This lecture presents the facts that motivate both stories, sketches the two interpretations, and reviews the Lucas Critique that chapter 2 both invokes and modifies.

It then previews, in *The road ahead*, how the remaining twelve lectures build the models, and closes by carrying the book's data through to the present.

Let's start with some imports:

```
import matplotlib.pyplot as plt
import numpy as np
import pandas as pd
from statsmodels.tsa.filters.bk_filter import bkfilter
```

Note

The figures in the next two sections reproduce the ones in chapter 1 of Sargent [1999], which were drawn from data available in the late 1990s.

We download the underlying series directly from FRED and restrict attention to the same historical window.

The section *Data patterns after 1999* then carries the most enlightening of these figures through to the present and asks what the additional quarter-century of data means for the two stories.

98.2 Facts

We begin with the single fact that the whole essay seeks to explain: the hump-shaped path of U.S. inflation since World War II.

For a much longer view of price levels, reaching back centuries and across countries, see Price Level Histories.

We measure inflation as the book does, by the annualized monthly change in the consumer price index (all items, not seasonally adjusted), smoothed with a 13-month centered moving average to remove seasonal and high-frequency noise.

The function below reads a series straight from FRED; we use it for the price index and for the unemployment rate that we need in the next section.

```
def fred_series(series_id):
    "Download a monthly series from FRED as a pandas Series."
    url = f'https://fred.stlouisfed.org/graph/fredgraph.csv?id={series_id}'
    frame = pd.read_csv(url, index_col=0, parse_dates=True, na_values='.')
    return frame.iloc[:, 0].rename(series_id)
```

(continues on next page)

(continued from previous page)

```
cpi_all = fred_series('CPIAUCNS')       # CPI, all items, not seasonally adjusted
u_all = fred_series('LNS14000028')      # unemployment rate, white men 20 and over

book_window = slice('1948', '1999-01')
cpi = cpi_all[book_window]

# annualized monthly inflation, then a 13-month centered moving average
inflation = 1200 * np.log(cpi).diff()
inflation_ma = inflation.rolling(13, center=True).mean()
```

Figure 1.1 plots the smoothed series over the book's window.

```
fig, ax = plt.subplots(figsize=(9, 5))
ax.plot(inflation_ma, lw=1.2)
ax.axhline(0, color='k', lw=0.5)
ax.set_xlabel('year')
ax.set_ylabel('inflation (percent, annualized)')
ax.set_title('Figure 1.1: Monthly inflation, CPI all items, '
             '13-month centered moving average')
plt.show()
```

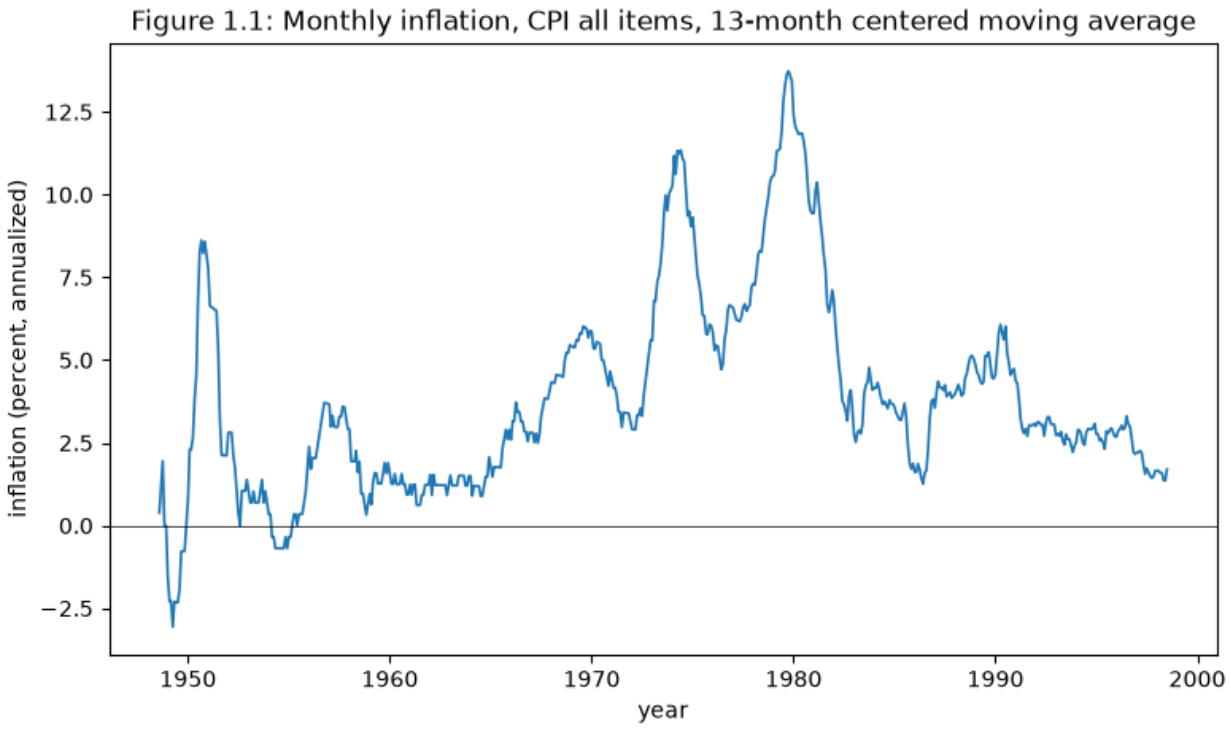

Fig. 98.1: Monthly CPI inflation, 13-month centered moving average, 1948-1999

Inflation was low during the late 1950s and early 1960s, swept upward into the 1970s, and then fell abruptly with Volcker's stabilization in the early 1980s.

Any explanation that treats inflation as under the Federal Reserve's control must account for this rise and fall.

98.3 The Phillips curve in the data

Despite its disrepute in some academic and policy-making circles, the Phillips curve persists in U.S. data, and simple procedures detect it.

To coax the Phillips curve from the data, we follow the book in two ways.

First, we use the unemployment rate for a single demographic group — white men 20 years and over — rather than the aggregate rate, which is contaminated by slow-moving shifts in the demographic mix.

Second, we look at *business-cycle* frequencies, filtering out slowly moving components so that the eye can spot the inverse relationship between inflation and unemployment.

The unemployment series begins in January 1954, so the joint sample does too.

```
u = u_all[book_window]

data = pd.concat([inflation.rename('inflation'),
                  u.rename('unemployment')], axis=1).dropna()
data.head()
```

```
                  inflation  unemployment
observation_date
1954-01-01         0.000000           3.6
1954-02-01         0.000000           3.8
1954-03-01         0.000000           4.1
1954-04-01        -4.469279           4.7
1954-05-01         4.469279           4.6
```

Figure 1.2 plots the two series together, with inflation smoothed as in Figure 1.1.

```
fig, ax = plt.subplots(figsize=(9, 5))
ax.plot(inflation_ma[data.index[0]:], 'C0', lw=1,
        label='inflation (CPI, 13-month centered moving average)')
ax.plot(u, 'C1:', lw=1.2, label='unemployment (white men 20+)')
ax.axhline(0, color='k', lw=0.5)
ax.set_xlabel('year')
ax.set_ylabel('percent')
ax.set_title('Figure 1.2: Monthly unemployment and inflation rates')
ax.legend()
plt.show()
```

To isolate the business-cycle relationship, we apply the finite-lag bandpass filter of Baxter and King [Baxter and King, 1999] to the monthly series.

Following the book, we keep fluctuations with periods between 24 and 84 months and use a lead-lag truncation of 84 months.

Because the filter needs 84 months of data on each side of a date, it drops the first and last seven years of the sample, so the filtered series begin in 1961.

```
# Baxter-King bandpass: periods between 24 and 84 months, truncation 84
bk = bkfilter(data, low=24, high=84, K=84)
bk.columns = ['inflation_cycle', 'unemployment_cycle']
print(f"filtered sample: {bk.index[0]:%Y-%m} to {bk.index[-1]:%Y-%m}")
```

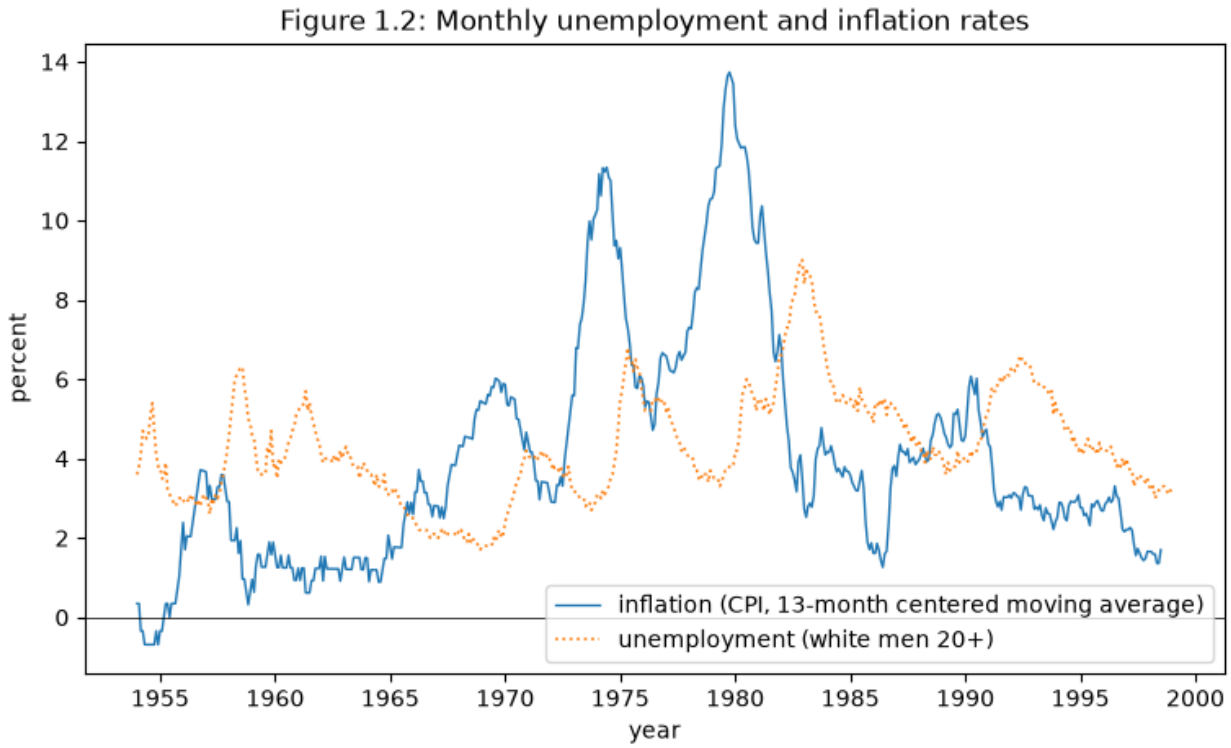

Fig. 98.2: Monthly unemployment (white men 20+) and inflation (13-month centered moving average)

```
filtered sample: 1961-01 to 1992-01
```

Figure 1.3 plots the filtered components.

```
fig, ax = plt.subplots(figsize=(9, 5))
ax.plot(bk.index, bk['inflation_cycle'], 'C0', lw=1, label='inflation')
ax.plot(bk.index, bk['unemployment_cycle'], 'C1:', lw=1.2,
        label='unemployment')
ax.axhline(0, color='k', lw=0.5)
ax.set_xlabel('year')
ax.set_ylabel('deviation from trend (percent)')
ax.set_title('Figure 1.3: Business-cycle components '
             '(Baxter-King bandpass filter)')
ax.legend()
plt.show()
```

The filtered components tend to move in opposite directions: a business-cycle Phillips curve.

We can see the tradeoff more directly in scatter plots for the subperiod that interests us most, 1960-1982.

As in the book, Figure 1.4 plots smoothed inflation against unemployment and Figure 1.5 plots the business-cycle components, with unemployment on the horizontal axis in both.

In Figure 1.5 a faint line joins successive months.

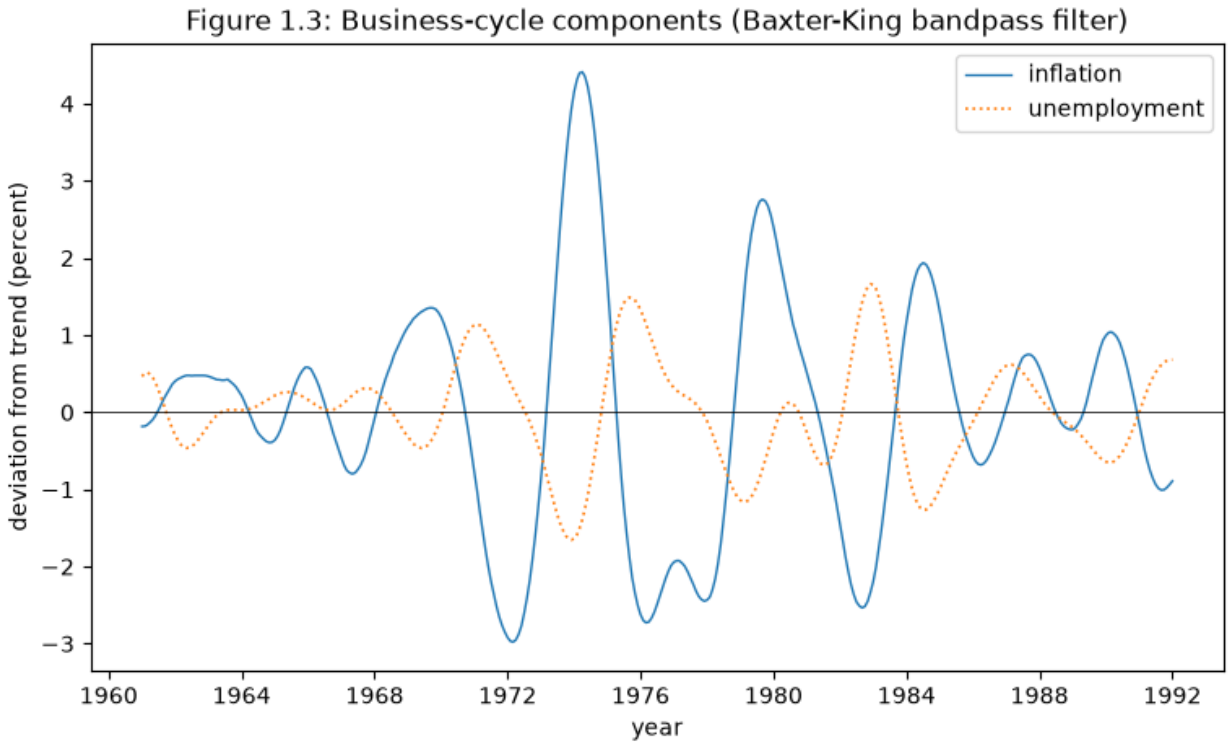

Fig. 98.3: Business-cycle components of inflation and unemployment, Baxter-King bandpass filter

```
sub = slice('1960', '1982')
cycle_sub = bk.loc[sub]

fig, axes = plt.subplots(1, 2, figsize=(12, 5))

axes[0].scatter(u[sub], inflation_ma[sub], s=8, alpha=0.6)
axes[0].set_xlabel('unemployment (white men 20+)')
axes[0].set_ylabel('inflation (13-month centered moving average)')
axes[0].set_title('Figure 1.4: Smoothed series, 1960-1982')

axes[1].plot(cycle_sub['unemployment_cycle'], cycle_sub['inflation_cycle'],
             lw=0.5, alpha=0.4)
axes[1].scatter(cycle_sub['unemployment_cycle'],
                cycle_sub['inflation_cycle'], s=8, alpha=0.6)
axes[1].set_xlabel('unemployment (business-cycle component)')
axes[1].set_ylabel('inflation (business-cycle component)')
axes[1].set_title('Figure 1.5: Business-cycle components, '
                  f'{cycle_sub.index[0].year}-{cycle_sub.index[-1].year}')

plt.tight_layout()
plt.show()
```

Focusing on the business-cycle components sharpens the apparent Phillips curve.

Figure 1.5 reveals **Phillips loops**: followed month by month, the business-cycle components trace out *clockwise* loops rather than a single stable curve.

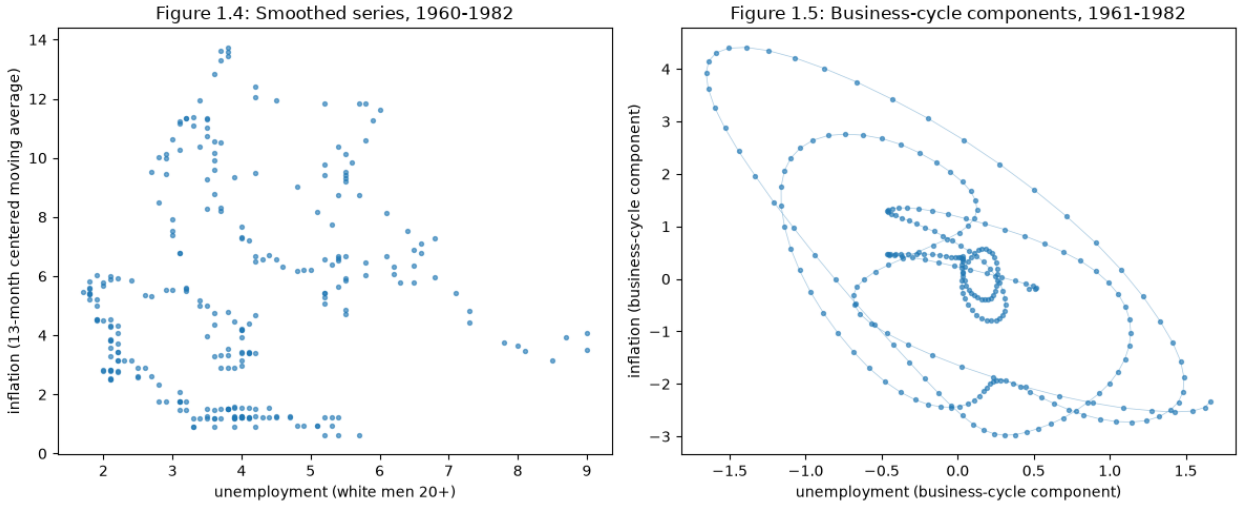

Fig. 98.4: Inflation against unemployment, 1960-1982: smoothed series and business-cycle components

Clockwise loops mean that inflation *lags* unemployment.

As unemployment falls, inflation is slow to rise, so the path runs leftward along the bottom of a loop; as unemployment rises again, inflation is slow to fall, so the path runs rightward along the top.

At these frequencies the negative correlation between inflation and unemployment is strongest when inflation is paired with unemployment about six months earlier (Exercise 98.9.1 asks you to verify this).

Slowly adjusting expectations of inflation, which the natural-rate theory places at the center of the story, are one possible source of that lag.

Note

The book adjusts for demographic change by choosing a single unemployment series, and in chapter 9 it uses these same data to estimate an adaptive model of policy making (*Econometric Policy Evaluation*).

A broader definition of unemployment would inject additional low-frequency demographic components, which one might model with a unit-root process.

The essay instead puts a unit root into the inflation-unemployment process from a different source: the *drifting beliefs* of a monetary authority cut loose from the discipline of Bretton Woods.

98.4 Two interpretations

Both stories start from the same initial conditions — the history of inflation and unemployment, and the state of expectations, inherited by policy makers around 1960 — and both assume that the data conform to the natural-rate hypothesis, whether or not policy makers realized it.

98.4.1 The triumph of natural-rate theory

Adherence to the gold standard and then to Bretton Woods gave the U.S. low inflation and low expected inflation.

In 1960, Paul Samuelson and Robert Solow [Samuelson and Solow, 1960] found a Phillips curve in U.S. data and taught that it was *exploitable* — that policy could raise inflation to reduce unemployment.

That is the lesson of their page 192; on page 193 they themselves warned that "it would be wrong, though, to think that our Figure 2 menu that relates obtainable price and unemployment behavior will maintain its same shape in the longer run."

Within a decade the recommendation was widely endorsed and implemented.

To everyone's dismay, the Phillips curve then shifted adversely: inflation rose, but unemployment on average did not fall.

Meanwhile Edmund Phelps [Phelps, 1967], Milton Friedman [Friedman, 1968], and Robert Lucas [Lucas, 1972] created and refined the concept of the natural rate of unemployment, which assigns a central role to expectations of inflation in locating the Phillips curve.

The natural-rate theory allowed only a *temporary* tradeoff and explained the adverse shifts; its rational expectations version implied that policy makers should ignore the temporary tradeoff and strive only for low inflation.

In this story, these ideas diffused from academics to policy makers and ultimately produced the lower inflation of the 1980s and 1990s.

Events were shaped by policy makers' beliefs — some false, others true — and the actions those beliefs inspired.

Lucas [Lucas, 1976] then used Samuelson and Solow's method of deducing policy from a statistical Phillips curve as an example of erroneous methodology.

His reasoning soon banished the method from academic research centers, but, as the book puts it, "the method survived and prospered within the Federal Reserve System" — a fact that inspires the second story.

98.4.2 The vindication of econometric policy evaluation

The alternative story ascribes Volcker's conquest partly to the *success* of the very econometric and policy-making procedures that Lucas challenged.

It had been told before, by Christopher Sims [Sims, 1988] and Heetaik Chung [Chung, 1990].

Policy makers accepted the Samuelson-Solow Phillips curve as an exploitable tradeoff and adopted their methods for learning from data and deducing policy.

Recurrently, they re-estimated a distributed-lag Phillips curve and used it to reset a target inflation-unemployment pair.

Interpreted mechanically — without identifying expectations as the hidden state variable — the adversely shifting empirical Phillips curve eventually led policy makers to pursue lower inflation.

This story is told with an *adaptive* theory of policy that departs minimally from rational expectations.

It connects a sequence of ideas that the rest of the suite develops: drifting coefficients, self-confirming equilibria, least squares and other recursive learning algorithms, convergence of least squares learners to self-confirming equilibria, and recurrent dynamics along *escape routes* from those equilibria.

The key idea, taken from Sims [1988], is that an adaptive model lets a government *learn* from its past attempts to exploit the Phillips curve, and eventually discover a version of the natural-rate hypothesis that instructs it to reduce inflation.

To Sims's insight the book adds an account of how the *escape-route dynamics* of the adaptive system can spontaneously generate regime shifts.

In this story inflation policy is not made in a vacuum or delivered as a natural experiment; it emerges gradually from an adaptive process.

Although it backs away slightly from rational expectations, the vindication story imposes *more* restrictions on government policy than the triumph story, which occasionally shifts free parameters describing government behavior to fit the facts.

98.5 Ignoring the Lucas Critique

Chapter 2 of the book confronts the obvious objection to the vindication story: doesn't the Lucas Critique forbid the mechanical, exploitable Phillips curve on which it rests?

The essay resurrects the econometric and policy-evaluation procedures that Lucas decisively criticized [Lucas, 1976], and emphasizes a neglected aspect of his Critique: **drifting coefficients**.

98.5.1 The Critique

An econometric model is a collection of stochastic difference equations, some of which describe private agents' decision rules.

Econometric policy evaluation in the Tinbergen-Theil tradition holds those private decision rules *fixed* while the government optimizes its own rule against an objective function.

Lucas noted that if private agents solve intertemporal optimization problems, their decision rules *depend on* the government's rule.

By missing this dependence, the Tinbergen-Theil method mistranslates the government's preferences over outcomes into an ordering over decision rules, and so gives unreliable policy advice.

A rational expectations equilibrium builds the dependence in, by requiring the law of motion that private agents perceive to coincide with the actual law of motion that their own decisions help generate (*Rational Expectations Equilibrium*).

Least Squares Learning in Self-Referential Models shows how agents who estimate their perceived law of motion by least squares can find such a fixed point, and the self-confirming equilibria below are fixed points of the same kind.

98.5.2 The appeal to drifting coefficients

Lucas conceded the impressive forecasting record of Keynesian models but argued that good forecasting is no evidence for the *invariance under intervention* that Tinbergen-Theil assumes.

He stressed that forecasters routinely adjusted the constant terms of key equations, and interpreted these adjustments as an adaptive-coefficients model in the spirit of Cooley and Prescott [Cooley and Prescott, 1973].

The intertemporal instability of estimated relationships — coefficient drift, presumably present even under stable operating rules for policy — undermined treating them as invariant to systematic changes in policy rules.

But Lucas did not read the drift as *confirming* his theoretical point that private decision rules vary with the government's rule.

His three examples compare stationary environments indexed by different government rules, and they are silent about drifting coefficients; the book recalls that many early readers misunderstood his reference to drifting coefficients as supporting his basic point.

Lucas left the drift *unexplained*, and neither the macroeconomic theory nor the rational expectations econometrics built after the Critique accounts for it: both focus on environments with time-invariant transition functions.

98.5.3 Parameter drift as a point of departure

The essay starts from parameter drift, treating it as a *smoking gun* — the key evidence that the government's beliefs about the economy, and hence its policy toward inflation, have evolved over time.

It builds a model from two components:

1. a Tinbergen-Theil theory of government decision making — the Phelps problem of *Adaptive Expectations and the Phelps Problem*; and
2. a drifting-coefficients econometric procedure for the government, featuring the constant adjustments that Lucas wrote about.

It disciplines the exercise by assuming that a rational expectations version of the natural-rate hypothesis is true, and it sets other explanations aside: "I do not examine unusual supply shocks and other plausible explanations of post-World War II U.S. inflation."

If the fundamentals of the environment are time-invariant, the forces behind consistency proofs in econometrics make the government's estimates and its decision rule converge [Marcet and Sargent, 1989].

In the limit there can emerge a **self-confirming equilibrium** (*Self-Confirming Equilibria*), in which the government's estimates are reinforced jointly by its own behavior and the private sector's reactions to it.

Within a self-confirming equilibrium, some of the force of the Lucas Critique vanishes.

Although the government's invariance assumption is wrong, it is not disappointed in outcomes, because those outcomes are statistically consistent with its beliefs.

A self-confirming equilibrium also restricts the government's model and its behavior: because the government's rule is derived from its fitted model, the free parameters that described government policy in Lucas's models disappear.

So a self-confirming equilibrium is a rational expectations equilibrium with *fewer* free parameters than the models of Lucas [1972] and Lucas [1976], and the lost parameters are exactly the ones we would shift to represent a regime change.

Sims [1982] implicitly appealed to a self-confirming equilibrium when he argued that regime changes are rare because existing policies are approximately optimal.

To admit regime changes and drifting coefficients, convergence to a self-confirming equilibrium must be *resisted*.

The essay arrests convergence by replacing the government's least squares estimator with a constant-gain, adaptive-coefficients algorithm like Cooley and Prescott's, which overweights recent data — endowing the government with a suspicion that the environment is unstable.

This weakens the pull toward a self-confirming equilibrium and sustains dynamics along an escape route, along which regime changes occur.

Ironically, as we shall see in *Adaptive Learning and Escape Dynamics*, the procedures that *violate* the Lucas Critique can yield better outcomes than ones that respect it.

98.6 A premature summary: triumph or vindication?

The rest of this suite builds models.

Before we start, it is worth previewing where they lead and the tension they leave unresolved — a premature summary of the journey, adapted from the concluding chapter of Sargent [1999].

Everything can be organized around two *benchmark* models.

In the first, due to Phelps [1967], the public forms expectations *adaptively* while the government chooses policy *optimally*, taking the public's rule as given.

In the second, the rational-expectations natural-rate model, the public is *rational* while the government's policy is treated as *exogenous and arbitrary*.

Lucas recommended replacing the first benchmark with the second.

Coming to grips with the two stories drives us to propose models that make various *compromises* between these poles — and the remaining lectures are those compromises.

98.6.1 The road ahead

We begin by imposing rationality on *both* sides.

- *The Credibility Problem* (chapter 3) studies the one-period model of Kydland and Prescott [1977], whose time-consistent (Nash) outcome is a pessimistic prediction: high inflation, with nothing gained for it.
- *Credible Government Policies* (chapter 4) repeats that economy forever. Computing the whole set of sustainable values with the recursive methods of Abreu *et al.* [1990], it finds so many outcomes sustainable that the theory replaces pessimism with *agnosticism*.

That agnosticism is the first reason to hesitate before declaring the triumph of natural-rate theory.

Following Sims and Chung, we then turn back from the Lucas Critique and start again from the Phelps benchmark.

- *Adaptive Expectations and the Phelps Problem* (chapter 5) solves the Phelps problem against an arbitrary adaptive-expectations Phillips curve and shows why the *induction hypothesis* matters.

Next we make one change: the government's model of the private sector is no longer arbitrary — it is *fit to historical data*.

Varying the details of that fitting problem generates the next five lectures.

- *Optimal Misspecified Beliefs* (chapter 6) introduces equilibria with optimal but misspecified forecasting functions, in Bray's market.
- *Self-Confirming Equilibria* (chapter 7) requires the government's Phillips curve to be self-confirming, and finds that self-confirming equilibria reproduce the Nash outcome or something worse, before closing with an equilibrium in which a subtly misspecified public forecast does better than Nash.

- *Adaptive Learning and Escape Dynamics* (chapter 8) makes the government a real-time econometrician, an "anticipated-utility" learner in the sense of Kreps [1998], and finds spontaneous, Volcker-like stabilizations when the gain is constant.
- *Escaping Nash Inflation* characterizes those escapes analytically, following Cho *et al.* [2002].
- *Priors, Escapes, and Learning Cycles* follows Sargent and Williams [2005] in showing how the government's prior about drifting coefficients shapes convergence, cycles, and escapes.

The next three lectures take the models to data.

- *Econometric Policy Evaluation* (chapter 9) estimates the adaptive model on U.S. data by maximum likelihood, following Chung, and asks whether the estimates vindicate econometric policy evaluation.
- *Drifts and Volatilities* follows Cogley and Sargent [2005] in fitting a vector autoregression with drifting coefficients and stochastic volatility to data through 2000, and asks whether the Great Inflation was bad policy or bad luck.
- *Drifts and Volatilities after 2000* brings that model up to date with the data since 2000.

Finally, *The Lost Conquest: Fed Policy in the 2020s* follows Sargent and Williams [2025] in turning the suite's tools, including an anticipated-utility Federal Reserve, on the inflation of the 2020s and the Federal Reserve's slow response to it, and so returns to the question with which this lecture's survey of the data ends: was the conquest lost?

Symbols change from lecture to lecture, because each lecture follows its source; *A note on notation* records the translations and the gain each lecture uses.

The adaptive models are a *disciplined* retreat from rational expectations, not an abandonment of it.

Apart from a single gain parameter, they carry no free parameters governing expectations, and period by period they impose the same cross-equation restrictions as a rational expectations model.

And because a self-confirming equilibrium is the attractor of their *mean dynamics*, under tranquil conditions, with a gain that eventually falls like $1/t$, they converge back to it, and hence, on the equilibrium path, to rational expectations, satisfying a desideratum of Kreps [1998].

That convergence holds for least squares; *Priors, Escapes, and Learning Cycles* exhibits other priors under which the self-confirming equilibrium is unstable.

But to match the data, our main interest, like Sims's, is in the dynamics that adaptation adds.

Those dynamics come in two kinds.

Sims [1988] and Chung [1990] gave their governments *Kalman filters* on drifting coefficients, whose gains do not vanish; Sims's government fit a static Phillips curve and Chung's a distributed lag.

In their simulations the government escapes from the Nash outcome once and then stays near the Ramsey outcome, apparently indefinitely.

The governments of Sargent [1999] and Cho *et al.* [2002] instead use constant-gain recursive least squares, and their escapes *recur*: each is followed by a return toward Nash, producing the sawtooth of *A government learning the Phillips curve*.

Why the two kinds of history differ was a puzzle until Sargent and Williams [2005] traced it to the government's prior: the drift covariance and the noise variance that its filter assumes.

Priors, Escapes, and Learning Cycles works through their account.

The learning governments of *Adaptive Learning and Escape Dynamics* and *Escaping Nash Inflation* are Sargent's: suspecting that the Phillips curve is prone to wander, they use a constant-gain algorithm, the sensible choice when coefficients drift.

The payoff is a striking one: the adaptive models produce abrupt *stabilizations* of inflation that defy the inferior self-confirming outcome toward which the mean dynamics point.

These regime shifts arise not from any change in the government's procedures, nor from large shocks, but from *changes in beliefs created by the government's own econometrics* — the mathematics of escape routes in the space of approximating models.

98.6.2 The induction hypothesis: villain and hero

At the center of the story sits the **induction hypothesis** — the restriction that the weights on lagged inflation in an expectations equation sum to one, so that a permanently higher inflation rate is eventually fully expected.

It was built almost without comment into the adaptive expectations hypothesis of Friedman [1957] and Cagan [1956], and it was the basis of Solow's and Tobin's early tests of the natural-rate hypothesis [Solow, 1968, Tobin, 1968].

Cast as a *villain* in Lucas's Critique — a naive restriction that rational expectations does not imply — the induction hypothesis re-emerges as the *hero* of the adaptive models: activating it is exactly what makes the government's Phelps problem call for near-Ramsey, low-inflation policy.

In the distributed-lag model of *Adaptive Learning and Escape Dynamics*, the escape routes are precisely the paths along which the government's estimated model, by using a unit root to approximate a constant, stumbles into believing the induction hypothesis.

Wrestling with such approximation problems, with several models simultaneously in play, is what led Sims [1980] to call bounded rationality a *wilderness*, set apart from the tidy one-model world of rational expectations.

98.6.3 The reservation

Which story, then — triumph or vindication?

The contest is not rational expectations versus an alternative, because *both* stories selectively apply and withdraw from rational expectations.

And the vindication story, however well it fits, is an exercise in *positive* economics, not *normative* economics.

It is tempting to read its long stretches of near-Ramsey inflation as an endorsement of the adaptive policy-making procedures that produce them — but that temptation should be resisted.

For the same adaptive dynamics that permit a stabilization also make it temporary: once beliefs come close to the induction hypothesis, the mean dynamics point *away* from it, back toward the region where the Phelps problem recommends resuscitating inflation.

It can take a long time for the mean dynamics to push the system back to the self-confirming equilibrium, but it is bound to happen.

The simulations contain long episodes that look like Paul Volcker — and others that look like Arthur Burns.

Theoretical work after Kydland and Prescott [1977], such as Rogoff [1985], insists that durable low inflation must rest on *commitment mechanisms* that keep a monetary authority from choosing sequentially — not on the hope that an adaptive government, armed with an approximate model, will by chance eventually learn to do approximately the right thing.

So the book ends on a hope rather than a verdict: we *hope* that the triumph story is the right one — that policy makers have learned a correct rational expectations version of the natural-rate hypothesis and have found devices to commit themselves to low inflation.

Because if instead the vindication story is closer to the truth, then the mean dynamics that pull beliefs back toward the self-confirming equilibrium are always waiting, eventually, to carry inflation back up.

The quarter-century of data since 1999 — a long, quiet *Great Moderation* interrupted by a sudden surge in 2021-2022 — is a running test of exactly this hope, and we turn to it next.

98.7 Data patterns after 1999

Sargent [1999] was written at the end of the long disinflation that began with Volcker.

We now have another quarter-century of data.

This section carries the book's most enlightening figures through to the present and asks what the new observations mean for the two stories.

We use the full FRED series, through the latest month available, and first check each for months that are missing inside the sample.

```
def missing_months(series):
    "Months between the first and last observation that have no value."
    months = pd.date_range(series.first_valid_index(),
                           series.last_valid_index(), freq='MS')
    return months.difference(series.dropna().index)

for series in (cpi_all, u_all):
    gaps = [f'{m:%Y-%m}' for m in missing_months(series)]
    print(f"{series.name:12s} last observation "
          f"{series.last_valid_index():%Y-%m}, missing months: {gaps}")
```

```
CPIAUCNS     last observation 2026-09, missing months: ['2025-10']
LNS14000028  last observation 2026-10, missing months: ['2025-10']
```

The federal government shutdown of late 2025 left the October 2025 observations of both series uncollected.

One missing month would turn every 13-month moving average and every 12-month change that touches it into a missing value, silently cutting the smoothed series short.

We therefore fill isolated missing months by interpolation, geometric for the price index and linear for unemployment, and leave longer gaps alone.

```
def fill_isolated(series, log=False):
    "Interpolate single missing months; leave longer gaps missing."
    s = np.log(series) if log else series
    isolated = s.isna() & s.shift(1).notna() & s.shift(-1).notna()
    s = s.where(~isolated, s.interpolate(limit_area='inside'))
    return np.exp(s) if log else s

cpi_full = fill_isolated(cpi_all['1948':], log=True)
u_full = fill_isolated(u_all)
print("still missing:",
      [f'{m:%Y-%m}' for m in missing_months(cpi_full).union(missing_months(u_full))])

# the book's measure (annualized monthly change, 13-month centered MA)
inflation_full = 1200 * np.log(cpi_full).diff()
inflation_ma_full = inflation_full.rolling(13, center=True).mean()

# year-over-year inflation: smoother, and the measure usually quoted today
inflation_yoy = 100 * (cpi_full / cpi_full.shift(12) - 1)
print(f"13-month centered average available through "
      f"{inflation_ma_full.last_valid_index():%Y-%m}")
```

```
still missing: []
13-month centered average available through 2026-03
```

A centered 13-month average needs six months of data on each side of a date, so the smoothed series ends six months before the latest observation.

98.7.1 The rise and fall, extended

Figure 1.1 showed inflation rising into the 1970s and falling under Volcker.

Extending it to the present adds three chapters the book could not see: the *Great Moderation* of low, stable inflation from the mid-1980s; a decade of low, below-target inflation after the 2008 financial crisis, dipping below zero in 2008-09 and briefly again in 2015; and a sudden surge in 2021-2022 to the highest rate since 1981, followed by a rapid decline.

```
fig, ax = plt.subplots(figsize=(11, 5))
ax.plot(inflation_ma_full, lw=1)
ax.axhline(0, color='k', lw=0.5)
ax.axvspan(pd.Timestamp('1948-01-01'), pd.Timestamp('1999-01-01'),
           color='C0', alpha=0.06, label="the book's window")
for date, y, txt in [('1951-01-01', 9.3, 'Korean\nWar'),
                     ('1970-01-01', 12.0, '1970s\nacceleration'),
                     ('1984-06-01', 0.5, 'Volcker'),
                     ('2009-07-01', -1.5, '2009\ndeflation scare'),
                     ('2022-06-01', 8.9, '2021-22\nsurge')]:
    ax.annotate(txt, (pd.Timestamp(date), y), ha='center', fontsize=9,
                color='C3')
ax.set_xlabel('year')
ax.set_ylabel('inflation (percent, annualized)')
ax.set_title('Inflation, CPI all items, 13-month centered moving average, '
             f'1948-{inflation_ma_full.last_valid_index().year}')
ax.legend(loc='upper right')
plt.show()
```

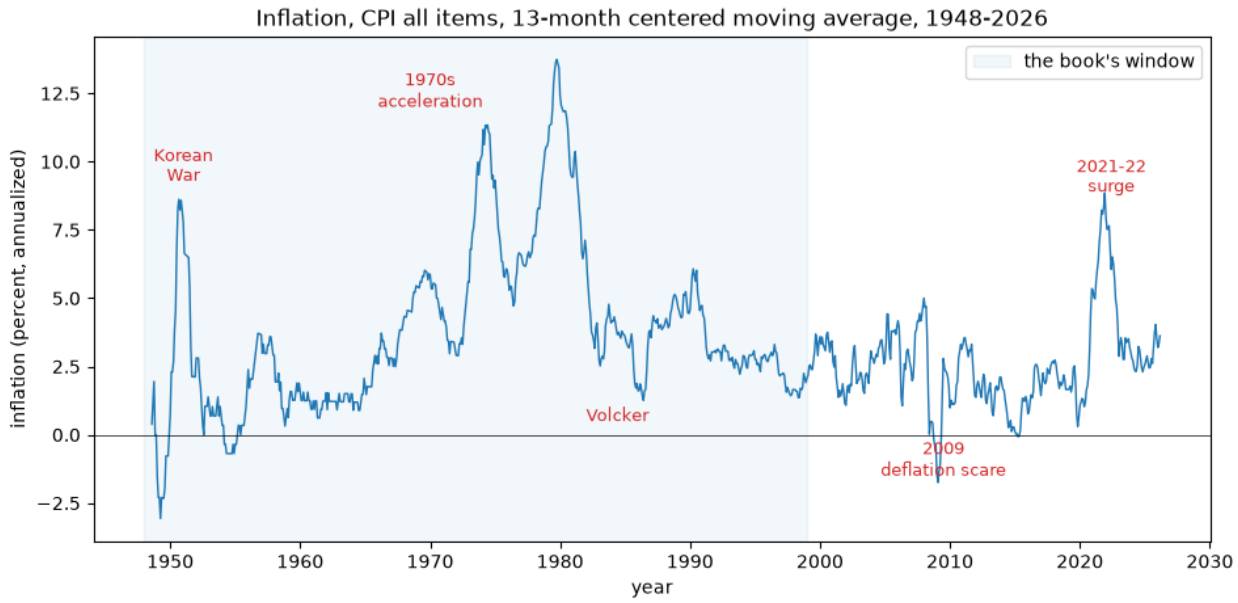

Fig. 98.5: Inflation extended to the present, with the book's window shaded

The hump that the book set out to explain is now one of *two*.

The second compressed a fast acceleration and an almost-as-fast disinflation into about three years.

Its closest precedent is not the 1970s but the Korean War spike of 1950-1951, inside the book's own window: inflation jumped by about eight percentage points within a year and was back near 2 percent within another, with no drawn-out acceleration of the kind that preceded Volcker.

98.7.2 Unemployment and inflation to the present

Figure 1.2 plotted the two series together for the post-war period.

Extending it shows the two most dramatic macroeconomic events of the new data: the COVID unemployment spike of 2020 — for white men 20 and over, the highest rate since the series began in 1954 — and the inflation surge that followed.

```
recent = slice('1990', None)

fig, ax = plt.subplots(figsize=(11, 5))
ax.plot(inflation_yoy[recent], 'C0', lw=1, label='inflation (CPI, year-over-year)')
ax.plot(u_full[recent], 'C1:', lw=1.2, label='unemployment (white men 20+)')
ax.axhline(0, color='k', lw=0.5)
ax.set_xlabel('year')
ax.set_ylabel('percent')
ax.legend()
plt.show()
```

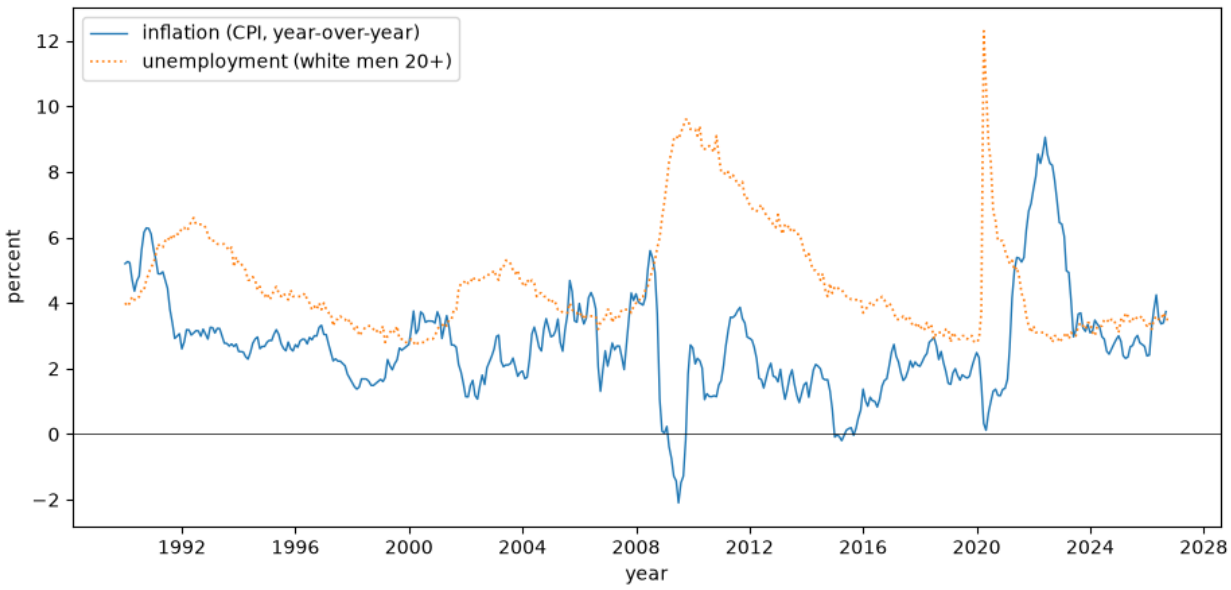

Fig. 98.6: Unemployment and inflation since 1990

Two features stand out.

From the mid-1990s to 2020, inflation stayed remarkably quiet even as unemployment swung widely: it fell in 2000 and again in 2019 to levels last seen in the early 1970s, and roughly tripled in the 2008 recession.

Then, after the COVID spike, unemployment fell back quickly while inflation surged.

Falling unemployment with rising inflation is a move *along* a downward-sloping Phillips curve, the signature of a demand disturbance.

But by itself the pattern cannot separate a demand-driven move along a steep Phillips curve from supply disturbances, and the mix of the two is still debated.

How far has inflation come back down?

```
since_peak = inflation_yoy['2022-07':]
at_or_below_2 = inflation_yoy[inflation_yoy <= 2]
print(f"peak year-over-year inflation: {inflation_yoy['2021':'2023'].max():.1f}% "
      f"({inflation_yoy['2021':'2023'].idxmax():%Y-%m})")
print(f"lowest reading since then:     {since_peak.min():.1f}% "
      f"({since_peak.idxmin():%Y-%m})")
print(f"latest reading:                {inflation_yoy.iloc[-1]:.1f}% "
      f"({inflation_yoy.index[-1]:%Y-%m})")
print(f"last month at or below 2%:     {at_or_below_2.index[-1]:%Y-%m}")
```

```
peak year-over-year inflation: 9.1% (2022-06)
lowest reading since then:     2.3% (2025-04)
latest reading:                3.7% (2026-09)
last month at or below 2%:     2021-02
```

Year-over-year CPI inflation came down quickly from its 2022 peak, but as of this writing it has not been back to 2 percent since early 2021.

98.7.3 The Phillips curve across three eras

The book coaxed a Phillips curve from 1960-1982 data.

The most striking post-1999 pattern is how *unstable* the inflation-unemployment scatter has been across eras.

We split the sample into the book's acceleration era, the Great Moderation, and the post-2008 period, and plot inflation against unemployment in each.

```
scatter_data = pd.concat([inflation_yoy.rename('inflation'),
                          u_full.rename('unemployment')], axis=1).dropna()

last_year = scatter_data.index[-1].year
eras = [('1960', '1983', '1960–1983 (acceleration)'),
        ('1984', '2007', '1984–2007 (Great Moderation)'),
        ('2008', None, f'2008–{last_year} (crisis, COVID, surge)')]

fig, axes = plt.subplots(1, 3, figsize=(14, 4.5), sharex=True, sharey=True)
for ax, (lo, hi, title) in zip(axes, eras):
    era_data = scatter_data.loc[lo:hi]
    ax.scatter(era_data['unemployment'], era_data['inflation'], s=8, alpha=0.5)
    ax.axhline(0, color='k', lw=0.5)
    ax.set_xlabel('unemployment')
    ax.set_title(title, fontsize=10)
axes[0].set_ylabel('inflation (year-over-year)')
plt.tight_layout()
plt.show()
```

Here are the correlation and the least squares slope of inflation on unemployment in each era.

```
for lo, hi, title in eras:
    era_data = scatter_data.loc[lo:hi]
```

(continues on next page)

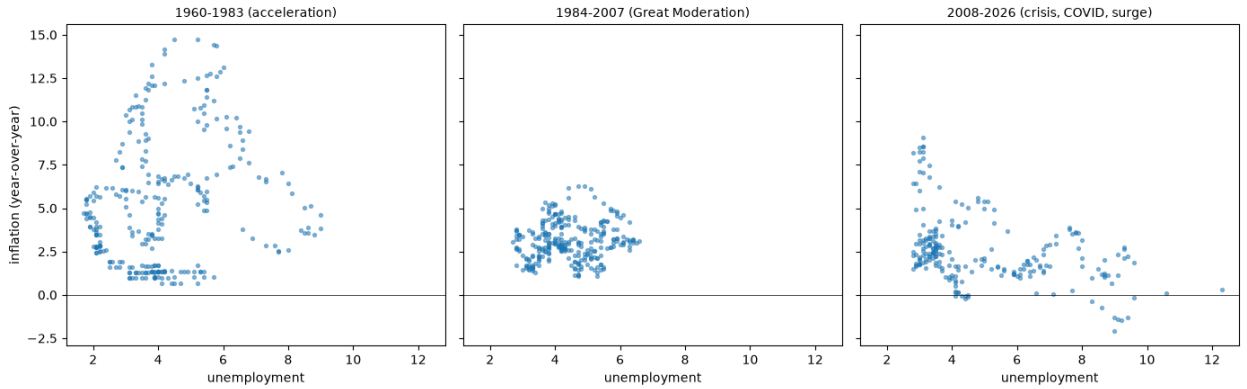

Fig. 98.7: The inflation-unemployment scatter across three eras

(continued from previous page)

```
    corr = era_data.corr().iloc[0, 1]
    slope = np.polyfit(era_data['unemployment'], era_data['inflation'], 1)[0]
    print(f"{title:38s} correlation {corr:+.2f}   slope {slope:+.2f}")
```

```
1960-1983 (acceleration)               correlation +0.19   slope +0.43
1984-2007 (Great Moderation)           correlation +0.11   slope +0.13
2008-2026 (crisis, COVID, surge)       correlation -0.42   slope -0.40
```

In 1960-1983 the points sprawl across a wide range of inflation rates — the era of shifting expectations and Phillips *loops*; in levels the correlation is weakly *positive*, because the adverse shifts swamp the tradeoff.

In 1984-2007 they collapse into a tight, low, nearly flat cloud — the Great Moderation, in which inflation barely responded to unemployment at all.

Since 2008 the scatter is L-shaped: flat at moderate and high unemployment, through the slow recovery from the financial crisis and the COVID recession, and nearly vertical at low unemployment, where the 2021-2022 surge sits.

Paradoxically, it is the only era whose correlation in levels is clearly negative.

An L shape is consistent with a convex Phillips curve, steep only when labor markets are tight, or with supply shocks that happened to arrive when unemployment was low.

Whatever the Phillips curve is, it is not a stable *reduced-form* relationship.

That is exactly what a natural-rate economy with drifting government beliefs predicts: the structural curve, which links unemployment to *surprise* inflation, can stay put while the empirical curve, which links it to inflation itself, drifts with expectations and policy.

Exercise 98.9.3 repeats the comparison at business-cycle frequencies, where the answer is different.

98.7.4 What the new data mean for the two stories

The additional quarter-century neither refutes nor confirms either story cleanly, but it sharpens both.

For the triumph of natural-rate theory. The Great Moderation reads as the triumph completed: with the natural-rate consensus entrenched and central-bank independence established, inflation stayed low and expectations stayed *anchored* for a generation.

In the book's language, policy makers had learned a correct rational expectations version of the natural-rate hypothesis and found devices to commit themselves to low inflation — the outcome the book hoped for.

Even the 2021-2022 surge, on this reading, supports the triumph: once the Federal Reserve moved decisively, inflation came down quickly from its peak and long-run expectations never came unmoored, although inflation has not yet returned to its pre-2021 level.

For the vindication of econometric policy evaluation. The surge is also a reminder that the monetary authority's *model* can still mislead it: the widely held 2021 view that inflation would be "transitory" was a model that the data falsified, and policy adjusted only after beliefs did.

The decade of low, below-target inflation before 2020 — the apparently *flat* Phillips curve, with neither the "missing disinflation" of 2009-2013 nor the "missing inflation" of 2015-2019 fitting a stable curve — is precisely the kind of drifting empirical relationship whose changing slope and intercept the book's adaptive government tracks in real time.

Exercise 98.9.2 asks you to track them as such a government would.

Note

A caveat the book itself insists on, for its own sample as much as for ours: its mechanisms assume that the *fundamentals* — the true data-generating process — are stable, so that all the action comes from the government's evolving beliefs.

As we saw above, the book declines to "examine unusual supply shocks", and that leaves out the oil shocks of 1973 and 1979 just as it leaves out the pandemic disruptions and energy prices of 2021-2022.

Disentangling shifting beliefs from shifting fundamentals is exactly the identification problem that makes this history so hard, and so interesting; *Drifts and Volatilities* takes it on directly.

The tools built in the rest of this suite — self-confirming equilibria, drifting coefficients, and escape dynamics — remain a natural language for asking the question the new data pose: will low inflation keep re-anchoring after each shock, or can a sequence of surprises still set beliefs drifting, as they did after 1965?

Put in the terms of the book's title: has the conquest of American inflation been lost?

Drifts and Volatilities and *Drifts and Volatilities after 2000* ask the data directly whether the coefficients of post-war U.S. macroeconomic dynamics really drifted, before and after 2000.

The closing lecture, *The Lost Conquest: Fed Policy in the 2020s*, turns the suite's tools on the 2021-2022 surge and asks why the Federal Reserve was so slow to respond.

We begin building the models in *The Credibility Problem*.

98.8 A note on notation

The lectures follow the notation of the source each one is based on, and those sources do not agree with one another.

Rather than impose a single scheme and diverge from the papers a reader may want to consult, we keep each lecture faithful to its source and record the translations here.

Readers arriving from the Bounded Rationality suite should note that there γ is the learning gain and the government's beliefs are α (*Notation across the series*, and the dictionary in *A government learning the Phillips curve*); from *Adaptive Expectations and the Phelps Problem* to *Priors, Escapes, and Learning Cycles*, γ is the government's beliefs.

object	symbol	where

learning gain	$1/t$, a_n	*The Credibility Problem* (least squares and its appendix)
	$1 - \lambda$	*Adaptive Expectations and the Phelps Problem* (Cagan–Friedman), *Adaptive Learning and Escape Dynamics* (constant gain $g_t = 1 - \lambda$)
	C	*Optimal Misspecified Beliefs*, *Self-Confirming Equilibria* (a gain chosen to fit the data)
	ε	the primer in *Adaptive Learning and Escape Dynamics*; *Escaping Nash Inflation*, *Priors, Escapes, and Learning Cycles*
	γ	*The Lost Conquest: Fed Policy in the 2020s*; the Bounded Rationality suite
discount factor	δ	*Credible Government Policies* – *Priors, Escapes, and Learning Cycles*
	β	*The Lost Conquest: Fed Policy in the 2020s*

Econometric Policy Evaluation estimates the model of chapter 9 of the book in the book's notation, that of *Adaptive Learning and Escape Dynamics*: inflation y, beliefs γ and β, forgetting factor λ, and discount factor δ.

Several letters change jobs, and a reader carrying symbols forward will otherwise be caught by them.

- The letter x changes sides: up to *Adaptive Learning and Escape Dynamics* it is what the *public* expects, while in *Escaping Nash Inflation* and *Priors, Escapes, and Learning Cycles* it is what the *government* sets. The two coincide in equilibrium, which is exactly what makes the switch easy to miss. In *The Lost Conquest: Fed Policy in the 2020s*, x is the output gap.
- The letter θ is the slope of the Phillips curve in the early lectures, the government's whole belief vector in *The Lost Conquest: Fed Policy in the 2020s*, and an *econometrician's* coefficients, not a government's beliefs, in *Drifts and Volatilities* and *Drifts and Volatilities after 2000*.
- The letter γ is the government's beliefs from *Adaptive Expectations and the Phelps Problem* to *Priors, Escapes, and Learning Cycles*, but the learning gain in *The Lost Conquest: Fed Policy in the 2020s*, as in the Bounded Rationality suite.
- The letter β is the government's Keynesian Phillips-curve coefficients in *Adaptive Expectations and the Phelps Problem*, *Self-Confirming Equilibria*, and *Adaptive Learning and Escape Dynamics*, the Federal Reserve's discount factor in *The Lost Conquest: Fed Policy in the 2020s* (where β_n is the discount factor of its New Keynesian model of the economy), and a block of covariance parameters in *Drifts and Volatilities*.
- The letter λ works several shifts: the Cagan–Friedman adaptation parameter in *Adaptive Expectations and the Phelps Problem*, a forgetting factor in *Adaptive Learning and Escape Dynamics*, a prior-tightening parameter in *Priors, Escapes, and Learning Cycles*, a block of parameters in *Drifts and Volatilities*, and a measured persistence root in *The Lost Conquest: Fed Policy in the 2020s*, where λ_x is also the weight on the output gap in the Federal Reserve's loss function.

The static model of *Escaping Nash Inflation* and *Priors, Escapes, and Learning Cycles* comes in two orderings, because each lecture follows its source paper.

Escaping Nash Inflation follows Cho *et al.* [2002] and lists the slope of the government's regression first, while *Priors, Escapes, and Learning Cycles* and *A government learning the Phillips curve* follow Sargent and Williams [2005] and list the intercept first.

The constant gains differ across lectures too, again following the sources.

gain	where	source
0.025	*Adaptive Learning and Escape Dynamics*	the book's forgetting factor $\lambda = .975$ (chapter 8)
0.02	*A government learning the Phillips curve*	the condensed model of the Bounded Rationality suite
a range	*Escaping Nash Inflation*	escape times as the gain varies
0.05 and 0.02	*Priors, Escapes, and Learning Cycles*	0.05, the largest gain in the tables of Sargent and Williams [2005], for the analysis; 0.02 for the constant-gain comparison with *A government learning the Phillips curve*
0.015	chapter 9 of the book and *Econometric Policy Evaluation*, quarterly data	the book fixes $\lambda = .985$ and $\delta = .999$ and estimates the rest
0.03	*The Lost Conquest: Fed Policy in the 2020s*	Sargent and Williams [2025], quarterly data

Because the length of a period differs across these settings, the numbers are not directly comparable: a gain g gives the data an effective memory of about $1/g$ periods.

Smaller gains make escapes from the self-confirming equilibrium rarer, but at gains like those of *Adaptive Learning and Escape Dynamics* and *A government learning the Phillips curve* escapes are frequent; *Escaping Nash Inflation* measures how escape times grow as the gain shrinks.

98.9 Exercises

Exercise 98.9.1

The claim that "focusing on the business-cycle components sharpens the apparent Phillips curve" can be made quantitative, and the loops in Figure 1.5 can be explained.

Work with the monthly series in `data` over 1961-1982, the part of the book's window that the filtered series cover.

1. Compute the correlation between inflation and unemployment for the raw monthly series and for the 13-month moving average of inflation plotted in Figure 1.4.
2. Split each raw series into three frequency bands — periods longer than 84 months, periods between 24 and 84 months (the Baxter-King components of Figure 1.5), and periods shorter than 24 months — and compute the correlation within each band. Hint: `bkfilter(data, low=2, high=84, K=84)` keeps all periods shorter than 84 months; subtracting it from the data leaves the low-frequency band, and subtracting the business-cycle band from it leaves the high-frequency band.
3. Which band carries the Phillips curve, and which carries the adverse shifts? Why is the raw correlation close to zero?
4. For the business-cycle components, compute $\mathrm{corr}(\pi_t, U_{t-k})$ for $k = 0, 1, \ldots, 24$ months, where π_t is inflation and U_t unemployment. At what lag is the correlation most negative, and how does that lag explain the direction of the loops in Figure 1.5?

Solution

We split the data into the three bands and compute the correlations.

```
window = slice('1961', '1982')

below_84 = bkfilter(data, low=2, high=84, K=84)    # periods under 84 months
below_84.columns = data.columns
cycle = bk.set_axis(data.columns, axis=1)           # periods of 24-84 months
bands = {'over 84 months': data.loc[below_84.index] - below_84,
         '24 to 84 months': cycle,
         'under 24 months': below_84 - cycle}

smoothed = pd.concat([inflation_ma, u], axis=1).dropna()
raw_var = data.loc[window, 'inflation'].var()

print(f"{'raw monthly series':28s} correlation "
      f"{data.loc[window].corr().iloc[0, 1]:+.2f}")
print(f"{'13-month moving average':28s} correlation "
      f"{smoothed.loc[window].corr().iloc[0, 1]:+.2f}")
for name, band in bands.items():
    b = band.loc[window]
    share = b['inflation'].var() / raw_var
    print(f"{'periods ' + name:28s} correlation {b.corr().iloc[0, 1]:+.2f}"
          f"   share of inflation variance {share:.2f}")
```

```
raw monthly series            correlation +0.04
13-month moving average       correlation +0.11
periods over 84 months        correlation +0.46   share of inflation variance 0.
 ↪45
periods 24 to 84 months       correlation -0.64   share of inflation variance 0.
 ↪14
periods under 24 months       correlation -0.15   share of inflation variance 0.
 ↪40
```

The raw correlation is close to zero because it mixes three bands with correlations of opposite sign.

At periods longer than seven years the correlation is *positive*: these are the adverse shifts of the Phillips curve, the slowly moving component that the natural-rate theory attributes to expected inflation, and the vindication story to the government's drifting beliefs.

At business-cycle periods the correlation is strongly negative: this band carries the Phillips curve.

At periods shorter than two years, which hold a large share of the variance of raw monthly inflation, much of it rounding and seasonal noise in the unadjusted index, the correlation is weak.

Smoothing alone does not help: the 13-month moving average removes most of the high-frequency band but leaves the positive low-frequency shifts in place, so its correlation is, if anything, slightly more positive than the raw one.

The bandpass filter works because it removes both.

Now the lead-lag pattern.

```
lags = np.arange(25)
cross = np.array([cycle['inflation'].corr(cycle['unemployment'].shift(k).
 ↪loc[window])
                  for k in lags])
k_star = lags[np.argmin(cross)]
print(f"corr(π_t, U_t)        = {cross[0]:+.2f}")
print(f"most negative at k = {k_star} months: corr(π_t, U_t-k) = {cross.min():+.2f}
 ↪")
```

```
corr(π_t, U_t)        = -0.64
most negative at k = 6 months: corr(π_t, U_t-k) = -0.81
```

The correlation is most negative when inflation is paired with unemployment about six months earlier, so inflation lags unemployment.

That lag is what makes the loops in Figure 1.5, with unemployment on the horizontal axis, run clockwise.

Start at a peak of unemployment, on the right of a loop.

As unemployment falls, inflation has not yet responded, so the path moves left along the bottom; after unemployment bottoms out, inflation reaches its peak about half a year later, so the path climbs the left side; as unemployment rises, inflation is still high, so the path moves right along the top; and so on around.

Exercise 98.9.2

Lucas observed that forecasters kept adjusting the constant terms of their equations.

Let's watch an econometrician do this to the empirical Phillips curve, regressing unemployment on inflation as the governments of *A government learning the Phillips curve*, *Escaping Nash Inflation*, and *Priors, Escapes, and Learning Cycles* do.

Let π_t be year-over-year CPI inflation (`inflation_yoy`), which uses only past data, and U_t unemployment

(`u_full`).

Estimate

$$U_t = a_t + b_t \pi_t + \text{error}$$

by recursive least squares.

Start from ordinary least squares estimates on 1954-1959 and update monthly from January 1960 to the latest month, using

$$R_t = R_{t-1} + g_t \left(z_t z_t^\top - R_{t-1} \right),$$
$$\begin{bmatrix} a_t \\ b_t \end{bmatrix} = \begin{bmatrix} a_{t-1} \\ b_{t-1} \end{bmatrix} + g_t R_t^{-1} z_t \left(U_t - a_{t-1} - b_{t-1} \pi_t \right),$$

where $z_t = (1, \pi_t)^\top$.

1. Use the constant gain $g_t = 0.02$ of *A government learning the Phillips curve*, which with monthly data gives an effective memory of about four years, and plot a_t and b_t.
2. Repeat with the decreasing gain $g_t = 1/t$ of ordinary least squares, counting t from the start of the 1954-1959 pre-sample, and compare.
3. How did the estimated slope b_t behave in the late 1960s, in the 1970s, and after 2008? What happened to the intercept a_t?
4. The static government of *A government learning the Phillips curve* would set target inflation $-a_t b_t / (1 + b_t^2)$. Compare that target with actual inflation.

Solution

Here is a recursive least squares routine that handles both gains.

```
def rls_phillips(π, U, coef0, R0, gain=None, t0=0):
    """
    Recursive least squares for U_t = a + b π_t, starting from estimates
    coef0 = (a, b) and moment matrix R0 based on t0 observations.  Uses a
    constant gain if `gain` is given and the gain 1/t of ordinary least
    squares otherwise.
    """
    coef, R = coef0.copy(), R0.copy()
    path = np.empty((len(π), 2))
    for t in range(len(π)):
        g = gain if gain is not None else 1 / (t0 + t + 1)
        z = np.array([1.0, π[t]])
        R = R + g * (np.outer(z, z) - R)
        coef = coef + g * np.linalg.solve(R, z * (U[t] - z @ coef))
        path[t] = coef
    return path

rls_data = pd.concat([inflation_yoy.rename('π'), u_full.rename('U')],
                     axis=1).dropna()
pre, est = rls_data.loc[:'1959'], rls_data.loc['1960':]

Z = np.column_stack([np.ones(len(pre)), pre['π']])
coef0 = np.linalg.lstsq(Z, pre['U'], rcond=None)[0]    # OLS on the pre-sample
R0 = Z.T @ Z / len(pre)
```

```
paths = {}
for label, gain in [('constant gain 0.02', 0.02), ('least squares, gain 1/t',␣
 ↪None)]:
    path = rls_phillips(est['π'].values, est['U'].values, coef0, R0,
                        gain=gain, t0=len(pre))
    paths[label] = pd.DataFrame(path, index=est.index, columns=['a', 'b'])
    paths[label]['target'] = (-paths[label]['a'] * paths[label]['b']
                              / (1 + paths[label]['b']**2))
```

We plot the drifting coefficients and the static rule's target.

```
fig, axes = plt.subplots(3, 1, figsize=(10, 9), sharex=True)
for label, p in paths.items():
    axes[0].plot(p['a'], lw=1.2, label=label)
    axes[1].plot(p['b'], lw=1.2, label=label)
    axes[2].plot(p['target'], lw=1.2, label=f'static target, {label}')
axes[2].plot(est['π'], 'k', lw=0.6, alpha=0.6, label='actual inflation')
axes[1].axhline(0, color='k', lw=0.5)
axes[0].set_ylabel('intercept $a_t$')
axes[1].set_ylabel('slope $b_t$')
axes[2].set_ylabel('percent')
axes[2].set_xlabel('year')
for ax in axes:
    ax.legend(fontsize=8, loc='upper left')
plt.tight_layout()
plt.show()
```

A few numbers make the comparison precise.

```
cg, ls = paths['constant gain 0.02'], paths['least squares, gain 1/t']
for lo, hi in [('1960', '1971'), ('1972', '2007'), ('2008', '2015'), ('2016',␣
 ↪None)]:
    b = cg.loc[lo:hi, 'b']
    print(f"steepest constant-gain slope, {lo}-{b.index[-1].year}: "
          f"{b.min():+.2f} ({b.idxmin():%Y-%m})")
print(f"constant-gain slope, 1974-1981: {cg.loc['1974':'1981', 'b'].min():+.2f} "
      f"to {cg.loc['1974':'1981', 'b'].max():+.2f}")
print(f"constant-gain intercept, range: {cg['a'].min():.1f} to {cg['a'].max():.1f}
 ↪")
print(f"least squares, after 1975:  intercept {ls.loc['1975':, 'a'].min():.1f} "
      f"to {ls.loc['1975':, 'a'].max():.1f},  slope {ls.loc['1975':, 'b'].min():+.
 ↪2f} "
      f"to {ls.loc['1975':, 'b'].max():+.2f}")
print(f"constant-gain static target, 1960-1985: "
      f"{cg.loc[:'1985', 'target'].min():.1f} to {cg.loc[:'1985', 'target'].max():.
 ↪1f};"
      f"  actual inflation peak {est.loc[:'1985', 'π'].max():.1f}")
```

```
steepest constant-gain slope, 1960-1971: -0.62 (1967-12)
steepest constant-gain slope, 1972-2007: -0.24 (1983-11)
steepest constant-gain slope, 2008-2015: -0.92 (2011-02)
steepest constant-gain slope, 2016-2026: -0.98 (2021-02)
constant-gain slope, 1974-1981: -0.11 to +0.17
constant-gain intercept, range: 2.7 to 8.1
least squares, after 1975:  intercept 3.4 to 4.6,  slope -0.09 to +0.10
constant-gain static target, 1960-1985: -0.5 to 1.9;  actual inflation peak 14.8
```

With the constant gain, the estimated slope is close to zero in the early 1960s and then turns strongly negative in the late 1960s: as the data then showed it, the tradeoff of Samuelson and Solow looked real and exploitable.

During the 1970s it flattens back to zero and at times turns positive, as inflation rose without bringing unemployment down.

That is the adverse shift, and in the static model of *Escaping Nash Inflation* a slope near zero is exactly the belief that leads the government to aim for zero inflation.

After 2008 the slope turns sharply negative twice, when the unemployment spikes of 2009 and 2020 arrived with falling inflation; these are the steepest slopes of the whole sample.

The intercept drifts too, jumping in the early 1980s, when the Volcker disinflation coincided with high unemployment, and again after 2008 and in 2020: these are Lucas's adjusted constants.

With the decreasing gain the estimates move only slowly after the mid-1970s, because least squares weights an observation from 1955 as heavily as one from last month and so stops tracking drift.

Before 1985 the static government's target never rises much above 2 percent, nowhere near the inflation of the 1970s.

A static, classical government fit to these data would never have recommended the Great Inflation; chapter 9 of the book finds that its own classical model "fails even to match the acceleration in inflation leading up to 1970" and prefers a distributed-lag Keynesian specification (*Econometric Policy Evaluation*).

Constant-gain least squares approximates a Kalman filter for coefficients that drift as random walks, under a particular prior about the drift (*Priors, Escapes, and Learning Cycles*); *Adaptive Learning and Escape Dynamics* puts such a learner inside the model, and *Drifts and Volatilities* lets an econometrician's VAR coefficients drift in the same way.

Exercise 98.9.3

The three-eras figure compares the eras in levels.

Repeat the comparison at business-cycle frequencies.

1. Apply the Baxter-King filter of Figure 1.3 to raw monthly inflation (`inflation_full`) and unemployment (`u_full`) over the whole sample. Where do the filtered series end, and why?
2. To reach the end of the sample, use the Christiano-Fitzgerald bandpass filter with the same band, `cffilter` in `statsmodels.tsa.filters.cf_filter`, which uses asymmetric weights near the ends of the sample instead of dropping them. Check that the two filters agree where both are available.
3. For 1960-1983, 1984-2007, and 2008 to the end of the sample, compute the correlation between the business-cycle components and the least squares slope of the inflation component on the unemployment component. Was the Great Moderation's Phillips curve flat at business-cycle frequencies? What happened after 2008?

Solution

We filter the full sample both ways.

```
from statsmodels.tsa.filters.cf_filter import cffilter

full = pd.concat([inflation_full.rename('inflation'),
                  u_full.rename('unemployment')], axis=1).dropna()

bk_full = bkfilter(full, low=24, high=84, K=84).set_axis(full.columns, axis=1)
cf_full = cffilter(full, low=24, high=84, drift=True)[0].set_axis(full.columns,␣
 ↪axis=1)

print(f"data end in {full.index[-1]:%Y-%m}; "
      f"Baxter-King components end in {bk_full.index[-1]:%Y-%m}")
overlap = bk_full.index
for col in full.columns:
    print(f"{col}: correlation of the two filters' components "
          f"{bk_full[col].corr(cf_full.loc[overlap, col]):.2f}")
```

```
data end in 2026-09; Baxter-King components end in 2019-09
inflation: correlation of the two filters' components 0.98
unemployment: correlation of the two filters' components 0.97
```

The Baxter-King filter is a two-sided moving average with 84 months on each side, so it loses the last seven years of data, including the whole 2021-2022 surge.

The Christiano-Fitzgerald components track the Baxter-King ones closely where both exist; near the end of the sample they rest on one-sided information and will be revised as new data arrive.

For comparison with Exercise 98.9.1, we also compute the correlation in the band of periods longer than 84 months, using the same filter.

```
below_84_cf = cffilter(full, low=2, high=84, drift=True)[0].set_axis(full.columns,␣
 ↪axis=1)
low_cf = full - below_84_cf                          # periods over 84 months

eras_bc = [('1960', '1983'), ('1984', '2007'), ('2008', None)]
for lo, hi in eras_bc:
    e = cf_full.loc[lo:hi]
    corr = e.corr().iloc[0, 1]
    slope = np.polyfit(e['unemployment'], e['inflation'], 1)[0]
    corr_low = low_cf.loc[lo:hi].corr().iloc[0, 1]
    print(f"{lo}-{e.index[-1].year}: business cycle: correlation {corr:+.2f}, "
          f"slope {slope:+.2f}, sd of inflation {e['inflation'].std():.2f};"
          f"  over 84 months: correlation {corr_low:+.2f}")
b = bk_full.loc['2008':'2019']
print(f"2008-{b.index[-1].year}, Baxter-King business cycle: correlation "
      f"{b.corr().iloc[0, 1]:+.2f}")
```

```
1960-1983: business cycle: correlation -0.67, slope -1.62, sd of inflation 1.72;
 ↪  over 84 months: correlation +0.31
1984-2007: business cycle: correlation -0.68, slope -1.10, sd of inflation 0.81;
 ↪  over 84 months: correlation +0.00
2008-2026: business cycle: correlation -0.25, slope -0.39, sd of inflation 1.45;
 ↪  over 84 months: correlation -0.38
2008-2019, Baxter-King business cycle: correlation -0.07
```

At business-cycle frequencies the Great Moderation's Phillips curve was about as tight as that of 1960-1983, with a similar negative correlation, but flatter, and its swings were smaller.

What disappeared after 1984 was the low-frequency drift that swamps the tradeoff in levels, whose correlation falls from positive to about zero, not the business-cycle tradeoff itself.

After 2008 the business-cycle correlation weakens sharply, and with the Baxter-King filter over 2008-2019, before the pandemic and the surge, it nearly vanishes.

So the "flat Phillips curve" of the 2010s, unlike the flatness of the Great Moderation, shows up at business-cycle frequencies too.

The ranking is the reverse of the one in levels, where the post-2008 era was the only one with a clearly negative correlation; that correlation comes mainly from movements slower than the business cycle.

Near the end of the sample these low-frequency components rest on one-sided information, so the last of these numbers is the least reliable.

99.1 Overview

This lecture describes a basic expectational Phillips curve model of the sort studied by Kydland and Prescott [1977] and Barro and Gordon [1983].

It is the first *modeling* lecture in a suite based on chapters of Sargent [1999], following *The Rise and Fall of U.S. Inflation*, which lays out the two stories and reviews the Lucas Critique.

This lecture follows chapter 3 of the book, and *Credible Government Policies* follows chapter 4.

Together the two lectures formalize

- the temptation to inflate that is unleashed by the discovery of a Phillips curve,
- the value of a commitment technology for resisting that temptation, and
- the fragility of reputational mechanisms as substitutes for commitment.

Throughout, rational expectations is the only equilibrium concept that we use.

Alterations in the *timing* of decisions by a government and a private sector induce different economies with distinct outcomes.

A government faces a **credibility problem** whenever it wishes to make decisions sooner than it must.

We shall compare outcomes under two timing protocols:

- In one, the government chooses inflation *before* the private sector sets its expectations, so the government takes into account how its choice shapes those expectations.
- In the other, the government chooses inflation *after* the private sector has set its expectations.

The deterioration in outcomes under the second protocol measures the loss from an inability to commit.

Time Inconsistency of Ramsey Plans studies the same time-inconsistency problem in Calvo's dynamic monetary model.

We also study two *out-of-equilibrium* dynamics that converge to the no-commitment (Nash) outcome:

- best response dynamics, and
- least squares learning.

Let's start with some standard imports:

```
import matplotlib.pyplot as plt
import numpy as np
```

99.2 A one-period economy

Although credibility problems are intrinsically dynamic, it is possible to describe them in a one-period model under different patterns of within-period timing.

This prepares the way for the multi-period analyses in subsequent lectures.

We describe a version of the one-period model of Kydland and Prescott [1977] in the terms used by Nancy Stokey [Stokey, 1989].

Let (U, y, x) be the unemployment rate, the inflation rate, and the public's expectation of the inflation rate, respectively.

The government's one-period payoff is

$$-\frac{1}{2}\left(U^2 + y^2\right). \tag{99.1}$$

Unemployment is determined by an expectations-augmented Phillips curve

$$U = U^* - \theta(y - x), \qquad \theta > 0. \tag{99.2}$$

The equation asserts that unemployment deviates from U^*, the natural rate, only when there is surprise inflation or deflation.

Substituting (99.2) into (99.1) expresses the government's payoff as a function $r(x, y)$:

$$r(x, y) = -\frac{1}{2}\left[\left(U^* - \theta(y - x)\right)^2 + y^2\right]. \tag{99.3}$$

We work with the following objects.

Rational expectations equilibrium: a triple (U, x, y) satisfying (99.2) and $y = x$.

Government (one-period) best response: given the public's expectation x, a decision rule $B(x) = \text{argmax}_y\, r(x, y)$ for setting y.

Nash equilibrium: a pair (x, y) satisfying (i) $x = y$, and (ii) $y = B(x)$.

Ramsey problem: $\max_y r(y, y)$.

The *Ramsey outcome* is the value of y that attains the maximum.

Best response dynamics: the dynamical system $y_t = B(y_{t-1})$, y_0 given.

A rational expectations equilibrium is a (U, x, y) triple that lies on the Phillips curve and for which private agents are not fooled, given x.

Substituting $x = y$ into the Phillips curve (99.2) shows that $U = U^*$ in any rational expectations equilibrium.

This identifies U^* as the natural rate of unemployment.

99.3 Nash and Ramsey outcomes

A Nash equilibrium builds in a best response by the government, taking the state of expectations x as given, together with a response $x = y$ by the market, i.e., rational expectations for a given y.

Maximizing (99.3) with respect to y for a fixed x gives the government's best response function

$$y = B(x) = \frac{\theta}{\theta^2 + 1} U^* + \frac{\theta^2}{\theta^2 + 1} x. \tag{99.4}$$

The Nash equilibrium sets $x = y = B(x)$, which gives

$$y^N = x^N = \theta U^*, \qquad U = U^*.$$

The Ramsey problem instead imposes $x = y$ *before* maximizing, so it maximizes $r(y, y) = -\frac{1}{2}(U^{*2} + y^2)$, which yields the Ramsey outcome

$$y^R = x^R = 0, \qquad U = U^*.$$

Thus $r(x^R, y^R) = -\frac{1}{2} U^{*2}$ while $r(x^N, y^N) = -\frac{1}{2}(1 + \theta^2) U^{*2}$.

Both outcomes deliver the natural rate U^*, but the Nash equilibrium delivers it with positive inflation and hence a strictly lower payoff.

Let's collect these formulas in a class.

```
class CredibilityModel:
    """
    A one-period expectational Phillips curve economy.
    """

    def __init__(self, θ=1.0, U_star=5.0):
        self.θ, self.U_star = θ, U_star

    def phillips(self, y, x):
        "Unemployment implied by inflation y and expected inflation x."
        return self.U_star - self.θ * (y - x)

    def r(self, x, y):
        "Government one-period payoff."
        U = self.phillips(y, x)
        return -0.5 * (U**2 + y**2)

    def B(self, x):
        "Government best response to expected inflation x."
        θ = self.θ
        return θ / (θ**2 + 1) * self.U_star + θ**2 / (θ**2 + 1) * x
```

(continues on next page)

(continued from previous page)

```
    def nash(self):
        "Nash equilibrium inflation (= expected inflation)."
        return self.θ * self.U_star

    def ramsey(self):
        "Ramsey inflation (= expected inflation)."
        return 0.0
```

The default calibration is $\theta = 1$ and $U^* = 5$.

```
cm = CredibilityModel()

y_N, y_R = cm.nash(), cm.ramsey()
print(f"Nash inflation      y^N = {y_N:.2f}")
print(f"Ramsey inflation    y^R = {y_R:.2f}")
print(f"Nash payoff         r   = {cm.r(y_N, y_N):.3f}")
print(f"Ramsey payoff       r   = {cm.r(y_R, y_R):.3f}")
```

```
Nash inflation      y^N = 5.00
Ramsey inflation    y^R = 0.00
Nash payoff         r   = -25.000
Ramsey payoff       r   = -12.500
```

The Nash payoff is worse than the Ramsey payoff.

The government would prefer the Ramsey outcome, but it cannot attain it without a technology for committing to $y = 0$ before the public forms its expectations.

The Nash equilibrium is supported by a timing protocol in which the government decides *after* the private sector sets its expectations.

The Ramsey outcome is associated with a timing protocol in which the government chooses *first*, knowing that in a rational expectations equilibrium the public's expectations will move with its choice because $y = x$.

99.3.1 A picture of the two outcomes

The government's indifference curves are circles centered at the origin in (U, y) space, because the payoff (99.1) depends only on $U^2 + y^2$.

For a given expectation x, the Phillips curve (99.2) is a downward-sloping line in (U, y) space.

The government's best response for y, given x, occurs where an indifference curve is tangent to the Phillips curve indexed by x.

```
fig, ax = plt.subplots(figsize=(7, 6))

U_grid = np.linspace(0, 12, 200)

# a family of Phillips curves indexed by expected inflation x
for x in [0.0, y_N / 2, y_N]:
    # U = U_star - θ (y - x)  =>  y = x + (U_star - U) / θ
    y_line = x + (cm.U_star - U_grid) / cm.θ
    ax.plot(U_grid, y_line, 'C0', lw=1)

# government indifference curves (circles U^2 + y^2 = const)
ξ = np.linspace(0, 2 * np.pi, 200)
```

(continues on next page)

(continued from previous page)

```
for R in [np.hypot(cm.U_star, y_R), np.hypot(cm.U_star, y_N)]:
    if R > 0:
        ax.plot(R * np.cos(ξ), R * np.sin(ξ), 'C1--', lw=1)

ax.plot(cm.U_star, y_N, 'ko')

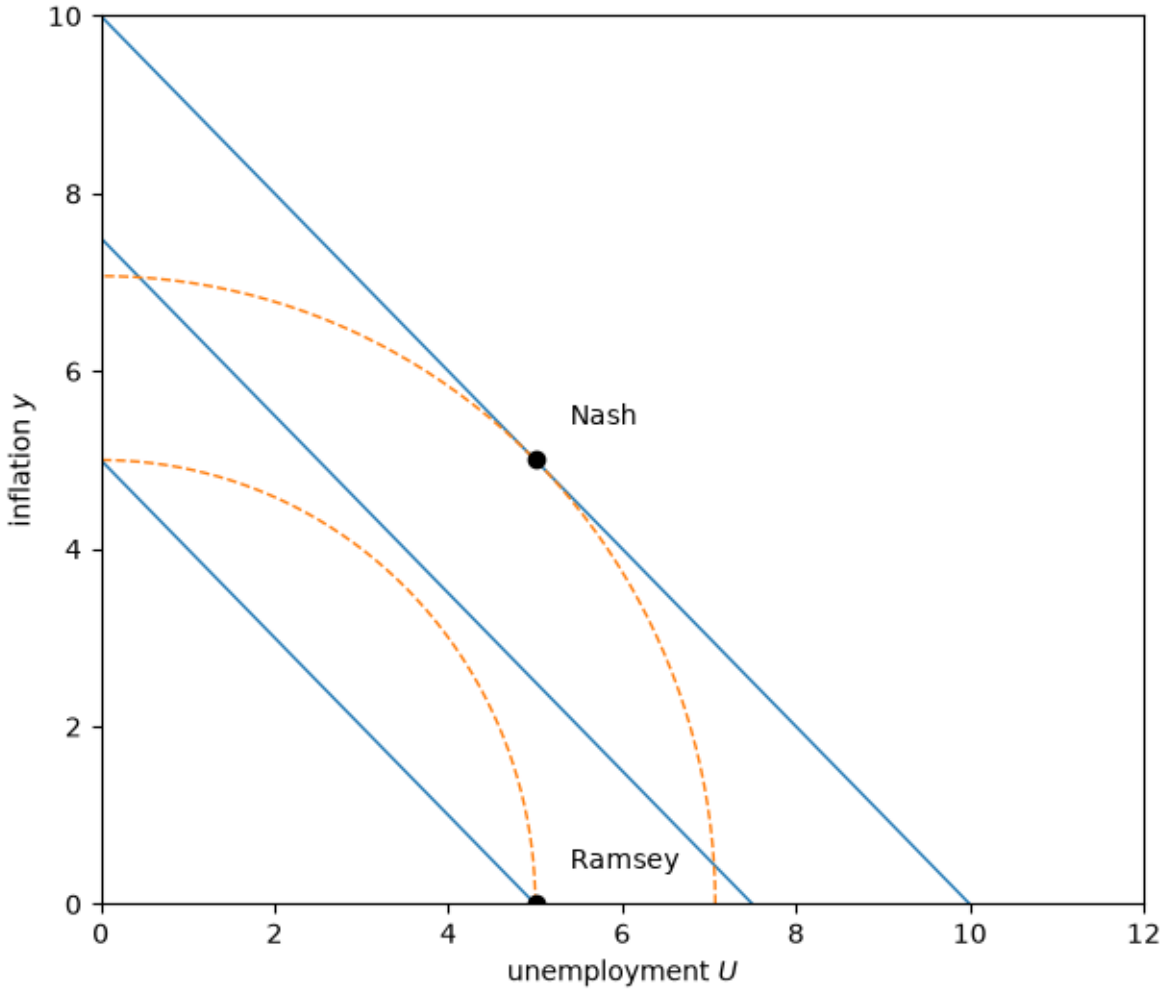

Fig. 99.1: Phillips curves indexed by expected inflation, government indifference curves, and the Nash and Ramsey outcomes

Solid lines are Phillips curves for expected inflation $x \in \{0, y^N/2, y^N\}$; dashed circles are government indifference

curves.

The Nash outcome (U^*, y^N) lies on a larger circle (lower payoff) than the Ramsey outcome $(U^*, 0)$.

99.4 Best response dynamics

Best response dynamics convert the one-period model into a dynamic one by positing an adaptive mechanism in which expected inflation equals last period's inflation, $x_t = y_{t-1}$.

This leads to the dynamics

$$y_t = B(y_{t-1}), \qquad y_0 \text{ given.}$$

Because B is an affine map with slope $\theta^2/(\theta^2+1) \in (0,1)$, iterating on it converges to the fixed point $y^N = \theta U^*$ from any starting point.

Let's plot the best response function against the 45-degree line and simulate the dynamics.

```
def best_response_path(cm, y0, T=20):
    "Iterate y_{t+1} = B(y_t)."
    y = np.empty(T + 1)
    y[0] = y0
    for t in range(T):
        y[t + 1] = cm.B(y[t])
    return y

y_path = best_response_path(cm, y0=0.0, T=20)
```

The figure traces this path as a cobweb between the best response function and the 45-degree line.

```
fig, ax = plt.subplots(figsize=(6, 6))

x_grid = np.linspace(0, y_N + 1, 100)
ax.plot(x_grid, cm.B(x_grid), 'C0', label='$B(x)$')
ax.plot(x_grid, x_grid, 'k--', lw=1, label='45 degrees')

# cobweb of the best response dynamics
for t in range(len(y_path) - 1):
    ax.plot([y_path[t], y_path[t]], [y_path[t], y_path[t + 1]], 'C1', lw=0.8)
    ax.plot([y_path[t], y_path[t + 1]], [y_path[t + 1], y_path[t + 1]],
            'C1', lw=0.8)

ax.plot(y_N, y_N, 'ko')
ax.annotate('Nash', (y_N, y_N), (y_N - 1.5, y_N + 0.3))
ax.set_xlabel('$x$')
ax.set_ylabel('$B(x)$')
ax.legend()
plt.show()
```

Starting from $x = 0$ (the Ramsey inflation rate), the government sets $y = B(0) > 0$.

This provokes the public to raise its expectation, which leads the government to raise inflation further.

The limit of this process is the Nash outcome $y = x = y^N$, a self-confirming situation.

Thus best response dynamics converge to the Nash equilibrium and reinforce (U^*, y^N) as the prediction of the model without a commitment technology.

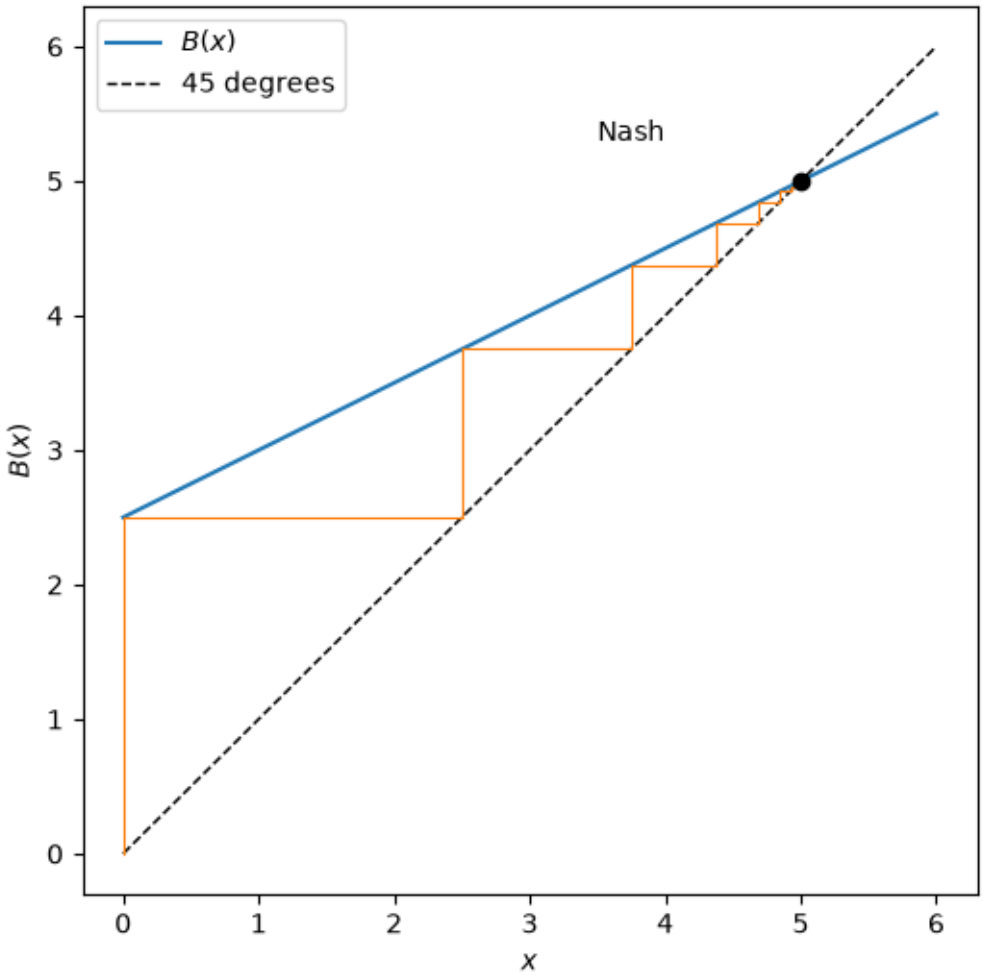

Fig. 99.2: Best response dynamics cobwebbing up to the Nash inflation rate

99.5 Least squares learning converges to Nash

A version of the best response dynamics also emerges from least squares learning.

Least squares learning plays a key role throughout this suite of lectures, and this simple example introduces analytical elements that reappear later in more complex settings.

Bray [1982] studied a competitive market in which traders formed the expected price by averaging past prices.

In the same spirit, assume that for $t \geq 2$ expected inflation x_t is the average of past inflation rates,

$$x_t = \frac{1}{t-1} \sum_{s=1}^{t-1} y_s,$$

which can be represented recursively as

$$x_t = x_{t-1} + \frac{1}{t-1}(y_{t-1} - x_{t-1}), \qquad x_1 = 0. \tag{99.5}$$

Actual inflation is a disturbed version of the best response mapping evaluated at x_t,

$$y_t = B(x_t) + \eta_t, \tag{99.6}$$

where η_t is an IID mean-zero term that represents the government's imperfect control of inflation.

Substituting (99.6), dated $t-1$, into (99.5) gives the stochastic recursion

$$x_t = x_{t-1} + \frac{1}{t-1}\left[B(x_{t-1}) - x_{t-1} + \eta_{t-1}\right]. \tag{99.7}$$

The forecast x_t depends only on shocks dated $t-1$ and earlier, as it must, because the public forms it before it sees y_t.

(The corresponding equation (8) of Sargent [1999] dates this shock t, a slip.)

This is Bray's market of *From relaxation to learning: Bray's market*, written in the notation of this lecture.

- The government's best response B plays the role of the firms' best response h.
- The forecast x_t plays the role of the firms' belief X^*_{t-1}, formed from data through $t-1$.
- Inflation y_t plays the role of realized average output X_t.

The feedback from beliefs to outcomes is

$$h' = B'(x) = \frac{\theta^2}{1+\theta^2} \in (0,1),$$

so Bray's condition $h' < 1$ for least squares learners to converge holds for every θ.

Least Squares Learning in Self-Referential Models analyzes Bray's model (its Example 2) in the general framework of Marcet and Sargent [1989].

By the theory of stochastic approximation, the limiting behavior of x_t is described by the associated ordinary differential equation (ODE)

$$\frac{dx}{dt} = B(x) - x. \tag{99.8}$$

The rest point of this ODE satisfies $x = B(x)$, which is the Nash equilibrium inflation rate $x = \theta U^*$.

Because the map B is affine, the ODE is linear with slope

$$\mathcal{M} = \frac{d}{dx}\left(B(x) - x\right) = B'(x) - 1 = -\frac{1}{\theta^2 + 1}.$$

Since $\mathcal{M} < 0$, the ODE is stable about its rest point.

In the language of *One recursion, many learners*, the Nash equilibrium is **E-stable** (expectationally stable): B maps perceived into actual inflation, and the derivative of that map, $h' = B'$, is less than one.

$\mathcal{M} = h' - 1$ is the E-stability eigenvalue of this one-dimensional system.

E-stability is what brings to bear the theorems of Marcet and Sargent [1989], which give conditions under which x_t converges to y^N globally.

The same number recurs throughout this suite.

When the government itself estimates a Phillips curve by least squares, the mean dynamics of its beliefs have eigenvalues -1 and $-1/(1+\theta^2)$ (*Uniqueness and E-stability*, *Mean dynamics near the self-confirming equilibrium*).

Let's simulate the recursion (99.7) and confirm convergence to the Nash outcome.

```
def ls_learning(cm, T=2000, σ_η=1.0, seed=0, ε=None):
    """
    Simulate learning of expected inflation.

    x[t] is the forecast formed after observing y_1, ..., y_t, which is the
    x_{t+1} of pc_expect1; x[0] = x_1 = 0, and y[0] is unused.

    With ε=None the gain is 1/t (least squares: the 1/(t-1) gain of
    pc_expect1, reindexed); otherwise it is the constant ε.
    """
    rng = np.random.default_rng(seed)
    x = np.empty(T + 1)
    y = np.full(T + 1, np.nan)
    x[0] = 0.0
    for t in range(1, T + 1):
        y[t] = cm.B(x[t - 1]) + σ_η * rng.standard_normal()
        gain = 1.0 / t if ε is None else ε
        x[t] = x[t - 1] + gain * (y[t] - x[t - 1])
    return x, y
```

We simulate 2000 periods at the default calibration.

```
x, y = ls_learning(cm, T=2000, σ_η=1.0)

fig, ax = plt.subplots(figsize=(9, 5))
ax.plot(x, 'C0', lw=1, label='expected inflation $x_t$')
ax.axhline(y_N, color='k', ls='--', lw=1, label='Nash $y^N$')
ax.axhline(y_R, color='C2', ls=':', lw=1, label='Ramsey $y^R$')
ax.set_xlabel('$t$')
ax.set_ylabel('inflation')
ax.legend()
plt.show()
```

The least squares dynamics confirm the pessimism of the best response dynamics.

As Sargent [1999] puts it, this pessimism undermines the *triumph of natural-rate theory* story of *The Rise and Fall of U.S. Inflation*, especially its triumph aspect.

Given an initial condition in the form of a low, gold-standard or Bretton Woods value of x, the best response or least squares dynamics can explain an *acceleration* of inflation.

But they cannot explain a Volcker-style *stabilization* that brings inflation back down.

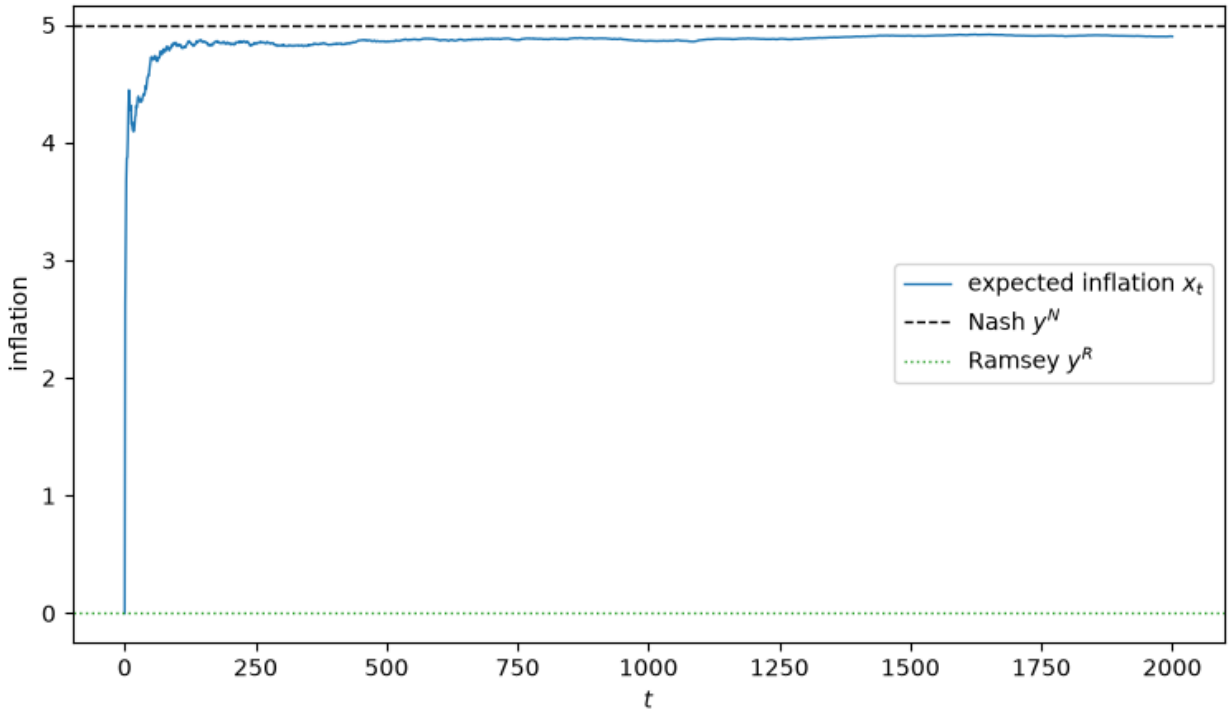

Fig. 99.3: Least squares learning of expected inflation converges to the Nash outcome

Later lectures reformulate versions of least squares learning in ways designed to moderate this pessimism, and in doing so they move us away from the triumph story and toward the vindication story.

99.5.1 How fast?

$\mathcal{M}$ also governs the *speed* of convergence (footnote 3 of chapter 3 of Sargent [1999]; Evans and Honkapohja [2001]).

Taking expectations of (99.7) shows that the mean error $Ex_t - y^N$ obeys the noise-free version of the recursion, so it shrinks like $t^{\mathcal{M}}$.

A necessary condition for convergence at the usual rate, with $\sqrt{t}\,(x_t - y^N)$ settling into a normal distribution, is $\mathcal{M} < -1/2$, which here requires $\theta < 1$.

When $-1/2 \leq \mathcal{M} < 0$, x_t still converges to y^N, but more slowly, at a rate governed by $|\mathcal{M}|$.

At $\theta = 1$, the value used here and in most later lectures, $\mathcal{M} = -1/2$ sits exactly on the boundary: the standard deviation of x_t shrinks like $\sqrt{\log t / t}$ instead of $1/\sqrt{t}$.

In the market of *From relaxation to learning: Bray's market*, by contrast, $h' = -1.5$ gives $\mathcal{M} = -2.5$, and errors shrink at the usual rate $t^{-1/2}$.

Exercise Exercise 99.8.1 measures these rates.

The $-1/2$ boundary concerns the convergence rate of a learner whose gain *decreases* like $1/t$.

It is not what governs how often a *constant*-gain learner escapes from the Nash outcome in later lectures; a large-deviation rate does that (*A primer on recursive algorithms*).

99.6 More foresight

Best response and least squares learning are out-of-equilibrium dynamics tacked onto a one-period economy.

They force all movement through expectation formation: in choosing inflation, the government forgets that the economy lasts more than one period.

Better outcomes can occur if the government plans for the future.

Subsequent lectures describe three ways of modeling foresight, which impute varying amounts of rationality and predict different qualities of outcomes:

1. A reputational approach that attributes rational expectations to both the government and the public, the subject of *Credible Government Policies*, which comes next.
   - Many outcomes are sustainable, ranging from repetition of the Ramsey outcome to paths worse than repetition of the Nash outcome, a multiplicity that turns out to be the theory's chief lesson.
2. An approach that keeps the government rational but gives the public *adaptive* expectations in the original Cagan-Friedman sense, the subject of *Adaptive Expectations and the Phelps Problem*.
   - Depending on a comparison between a discount factor and an adaptation parameter, this setup can improve outcomes and possibly sustain repetition of the Ramsey outcome.
3. Approaches that make the government boundedly rational as well.
   - In *Self-Confirming Equilibria*, prepared by *Optimal Misspecified Beliefs*, the government holds a possibly misspecified model of the Phillips curve that the data it generates confirm.
   - From *Adaptive Learning and Escape Dynamics* on, it re-estimates that model in real time.
   - The outcomes depend on details of the beliefs assigned to the government, and a vindication of econometric policy evaluation can emerge.

99.7 Appendix: stochastic approximation

Here we sketch why the ODE (99.8) governs the tail behavior of the stochastic difference equation (99.7).

The argument, due to Kushner and Clark [1978], has two key components: a shift in time scale and a liberal application of averaging.

The subsection "Stochastic approximation and E-stability" of *One recursion, many learners* presents the same tools from the standpoint of the Bounded Rationality suite, and *Least Squares Learning in Self-Referential Models* states the Marcet–Sargent convergence theorems for vectors of beliefs.

Let $\{a_n\}_{n\geq 0}$ be a positive sequence of gains satisfying

$$\lim_{n\to\infty} a_n = 0, \qquad \sum_n a_n = +\infty, \qquad \sum_n a_n^2 < +\infty.$$

The choice $a_n = 1/(n+1)$ satisfies these assumptions.

Relabel (99.7) so that its x_{n+1} and η_{n+1} become x_n and η_n.

Then the gain is $a_n = 1/(n+1)$ and the recursion reads

$$x_{n+1} = x_n + a_n \left[B(x_n) - x_n + \eta_n \right], \tag{99.9}$$

where η_n is IID with mean zero and finite variance.

Introduce the transformed time scale $t_0 = 0$, $t_n = \sum_{i=0}^{n-1} a_i$, and interpolate the discrete sequence $\{x_n\}$ into a continuous-time process $x^0(t)$.

The map $m(t) = \max\{n : t_n \leq t\}$ takes transformed time back to the original index.

Kushner and Clark show that on this transformed time scale the interpolated process is well approximated by the integral equation

$$x^0(t) = x^0(0) + \int_0^t [B(x^0(s)) - x^0(s)]\, ds + R(t),$$

where the approximation error $R(t)$ has two components — one from approximating a distributed lag in $B(x) - x$ by an integral, and one from a distributed lag in η_s.

Studying a sequence of left-shifted versions of the process, they show that both error components can be driven to zero as $n \to \infty$.

For the noise component, the key step is to note that over the stretch of transformed time from t_n to $t_n + t$ the noise enters through the martingale $W_n(t) = \sum_{i=n}^{m(t_n+t)} a_i \eta_i$.

Its variance is $\mathbb{V}[\eta] \sum_{i=n}^{m(t_n+t)} a_i^2$, a *tail* sum of the convergent series $\sum_i a_i^2$, and so it goes to zero as $n \to \infty$.

The remaining error is sent to zero because $a_i \to 0$ shrinks the mesh of the Riemann sum used to approximate the integral.

In the limit, the stochastic difference equation (99.9) shares the behavior of the non-stochastic ODE

$$\frac{d}{dt}\tilde{x}(t) = B(\tilde{x}(t)) - \tilde{x}(t),$$

which is said to describe the *mean dynamics* of the original system.

Later lectures study systems like (99.9) in which a_i does *not* approach zero as i grows — so-called constant gain algorithms.

Exercise Exercise 99.8.2 gives a first look at one.

The mean dynamics (99.8) and these constant-gain algorithms become the central tools of *Adaptive Learning and Escape Dynamics*, *Escaping Nash Inflation*, and *Priors, Escapes, and Learning Cycles*, where the scalar expectation x studied here grows into a whole vector of drifting Phillips-curve coefficients.

99.8 Exercises

Exercise 99.8.1

This exercise measures how the speed of least squares learning depends on $\mathcal{M} = -1/(1+\theta^2)$.

Let $e_t = x_t - \theta U^*$ be the forecast error relative to Nash.

1. Show that the mean error Ee_t obeys the noise-free version of (99.7), and that it shrinks like $t^{\mathcal{M}}$.
2. For $\theta \in \{0.5, 1, 2\}$ and $U^* = 5$, simulate 200 paths of length $T = 3000$ (seeds $0, \ldots, 199$). On log–log axes, plot $|\bar{e}_t|/(\theta U^*)$, where $\bar{e}_t$ is the average error across paths, and compare it with the exact mean error. Dividing by θU^*, the initial error, makes the three cases comparable.
3. Plot $\sqrt{t}$ times the standard deviation of x_t across paths, and explain why it levels off only for $\theta < 1$.
4. What fraction of the $\theta = 2$ paths is still below the Nash rate at $t = 3000$? Does the $\theta = 2$ learner wander around its limit?

Solution

Write $B(x) - x = \mathcal{M}(x - y^N)$.

Shifted forward one period, (99.7) says $e_{t+1} = (1 + \mathcal{M}/t)\, e_t + \eta_t/t$, with $e_1 = -\theta U^*$, and taking expectations removes the shock.

So the mean error is exactly the path that `ls_learning` produces with $\sigma_\eta = 0$:

$$Ee_{t+1} = e_1 \prod_{s=1}^{t} \left(1 + \frac{\mathcal{M}}{s}\right) \approx \frac{e_1\, t^{\mathcal{M}}}{\Gamma(1 + \mathcal{M})},$$

because $\log \prod_s (1 + \mathcal{M}/s) \approx \mathcal{M} \sum_{s \le t} 1/s \approx \mathcal{M} \log t$.

The variance v_t of e_t obeys $v_{t+1} = (1 + \mathcal{M}/t)^2 v_t + \sigma_\eta^2/t^2$.

Its solution behaves like $\sigma_\eta^2/[(-2\mathcal{M} - 1)\, t]$ when $\mathcal{M} < -1/2$, like $\sigma_\eta^2 \log t/t$ when $\mathcal{M} = -1/2$, and like a multiple of $t^{2\mathcal{M}}$ when $\mathcal{M} > -1/2$.

The simulation below computes the mean error both ways and fits slopes on $100 \le t \le 3000$.

```
T, n_paths = 3000, 200
t = np.arange(1, T + 1)
fit = t >= 100

fig, axes = plt.subplots(1, 2, figsize=(12, 4.5))

↪00
```

The exact mean errors fall with slopes equal to $\mathcal{M}$: -0.8, -0.5, and -0.2.

For $\theta = 1$ and $\theta = 2$ the 200-path average lies on top of the exact mean.

For $\theta = 0.5$ it does so only for a few dozen periods.

After that the mean error is smaller than the Monte Carlo standard error, and the average is noise.

That is the first lesson: when $\mathcal{M} < -1/2$, the initial condition is forgotten (like $t^{-0.8}$) faster than sampling noise dies out (like $t^{-1/2}$).

So convergence is limited by the noise, and $\sqrt{t}$ times the standard deviation levels off at $\sigma_\eta / \sqrt{-2\mathcal{M} - 1} \approx 1.29$.

When $\mathcal{M} > -1/2$ the ranking reverses.

For $\theta = 2$ both the mean error and the standard deviation shrink only like $t^{-0.2}$, so $\sqrt{t}$ times the standard deviation keeps growing, and the mean error dominates.

After 3000 periods the average $\theta = 2$ learner is still about 1.7 points below Nash, several standard deviations away, and every one of the 200 paths is below Nash.

The $\theta = 2$ learner does not wander around its limit: it climbs slowly, and nearly monotonically, from below.

The default $\theta = 1$ is the boundary between the two cases.

There the mean error and the standard deviation both shrink like $t^{-1/2}$, up to the factor $\sqrt{\log t}$ that makes $\sqrt{t}$ times the standard deviation creep upward.

Exercise 99.8.2

Replace the decreasing gain $1/(t-1)$ in (99.5) by a constant gain $\varepsilon \in (0, 1)$, so that $x_{t+1} = x_t + \varepsilon(y_t - x_t)$.

This is the adaptive-expectations rule of *Adaptive Expectations and the Phelps Problem* with $\varepsilon = 1 - \lambda$, but here the

government keeps best-responding one period at a time.

1. Show that $e_t = x_t - y^N$ is a first-order autoregression with coefficient $1 + \varepsilon\mathcal{M}$. Show that, when it is stationary, its variance is

$$V(\varepsilon) = \frac{\varepsilon\sigma_\eta^2}{(1-h')(2-\varepsilon(1-h'))}, \qquad h' = \frac{\theta^2}{1+\theta^2}.$$

   This is the formula of Exercise **??** for Bray's market, with $h' = B'$. For which gains is the recursion stable?

2. With $\theta = 1$ and $\sigma_\eta = 1$, use the option `ε` of `ls_learning` to simulate 100,000 periods for $\varepsilon \in \{0.01, 0.025, 0.05, 0.1, 0.2\}$. Drop the first 5,000 periods, and compare the sample variance of e_t with $V(\varepsilon)$.

3. Plot 3000 periods of x_t under $\varepsilon = 0.025$ and under the least squares gain, using the same shocks. What does a constant gain buy, and what does it cost?

Solution

Because $B(x) - x = \mathcal{M}(x - y^N)$, the update gives $e_{t+1} = (1 + \varepsilon\mathcal{M})\, e_t + \varepsilon\eta_t$.

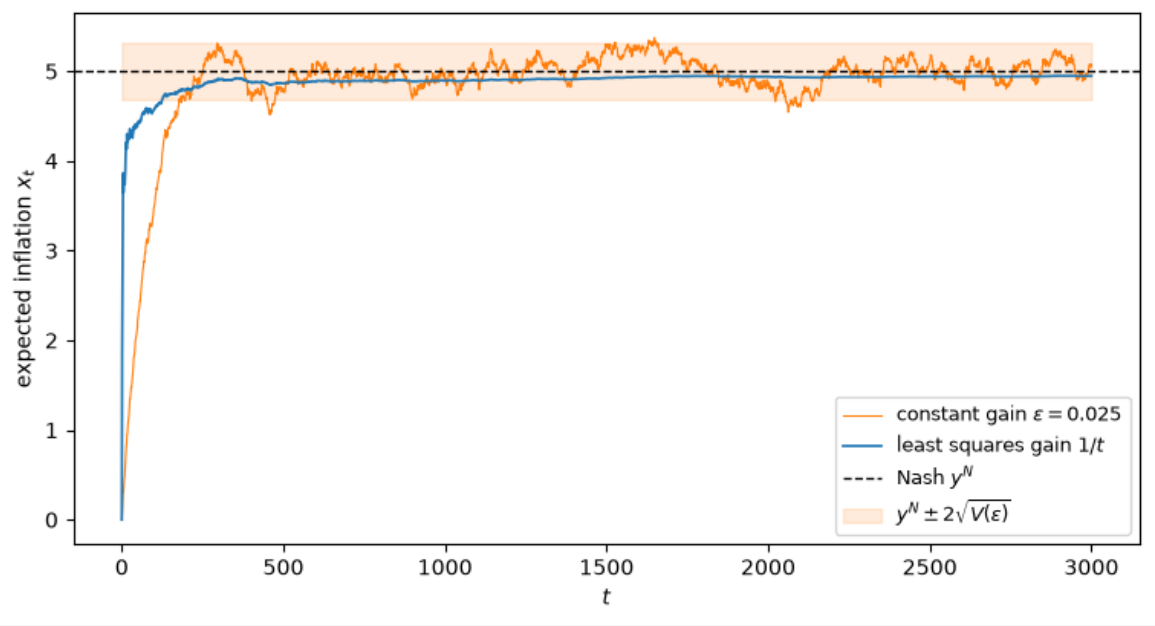
With $\rho = 1+\varepsilon\mathcal{M} = 1-\varepsilon(1-h')$, the autoregression is stable when $|\rho| < 1$, that is, when $\varepsilon < 2/(1-h') = 2(1+\theta^2)$, which every gain below one satisfies.

Its variance is $\varepsilon^2\sigma_\eta^2/(1-\rho^2)$, and $1 - \rho^2 = \varepsilon(1-h')(2-\varepsilon(1-h'))$ gives the formula.

For small gains $V(\varepsilon) \approx \varepsilon\sigma_\eta^2/(2|\mathcal{M}|)$, which equals ε when $\theta = \sigma_\eta = 1$.

```
cm_1 = CredibilityModel(θ=1.0, U_star=5.0)
h_prime = cm_1.θ**2 / (1 + cm_1.θ**2)

print("   ε      sample variance     V(ε)     variance / ε")
for ε in (0.01, 0.025, 0.05, 0.1, 0.2):
    x_ε, _ = ls_learning(cm_1, T=100_000, seed=3, ε=ε)
    e_ε = x_ε[5_000:] - cm_1.nash()
    V = ε / ((1 - h_prime) * (2 - ε * (1 - h_prime)))
    print(f"{ε:6.3f}    {e_ε.var():12.5f}    {V:10.5f}    {e_ε.var() / ε:9.3f}")
```



```
   ε      sample variance     V(ε)     variance / ε
 0.010         0.00968       0.01003        0.968
 0.025         0.02513       0.02516        1.005
 0.050         0.05054       0.05063        1.011
 0.100         0.10223       0.10256        1.022
 0.200         0.20959       0.21053        1.048
```

The sample variances match the formula, and the variance is nearly proportional to the gain.

The figure compares a constant gain with the least squares gain on the same shocks.

```
x_c, _ = ls_learning(cm_1, T=3000, seed=4, ε=0.025)
x_ls, _ = ls_learning(cm_1, T=3000, seed=4)
band = 2 * np.sqrt(0.025 / ((1 - h_prime) * (2 - 0.025 * (1 - h_prime))))

fig, ax = plt.subplots(figsize=(9, 4.5))
ax.plot(x_c, 'C1', lw=0.8, label=r'constant gain $\varepsilon = 0.025$')
ax.plot(x_ls, 'C0', lw=1.2, label='least squares gain $1/t$')
ax.axhline(cm_1.nash(), color='k', ls='--', lw=1, label='Nash $y^N$')
ax.fill_between(np.arange(3001), cm_1.nash() - band, cm_1.nash() + band,
                color='C1', alpha=0.15, label=r'$y^N \pm 2\sqrt{V(\varepsilon)}$')
ax.set_xlabel('$t$')
ax.set_ylabel('expected inflation $x_t$')
ax.legend(fontsize=9)
plt.show()
```

A constant gain buys a faster rate of forgetting.

The constant-gain learner forgets its initial condition geometrically, at rate $1 - \varepsilon(1 - h')$ per period.

The least squares learner moves faster at first, because its gain $1/t$ exceeds 0.025 for the first 40 periods.

But its mean error then shrinks only like $t^{-1/2}$, as Exercise 99.8.1 showed, and after a few hundred periods it is larger than the constant-gain learner's.

The cost is that the constant-gain learner never settles.

It converges only in distribution, to a cloud around y^N whose variance is proportional to the gain.

In this scalar model the cloud is all that happens, because the mean dynamics pull x straight back toward y^N and there is nowhere else to go.

In *Adaptive Learning and Escape Dynamics* the government's beliefs are a whole vector of Phillips-curve coefficients, learned with the same gain 0.025.

There the noise can push beliefs along a path that leads toward the Ramsey outcome, and the mean dynamics then pull them back toward Nash.

These are the recurrent escapes of Sargent [1999] and Cho *et al.* [2002].

Exercise 99.8.3

This exercise studies the *inflation bias* $y^N - y^R$ and two remedies discussed in *Remedies*.

Replace the government's payoff (99.1) by $-\frac{1}{2}\left[(U - kU^*)^2 + \alpha y^2\right]$, with $k \in [0, 1]$ and $\alpha > 0$.

The lecture's case is $k = 0$, $\alpha = 1$.

1. Show that the best response is $B(x) = [\theta(1 - k)U^* + \theta^2 x]/(\theta^2 + \alpha)$ and that Nash inflation is $y^N = \theta(1 - k)U^*/\alpha$. Check the formula by iterating the best response.
2. Alan Blinder's remedy is an authority who knows the natural rate and never wants unemployment to differ from it ($k = 1$). Rogoff [1985]'s remedy is a conservative central banker who weights inflation more heavily than

society does ($\alpha > 1$). What does each do to the inflation bias?

3. Now let the Phillips curve be $U = U^* - \theta(y - x) + \zeta$. Here ζ is an IID shock with mean zero and variance σ_ζ^2, which the policymaker sees before setting y but the public does not see when it forms x. Show that in the Nash equilibrium $x = \theta(1-k)U^*/\alpha$, $y = x + \theta\zeta/(\theta^2 + \alpha)$, and $U = U^* + \alpha\zeta/(\theta^2 + \alpha)$.
4. Society keeps the payoff (99.1). Set $\theta = 1$ and $U^* = 5$. For a Rogoff banker ($k = 0$) and $\sigma_\zeta \in \{1, 2.5, 5\}$, plot society's expected loss $\frac{1}{2}E(U^2 + y^2)$ against α and find the best α. Compare with Blinder's authority ($k = 1$, $\alpha = 1$).

Solution

1. The first-order condition is $\theta\left[(1-k)U^* - \theta(y - x)\right] = \alpha y$, which gives $B(x)$.

Setting $x = B(x)$ gives $\alpha y^N = \theta(1-k)U^*$.

Because the slope $\theta^2/(\theta^2 + \alpha)$ of B is less than one, best response dynamics converge to y^N, which lets us check the formula.

```
def B_general(x, θ, U_star, k, α):
    "Best response of a policymaker with payoff -[(U - k U*)^2 + α y^2]/2."
    return (θ * (1 - k) * U_star + θ**2 * x) / (θ**2 + α)

θ_b, U_b = 1.0, 5.0
for k, α in [(0, 1), (0, 2), (0, 5), (0.5, 1), (1, 1)]:
    y = 0.0
    for _ in range(2000):
        y = B_general(y, θ_b, U_b, k, α)
    print(f"k = {k:3}, α = {α}:  iterated best response {y:.4f},  "
          f"θ(1-k)U*/α = {θ_b * (1 - k) * U_b / α:.4f}")
```

```
k =   0, α = 1:  iterated best response 5.0000,  θ(1-k)U*/α = 5.0000
k =   0, α = 2:  iterated best response 2.5000,  θ(1-k)U*/α = 2.5000
k =   0, α = 5:  iterated best response 1.0000,  θ(1-k)U*/α = 1.0000
k = 0.5, α = 1:  iterated best response 2.5000,  θ(1-k)U*/α = 2.5000
k =   1, α = 1:  iterated best response 0.0000,  θ(1-k)U*/α = 0.0000
```

2. Both remedies leave unemployment at the natural rate, which is all any policymaker can achieve on average, so what they change is inflation.

Blinder's authority ($k = 1$) eliminates the bias altogether: it has no reason to push unemployment below U^*, and $y^N = 0$ is the Ramsey outcome.

Rogoff's banker shrinks the bias in proportion to $1/\alpha$, and eliminates it only as $\alpha \to \infty$.

3. With the shock, the first-order condition becomes $\theta\left[(1-k)U^* + \zeta - \theta(y - x)\right] = \alpha y$.

Taking expectations, and using $x = Ey$, gives $x = \theta(1-k)U^*/\alpha$; subtracting gives $y - x = \theta\zeta/(\theta^2 + \alpha)$.

Then $U = U^* + \zeta - \theta(y - x) = U^* + \alpha\zeta/(\theta^2 + \alpha)$.

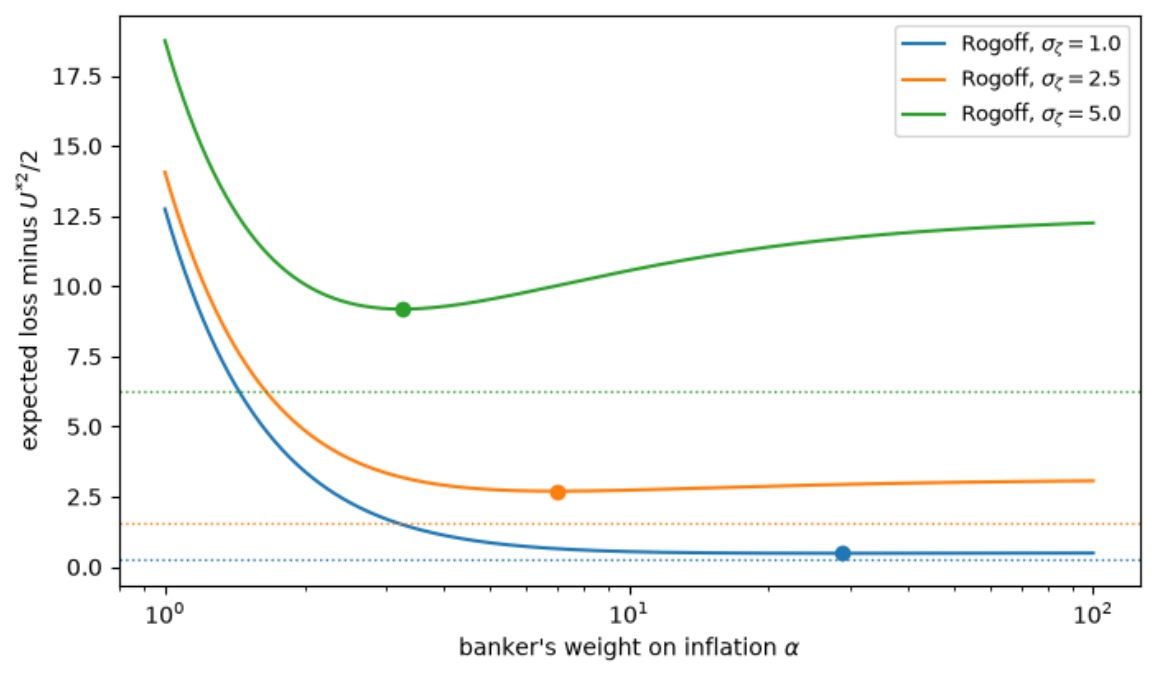
A more conservative banker offsets less of the shock, so a larger α makes unemployment *more* variable and inflation less variable.

4. Society's expected loss is

$$\frac{1}{2}\left[U^{*2} + \left(\frac{\theta(1-k)U^*}{\alpha}\right)^2 + \sigma_\zeta^2 \frac{\alpha^2 + \theta^2}{(\theta^2 + \alpha)^2}\right].$$

The middle term is the inflation bias and the last term is the cost of the shocks.

The bias term falls with α.



The shock term is smallest at $\alpha = 1$, where it equals $\sigma_\zeta^2/(1+\theta^2)$, and it rises toward σ_ζ^2 as $\alpha \to \infty$.

That is Rogoff's tradeoff.

```
def society_loss(α, k, σ_ζ, θ=θ_b, U_star=U_b):
    "Society's expected loss (1/2) E(U^2 + y^2) when an authority (k, α) sets y."
    bias = θ * (1 - k) * U_star / α
    return 0.5 * (U_star**2 + bias**2
                  + σ_ζ**2 * (α**2 + θ**2) / (θ**2 + α)**2)

α_grid = np.geomspace(1, 100, 4001)
fig, ax = plt.subplots(figsize=(8, 4.5))
for j, σ_ζ in enumerate([1.0, 2.5, 5.0]):
    loss = society_loss(α_grid, 0, σ_ζ) - 0.5 * U_b**2
    i = loss.argmin()
    blinder = society_loss(1.0, 1, σ_ζ) - 0.5 * U_b**2
    ax.plot(α_grid, loss, color=f'C{j}', label=rf'Rogoff, $\sigma_\zeta = {σ_ζ}$')
    ax.plot(α_grid[i], loss[i], 'o', color=f'C{j}')
    ax.axhline(blinder, color=f'C{j}', ls=':', lw=1)
    print(f"σ_ζ = {σ_ζ}:  best α = {α_grid[i]:.2f},  excess loss there {loss[i]:.
↪3f};"
          f"  at α = 1 {loss[0]:.3f};  Blinder {blinder:.3f}")
ax.set_xscale('log')
ax.set_xlabel(r"banker's weight on inflation $\alpha$")
ax.set_ylabel(r'expected loss minus $U^{*2}/2$')
ax.legend(fontsize=9)
plt.show()
```

```
σ_ζ = 1.0:  best α = 28.71,  excess loss there 0.483;  at α = 1 12.750; ␣
↪Blinder 0.250
σ_ζ = 2.5:  best α = 6.97,  excess loss there 2.697;  at α = 1 14.062;  Blinder␣
↪1.562
σ_ζ = 5.0:  best α = 3.24,  excess loss there 9.185;  at α = 1 18.750;  Blinder␣
↪6.250
```

The dotted lines are Blinder's authority.

For each σ_ζ the best Rogoff banker is more conservative than society ($\alpha > 1$) but not infinitely so, and the noisier the economy, the less conservative the best banker.

Blinder's authority beats every Rogoff banker.

It removes the bias without distorting stabilization: its loss, $\frac{1}{2}\left[U^{*2} + \sigma_\zeta^2/(1+\theta^2)\right]$, is what society would get by committing to the best state-contingent rule $y = \theta\zeta/(1+\theta^2)$.

The reason is that $-\frac{1}{2}(U - U^*)^2$ differs from $-\frac{1}{2}U^2$ by a term that is linear in U, and that linear term is the whole source of the temptation to inflate.

100.1 Overview

The Credibility Problem left the government in a trap.

Without a technology for committing itself, a government that re-optimizes every period ends at the Nash outcome, inflating at rate θU^* and getting nothing for it.

That was a one-period story, and it invited an obvious objection: a government that expects to face the same public again tomorrow has a *reputation* to protect.

This lecture, following chapter 4 of Sargent [1999], takes the objection seriously.

We repeat the Kydland–Prescott economy forever, let the government's current action depend on the whole history of outcomes, and ask which outcome paths can be supported as **subgame perfect equilibria**.

The answer is not the one the objection anticipated.

Reputation does not single out the Ramsey outcome, and it does not confirm the Nash outcome either.

It delivers a *continuum* of equilibrium values, some better than Nash and some considerably worse, with no principle inside the model to select among them.

That is the conclusion this lecture exists to establish, and Sargent states it in one sentence:

> My conclusion is that the multiplicity of credible plans replaces pessimism with agnosticism.

It matters for the argument of the whole suite.

The Rise and Fall of U.S. Inflation rests part of its case against the *triumph of natural-rate theory* on exactly this weakness: a theory with so many equilibria makes few predictions, so a story that depends on policy makers having learned the right one is doing work the theory cannot do for it.

100.1.1 What we build

The machinery is the recursive method of Abreu, Pearce, and Stacchetti [Abreu *et al.*, 1990], which computes not an optimal *value* but the whole *set* of equilibrium values.

Ordinary dynamic programming iterates an operator that maps continuation *values* into values.

APS iterate an operator that maps *sets* of continuation values into sets of values, and the set of subgame perfect equilibrium values is its largest fixed point.

Note

Making a promised value into a state variable, and then doing dynamic programming in that state, is the technique sometimes called **dynamic programming squared**.

It is the organizing idea of the QuantEcon lecture on Stackelberg plans and of the recursive treatments of Ramsey problems in Ljungqvist and Sargent [2018].

This lecture is a compact instance: the state is a promised value, and the object we compute is a set.

A *scalar* promised value suffices here because the private sector's problem is static: the public's forecast x_t concerns only this period's inflation, so it is pinned down by the government's current prescription.

In the monetary model of Chang [1998], households' money demand looks forward, so the government must also promise them a continuation marginal value of money, and the state becomes a pair; Competitive Equilibria of a Model of Chang and Credible Government Policies in a Model of Chang compute the resulting two-dimensional sets with the same set-iteration idea.

Sustainable Plans for a Calvo Model builds Abreu's stick-and-carrot plans, which appear below, in a linear-quadratic version of Calvo's model.

We then use the machinery three ways.

We construct particular equilibria by guess-and-verify — infinite repetition of Nash, infinite repetition of something better, and Abreu's stick-and-carrot, which can be *worse* than Nash.

We compute the best and worst equilibrium values from two small programming problems, and check them against a direct iteration of the APS operator.

And we exhibit three quite different equilibria that all attain the same worst value, which is the sharpest illustration of how little the equilibrium concept pins down.

Note

Sargent's own advice to the reader is worth passing on: this chapter is difficult if you have not seen the theory before, and a reader willing to accept its verdict — that the theory of credible policy yields agnosticism rather than a prediction — can go straight to *Adaptive Expectations and the Phelps Problem* without losing the thread of the argument.

Let's start with our imports:

```
import matplotlib.pyplot as plt
import numpy as np
import pandas as pd
from typing import NamedTuple
```

100.2 The repeated economy

The one-period economy is the one from *The Credibility Problem*.

Let (U, y, x) be unemployment, inflation, and the public's expectation of inflation.

Unemployment obeys the expectations-augmented Phillips curve $U = U^* - \theta(y - x)$, and the government's one-period payoff, written as a function of (x, y), is

$$r(x, y) = -\frac{1}{2}\left[\left(U^* - \theta(y - x)\right)^2 + y^2\right]. \tag{100.1}$$

The government's one-period best response to an expectation x is

$$B(x) = \frac{\theta\,(U^* + \theta x)}{\theta^2 + 1}, \tag{100.2}$$

the Nash outcome is $y^N = \theta U^*$, and the Ramsey outcome is $y^R = 0$.

Two things are new.

First, the economy repeats for $t = 1, 2, \ldots$, and the government ranks outcome paths $(x, y) = \{x_t, y_t\}_{t=1}^{\infty}$ by

$$V^g(x, y) = (1 - \delta)\sum_{t=1}^{\infty} \delta^{t-1} r(x_t, y_t), \qquad \delta \in (0, 1). \tag{100.3}$$

The factor $(1 - \delta)$ puts V^g in the same units as a one-period payoff, so values and one-period returns can be compared directly.

Second, inflation is confined to a bounded interval $Y = [0, y^{\#}]$.

The lower bound is the Ramsey outcome; the upper bound $y^{\#}$ is what makes the government's problem non-trivial, as we shall see when we look for the *worst* equilibrium.

We use the parameter values of the numerical example in chapter 4 of Sargent [1999]: $\theta = 1.25$, $U^* = 5.5$, $y^{\#} = 10$, and $\delta = 0.95$.

They differ from the $\theta = 1$, $U^* = 5$ of *The Credibility Problem*, so that our numbers can be checked against the book's.

```
class Model(NamedTuple):
    θ: float = 1.25          # slope of the Phillips curve
    U_star: float = 5.5      # natural rate of unemployment
    y_max: float = 10.0      # y^#, the highest admissible inflation rate
    δ: float = 0.95          # discount factor

def r(m, x, y):
    "One-period government payoff when the public expects x and inflation is y."
    U = m.U_star - m.θ * (y - x)
    return -0.5 * (U**2 + y**2)
```

(continues on next page)

(continued from previous page)

```
def B(m, x):
    "The government's one-period best response to expected inflation x."
    return m.θ * (m.U_star + m.θ * x) / (m.θ**2 + 1)

def y_nash(m):
    return m.θ * m.U_star
```

Two payoff schedules do all the work below, both read as functions of a single inflation rate y that the public has come to expect.

The first is the **rational-expectations payoff** $r(y, y)$: what the government gets if it delivers the inflation the public expects.

The second is the **deviation payoff** $r(y, B(y))$: what it gets if the public expects y but the government yields to temptation and best-responds.

Both have closed forms worth recording, because they explain everything that follows:

$$r(y, y) = -\frac{1}{2}\left(U^{*2} + y^2\right), \qquad r(y, B(y)) = -\frac{\left(U^* + \theta y\right)^2}{2\left(1 + \theta^2\right)}. \tag{100.4}$$

```
def r_keep(m, y):
    "Payoff from delivering the expected inflation rate: r(y, y)."
    return -0.5 * (m.U_star**2 + y**2)

def r_cheat(m, y):
    "Payoff from best-responding to an expectation of y: r(y, B(y))."
    return -(m.U_star + m.θ * y)**2 / (2 * (1 + m.θ**2))

m = Model()
ys = np.linspace(0, m.y_max, 7)
print("closed forms agree with the definitions:",
      np.allclose(r_keep(m, ys), r(m, ys, ys)),
      np.allclose(r_cheat(m, ys), r(m, ys, B(m, ys))))
```

```
closed forms agree with the definitions: True True
```

The gap between them is a perfect square,

$$r(y, B(y)) - r(y, y) = \frac{\left(y - y^N\right)^2}{2\left(1 + \theta^2\right)} \;\geq\; 0. \tag{100.5}$$

So the deviation schedule lies above the other everywhere except at the Nash rate, where the two curves are *tangent*: there the temptation to deviate vanishes because $B(y^N) = y^N$.

```
grid = np.linspace(0, m.y_max, 400)
yN = y_nash(m)
v_R, v_N = r_keep(m, 0.0), r_keep(m, yN)
v_cand = r_cheat(m, m.y_max)                    # candidate worst value

fig, ax = plt.subplots(figsize=(7.5, 5.5))
ax.plot(grid, r_keep(m, grid), 'C0', lw=1.6, label='$r(y, y)$: deliver what is␣
↪expected')
```

(continues on next page)

(continued from previous page)

```
ax.plot(grid, r_cheat(m, grid), 'C1', lw=1.6, label='$r(y, B(y))$: deviate')
ax.plot(0.0, v_R, 'ko', ms=6)
ax.annotate('$v^R$', (0.0, v_R), textcoords='offset points', xytext=(8, 4))
ax.plot(yN, v_N, 'ko', ms=6)
ax.annotate('$v^N$', (yN, v_N), textcoords='offset points', xytext=(8, 4))
ax.plot(m.y_max, v_cand, 'ko', ms=6)
ax.annotate(r'$r(y^\#, B(y^\#))$', (m.y_max, v_cand), textcoords='offset points',
            xytext=(-70, 6))
ax.axvline(yN, color='k', lw=0.6, ls=':')
ax.set_xlabel('inflation rate $y$ expected by the public')
ax.set_ylabel('one-period payoff')
ax.legend(loc='lower left')
plt.show()
```

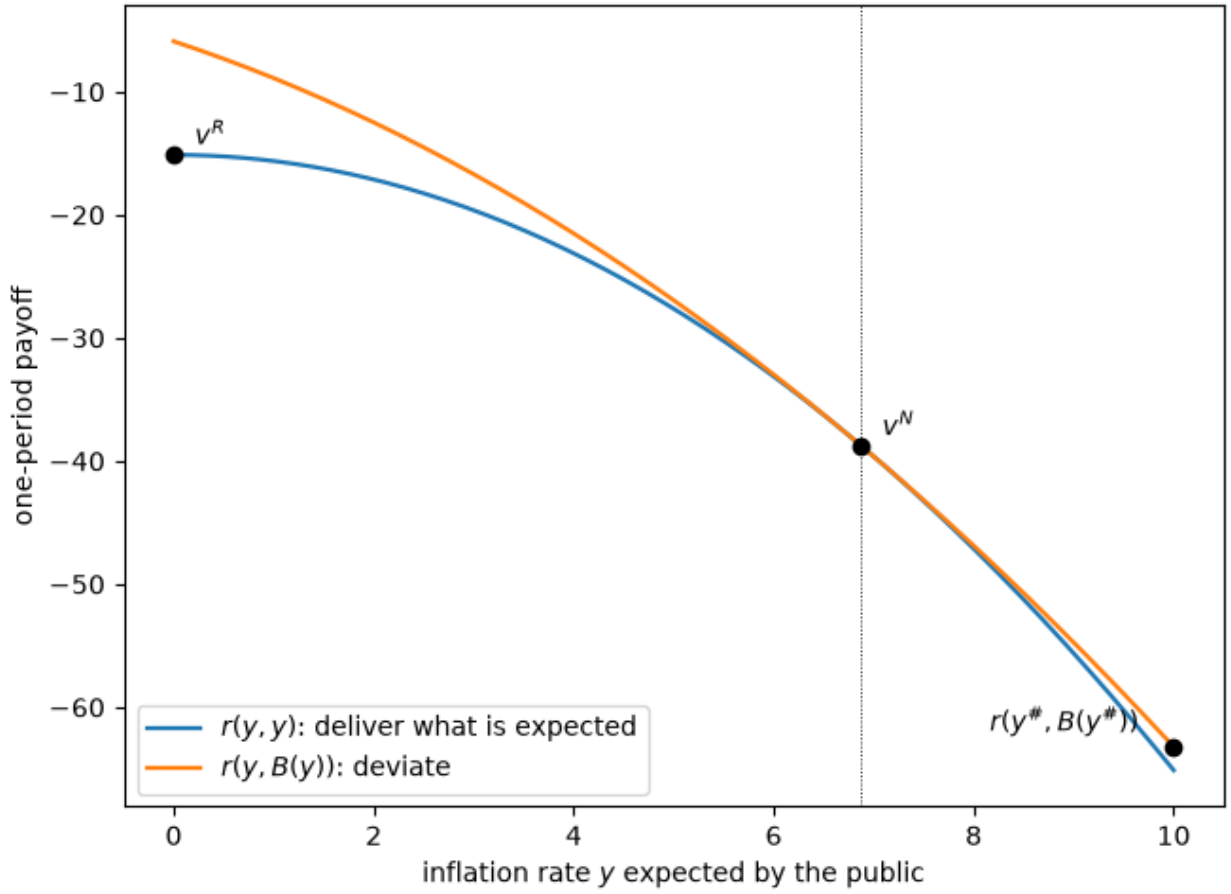

Fig. 100.1: The two payoff schedules: delivering expected inflation against deviating from it

The vertical gap between the curves is the government's one-period gain from deviating.

Below y^N, which includes the Ramsey outcome, $B(y) > y$, so the temptation is to inflate *more* than expected.

Above y^N, $B(y) < y$, and the temptation is to inflate *less* than expected.

By (100.5) the gap is symmetric about y^N, so the gap alone does not favor the top of Y.

What will put the *worst* equilibrium at the top of Y is the level of the deviation schedule.

$r(y, B(y))$ falls monotonically in y, so the least a government can secure for itself by deviating is smallest when the public expects $y^{\#}$.

The point $r(y^{\#}, B(y^{\#}))$ marked in the figure is our first candidate for the worst equilibrium value.

100.3 Recursive strategies and promised values

A government strategy must be able to condition today's action on the entire past.

Carrying whole histories around is unmanageable, so we follow Sargent [1999] in restricting attention to strategies with a recursive representation — a restriction that costs nothing, since it excludes no equilibrium *values*.

Definition 100.3.1 (Recursive government strategy)

A recursive government strategy is a pair of functions $\sigma = (\sigma_1, \sigma_2)$ together with an initial condition v_1, with the structure

$$v_1 \in \mathbb{R} \text{ given}, \qquad y_t = \sigma_1(v_t), \qquad v_{t+1} = \sigma_2(v_t, x_t, y_t),$$

where v_t is a state variable that summarizes the history of outcomes before t.

Each member of the private sector knows v_t and knows σ, and so forecasts

$$x_t = \sigma_1(v_t). \tag{100.6}$$

Equation (100.6) builds rational expectations into the private sector: the public is never surprised along the equilibrium path.

A strategy (σ, v_1) generates an entire outcome path, and hence a value $V^g(\sigma, v_1)$ through (100.3).

The theory of credible policy now does something that at first looks like a trick.

It ties the past to the future by requiring the state variable to *be* the value it generates,

$$v = V^g(\sigma, v). \tag{100.7}$$

So v works two shifts at once.

In $v_{t+1} = \sigma_2(v_t, x_t, y_t)$ it is a bookkeeping device that records what has happened.

In (100.7) it is a **promised value** — the discounted future the government is owed on entering the period.

Reading it the second way is what makes the machinery go: the strategy hands the government current and future outcomes that make it *want* to do what is expected of it.

Note

Two readings of σ are available and, within an equilibrium, impossible to tell apart.

It can be a decision rule that the government chooses, or a description of a system of public expectations to which the government conforms.

We return to this ambiguity in the interpretation section, because it is where the theory's agnosticism comes from.

100.3.1 Historical antecedents

Formalizing credibility was an achievement of the 1980s, but a sophisticated grasp of the idea is much older.

In 1784 the finance minister Jacques Necker explained to Louis XVI why an absolute monarch, free to renege on debt payments, found it hard to borrow [Sargent and Velde, 1995]:

> Therefore one can rekindle or sustain public trust only by giving reassurances on the sovereign's intentions, and by proving that no motive can incite him to fail his obligations.

Every clause of that sentence is in the modern definition.

A king proves he will never fail his obligations by never *wanting* to fail them — by conforming to a system of expectations that carries its own incentive constraints, so that at every date and in every contingency his current payoff plus continuation value is higher if he confirms expectations than if he disappoints them.

Definition 100.3.2 (Subgame perfect equilibrium)

A recursive strategy with promised value v is a **subgame perfect equilibrium** (SPE) if and only if

(a) $\sigma_2(v, \sigma_1(v), \eta)$ is itself a value attainable by a subgame perfect equilibrium, for every $\eta \in Y$; and

(b) writing $y = \sigma_1(v)$,

$$v = (1-\delta)\, r(y,y) + \delta\, \sigma_2(v,y,y) \;\geq\; (1-\delta)\, r(y,\eta) + \delta\, \sigma_2(v,y,\eta), \qquad \forall\, \eta \in Y.$$

The definition attaches four objects to an equilibrium: a promised value v; a first-period outcome (y, y); a continuation value v' if the prescribed outcome is observed; and another continuation value $\tilde{v}$ if it is not.

In those terms condition (b) reads

$$v = (1-\delta) r(y,y) + \delta v' \;\geq\; (1-\delta) r(y,\eta) + \delta \tilde{v}, \qquad \forall \eta \in Y,$$

which simply says the government does better adhering than departing.

Condition (a) says the continuation values must themselves be equilibrium values.

The definition is circular — equilibrium values appear on both sides — and that circularity is exactly what recursivity buys, and what APS learned to exploit.

100.4 The Abreu–Pearce–Stacchetti method

Dynamic programming computes an optimal value function by iterating the Bellman equation, a map that turns tomorrow's value function into today's.

APS adapted the idea to equilibrium *sets*.

Start with a candidate set $W \subset \mathbb{R}$ of continuation values.

Pick a first-period rational-expectations outcome (y, y) and two continuation values from W: a w_1 to reward adherence and a w_2 to punish deviation.

If w_1 is high enough and w_2 low enough, the pair supports y, and delivers the value

$$w = (1-\delta) r(y,y) + \delta w_1 \;\geq\; (1-\delta) r(y,\eta) + \delta w_2, \qquad \forall \eta \in Y.$$

Definition 100.4.1 (Admissibility)

A pair (y, w) is **admissible** with respect to a set of continuation values W if there exist $w_1, w_2 \in W$ with $w = (1-\delta)r(y,y) + \delta w_1 \geq (1-\delta)r(y,\eta) + \delta w_2$ for all $\eta \in Y$.

Let $\mathcal{T}(W)$ collect the w components of all admissible pairs.

APS and Sargent [1999] call this operator B; we write $\mathcal{T}$ to keep B for the government's best response.

This construction builds in condition (b) of *Definition 100.3.2* but ignores condition (a), because the continuation values were drawn from an arbitrary set.

Definition 100.4.2 (Self-generation)

A set W of prospective continuation values is **self-generating** if $W \subseteq \mathcal{T}(W)$.

Every value in a self-generating set is supported by continuation values drawn from that same set — which is condition (a).

APS proved four things:

1. the set V of SPE values is the largest self-generating set;
2. $\mathcal{T}$ maps compact sets into compact sets;
3. $\mathcal{T}$ is monotone: $W_2 \subseteq W_1$ implies $\mathcal{T}(W_2) \subseteq \mathcal{T}(W_1)$;
4. starting from any compact W_0 with $V \subseteq \mathcal{T}(W_0) \subseteq W_0$, the iteration $W_j = \mathcal{T}(W_{j-1})$ converges monotonically to $V = \mathcal{T}(V)$ (Abreu *et al.* [1990], Theorem 5).

The requirement $V \subseteq \mathcal{T}(W_0)$ in the last item cannot be dropped, although the book's statement of the theorem omits it.

The single point $W_0 = \{v^N\}$ satisfies $\mathcal{T}(W_0) \subseteq W_0$, yet it is a fixed point of $\mathcal{T}$ far smaller than V (exercise Exercise 100.10.6).

A safe choice is the set of all feasible values, $W_0 = [r(y^\#, y^\#),\ 0]$.

It contains V, and $\mathcal{T}$ maps it into itself, so monotonicity gives $V = \mathcal{T}(V) \subseteq \mathcal{T}(W_0) \subseteq W_0$.

100.4.1 Computing the operator

Two simplifications make $\mathcal{T}$ easy to evaluate here.

Because the government's temptation is worst when it best-responds, the constraint in *Definition 100.4.1* binds hardest at $\eta = B(y)$, so we may replace "for all η" by that single deviation.

And because a lower punishment relaxes the constraint, we may always set w_2 to the smallest element of W.

Writing $W = [\underline{w}, \overline{w}]$, the outcome y is then admissible provided some $w_1 \in W$ satisfies

$$w_1 \;\geq\; \frac{(1-\delta)\,[r(y, B(y)) - r(y,y)]}{\delta} + \underline{w} \;\equiv\; \ell(y), \tag{100.8}$$

and the values it generates sweep out the interval

$$\left[(1-\delta)r(y,y) + \delta \max(\underline{w}, \ell(y)),\ (1-\delta)r(y,y) + \delta\overline{w}\right].$$

```
def T_operator(m, W, n_grid=4001):
    """
    One application of the APS operator 𝒯 to an interval W = [w_lo, w_hi].

    Returns the new interval, or None if no first-period outcome is admissible.
    """
    w_lo, w_hi = W
    y = np.linspace(0.0, m.y_max, n_grid)
    ℓ = (1 - m.δ) * (r_cheat(m, y) - r_keep(m, y)) / m.δ + w_lo    # the bound ℓ(y) of␣
↪cp_bound
    ok = ℓ <= w_hi                                                  # admissible␣
↪outcomes
    if not ok.any():
        return None
    keep = (1 - m.δ) * r_keep(m, y)
    lows = keep[ok] + m.δ * np.maximum(w_lo, ℓ[ok])
    highs = keep[ok] + m.δ * w_hi
    return lows.min(), highs.max()

def solve_aps(m, W0=None, tol=1e-12, max_iter=10_000):
    """
    Iterate the APS operator from W0 until it settles.

    The default W0 is the set of all feasible values, [r(y^#, y^#), 0].
    """
    W = (r_keep(m, m.y_max), 0.0) if W0 is None else W0
    for it in range(max_iter):
        W_new = T_operator(m, W)
        if W_new is None:
            return None, it
        if max(abs(W_new[0] - W[0]), abs(W_new[1] - W[1])) < tol:
            return W_new, it
        W = W_new
    return W, max_iter
```

We start from $W_0 = [r(y^\#, y^\#),\, 0]$ and iterate.

```
W, iters = solve_aps(m)
print(f"converged in {iters} iterations")
print(f"set of SPE values V = [{W[0]:.4f}, {W[1]:.4f}]")
```

```
converged in 534 iterations
set of SPE values V = [-63.2195, -15.1250]
```

100.5 The best and the worst equilibrium

APS's iteration is general but tells us little about *why* the set ends where it does.

For this economy both endpoints can be found by hand, and the arguments are instructive.

100.5.1 The worst

The worst equilibrium value solves

$$\underline{v} = \min_{y \in Y,\, v_1 \in V} [(1-\delta) r(y,y) + \delta v_1] \quad \text{subject to} \quad (1-\delta) r(y,y) + \delta v_1 \geq (1-\delta) r(y, B(y)) + \delta \underline{v},$$

where the *worst* value is used as the continuation in the event of a deviation — the harshest punishment available.

For a given y, the objective is smallest when v_1 is as low as the constraint allows, so at the minimum the constraint binds, and the two sides collapse to $\underline{v} = r(y, B(y))$ for the minimizing y.

If every $y \in Y$ could be used, finding the worst equilibrium would reduce to a one-dimensional problem:

$$\underline{v} = \min_{y \in Y} r(y, B(y)) = -\frac{\left(U^* + \theta y^\#\right)^2}{2\left(1+\theta^2\right)}, \tag{100.9}$$

where the closed form follows from (100.4), and the minimizing action is $y^\#$ because the deviation payoff falls monotonically in y.

But (100.9) is only a *candidate*.

To deliver it with a first period at $y^\#$, the strategy must reward adherence with the continuation value v_1 that solves $\underline{v} = (1-\delta) r(y^\#, y^\#) + \delta v_1$,

$$v_1 = \frac{r(y^\#, B(y^\#)) - (1-\delta)\, r(y^\#, y^\#)}{\delta}, \tag{100.10}$$

and that reward must itself be an equilibrium value: $v_1 \leq \overline{v}$.

That check is the last step of the book's construction: compute the candidate, compute the best value $\overline{v}$ that it implies (below), and verify $v_1 \leq \overline{v}$.

The check can fail.

The reward (100.10) grows like $1/\delta$: an impatient government cannot be promised enough future reward to accept a period at $y^\#$.

The worst equilibrium then starts at a lower inflation rate, the two programming problems must be solved jointly, and we let the APS iteration do that.

Now the role of the upper bound $y^\#$ is clear.

The coefficient on $y^{\#2}$ in (100.10) is $\left[(1-\delta) - \theta^2/(1+\theta^2)\right]/(2\delta)$.

So when $\delta > 1/(1+\theta^2)$, the reward needed falls without limit as $y^\#$ rises, the check keeps passing, and $y^\#$ is what keeps the worst punishment finite.

For a less patient government the check eventually fails, and beyond some point raising $y^\#$ changes nothing.

Proposition 100.5.1 (The worst SPE is self-enforcing)

At the worst equilibrium the continuation value following a deviation equals the initial promised value, so a deviation simply restarts the equilibrium.

100.5.2 The best

Given $\underline{v}$ as the threat, the best value solves

$$\overline{v} = \max_{y \in Y} r(y,y) \quad \text{subject to} \quad r(y,y) \geq (1-\delta) r(y, B(y)) + \delta \underline{v}, \tag{100.11}$$

where we have used the fact that the best value must reward adherence with itself, so that $\overline{v} = (1-\delta) r(y,y) + \delta \overline{v} = r(y,y)$.

Proposition 100.5.2 (The best SPE is self-rewarding)

At the best equilibrium the continuation value following adherence equals the promised value.

The code below implements both programming problems, with the check.

```
def next_value(m, v):
    "Solve v = (1-δ) r(y^#, y^#) + δ v' for the continuation value v'."
    return (v - (1 - m.δ) * r_keep(m, m.y_max)) / m.δ

def best_value(m, v_lo, n_grid=200_001):
    "The best SPE value, given the worst value as the punishment threat."
    y = np.linspace(0.0, m.y_max, n_grid)
    feasible = r_keep(m, y) >= (1 - m.δ) * r_cheat(m, y) + m.δ * v_lo
    if not feasible.any():
        return None, None
    vals = np.where(feasible, r_keep(m, y), -np.inf)
    k = vals.argmax()
    return vals[k], y[k]

def worst_value(m):
    """
    The worst SPE value and the action that attains it.

    The candidate r(y^#, B(y^#)) of cp_worst is accepted if the reward v_1 of
    cp_reward is no larger than the best value the candidate implies.
    Otherwise the worst value comes from the APS iteration, and it is attained
    at the highest action whose required reward ℓ(y) of cp_bound equals the
    best value (solved for y using cp_gap).
    """
    v_cand = r_cheat(m, m.y_max)
    v_best, _ = best_value(m, v_cand)
    if next_value(m, v_cand) <= v_best:
        return v_cand, m.y_max
    (w_lo, w_hi), _ = solve_aps(m)
    y_hat = y_nash(m) + np.sqrt(2 * (1 + m.θ**2) * m.δ * (w_hi - w_lo) / (1 - m.δ))
    return w_lo, y_hat

v_lo, y_sharp = worst_value(m)
v_hi, y_best = best_value(m, v_lo)

print(f"worst value  v_lo = {v_lo:.4f}   attained with y = {y_sharp:.2f}")
print(f"reward required by the candidate  v_1 = {next_value(m, v_lo):.4f}"
      f"  <= v_hi? {next_value(m, v_lo) <= v_hi}")
```

(continues on next page)

(continued from previous page)

```
print(f"best  value  v_hi = {v_hi:.4f}   attained with y = {y_best:.2f}")
print(f"APS iteration gave [{W[0]:.4f}, {W[1]:.4f}]")
print(f"the two agree: {np.allclose(W, (v_lo, v_hi), atol=1e-6)}")
```

```
worst value  v_lo = -63.2195   attained with y = 10.00
reward required by the candidate  v_1 = -63.1192  <= v_hi? True
best  value  v_hi = -15.1250   attained with y = 0.00
APS iteration gave [-63.2195, -15.1250]
the two agree: True
```

The programming problems and the set iteration agree, and at this discount factor the best equilibrium is Ramsey itself.

The check passes easily at $\delta = 0.95$, but not for every discount factor.

```
print("    δ    candidate   reward v_1   best given candidate   check   worst value␣
↪at y")
for δ in (0.02, 0.04, 0.05, 0.2, 0.95):
    md = m._replace(δ=δ)
    v_cand = r_cheat(md, md.y_max)
    v_1, v_best = next_value(md, v_cand), best_value(md, v_cand)[0]
    v_worst, y_worst = worst_value(md)
    print(f"{δ:6.2f} {v_cand:11.4f} {v_1:12.4f} {v_best:16.4f} {str(v_1 <= v_best):>
↪11}"
          f" {v_worst:12.4f} {y_worst:6.2f}")
```

```
     δ    candidate   reward v_1   best given candidate   check   worst value  at y
  0.02    -63.2195      30.1494         -27.3125       False     -49.0384   8.28
  0.04    -63.2195     -17.4878         -22.8882       False     -60.5483   9.69
  0.05    -63.2195     -27.0152         -21.2924        True     -63.2195  10.00
  0.20    -63.2195     -55.5976         -15.1250        True     -63.2195  10.00
  0.95    -63.2195     -63.1192         -15.1250        True     -63.2195  10.00
```

For the two smallest discount factors the reward the candidate needs exceeds the best equilibrium value.

The worst equilibrium then starts below $y^{\#}$, and its value lies above $r(y^{\#}, B(y^{\#}))$; exercise Exercise 100.10.2 finds the discount factor at which this begins.

The next cell varies the upper bound $y^{\#}$ for a patient and an impatient government.

```
print(f"1/(1 + θ²) = {1 / (1 + m.θ**2):.3f}")
for δ in (0.2, 0.95):
    for y_max in (10.0, 30.0, 100.0):
        v_worst, y_worst = worst_value(m._replace(δ=δ, y_max=y_max))
        print(f"δ = {δ:4.2f}, y^# = {y_max:5.1f}:  worst value {v_worst:10.2f}"
              f"  attained with y = {y_worst:6.2f}")
```

```
1/(1 + θ²) = 0.390
δ = 0.20, y^# =  10.0:  worst value     -63.22  attained with y =  10.00
δ = 0.20, y^# =  30.0:  worst value    -249.29  attained with y =  24.20
δ = 0.20, y^# = 100.0:  worst value    -248.94  attained with y =  24.18
δ = 0.95, y^# =  10.0:  worst value     -63.22  attained with y =  10.00
δ = 0.95, y^# =  30.0:  worst value    -360.78  attained with y =  30.00
δ = 0.95, y^# = 100.0:  worst value   -3322.98  attained with y = 100.00
```

For the patient government the worst value keeps falling as $y^{\#}$ rises, and it is always attained at $y^{\#}$.

For the impatient government it stops falling: once $y^{\#}$ is large enough, the worst equilibrium starts at the same inflation rate below $y^{\#}$, whatever the bound (the small differences in the output come from the grid in `T_operator`).

Without a bound on inflation, almost anything could be supported, but only for a patient government.

100.6 Examples of recursive equilibria

We now construct particular equilibria by guess-and-verify, in the order in which the literature found them.

100.6.1 Infinite repetition of Nash

The easiest equilibrium repeats the one-period Nash outcome forever.

Take $v_1 = v^N = r(y^N, y^N)$, $\sigma_1(v) = y^N$ for every v, and $\sigma_2(v, x, y) = v^N$ for every (v, x, y).

Condition (a) holds by construction, and condition (b) collapses to $r(y^N, y^N) \geq r(y^N, B(y^N))$, which holds *with equality* because y^N is a fixed point of the best response map.

Nothing deters the government here, and nothing needs to: it is already doing what it most wants to do.

This is the Markov perfect equilibrium of the repeated game.

The economy has no payoff-relevant state variable, so a Markov strategy cannot condition on anything, and the government simply plays its one-period best response every period (*Markov Perfect Equilibrium* studies Markov perfect equilibria of dynamic games that do have states).

100.6.2 Infinite repetition of something better

Let $v^b = r(y^b, y^b) > v^N$ be a better-than-Nash value, and suppose

$$r(y^b, B(y^b)) - r(y^b, y^b) \;\leq\; \frac{\delta}{1-\delta}\,(v^b - v^N)\,. \tag{100.12}$$

The left side is the one-period gain from cheating; the right side is the discounted loss from reverting to Nash forever.

When (100.12) holds, the strategy that prescribes y^b while the promised value is v^b and reverts to Nash after any deviation is an SPE.

Barro and Gordon [1983] and Stokey [1989] studied the case $y^b = y^R$: anticipated reversion to Nash supports Ramsey forever.

Whether it does depends on patience, and for this economy the threshold has a remarkably clean form.

Setting $y^b = 0$ in (100.12) and using the closed forms (100.4), every U^* and every scale factor cancels, leaving

$$\delta \;\geq\; \delta^\star = \frac{1}{2+\theta^2}. \tag{100.13}$$

```
def supports_ramsey_by_nash(m):
    "Does reversion to Nash sustain Ramsey forever?"
    gain = r_cheat(m, 0.0) - r_keep(m, 0.0)
    loss = m.δ / (1 - m.δ) * (r_keep(m, 0.0) - r_keep(m, y_nash(m)))
    return gain <= loss

δ_star = 1 / (2 + m.θ**2)
print(f"closed-form cutoff  δ* = 1/(2 + θ²) = {δ_star:.6f}\n")
for δ in (0.20, 0.27, δ_star - 1e-6, δ_star + 1e-6, 0.50, 0.95):
    md = m._replace(δ=δ)
    print(f"  δ = {δ:.8f}: Nash reversion supports Ramsey? "
          f"{supports_ramsey_by_nash(md)}")
```

```
closed-form cutoff  δ* = 1/(2 + θ²) = 0.280702

  δ = 0.20000000: Nash reversion supports Ramsey? False
  δ = 0.27000000: Nash reversion supports Ramsey? False
  δ = 0.28070075: Nash reversion supports Ramsey? False
  δ = 0.28070275: Nash reversion supports Ramsey? True
  δ = 0.50000000: Nash reversion supports Ramsey? True
  δ = 0.95000000: Nash reversion supports Ramsey? True
```

Above $\delta^\star \approx 0.28$ the threat of reverting to Nash is enough to hold the government at zero inflation; below it, the threat is too weak.

100.6.3 Something worse: Abreu's stick and carrot

When reversion to Nash is not a strong enough threat, a *worse* equilibrium might serve as the punishment.

Abreu [1986], studying oligopoly, and Stokey [1991], studying credible public policy, showed how to construct one; Abreu [1988] developed the general theory of such optimal punishments.

The device is a stick-and-carrot strategy: the government is required to inflate at the maximum rate $y^\#$ for one period — the stick — after which it is rewarded with the Ramsey outcome forever.

The value is

$$\tilde{v} = (1-\delta)\, r(y^\#, y^\#) + \delta\, v^R, \tag{100.14}$$

and a deviation at any date, in either phase, *restarts* the whole strategy, so the continuation value after a deviation is always $\tilde{v}$ itself.

The strategy is an SPE only if neither phase tempts the government.

The stick. In the first period the incentive constraint is

$$\tilde{v} = (1-\delta)\, r(y^\#, y^\#) + \delta\, v^R \;\geq\; (1-\delta)\, r(y^\#, B(y^\#)) + \delta\, \tilde{v}.$$

Moving $\delta\tilde{v}$ to the left and dividing by $1-\delta$ leaves $\tilde{v} \geq r(y^\#, B(y^\#))$: the stick must be worth at least the candidate worst value (100.9).

The carrot. Once at Ramsey, the government must prefer staying there to grabbing the one-period gain from $B(0)$ and restarting the stick:

$$v^R \;\geq\; (1-\delta)\, r(0, B(0)) + \delta\, \tilde{v}. \tag{100.15}$$

Substituting (100.14), and using (100.5) and $v^R - r(y^\#, y^\#) = y^{\#2}/2$, the two constraints become

$$\delta \;\geq\; \frac{\left(y^\# - y^N\right)^2}{(1+\theta^2)\, y^{\#2}} \quad \text{(stick)}, \qquad \delta \;\geq\; \delta_A = \frac{\theta^2 U^{*2}}{(1+\theta^2)\, y^{\#2}} \quad \text{(carrot)}.$$

Here $y^N > y^\# - y^N$, so the carrot is the constraint that binds.

```
def abreu_value(m):
    "Value of the stick-and-carrot strategy: one period at y^#, then Ramsey."
    return (1 - m.δ) * r_keep(m, m.y_max) + m.δ * r_keep(m, 0.0)

def supports_ramsey_with_threat(m, threat):
    "Does a permanent threat value sustain Ramsey forever?"
```

(continues on next page)

(continued from previous page)

```
    return r_keep(m, 0.0) >= (1 - m.δ) * r_cheat(m, 0.0) + m.δ * threat

def is_abreu_spe(m):
    """
    Check both incentive constraints of the stick-and-carrot strategy, in which
    any deviation restarts the strategy.

    Returns (stick constraint holds, carrot constraint holds, both hold).
    """
    v_tilde = abreu_value(m)
    stick = v_tilde >= (1 - m.δ) * r_cheat(m, m.y_max) + m.δ * v_tilde
    carrot = supports_ramsey_with_threat(m, v_tilde)        # cp_abreu_carrot
    return stick, carrot, stick and carrot

δ_stick = (m.y_max - y_nash(m))**2 / ((1 + m.θ**2) * m.y_max**2)
δ_A = m.θ**2 * m.U_star**2 / ((1 + m.θ**2) * m.y_max**2)
print(f"stick holds for δ >= {δ_stick:.4f};  carrot holds for δ >= δ_A = {δ_A:.4f}\n")
for δ in (0.10, 0.20, 0.95):
    md = m._replace(δ=δ)
    va, vn = abreu_value(md), r_keep(md, y_nash(md))
    stick, carrot, spe = is_abreu_spe(md)
    print(f"δ = {δ:4.2f}:  v_abreu = {va:8.4f}   v^N = {vn:8.4f}   "
          f"worse than Nash? {str(va < vn):5}   stick? {str(stick):5}   "
          f"carrot? {str(carrot):5}   SPE? {spe}")
```

```
stick holds for δ >= 0.0381;  carrot holds for δ >= δ_A = 0.1845

δ = 0.10:  v_abreu = -60.1250   v^N = -38.7578   worse than Nash? True    stick?␣
 ↪True    carrot? False   SPE? False
δ = 0.20:  v_abreu = -55.1250   v^N = -38.7578   worse than Nash? True    stick?␣
 ↪True    carrot? True    SPE? True
δ = 0.95:  v_abreu = -17.6250   v^N = -38.7578   worse than Nash? False   stick?␣
 ↪True    carrot? True    SPE? True
```

At $\delta = 0.95$ the stick-and-carrot value is *better* than Nash, because a single bad period is heavily outweighed by an eternity of Ramsey.

At $\delta = 0.2$ it is far *worse* than Nash — and that is the point.

At $\delta = 0.1$ the government would still accept the stick, but it would not stay at Ramsey: the one-period gain from inflating outweighs the discounted cost of restarting the stick.

So at $\delta = 0.1$ the strategy is not an equilibrium, even though its first-period constraint holds.

The carrot constraint (100.15) asks whether the threat $\tilde{v}$ sustains Ramsey forever.

A punishment worse than Nash is a stronger deterrent than reversion to Nash, so it can support outcomes that Nash reversion cannot.

```
m2 = m._replace(δ=0.20)

print(f"at δ = 0.2:")
print(f"  threat = Nash     ({r_keep(m2, y_nash(m2)):8.4f}): "
      f"supports Ramsey? {supports_ramsey_with_threat(m2, r_keep(m2, y_nash(m2)))}")
print(f"  threat = Abreu    ({abreu_value(m2):8.4f}): "
      f"supports Ramsey? {supports_ramsey_with_threat(m2, abreu_value(m2))}")
```

```
at δ = 0.2:
  threat = Nash    (-38.7578): supports Ramsey? False
  threat = Abreu   (-55.1250): supports Ramsey? True
```

At $\delta = 0.2$, an impatient government cannot be held at Ramsey by the prospect of Nash, but *can* be held there by the prospect of Abreu's stick.

The worst equilibrium value $\underline{v}$ is a harsher punishment still, and it holds Ramsey in place down to an even lower discount factor (exercise Exercise 100.10.4).

Two definitions name the structures we have just met.

Definition 100.6.1 (Self-enforcing and self-rewarding)

A recursive SPE is **self-enforcing** if the continuation value following a deviation equals the initial promised value, and **self-rewarding** if the continuation value following adherence equals the promised value.

Abreu's stick-and-carrot is self-enforcing; infinite repetition of a better-than-Nash outcome is self-rewarding.

Proposition 100.5.1 and *Proposition 100.5.2* say that these two structures are not curiosities: they are exactly what the extreme equilibria look like.

100.7 Multiplicity

Two layers of multiplicity inhabit this theory.

There is a continuum of equilibrium *values*, and — the sharper point — many different outcome *paths* attain the same value.

To see the second, we construct three equilibria that all deliver the worst value $\underline{v}$.

All three begin the same way: the first-period promised value is $\underline{v}$, the prescribed action is $y^{\#}$, and the continuation value v_2 solves $\underline{v} = (1-\delta) r(y^{\#}, y^{\#}) + \delta v_2$.

They differ in what they do afterwards.

The code reuses `next_value` from the worst-value section.

```
def action_delivering(m, v):
    "The inflation rate ȳ with r(ȳ, ȳ) = v."
    return np.sqrt(max(-2.0 * v - m.U_star**2, 0.0))

def method_1(m, v_lo, v_hi, max_steps=500):
    "Climb at y^# until one more step would overshoot v_hi, then settle at v_hi."
    v, y = [v_lo], []
    for _ in range(max_steps):
        nxt = next_value(m, v[-1])
        if nxt > v_hi:
            break
        y.append(m.y_max)
        v.append(nxt)
    target = (v[-1] - m.δ * v_hi) / (1 - m.δ)      # r(ȳ, ȳ) for the switching period
    y.append(action_delivering(m, target))
    v.append(v_hi)
    y.append(action_delivering(m, v_hi))           # stay at v_hi forever after
```

(continues on next page)

(continued from previous page)

```
    return np.array(v), np.array(y)

def method_2(m, v_lo, max_steps=500):
    "Climb at y^# only until the promised value first exceeds v^N, then freeze."
    v_N = r_keep(m, y_nash(m))
    v, y = [v_lo], []
    for _ in range(max_steps):
        nxt = next_value(m, v[-1])
        y.append(m.y_max)
        v.append(nxt)
        if nxt > v_N:
            break
    y.append(action_delivering(m, v[-1]))          # freeze at v** forever
    return np.array(v), np.array(y)

def method_3(m, v_lo):
    "One period at y^#, then freeze immediately at v_2."
    v_2 = next_value(m, v_lo)
    return (np.array([v_lo, v_2, v_2]),
            np.array([m.y_max, action_delivering(m, v_2),
                      action_delivering(m, v_2)]))
```

The figure plots the promised values and inflation rates along the three paths.

```
paths = {'method 1': method_1(m, v_lo, v_hi),
         'method 2': method_2(m, v_lo),
         'method 3': method_3(m, v_lo)}

fig, axes = plt.subplots(2, 3, figsize=(13, 6.5), sharex='col')
for k, (name, (v, y)) in enumerate(paths.items()):
    axes[0, k].plot(range(1, len(v) + 1), v, 'C0o-', ms=3.5, lw=1)
    axes[0, k].axhline(v_lo, color='k', ls='--', lw=0.8)
    axes[0, k].axhline(v_hi, color='C2', ls=':', lw=0.8)
    axes[0, k].set_title(f'{name}: continuation values', fontsize=10)
    axes[1, k].plot(range(1, len(y) + 1), y, 'C1o-', ms=3.5, lw=1)
    axes[1, k].set_ylim(-0.4, m.y_max + 0.4)
    axes[1, k].set_xlabel('$t$')
    axes[1, k].set_title(f'{name}: inflation', fontsize=10)
axes[0, 0].set_ylabel('promised value $v_t$')
axes[1, 0].set_ylabel('inflation $y_t$')
plt.tight_layout()
plt.show()
```

Here are their lengths and terminal values.

```
print(f"Nash value {r_keep(m, y_nash(m)):.4f} at inflation {y_nash(m):.4f};  "
      f"worst value {v_lo:.4f}\n")
for name, (v, y) in paths.items():
    print(f"{name:9s}: {len(y):3d} periods before settling,  "
          f"first-period value {v[0]:.4f},  "
          f"terminal value {v[-1]:8.4f} at inflation {y[-1]:.4f}")
```

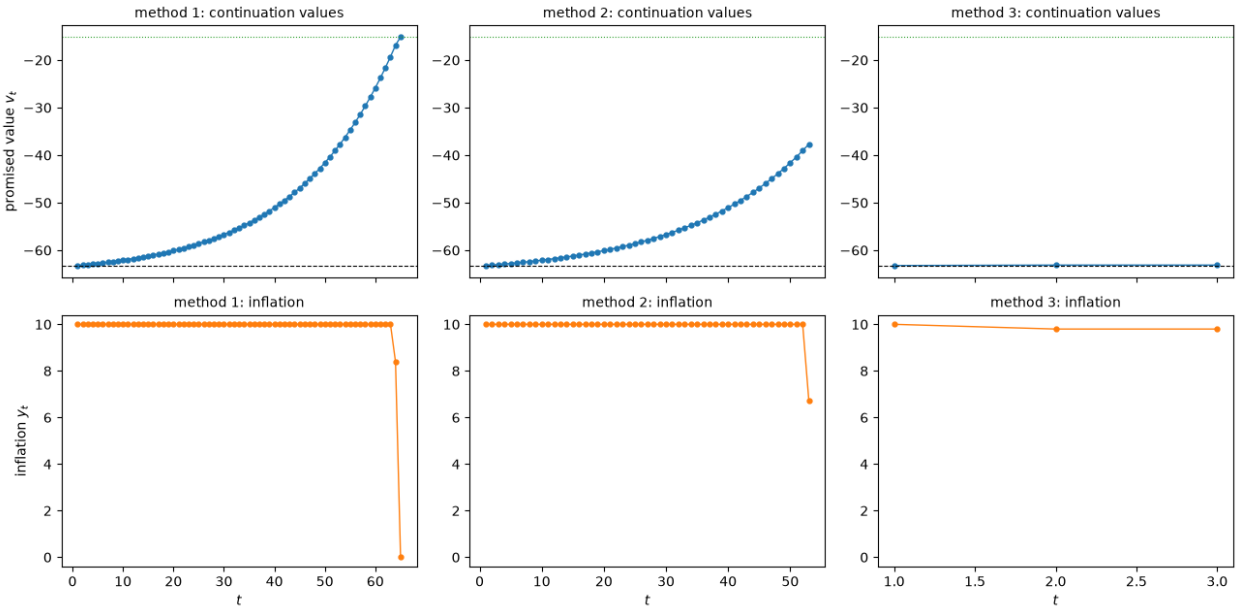

Fig. 100.2: Three subgame perfect equilibria that attain the same worst value (the book's Figures 4.2-4.4)

```
Nash value -38.7578 at inflation 6.8750;  worst value -63.2195

method 1 :  65 periods before settling,  first-period value -63.2195,  terminal␣
 ↪value -15.1250 at inflation 0.0000
method 2 :  53 periods before settling,  first-period value -63.2195,  terminal␣
 ↪value -37.6853 at inflation 6.7172
method 3 :   3 periods before settling,  first-period value -63.2195,  terminal␣
 ↪value -63.1192 at inflation 9.7974
```

The three paths could hardly be less alike.

The first climbs at maximum inflation for about sixty periods before easing down to Ramsey.

The second climbs for a shorter spell and then freezes forever at a value just *better* than Nash, sustained by an inflation rate just below the Nash rate.

The third inflates at the maximum for a single period and then settles immediately, at a value barely above the worst one.

All three are subgame perfect, and all three deliver exactly the same value to the government.

The equilibrium concept has nothing to say about which of them describes the world.

100.8 Numerical example

Here is the numerical example reported in chapter 4 of Sargent [1999], computed from scratch.

```
rows = [
    ("$\\theta$", m.θ, ""),
    ("$U^*$", m.U_star, ""),
    ("$y^\\#$", m.y_max, ""),
    ("$\\delta$", m.δ, ""),
    ("$y^N$ (Nash inflation)", y_nash(m), "6.8750"),
```

(continues on next page)

(continued from previous page)

```
    ("$y^R$ (Ramsey inflation)", 0.0, "0"),
    ("$v^R$", r_keep(m, 0.0), "-15.1250"),
    ("$v^N$", r_keep(m, y_nash(m)), "-38.7578"),
    ("$\\underline v$", v_lo, "-63.2195"),
    ("$v_{\\rm abreu}$", abreu_value(m), "-17.6250"),
]
pd.DataFrame(rows, columns=["object", "computed", "reported in the book"]).set_index(
 ↪"object")
```

object	computed	reported in the book
θ	1.250000	
U^*	5.500000	
$y^\#$	10.000000	
δ	0.950000	
y^N (Nash inflation)	6.875000	6.8750
y^R (Ramsey inflation)	0.000000	0
v^R	-15.125000	-15.1250
v^N	-38.757812	-38.7578
$\underline v$	-63.219512	-63.2195
$v_{\rm abreu}$	-17.625000	-17.6250

The book also reports the Nash-reversion cutoff and the value of the stick and carrot at $\delta = 0.2$.

```
print(f"cutoff discount factor δ*        : {1 / (2 + m.θ**2):.4f}  (book reports 0.
 ↪2807)")
print(f"Abreu stick-and-carrot at δ = 0.2: {abreu_value(m._replace(δ=0.2)):.4f}"
      f"  (book reports -55.125)")
```

```
cutoff discount factor δ*        : 0.2807  (book reports 0.2807)
Abreu stick-and-carrot at δ = 0.2: -55.1250  (book reports -55.125)
```

Every entry reproduces the book.

100.9 Interpretations

The literature on credible plans bears mixed news for the *triumph of natural-rate theory* story of *The Rise and Fall of U.S. Inflation*.

It certainly rescues the government from the pessimism of *The Credibility Problem*: better outcomes than Nash are available, and at plausible discount factors Ramsey itself is an equilibrium.

But it rescues too much.

Values worse than Nash are equilibria too, and between the extremes lies a continuum.

The multitude of outcomes mutes the model empirically, and it undoes the very thing early rational-expectations researchers wanted from the hypothesis — the elimination of free parameters describing expectations.

100.9.1 Whose expectations are they?

In his 1979 review of an OECD report edited by Paul McCracken, Lucas protested the report's recommendation that "governments should try to promote good expectations," as though expectations were an extra set of policy instruments.

In 1979 that protest was well aimed: rational-expectations models then took government policy as exogenous and made expectations a *function* of it, linked by cross-equation restrictions.

The theory of credible policy changes the picture in a way that vindicates neither side cleanly.

It turns systems of expectations into free parameters that influence outcomes — but into parameters that nobody inside the model gets to choose.

The government complies with equilibrium expectations about its own behavior.

Within an equilibrium, the government's strategy is simultaneously a decision rule and a description of the public's expectations, and the two cannot be disentangled.

As Sargent puts it: the authors of the McCracken report believed in multiplicity and manipulation, while Lucas doubted both; the literature on credible plans supports multiplicity but not manipulation.

100.9.2 Remedies

Reputation alone is a weak foundation for anti-inflation policy, and that weakness has inspired proposals to change the game rather than to hope for a good equilibrium within it.

Rogoff [1985] proposed delegating monetary policy to someone who cares less about unemployment than society does.

Assigning it to someone unaware even of a *temporary* tradeoff would be equally effective, and Alan Blinder later suggested a related device: an authority who knows the natural rate and never wants unemployment to differ from it.

Exercise Exercise **??** works out both remedies in the one-period economy of *The Credibility Problem*, including the price Rogoff's remedy pays when there are shocks to stabilize.

Maintaining a pool of potential central bankers with different inflation–unemployment preferences, some like Rogoff's conservative and others like the authority in Kydland and Prescott's model, can also improve outcomes [Ball, 1995, Barro and Gordon, 1983].

When the public does not know which kind of banker is in office, even a government of the inflationary kind can gain by acting like the conservative kind and building a reputation; Backus and Driffill [1985] and Barro [1986] model this as a game of incomplete information.

100.9.3 Where this leaves us

Every remedy just listed changes the *institutions*, not the theory.

Within the theory, the multiplicity is irreducible, and Sargent locates its source precisely: it stems from the rationality imputed to *everyone* in the system.

Perfection is what generates the continuum, because a system of expectations sophisticated enough to support one equilibrium is sophisticated enough to support many.

So the book retreats from perfection.

The remaining lectures replace fully rational participants with ones whose understanding of the economy is limited.

First the public forecasts adaptively, in *Adaptive Expectations and the Phelps Problem*, which comes next.

Then agents fit misspecified models to the data their own beliefs generate, in *Optimal Misspecified Beliefs* and *Self-Confirming Equilibria*; in the self-confirming equilibria of the latter, the misspecified agent is the government.

Finally, from *Adaptive Learning and Escape Dynamics* on, the government re-estimates its model in real time.

Those models are closer to what Lucas had in mind when he criticized the McCracken report, and, unlike the theory of this lecture, they make predictions.

100.10 Exercises

Exercise 100.10.1

The cutoff (100.13) claims that reversion to Nash sustains Ramsey forever if and only if $\delta \geq 1/(2+\theta^2)$ — a threshold that depends on θ alone, and not on the natural rate U^* or the upper bound $y^\#$.

Verify both claims numerically.

For a grid of θ values, find the smallest δ on a fine grid at which reversion to Nash supports Ramsey, and compare it with $1/(2+\theta^2)$.

Then check that changing U^* leaves the answer untouched.

Solution

```
δ_grid = np.linspace(0.01, 0.99, 9801)

rows = []
for θ in (0.5, 1.0, 1.25, 2.0, 3.0):
    for U_star in (5.5, 11.0):
        md = Model(θ=θ, U_star=U_star)
        ok = [δ for δ in δ_grid
              if supports_ramsey_by_nash(md._replace(δ=δ))]
        rows.append((θ, U_star, min(ok), 1 / (2 + θ**2)))

pd.DataFrame(rows, columns=["$\\theta$", "$U^*$", "smallest $\\delta$ found",
                            "$1/(2+\\theta^2)$"]).round(4)
```

	θ	U^*	smallest δ found	$1/(2+\theta^2)$
0	0.50	5.5	0.4445	0.4444
1	0.50	11.0	0.4445	0.4444
2	1.00	5.5	0.3334	0.3333
3	1.00	11.0	0.3334	0.3333
4	1.25	5.5	0.2808	0.2807
5	1.25	11.0	0.2808	0.2807
6	2.00	5.5	0.1667	0.1667
7	2.00	11.0	0.1667	0.1667
8	3.00	5.5	0.0910	0.0909
9	3.00	11.0	0.0910	0.0909

The grid search matches the closed form to within the grid spacing, and doubling U^* changes nothing.

The reason both U^* and $y^\#$ drop out is visible in (100.4): the one-period temptation at $y = 0$ and the Nash–Ramsey value gap are both proportional to U^{*2}, so the scale cancels from the inequality, and $y^\#$ never enters because neither side involves the upper bound.

A larger unemployment response θ to surprise inflation makes the Nash outcome worse relative to Ramsey, which strengthens the threat and lets a *less* patient government be held at zero inflation.

(In the (U, y) plane of *The Credibility Problem* the Phillips curve has slope $-1/\theta$, so a larger θ means a *flatter* curve.)

Exercise 100.10.2

The set of equilibrium values shrinks as the government becomes impatient.

Use `solve_aps` to compute $V = [\underline{v}, \overline{v}]$ for discount factors between 0.001 and 0.98, and plot both endpoints against δ on a logarithmic axis, marking the Nash and Ramsey values.

1. Below what discount factor δ_R does the best equilibrium value stop being Ramsey? Find δ_R exactly, by asking when the punishment $r(y^\#, B(y^\#))$ makes the government prefer Ramsey to the one-period gain from deviating, and confirm it with `solve_aps`.
2. At small δ the lower edge of V bends away from $r(y^\#, B(y^\#))$. Find where, and explain why, using the check of the worst-value section.
3. What happens to V as $\delta \to 0$, and why is that the answer you should expect?

Solution

Let $G = r(0, B(0)) - v^R$ be the one-period gain from deviating at Ramsey.

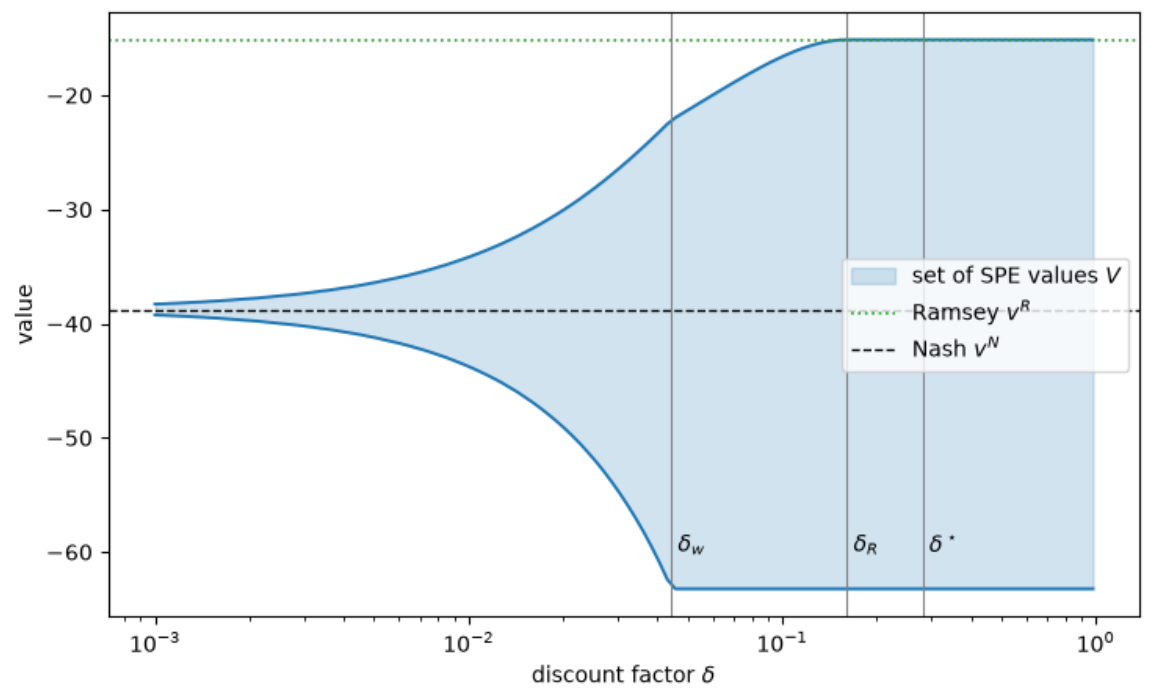
With $\underline{v}$ as a permanent punishment, Ramsey is sustained when $v^R \geq (1-\delta)(v^R + G) + \delta \underline{v}$, that is, when $\delta \geq \delta_R = G/(G + v^R - \underline{v})$.

For the bend, we find by bisection the discount factor δ_w at which the reward (100.10) that the candidate $r(y^\#, B(y^\#))$ requires just equals the best value it implies.

```
v_R, v_N = r_keep(m, 0.0), r_keep(m, y_nash(m))
v_cand = r_cheat(m, m.y_max)
G = r_cheat(m, 0.0) - v_R                    # one-period gain from deviating at␣
↪Ramsey
δ_R = G / (G + v_R - v_cand)

def check_gap(δ):
    "Reward required by the candidate worst value minus the best value it implies."
    md = m._replace(δ=δ)
    return next_value(md, v_cand) - best_value(md, v_cand)[0]

lo, hi = 0.01, 0.1                       # the check fails at lo and passes at hi
for _ in range(50):
    mid = (lo + hi) / 2
    lo, hi = (mid, hi) if check_gap(mid) > 0 else (lo, mid)
δ_w = hi



print(f"δ_R = {δ_R:.4f};  δ_w = {δ_w:.4f};  δ* = {1 / (2 + m.θ**2):.4f}")
for δ in (δ_R - 0.001, δ_R + 0.001):
    Wδ, _ = solve_aps(m._replace(δ=δ))
    print(f"  δ = {δ:.4f}: best value {Wδ[1]:.4f}, equals Ramsey? "
          f"{np.isclose(Wδ[1], v_R, atol=1e-6)}")
for δ in (0.001, 0.01, 0.02):
    Wδ, _ = solve_aps(m._replace(δ=δ))
    print(f"  δ = {δ:.3f}: V = [{Wδ[0]:.3f}, {Wδ[1]:.3f}], "
          f"width / δ = {(Wδ[1] - Wδ[0]) / δ:.0f}")
```

```
δ_R = 0.1609;  δ_w = 0.0443;  δ* = 0.2807
  δ = 0.1599: best value -15.1254, equals Ramsey? False
  δ = 0.1619: best value -15.1250, equals Ramsey? True
  δ = 0.001: V = [-39.241, -38.279], width / δ = 962
  δ = 0.010: V = [-43.738, -34.175], width / δ = 956
  δ = 0.020: V = [-49.038, -30.072], width / δ = 948
```

The figure marks the three discount factors.

```
δs = np.geomspace(0.001, 0.98, 120)
lows, highs = [], []
for δ in δs:
    Wδ, _ = solve_aps(m._replace(δ=δ))
    lows.append(Wδ[0])
    highs.append(Wδ[1])

fig, ax = plt.subplots(figsize=(8.5, 5))
ax.fill_between(δs, lows, highs, alpha=0.2, color='C0', label='set of SPE values $V
↪$')
ax.plot(δs, highs, 'C0', lw=1.4)
ax.plot(δs, lows, 'C0', lw=1.4)
ax.axhline(v_R, color='C2', ls=':', lw=1.2, label='Ramsey $v^R$')
ax.axhline(v_N, color='k', ls='--', lw=1, label='Nash $v^N$')
for δ_mark, name in [(δ_w, r'$\delta_w$'), (δ_R, r'$\delta_R$'),
                     (1 / (2 + m.θ**2), r'$\delta^\star$')]:
    ax.axvline(δ_mark, color='gray', lw=0.8)
    ax.annotate(name, (δ_mark, -60), textcoords='offset points', xytext=(3, 0))
ax.set_xscale('log')
ax.set_xlabel(r'discount factor $\delta$')
ax.set_ylabel('value')
ax.legend(loc='center right')
plt.show()
```

The best equilibrium value equals Ramsey for $\delta \geq \delta_R \approx 0.161$, well *below* the $\delta^\star \approx 0.28$ of (100.13).

The cutoff $\delta^\star$ uses reversion to *Nash* as the threat, while the APS set uses the worst equilibrium, a much harsher threat, so Ramsey survives at lower discount factors than Barro and Gordon's argument alone would suggest.

Below $\delta_w \approx 0.044$ the check of the worst-value section fails.

The reward (100.10) needed to make one period at $y^\#$ acceptable grows like $1/\delta$, and below δ_w it exceeds the best equilibrium value.

The worst equilibrium must then start at a lower inflation rate, and the lower edge of V rises above $r(y^\#, B(y^\#))$ toward v^N.

As $\delta \to 0$ the set collapses toward the single point v^N, with a width roughly proportional to δ.

That is what it must do: an entirely impatient government cares only about the current period, promises about the future carry no weight, and the only outcome that can be sustained is the one the government would choose myopically — the Nash outcome.

The sets are nested, growing with δ; Abreu *et al.* [1990] prove that, in their setting, the set of average equilibrium values is monotone in the discount factor.

Exercise 100.10.3

Method 3 in the multiplicity section is the boldest of the three: it inflates at $y^\#$ for a single period and then freezes forever at a constant inflation rate.

Because it settles immediately, its incentive constraint is the tightest of the three, so it is worth checking rather than assuming.

Verify directly that method 3 is a subgame perfect equilibrium: confirm that its first-period promise is honoured, that its frozen continuation value lies inside V, and that the government prefers adherence to deviation in *both* phases, using $\underline{v}$ as the punishment.

Solution

```
v_2 = next_value(m, v_lo)
y_tilde = action_delivering(m, v_2)

# phase 1: promised v_lo, prescribed action y^#, continuation v_2 on adherence
lhs_1 = (1 - m.δ) * r_keep(m, m.y_max) + m.δ * v_2
rhs_1 = (1 - m.δ) * r_cheat(m, m.y_max) + m.δ * v_lo

# phase 2: promised v_2, prescribed action ỹ, continuation v_2 on adherence
lhs_2 = (1 - m.δ) * r_keep(m, y_tilde) + m.δ * v_2
rhs_2 = (1 - m.δ) * r_cheat(m, y_tilde) + m.δ * v_lo

print(f"v_2 = {v_2:.4f},  ỹ = {y_tilde:.4f}")
print(f"v_2 lies inside V = [{v_lo:.4f}, {v_hi:.4f}]: "
      f"{v_lo <= v_2 <= v_hi}")
print(f"phase 1 delivers the promise: {np.isclose(lhs_1, v_lo)}")
print(f"phase 1 incentive: {lhs_1:.4f} vs {rhs_1:.4f}  ->  "
      f"holds with equality? {np.isclose(lhs_1, rhs_1)}")
print(f"phase 2 delivers the promise: {np.isclose(lhs_2, v_2)}")
print(f"phase 2 incentive: {lhs_2:.4f} >= {rhs_2:.4f}  ->  {lhs_2 >= rhs_2}")
print(f"slack in phase 2: {lhs_2 - rhs_2:.6f}")
```

```
v_2 = -63.1192,  ỹ = 9.7974
v_2 lies inside V = [-63.2195, -15.1250]: True
phase 1 delivers the promise: True
phase 1 incentive: -63.2195 vs -63.2195  ->  holds with equality? True
phase 2 delivers the promise: True
phase 2 incentive: -63.1192 >= -63.1312  ->  True
slack in phase 2: 0.011955
```

All the conditions hold, and the first-period promise is delivered exactly.

The phase-1 constraint holds with equality, and that is just the definition of $\underline{v}$: at $y^{\#}$ the government can always deviate to $B(y^{\#})$ and accept the punishment $\underline{v}$, which is worth $(1-\delta)r(y^{\#}, B(y^{\#})) + \delta\underline{v}$, and $\underline{v} = r(y^{\#}, B(y^{\#}))$ promises exactly that much.

The margin in the second phase is very thin, and that is not an accident either.

The frozen value v_2 is only barely above $\underline{v}$, so the punishment for deviating is only barely worse than the equilibrium itself — which is precisely what it means to be near the bottom of the set of equilibrium values.

Exercise 100.10.4

This exercise compares three ways of holding the government at Ramsey forever.

1. Suppose any deviation from Ramsey is followed by a continuation value v_p that does not depend on δ. Show that Ramsey is sustained if and only if $\delta \geq G/(G + v^R - v_p)$, where $G = r(0, B(0)) - v^R$.
2. Evaluate this threshold for Nash reversion ($v_p = v^N$) and for the worst equilibrium ($v_p = \underline{v} = r(y^{\#}, B(y^{\#}))$, the worst value for every δ above the δ_w of exercise Exercise 100.10.2).
3. Abreu's stick and carrot punishes with $\tilde{v}$, which depends on δ; its threshold is the δ_A of *Something worse: Abreu's stick and carrot*. Compare $\tilde{v}$ at δ_A with $\underline{v}$, and explain the difference.
4. Order the three thresholds, and check δ_A with `is_abreu_spe`.

Solution

1. Deviating from Ramsey earns $r(0, B(0)) = v^R + G$ for one period and v_p thereafter, so the constraint is $v^R \geq (1-\delta)(v^R + G) + \delta v_p$, which rearranges to $\delta(G + v^R - v_p) \geq G$.

2. By (100.5), $G = \theta^2 U^{*2}/(2(1+\theta^2))$, and $v^R - v^N = \theta^2 U^{*2}/2$, so Nash reversion gives $1/(2+\theta^2)$, the cutoff (100.13).

The worst equilibrium gives the δ_R of exercise Exercise 100.10.2.

```
def ramsey_threshold(m, v_p):
    "Smallest δ at which the permanent punishment v_p sustains Ramsey."
    G = r_cheat(m, 0.0) - r_keep(m, 0.0)
    return G / (G + r_keep(m, 0.0) - v_p)

δ_nash = ramsey_threshold(m, r_keep(m, y_nash(m)))
δ_opt = ramsey_threshold(m, r_cheat(m, m.y_max))
δ_A = m.θ**2 * m.U_star**2 / ((1 + m.θ**2) * m.y_max**2)
print(f"Nash reversion      δ* = {δ_nash:.4f}")

      f"{r_cheat(m, m.y_max):.4f},  reward after the stick in the worst␣
 ↪equilibrium "
      f"{next_value(m_A, r_cheat(m, m.y_max)):.4f}\n")
for δ in (δ_A - 1e-4, δ_A + 1e-4):
    print(f"δ = {δ:.5f}: stick and carrot is an SPE? {is_abreu_spe(m._
 ↪replace(δ=δ))[2]}")
```

```
Nash reversion      δ* = 0.2807
Abreu stick/carrot  δ_A = 0.1845
worst equilibrium   δ_R = 0.1609

at δ_A: Abreu's punishment -55.9024,  worst value -63.2195,  reward after the␣
 ↪stick in the worst equilibrium -54.7944

δ = 0.18435: stick and carrot is an SPE? False
δ = 0.18455: stick and carrot is an SPE? True
```

3. Both punishments begin with a period at $y^{\#}$.

Abreu's then pays the full carrot, Ramsey forever.

The worst equilibrium pays a smaller reward after the stick, the v_1 of (100.10), which is itself worse than Nash, so its punishment is harsher.

4. The ordering is $\delta^\star > \delta_A > \delta_R$.

The harsher the punishment, the lower the discount factor at which it deters the one-period gain G.

Nash reversion is the mildest of the three punishments, the worst equilibrium the harshest, and Abreu's simple stick and carrot lies between them.

Exercise 100.10.5

For $\delta < \delta^\star$, reversion to Nash cannot sustain Ramsey.

The best value it can sustain is equation (25) of chapter 4 of Sargent [1999]:

$$v^{nr} = r(y^{nr}, y^{nr}) = (1-\delta)\, r(y^{nr}, B(y^{nr})) + \delta\, v^N,$$

where y^{nr} is the lowest inflation rate at which adhering is at least as good as deviating and reverting to Nash forever.

1. Using (100.5), show that for $\delta \leq \delta^\star$

$$y^{nr} = \theta U^* \frac{1 - \delta(2+\theta^2)}{1+\delta\theta^2}.$$

2. Plot v^{nr} against $\delta \in (0, \delta^\star]$, together with the best SPE value $\overline{v}$ from `solve_aps`, and compare the two at $\delta = 0.2$.

Solution

1. The constraint $r(y,y) \geq (1-\delta) r(y, B(y)) + \delta v^N$ is equivalent to $\delta\left[r(y,y) - v^N\right] \geq (1-$

$\delta)\,[r(y, B(y)) - r(y, y)]$.

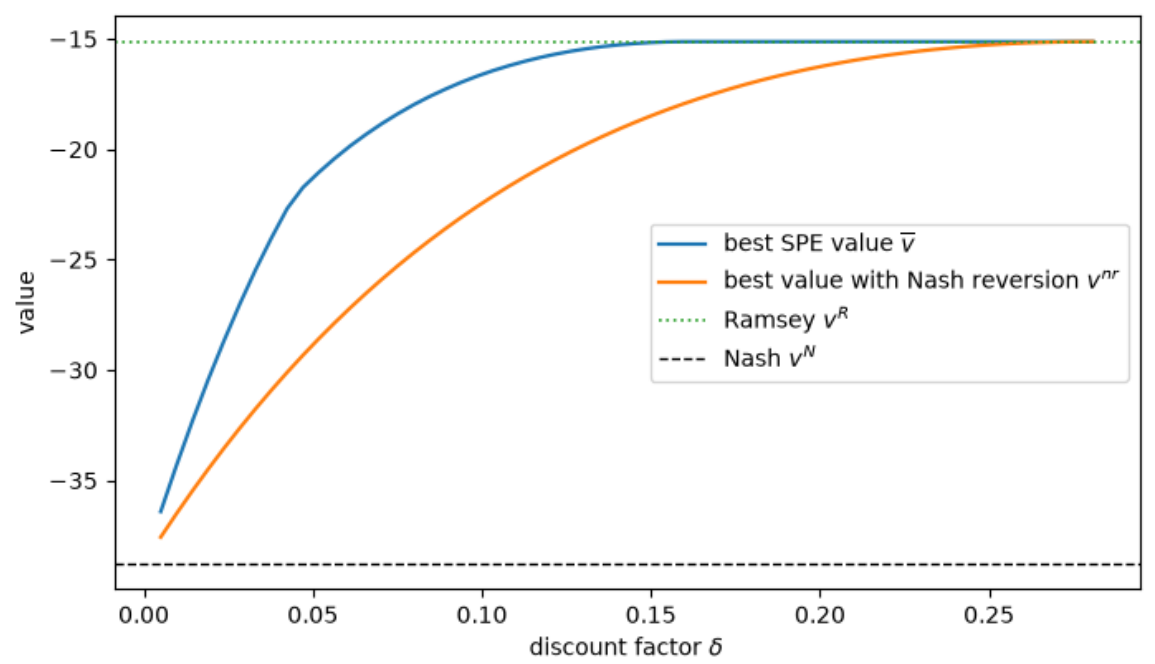
Write $z = y^N - y \geq 0$ for the distance below Nash.

Then $r(y, y) - v^N = z(2y^N - z)/2$, and by (100.5) the right side is $(1-\delta)z^2/(2(1+\theta^2))$.

Dividing by $z > 0$, the constraint becomes $z \leq 2y^N\delta(1+\theta^2)/(1+\delta\theta^2)$.

The lowest admissible inflation rate is y^N minus that bound, which gives the formula.

It reaches zero exactly at $\delta = 1/(2+\theta^2) = \delta^\star$.



Every value between v^N and v^{nr} can also be sustained by Nash reversion, but no value above v^{nr}.

```
def nash_reversion_best(m):
    "The best value sustainable by reversion to Nash (book eq. (25)) and its␣
 ↪action."
    y_nr = max(y_nash(m) * (1 - m.δ * (2 + m.θ**2)) / (1 + m.δ * m.θ**2), 0.0)
    return r_keep(m, y_nr), y_nr

δ_star = 1 / (2 + m.θ**2)
δs_nr = np.linspace(0.005, δ_star, 60)
v_nr = [nash_reversion_best(m._replace(δ=δ))[0] for δ in δs_nr]
v_best = [solve_aps(m._replace(δ=δ))[0][1] for δ in δs_nr]

fig, ax = plt.subplots(figsize=(8, 4.5))
ax.plot(δs_nr, v_best, 'C0', lw=1.6, label=r'best SPE value $\overline{v}$')
ax.plot(δs_nr, v_nr, 'C1', lw=1.6, label=r'best value with Nash reversion $v^{nr}$
 ↪')
ax.axhline(r_keep(m, 0.0), color='C2', ls=':', lw=1.2, label='Ramsey $v^R$')
ax.axhline(r_keep(m, y_nash(m)), color='k', ls='--', lw=1, label='Nash $v^N$')
ax.set_xlabel(r'discount factor $\delta$')
ax.set_ylabel('value')
ax.legend()
plt.show()

m_02 = m._replace(δ=0.2)
v_nr_02, y_nr_02 = nash_reversion_best(m_02)
print(f"δ = 0.2: Nash reversion sustains at best {v_nr_02:.4f}, with y = {y_nr_02:.
 ↪4f};"
      f"  best SPE value {solve_aps(m_02)[0][1]:.4f}")
```

```
δ = 0.2: Nash reversion sustains at best -16.2589, with y = 1.5060;  best SPE␣
↪value -15.1250
```

At $\delta = 0.2$, Nash reversion can at best hold inflation down to about 1.5 percent, while the optimal punishment sustains Ramsey itself.

The two curves meet at $\delta^\star$, where Nash reversion first sustains Ramsey.

As $\delta \to 0$ both curves fall back to v^N, because the worst equilibrium value itself approaches v^N (exercise Exercise 100.10.2).

The gap closes only in levels: measured from v^N, the optimal punishment still sustains about twice the improvement that Nash reversion does.

```
v_N = r_keep(m, y_nash(m))
for δ in [0.02, 0.005]:
    m_δ = m._replace(δ=δ)
    ratio = (solve_aps(m_δ)[0][1] - v_N) / (nash_reversion_best(m_δ)[0] - v_N)
    print(f"δ = {δ}: (v̄ - v^N) / (v^nr - v^N) = {ratio:.2f}")
```

```
δ = 0.02: (v̄ - v^N) / (v^nr - v^N) = 1.95
δ = 0.005: (v̄ - v^N) / (v^nr - v^N) = 1.98
```

Exercise 100.10.6

The algorithm theorem of *The Abreu–Pearce–Stacchetti method* requires the starting set to satisfy $V \subseteq \mathcal{T}(W_0) \subseteq W_0$.

1. Show that $W_0 = \{v^N\}$ satisfies $\mathcal{T}(W_0) = W_0$. Confirm it with `T_operator` and `solve_aps`, and say which hypothesis of the theorem fails.
2. Start instead from $W_0 = \{v^R\}$. Where does the iteration go, and why?
3. What do the two experiments say about what a set of continuation values needs in order to support anything other than Nash?

Solution

1. With a single continuation value w, the reward and the punishment coincide, $w_1 = w_2 = w$, so admissibility requires $(1-\delta)r(y,y) \geq (1-\delta)r(y,B(y))$.

By (100.5) only $y = y^N$ qualifies, and it generates the single value $(1-\delta)v^N + \delta w$.

So $\mathcal{T}(\{w\}) = \{(1-\delta)v^N + \delta w\}$, and $\mathcal{T}(\{v^N\}) = \{v^N\}$.

The hypothesis that fails is $V \subseteq \mathcal{T}(W_0)$.

The Nash rate $y^N = 6.875$ is a point of the grid in `T_operator`, so the numerical operator finds it.

```
v_N, v_R = r_keep(m, y_nash(m)), r_keep(m, 0.0)
print(f"v^N = {v_N:.4f};  T({{v^N}}) = {T_operator(m, (v_N, v_N))}")
W_N, it_N = solve_aps(m, W0=(v_N, v_N))
print(f"iterating from {{v^N}}: stops after {it_N} iterations at {W_N}")
W_R, it_R = solve_aps(m, W0=(v_R, v_R))
print(f"iterating from {{v^R}}: stops after {it_R} iterations at "
      f"[{W_R[0]:.4f}, {W_R[1]:.4f}]")
```

```
v^N = -38.7578;  T({v^N}) = (np.float64(-38.7578125), np.float64(-38.7578125))
iterating from {v^N}: stops after 0 iterations at (np.float64(-38.7578125), np.
↪float64(-38.7578125))
iterating from {v^R}: stops after 542 iterations at [-38.7578, -38.7578]
```

2. Starting from $\{v^R\}$, the iterates are the single points $(1-\delta^j)\,v^N + \delta^j v^R$, which converge to $\{v^N\}$, not to V.

This start fails the other hypothesis, since $\mathcal{T}(\{v^R\}) \not\subseteq \{v^R\}$.

3. Incentives come from the *spread* between the reward for adhering and the punishment for deviating.

A single continuation value offers no spread, so the only outcome it can support is the one the government chooses without incentives, the static best response.

A starting set must be wide enough to contain every reward and every punishment that equilibria use, which is what $V \subseteq \mathcal{T}(W_0)$ guarantees, and what the set of all feasible values $[r(y^\#, y^\#), 0]$ provides.

101.1 Overview

> They cannot look out far. They cannot look in deep. But when was that ever a bar To any watch they keep?
>
> – Robert Frost

This lecture continues the study of Phillips curve tradeoffs begun in *The Credibility Problem*.

It follows chapter 5 of Sargent [1999].

Credible Government Policies pursued better-than-Nash outcomes while keeping *everyone* rational, and found too many of them: a continuum of sustainable values, with nothing inside the theory to choose among them.

Here we retreat from that perfection in the smallest way we can, by keeping the government rational and giving the public a mechanical forecasting rule.

We describe

- the Cagan-Friedman adaptive expectations hypothesis,
- how Phelps [1967] used it to formulate a government control problem,

- the sacrifice ratio that the hypothesis implies, and
- the role of adaptive expectations in early econometric tests of the natural-rate hypothesis, and the rational expectations critique of those tests.

The key object is the **Phelps problem**: a government that is rational solves an optimal control problem while the public forecasts inflation with a fixed, mechanical adaptive rule.

Unlike the one-period model of *The Credibility Problem*, the government now takes into account that the economy lasts more than one period, and that today's inflation shapes tomorrow's expectations.

This intertemporal link can improve outcomes and, in a limiting case, even sustain the Ramsey outcome.

The Phelps problem is a linear-quadratic (LQ) control problem, so we solve it with the *LQ control* tools from QuantEcon.

Let's start with some imports:

```
import matplotlib.pyplot as plt
import numpy as np
import quantecon as qe
from scipy.signal import lfilter
```

101.2 Adaptive expectations

Phelps [1967] formulated a control problem for a natural-rate model.

He dropped rationality for the public but not for the government, and assigned the public a particular mechanical forecasting rule that is known to the government.

The public uses the adaptive expectations scheme of Milton Friedman and Cagan [1956] (see Monetarist Theory of Price Levels with Adaptive Expectations for Cagan's own use of it):

$$x_t - x_{t-1} = (1-\lambda)(y_{t-1} - x_{t-1}), \qquad \lambda \in (0,1), \tag{101.1}$$

where x_t is the public's expectation of inflation and y_t is inflation.

Rearranging, $x_t = \lambda x_{t-1} + (1-\lambda) y_{t-1}$, so expected inflation is a geometric distributed lag of past inflation,

$$x_t = (1-\lambda)\sum_{i=1}^{\infty} \lambda^{i-1} y_{t-i}. \tag{101.2}$$

Notice that (101.1) is a *constant gain* version of the least squares learning algorithm from *The Credibility Problem*, with the constant $(1-\lambda)$ playing the role that the decreasing gain t^{-1} played there.

It is also the relaxation algorithm of *From relaxation to learning: Bray's market*, run in calendar time with gain $1-\lambda$.

Note

Here λ is the weight on the old forecast, so the *gain* is $1-\lambda$.

The Bounded Rationality lectures write the gain itself as λ (*Notation across the series*), and *Optimal Misspecified Beliefs* and *Self-Confirming Equilibria* write it as $C = 1-\lambda$.

Equation (101.2) possesses what Cho and Matsui [1995] call an **induction property**: if the government keeps repeating a constant $y_t = \tilde{y}$ policy, eventually the public comes to set $x_t \approx \tilde{y}$.

The weights $(1-\lambda)\lambda^{i-1}$ sum to one, so a permanently maintained inflation rate is eventually expected.

Let's confirm the induction property numerically.

```
def adaptive_forecast(y, λ, x0=0.0):
    "Simulate x_t = λ x_{t-1} + (1-λ) y_{t-1}."
    T = len(y)
    x = np.empty(T)
    x[0] = x0
    for t in range(1, T):
        x[t] = λ * x[t - 1] + (1 - λ) * y[t - 1]
    return x

T = 60
y_const = np.full(T, 10.0)                  # a constant inflation policy

fig, ax = plt.subplots(figsize=(9, 4.5))
for λ in [0.7, 0.9]:
    x = adaptive_forecast(y_const, λ)
    ax.plot(x, lw=1.5, label=rf'$\lambda = {λ}$')
ax.axhline(10.0, color='k', ls='--', lw=1, label='policy $\\tilde y$')
ax.set_xlabel('$t$')
ax.set_ylabel('expected inflation $x_t$')
ax.legend()
plt.show()
```

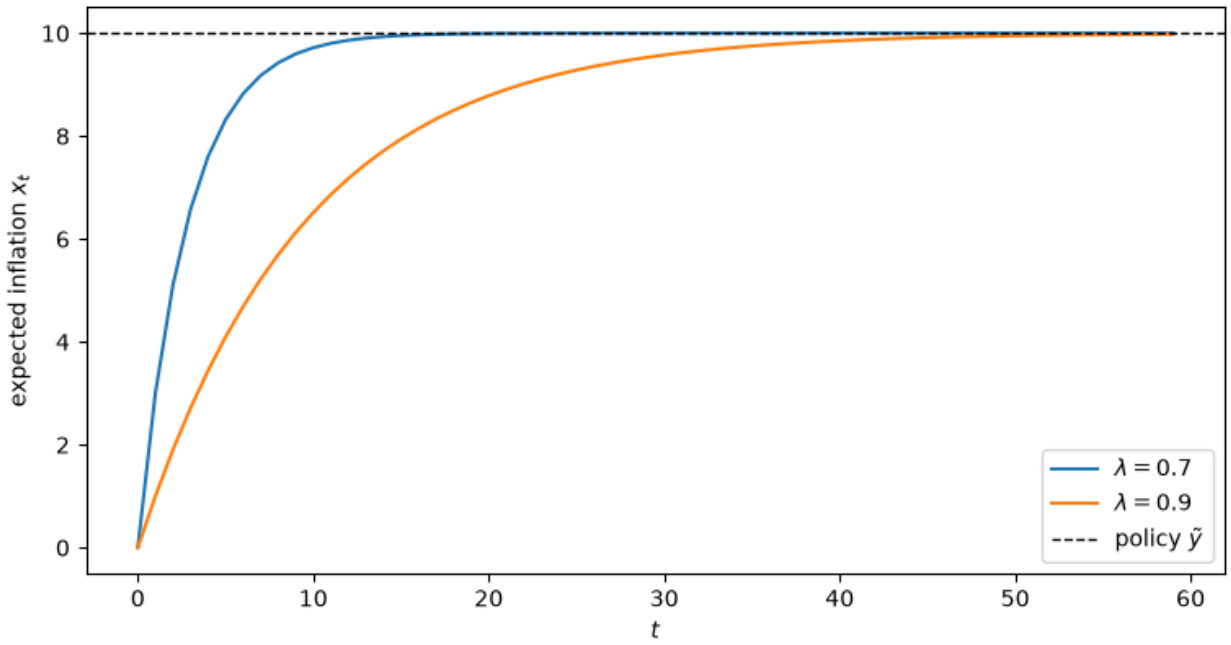

Fig. 101.1: Adaptive expectations converge to a constant inflation policy: the induction property

Under a constant policy the public's expectation converges to the policy, more slowly the larger is λ.

Solow and Tobin exploited this induction property when they tested the natural-rate hypothesis, as we discuss *below*.

101.3 The Phelps problem

The economy repeats forever, and the government evaluates outcome sequences with the discounted criterion

$$V^g = (1-\delta)\sum_{t=1}^{\infty}\delta^{t-1}p(U_t,y_t), \qquad p(U_t,y_t) = -\frac{1}{2}(U_t^2+y_t^2), \qquad \delta\in(0,1]. \tag{101.3}$$

When $\delta = 1$ we interpret (101.3) in the limit-of-means (Cesàro) sense.

Under that criterion only the limit of the outcome sequence matters, so every path that drives y_t to 0 is optimal and the transition path is not pinned down.

The $\delta = 1$ results below are therefore limits as $\delta \uparrow 1$: the code sets $\beta = 1 - 10^{-7}$, and the rule barely changes as that number shrinks further.

The government maximizes (101.3) by choice of a rule for inflation y_t, subject to the adaptive expectations scheme (101.1) and the expectations-augmented Phillips curve

$$U_t = U^* - \theta(y_t - x_t). \tag{101.4}$$

Because expected inflation x_t is predetermined at the start of period t, it is the only endogenous state variable.

The government's problem is therefore a discounted LQ control problem with

- state $s_t = \begin{bmatrix}1 & x_t\end{bmatrix}^\top$,
- control y_t, and
- transition $x_{t+1} = \lambda x_t + (1-\lambda)y_t$.

101.3.1 Casting the problem in LQ form

Write $U_t = a^\top s_t - \theta y_t$ with $a = \begin{bmatrix}U^* & \theta\end{bmatrix}^\top$.

The per-period loss $\frac{1}{2}(U_t^2+y_t^2)$ then equals

$$\frac{1}{2}\left[s_t^\top(aa^\top)s_t + (\theta^2+1)y_t^2 - 2\theta\, y_t\,(a^\top s_t)\right].$$

Matching this to the QuantEcon LQ loss $s_t^\top R s_t + y_t^\top Q y_t + 2y_t^\top N s_t$ (see *Eliminating Cross Products* for how such cross products are handled), and matching the transition to $s_{t+1} = As_t + By_t$, gives

$$R = \tfrac{1}{2}aa^\top, \quad Q = \tfrac{1}{2}(\theta^2+1), \quad N = -\tfrac{1}{2}\theta\, a^\top, \quad A = \begin{bmatrix}1 & 0\\ 0 & \lambda\end{bmatrix}, \quad B = \begin{bmatrix}0\\ 1-\lambda\end{bmatrix}.$$

The discount factor is $\beta = \delta$; the scaling $(1-\delta)$ in (101.3) does not affect the optimal policy.

```
class PhelpsProblem:
    """
    The Phelps optimal-control problem: a rational government facing a
    public that forecasts inflation adaptively with parameter λ.
    """

    def __init__(self, θ=1.0, U_star=5.0, λ=0.7, δ=0.96):
        self.θ, self.U_star, self.λ, self.δ = θ, U_star, λ, δ

        a = np.array([[U_star], [θ]])
```

(continues on next page)

(continued from previous page)

```
        R = 0.5 * (a @ a.T)
        Q = np.array([[0.5 * (θ**2 + 1)]])
        N = -0.5 * θ * a.T
        A = np.array([[1.0, 0.0], [0.0, λ]])
        B = np.array([[0.0], [1 - λ]])

        # δ = 1 (limit of means) is handled as the limit δ → 1
        β = min(δ, 1 - 1e-7)
        self.lq = qe.LQ(Q, R, A, B, N=N, beta=β)
        P, F, d = self.lq.stationary_values()

        # optimal rule y_t = f1 + f2 x_t
        self.f1, self.f2 = -F[0, 0], -F[0, 1]

    def simulate(self, x0=12.0, T=60):
        "Disinflation path (U_t, y_t) starting from expectation x0."
        θ, U_star, λ = self.θ, self.U_star, self.λ
        U, y, x = np.empty(T), np.empty(T), x0
        for t in range(T):
            y[t] = self.f1 + self.f2 * x
            U[t] = U_star - θ * (y[t] - x)
            x = λ * x + (1 - λ) * y[t]
        return U, y
```

The optimal rule takes the form $y_t = f_1 + f_2 x_t$ with $f_1 \neq 0$ and $f_2 \neq 1$.

These inequalities reflect that the public does not use an optimal forecasting rule; if instead $f_1 = 0$ and $f_2 = 1$, we would have $y_t = x_t$ for all histories.

```
pp = PhelpsProblem(θ=1.0, U_star=5.0, λ=0.7, δ=0.96)
print(f"optimal rule:  y_t = {pp.f1:.3f} + {pp.f2:.3f} x_t")
```

```
optimal rule:  y_t = 0.406 + 0.334 x_t
```

101.3.2 A proposition

The reason the Phelps problem is interesting is the following result.

Proposition 101.3.1 (δ = 1 eventually sustains Ramsey)

In the absence of discounting ($\delta = 1$), the government drives y_t to 0, the Ramsey outcome.

When $\delta = 1$, λ governs the speed of convergence to the Ramsey outcome.

When $\delta < 1$, the limit point of y_t depends on a comparison of λ with δ, which we can make exact.

Let q_t denote the marginal value to the government of expected inflation x_t.

The first-order condition for y_t and the envelope condition for x_t are

$$\theta U_t - y_t + \delta(1-\lambda) q_{t+1} = 0, \qquad q_t = -\theta U_t + \delta\lambda q_{t+1}.$$

In a steady state $x = y$, so $U = U^*$ and $q = -\theta U^*/(1-\delta\lambda)$, and the first-order condition gives

$$y_\infty = \theta U^* \frac{1-\delta}{1-\delta\lambda}. \tag{101.5}$$

The formula has a marginal interpretation.

A permanent one-point cut in inflation from the steady state lowers the inflation loss by y_∞ every period, a discounted benefit of $y_\infty/(1-\delta)$.

It also raises unemployment by $\theta\lambda^t$ in period t, while expectations catch up, and each point of unemployment costs about U^* at the margin, a discounted cost of $\theta U^*/(1-\delta\lambda)$.

Equating the two gives (101.5).

Because $1-\delta\lambda = (1-\delta)+\delta(1-\lambda)$, steady-state inflation is a fraction $(1-\delta)/[(1-\delta)+\delta(1-\lambda)]$ of the Nash rate θU^*.

It is close to the Ramsey value 0 only when the government's impatience $1-\delta$ is small relative to the public's gain $1-\lambda$.

That is what chapter 5 of Sargent [1999] means by $\lambda \ll \delta$ with δ close to one.

It is not enough that $\lambda < \delta$: with $\lambda = 0.98$ and $\delta = 0.99$, formula (101.5) gives $y_\infty \approx 0.34\,\theta U^*$.

The public's expectations are wrong along the transition path but are correct in the steady state, by virtue of the induction property.

The steady state of the rule $y_t = f_1 + f_2 x_t$ is $f_1/(1-f_2)$, so we can check (101.5) against the LQ solution.

```
for λ, δ in [(0.7, 0.96), (0.9, 0.96), (0.7, 0.99), (0.98, 0.99)]:
    pp = PhelpsProblem(λ=λ, δ=δ)
    y_lq = pp.f1 / (1 - pp.f2)
    y_cf = pp.θ * pp.U_star * (1 - δ) / (1 - δ * λ)
    print(f"λ = {λ}, δ = {δ}:  LQ steady state = {y_lq:.4f},  formula = {y_cf:.4f}")
```

```
λ = 0.7, δ = 0.96:  LQ steady state = 0.6098,  formula = 0.6098
λ = 0.9, δ = 0.96:  LQ steady state = 1.4706,  formula = 1.4706
λ = 0.7, δ = 0.99:  LQ steady state = 0.1629,  formula = 0.1629
λ = 0.98, δ = 0.99:  LQ steady state = 1.6779,  formula = 1.6779
```

101.4 Disinflation paths

We now reproduce the disinflation experiments of chapter 5 of Sargent [1999].

Set $\theta = 1$ and $U^* = 5$, and start the government's problem from late-1970s initial conditions $x_{-1} = y_{-1} = 12$, which imply $U = U^* = 5$.

The following tables record paths of unemployment U and inflation y at selected lags, for two discount factors $\delta \in \{0.96, 1\}$ and two adaptation parameters $\lambda \in \{0.7, 0.9\}$.

```
def disinflation_table(δ, lags=(1, 5, 20, 50)):
    rows = []
    for λ in [0.7, 0.9]:
        U, y = PhelpsProblem(λ=λ, δ=δ).simulate(x0=12.0, T=max(lags) + 1)
        for lag in lags:
            rows.append((λ, lag, U[lag - 1], y[lag - 1]))
    return rows

for δ in [0.96, 1.0]:
    print(f"\n δ = {δ}")
    print(f" {'λ':>4} {'lag':>4} {'U':>7} {'y':>7}")
    for λ, lag, U, y in disinflation_table(δ):
        print(f" {λ:>4} {lag:>4} {U:>7.2f} {y:>7.2f}")
```

```
δ = 0.96
   λ  lag       U       y
 0.7    1   12.59    4.41
 0.7    5    8.11    2.17
 0.7   20    5.11    0.66
 0.7   50    5.00    0.61
 0.9    1   11.87    5.13
 0.9    5   10.24    4.27
 0.9   20    6.91    2.49
 0.9   50    5.25    1.61

δ = 1.0
   λ  lag       U       y

 0.9    5   11.28    2.70
 0.9   20    7.12    0.91
 0.9   50    5.24    0.10
```

For each parameter setting the government engineers a major recession and immediately brings inflation down more than halfway toward its eventual limiting value.

In the discounted case ($\delta = 0.96$), inflation settles at the positive level y_∞ of (101.5), and the government accepts a longer but milder recession when $\lambda = 0.9$ than when $\lambda = 0.7$.

In the undiscounted case ($\delta = 1$), inflation is driven all the way to the Ramsey value of zero, more slowly the larger is λ.

Let's plot the full paths, with the inherited inflation rate of 12 shown at $t = 0$.

```
T = 40
t = np.arange(T + 1)
fig, axes = plt.subplots(2, 2, figsize=(11, 7), sharex=True)

for j, δ in enumerate([0.96, 1.0]):
    for λ in [0.7, 0.9]:
        U, y = PhelpsProblem(λ=λ, δ=δ).simulate(x0=12.0, T=T)
        axes[0, j].plot(t, np.concatenate([[12.0], y]), lw=1.5,
                        label=rf'$\lambda = {λ}$')
        axes[1, j].plot(t, np.concatenate([[5.0], U]), lw=1.5,
                        label=rf'$\lambda = {λ}$')
    axes[0, j].set_title(rf'$\delta = {δ}$')
    axes[0, j].set_ylabel('inflation $y_t$')
    axes[1, j].axhline(5.0, color='k', ls=':', lw=1)
    axes[1, j].set_ylabel('unemployment $U_t$')
    axes[1, j].set_xlabel('period ($t = 0$: inherited $y = 12$)')
    axes[0, j].legend()

plt.tight_layout()
plt.show()
```

The undiscounted problem drives inflation to the Ramsey outcome; the discounted problem stops short of it.

In both, the government buys its immediate disinflation with a recession: unemployment jumps far above U^* in the first period and returns to U^* as expectations catch up.

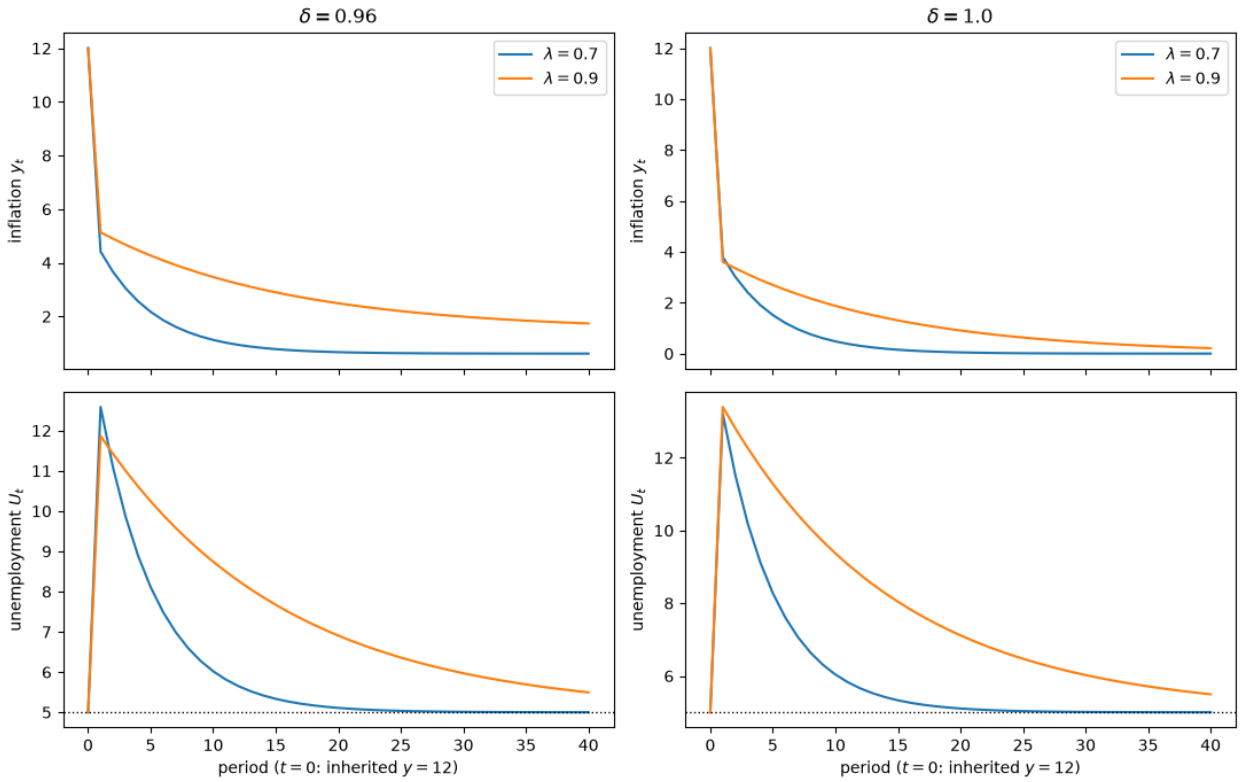

Fig. 101.2: Optimal disinflation paths from the Phelps problem, discounted and undiscounted

101.5 The general Phelps problem

For the government's control problem, what matters is the *reduced form* of the Phillips curve, not the underlying structure that identifies x_t.

It is useful to state a more general version of the Phelps problem in which the government's model is a reduced-form distributed lag Phillips curve.

Following Sargent [1999], define the vectors

$$X_{U,t-1} = \begin{bmatrix} U_{t-1} & \cdots & U_{t-m_U} \end{bmatrix}^\top, \qquad X_{y,t-1} = \begin{bmatrix} y_{t-1} & \cdots & y_{t-m_y} \end{bmatrix}^\top,$$

and $X_{t-1} = \begin{bmatrix} X_{U,t-1}^\top & X_{y,t-1}^\top & 1 \end{bmatrix}^\top$, which collects information dated $t-1$ and earlier.

X_{t-1} is the state vector of the general Phelps problem.

We can write two reduced-form Phillips curves that differ only in their *direction of fit*:

$$\text{Classical:} \quad U_t = \gamma^\top X_{C,t} + \varepsilon_{C,t}, \qquad X_{C,t} = \begin{bmatrix} y_t & X_{t-1}^\top \end{bmatrix}^\top,$$

$$\text{Keynesian:} \quad y_t = \beta^\top X_{K,t} + \varepsilon_{K,t}, \qquad X_{K,t} = \begin{bmatrix} U_t & X_{t-1}^\top \end{bmatrix}^\top.$$

The subscripts C and K stand for *Classical* (regress U on y) and *Keynesian* (regress y on U).

The general **Phelps problem** is to choose a control law $\hat{y}_t = hX_{t-1}$ to maximize the expected value of (101.3) subject to the government's believed Phillips curve and to $y_t = \hat{y}_t + v_{2t}$, where v_{2t} is a control error.

This induces a mapping from the government's beliefs γ to its decision rule h:

$$h = h(\gamma). \tag{101.6}$$

These objects — γ, β, $h(\gamma)$, and the two directions of fit — are exactly the ingredients we will need to define **self-confirming equilibria** in *Self-Confirming Equilibria*.

101.5.1 The adaptive case in general form

The specific problem solved above is the special case in which γ is restricted by substituting the adaptive expectations hypothesis (101.1) into the Phillips curve (101.4).

To find the restriction, use (101.4) at $t-1$ to write $x_{t-1} = y_{t-1} + (U_{t-1} - U^*)/\theta$, substitute it into (101.1), and substitute the result into (101.4):

$$U_t = (1-\lambda)U^* - \theta y_t + \lambda U_{t-1} + \theta y_{t-1}. \tag{101.7}$$

This is a classical Phillips curve with one lag of each variable ($m_U = m_y = 1$) and coefficients $\gamma = \begin{bmatrix} -\theta & \lambda & \theta & (1-\lambda)U^* \end{bmatrix}^\top$ on $X_{C,t} = \begin{bmatrix} y_t & U_{t-1} & y_{t-1} & 1 \end{bmatrix}^\top$.

Once that substitution is made, the state variable x_t disappears from view.

The induction hypothesis is visible in (101.7): the weights on current and lagged inflation sum to $-\theta + \theta = 0$.

Solved for y_t, (101.7) becomes the Keynesian curve $y_t = y_{t-1} + \theta^{-1}\left[(1-\lambda)U^* + \lambda U_{t-1} - U_t\right]$, with a weight of exactly one on lagged inflation.

Because $x_t = y_{t-1} + \lambda(U_{t-1} - U^*)/\theta$, the rule $y_t = f_1 + f_2 x_t$ of the original problem is, in terms of $X_{t-1} = \begin{bmatrix} U_{t-1} & y_{t-1} & 1 \end{bmatrix}^\top$,

$$h = \begin{bmatrix} f_2\lambda/\theta & f_2 & f_1 - f_2\lambda U^*/\theta \end{bmatrix}. \tag{101.8}$$

Let's confirm this by solving the general Phelps problem directly.

With state X_{t-1}, control y_t, and a believed curve $U_t = \gamma_y y_t + c^\top X_{t-1}$, where γ_y is the coefficient on y_t and c collects the rest, the problem is again an LQ problem.

Adaptive Learning and Escape Dynamics solves the same problem, with two lags of each variable, for a government that re-estimates γ every period.

```
def phelps_general(γ, δ):
    """
    Solve the general Phelps problem for the believed classical curve
    U_t = γ[0] y_t + γ[1] U_{t-1} + γ[2] y_{t-1} + γ[3].
    Returns h, with ŷ_t = h @ [U_{t-1}, y_{t-1}, 1].
    """
    γ_y = γ[0]
    c = np.asarray(γ[1:], dtype=float).reshape(-1, 1)
    R = 0.5 * (c @ c.T)
    Q = np.array([[0.5 * (γ_y**2 + 1)]])
    N = 0.5 * γ_y * c.T
    A = np.vstack([c.T, [0.0, 0.0, 0.0], [0.0, 0.0, 1.0]])  # next state (U_t, y_t, 1)
    B = np.array([[γ_y], [1.0], [0.0]])
    lq = qe.LQ(Q, R, A, B, N=N, beta=min(δ, 1 - 1e-7))
    P, F, d = lq.stationary_values()
    return -F[0]
```

(continues on next page)

(continued from previous page)

```
θ, U_star, λ, δ = 1.0, 5.0, 0.7, 0.96
y_adaptive = np.array([-θ, λ, θ, (1 - λ) * U_star])
pp = PhelpsProblem(θ=θ, U_star=U_star, λ=λ, δ=δ)

h_general = phelps_general(y_adaptive, δ)
h_from_x = np.array([pp.f2 * λ / θ, pp.f2, pp.f1 - pp.f2 * λ * U_star / θ])
print("h from the general problem:  ", h_general.round(4))
print("h from the x-state rule:     ", h_from_x.round(4))
```

```
h from the general problem:   [ 0.2338  0.334  -0.7628]
h from the x-state rule:      [ 0.2338  0.334  -0.7628]
```

The two agree: the original Phelps problem is the general one with γ restricted by (101.7).

Note

The **induction hypothesis** is the restriction that, in the Keynesian Phillips curve $y_t = \beta^\top X_{K,t} + \varepsilon_{K,t}$, the weights on lagged y's sum to unity (equivalently, in the classical form the weights on current and lagged y's sum to zero).

Under adaptive expectations this holds because the weights in (101.2) sum to one, as (101.7) shows.

101.6 Testing the natural-rate hypothesis

Robert Solow and James Tobin [Solow, 1968, Tobin, 1968] exploited the induction hypothesis to test the natural-rate hypothesis.

Substituting the geometric distributed lag (101.2) into an inverted Phillips curve gives

$$y_t = (1-\lambda)\sum_{i=1}^{\infty}\lambda^{i-1}y_{t-i} + \theta^{-1}(U^* - U_t). \tag{101.9}$$

They proposed to test the natural-rate hypothesis by running the regression

$$y_t = b_0 + b_1(1-\lambda)\sum_{i=1}^{\infty}\lambda^{i-1}y_{t-i} + b_2 U_t + \varepsilon_t, \tag{101.10}$$

and interpreting a finding of $b_1 < 1$ as evidence of a long-run tradeoff between inflation and unemployment.

In a steady state with constant inflation, (101.10) implies the long-run slope $dU/dy = (1-b_1)/b_2$, which equals $\theta(b_1-1)$ when b_2 takes its value $-1/\theta$ from (101.9).

Early implementations found $b_1 < 1$ and so rejected the natural-rate hypothesis in favor of a long-run tradeoff.

Later implementations of the same tests failed to reject it.

Lucas [1972] and Sargent [1971] argued that the rejections did not bear on the natural-rate hypothesis.

Solow and Tobin had deduced the restriction $b_1 = 1$ by using the induction hypothesis to identify expected inflation.

But the induction hypothesis describes one particular experiment, a permanent and fixed inflation rate, which may be very unlikely under the stochastic process that actually governs inflation in the sample.

Under rational expectations, the weights that link expected to past inflation are restricted by that process, and they need not sum to one.

For example, suppose that inflation is a stationary AR(1) process with root ρ, that $x_t = \mathbb{E}_{t-1} y_t$, and that the natural-rate Phillips curve holds.

Then the population regression (101.10) delivers

$$b_1 = \frac{\rho(1+\lambda)}{1+\lambda\rho} < 1, \tag{101.11}$$

a "rejection" of a hypothesis that is true (Exercise 101.8.2 derives the formula and checks it by simulation).

The estimate approaches one as $\rho \to 1$.

According to an argument of Sargent [1971] and King and Watson [1994], this is why the pattern of rejections and non-rejections is consistent with the tendency of inflation to have a unit root after the 1960s but not before: the unit-sum restriction $b_1 = 1$ is *compatible* with rational expectations when y_t has a unit root.

The self-confirming equilibria of *Self-Confirming Equilibria* give another illustration: rational expectations and the natural-rate hypothesis both hold there, and the induction hypothesis fails.

From the viewpoint of Phelps's control problem, it is incidental whether the natural-rate hypothesis holds: the Phelps problem imparts interesting dynamics to the inflation-unemployment choice whether or not $b_1 = 1$.

The public's expectations themselves disappear from the problem; what matters is the zero-frequency behavior of the distributed lag of y in (101.10).

101.7 Sacrifice ratios and the subversion of the Phelps model

Large *sacrifice ratios* — estimated amounts of foregone output required to bring inflation down one percentage point — circulated widely in the late 1970s.

The adaptive model delivers a sacrifice ratio in a simple exact form.

101.7.1 The sacrifice ratio

By (101.4) and (101.1),

$$U_t - U^* = -\theta(y_t - x_t) = -\frac{\theta}{1-\lambda}(x_{t+1} - x_t).$$

Summing over $t = 1, \dots, T$ telescopes the right side:

$$\sum_{t=1}^{T}(U_t - U^*) = \frac{\theta}{1-\lambda}\,(x_1 - x_{T+1}). \tag{101.12}$$

Cumulative excess unemployment per point of reduction in expected inflation is therefore $\theta/(1-\lambda)$, for *any* policy path and whatever the government's discount factor.

Because expected and actual inflation coincide in a steady state, this is also the cost of each point of permanent disinflation.

The government cannot change the ratio.

It can choose only how far to disinflate and how to spread the unemployment over time; with a quadratic loss it spreads it out.

With $\theta = 1$ the ratio is 3.33 when $\lambda = 0.7$ and 10 when $\lambda = 0.9$.

Let's check this along the optimal paths.

```
for λ in [0.7, 0.9]:
    for δ in [0.96, 1.0]:
        U, y = PhelpsProblem(λ=λ, δ=δ).simulate(x0=12.0, T=2000)
        ratio = np.sum(U - 5.0) / (12.0 - y[-1])
        print(f"λ = {λ}, δ = {δ}:  sacrifice ratio = {ratio:.3f},  "
              f"θ/(1-λ) = {1 / (1 - λ):.3f}")
```

```
λ = 0.7, δ = 0.96:  sacrifice ratio = 3.333,  θ/(1-λ) = 3.333
λ = 0.7, δ = 1.0:  sacrifice ratio = 3.333,  θ/(1-λ) = 3.333
λ = 0.9, δ = 0.96:  sacrifice ratio = 10.000,  θ/(1-λ) = 10.000
λ = 0.9, δ = 1.0:  sacrifice ratio = 10.000,  θ/(1-λ) = 10.000
```

Long expectations lags, λ near one, imply large sacrifice ratios.

101.7.2 The subversion of the Phelps model

Despite its encouraging implications for sustaining the Ramsey outcome under the induction hypothesis, Phelps's control problem carries a tattered past.

For a fixed $\delta < 1$, it is always possible to find a λ close enough to one that high inherited inflationary expectations make the government want to avoid the Ramsey outcome.

Formula (101.5) shows why: $y_\infty \to \theta U^*$, the Nash rate, as $\lambda \to 1$.

The next cell fixes $\delta = 0.96$ and lets λ approach one.

```
δ = 0.96
print(f"{'λ':>6} {'first-period y':>15} {'y_∞':>7} {'θ/(1-λ)':>9}")
for λ in [0.7, 0.9, 0.95, 0.99, 0.999]:
    pp = PhelpsProblem(λ=λ, δ=δ)
    y_first = pp.f1 + pp.f2 * 12.0
    y_inf = pp.θ * pp.U_star * (1 - δ) / (1 - δ * λ)
    print(f"{λ:>6} {y_first:>15.2f} {y_inf:>7.2f} {pp.θ / (1 - λ):>9.1f}")
```

```
     λ  first-period y     y_∞   θ/(1-λ)
   0.7            4.41    0.61       3.3
   0.9            5.13    1.47      10.0
  0.95            5.92    2.27      20.0
  0.99            7.64    4.03     100.0
 0.999            8.40    4.88    1000.0
```

The government still cuts inflation sharply in the first period, but it stops far short of zero, and each point of disinflation costs $\theta/(1-\lambda)$ points of unemployment.

In the late 1970s, models with long expectations-adjustment lags were used in this way to recommend *against* reducing inflation, fortifying those who advocated learning to live with high inflation.

By stressing the cross-equation restrictions of rational expectations, Lucas [1972] and Sargent [1971] argued that historical estimates of λ are silent about the optimal speed of disinflation: λ describes how expectations responded to past policy, not how they would respond to a new one.

The lesson to carry forward is that activating the induction hypothesis can eventually lead to better outcomes, but in the form that Phelps, Tobin, and Solow used it, the induction hypothesis retreats from rational expectations.

In *Optimal Misspecified Beliefs* and *Self-Confirming Equilibria* the adaptation parameter becomes an equilibrium outcome, $C = 1 - \lambda$, chosen by the public to fit the data that its own forecasts help generate.

From *Adaptive Learning and Escape Dynamics* on, the government applies updating schemes like (101.1) to functions, the coefficients of its Phillips curve, rather than to numbers.

The LQ Phelps problem solved here returns in *Adaptive Learning and Escape Dynamics*, *Escaping Nash Inflation*, *Priors, Escapes, and Learning Cycles*, and *The Lost Conquest: Fed Policy in the 2020s*, where a learning government re-solves it every period.

In *Adaptive Learning and Escape Dynamics*, it is the drift of the government's estimated Phillips curve toward the induction hypothesis that triggers the Volcker-like stabilizations.

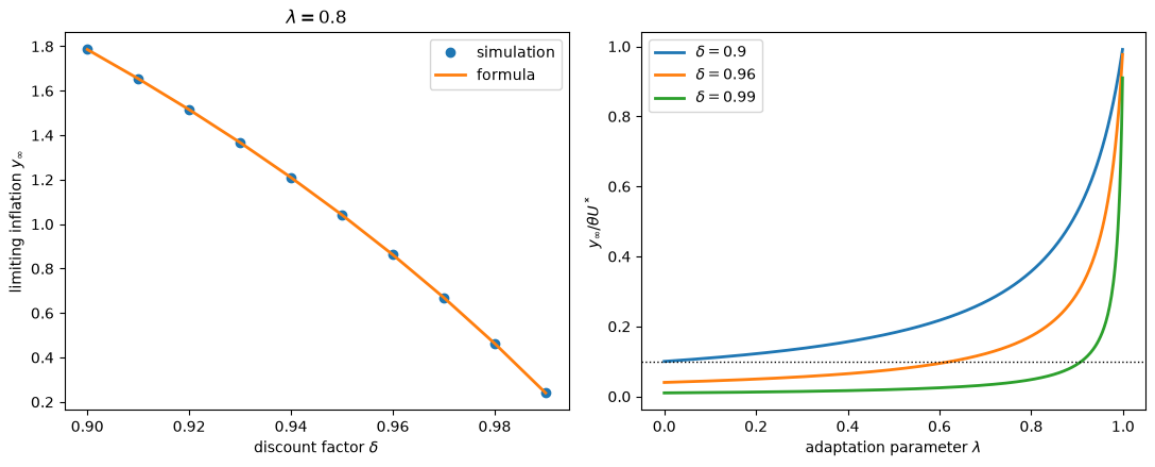
101.8 Exercises

Exercise 101.8.1

Formula (101.5) makes the comparison of λ with δ exact.

1. For $\lambda = 0.8$, compute the limiting inflation rate y_∞ (the value that y_t settles at after a long simulation) for a grid of discount factors $\delta \in \{0.90, 0.91, \ldots, 0.99\}$, plot it against δ, and overlay (101.5).
2. Plot $y_\infty / \theta U^*$ against $\lambda \in [0, 0.999]$ for $\delta \in \{0.9, 0.96, 0.99\}$.
3. For each of these δ, how small must λ be for y_∞ to be within 10% of the Ramsey value, that is, $y_\infty \leq 0.1\, \theta U^*$?

Solution



```
δ_grid = np.arange(0.90, 0.995, 0.01)
y_sim = [PhelpsProblem(λ=0.8, δ=δ).simulate(x0=12.0, T=400)[1][-1]
         for δ in δ_grid]
y_formula = 5.0 * (1 - δ_grid) / (1 - δ_grid * 0.8)

λ_grid = np.linspace(0, 0.999, 500)

fig, axes = plt.subplots(1, 2, figsize=(11, 4.5))
axes[0].plot(δ_grid, y_sim, 'o', label='simulation')
axes[0].plot(δ_grid, y_formula, lw=2, label='formula')
axes[0].set_xlabel(r'discount factor $\delta$')
axes[0].set_ylabel(r'limiting inflation $y_\infty$')
axes[0].set_title(r'$\lambda = 0.8$')
axes[0].legend()

for δ in [0.9, 0.96, 0.99]:
    axes[1].plot(λ_grid, (1 - δ) / (1 - δ * λ_grid), lw=2,
                 label=rf'$\delta = {δ}$')
    λ_max = (1 - 10 * (1 - δ)) / δ
    print(f"δ = {δ}: y_∞ ≤ 0.1 θU* requires λ ≤ {λ_max:.3f}")
axes[1].axhline(0.1, color='k', ls=':', lw=1)
axes[1].set_xlabel(r'adaptation parameter $\lambda$')
axes[1].set_ylabel(r'$y_\infty / \theta U^*$')
axes[1].legend()
plt.tight_layout()
plt.show()
```

```
δ = 0.9: y_∞ ≤ 0.1 θU* requires λ ≤ 0.000
δ = 0.96: y_∞ ≤ 0.1 θU* requires λ ≤ 0.625
δ = 0.99: y_∞ ≤ 0.1 θU* requires λ ≤ 0.909
```

The simulated limits lie on the formula.

As δ rises toward one, the government becomes willing to accept the transitional recession needed to reap the long-run benefit of low expected inflation, so the limiting inflation rate falls toward the Ramsey value of zero.

From (101.5), $y_\infty \leq 0.1\,\theta U^*$ requires $1 - \delta\lambda \geq 10(1-\delta)$, that is, $\lambda \leq [1 - 10(1-\delta)]/\delta$.

When $\delta = 0.9$ no $\lambda \in (0,1)$ qualifies, and even when $\delta = 0.99$ the public must adapt fast enough that λ is below about 0.91.

As $\lambda \to 1$ every curve rises to one: very slow adaptation subverts the Phelps model, whatever the discount factor.

Exercise 101.8.2

This exercise reproduces the Lucas–Sargent critique of the Solow–Tobin test, in the form of (101.11).

Consider an economy in which both the natural-rate hypothesis and rational expectations hold:

$$y_t = (1-\rho)\mu + \rho y_{t-1} + e_t, \qquad x_t = \mathbb{E}_{t-1} y_t, \qquad U_t = U^* - \theta(y_t - x_t) + v_{1t},$$

where e_t and v_{1t} are independent white noises with variances σ_e^2 and σ_1^2, and $|\rho| < 1$.

1. Show that the population regression (101.10) has $b_1 = \rho(1+\lambda)/(1+\lambda\rho)$ and $b_2 = -\theta\sigma_e^2/(\theta^2\sigma_e^2 + \sigma_1^2)$.
2. Verify both by simulation, with $\lambda = 0.7$, $\theta = 1$, $U^* = 5$, $\mu = 4$, $\sigma_e = 1$, $\sigma_1 = 0.5$, and $\rho \in \{0, 0.5, 0.9, 0.99\}$.
3. Interpret the results.

Solution

Write $z_t = (1-\lambda)\sum_{i\geq 1} \lambda^{i-1} y_{t-i}$ for the regressor in (101.10).

Under rational expectations $y_t = x_t + e_t$ with $x_t = (1-\rho)\mu + \rho y_{t-1}$, and $U_t - U^* = -\theta e_t + v_{1t}$.

Because U_t depends only on current shocks, it is uncorrelated with z_t and with x_t, so the two slopes can be computed one at a time.

The coefficient on U_t is $b_2 = \operatorname{cov}(e_t, U_t)/\mathbb{V}[U_t] = -\theta\sigma_e^2/(\theta^2\sigma_e^2 + \sigma_1^2)$.

The coefficient on z_t is $b_1 = \operatorname{cov}(x_t, z_t)/\mathbb{V}[z_t] = \rho \operatorname{cov}(y_{t-1}, z_t)/\mathbb{V}[z_t]$.

With $\gamma_0 = \mathbb{V}[y_t]$ and autocovariances $\gamma_0 \rho^j$,

$$\operatorname{cov}(y_{t-1}, z_t) = \frac{(1-\lambda)\gamma_0}{1-\lambda\rho}, \qquad \mathbb{V}[z_t] = \frac{(1-\lambda)^2\gamma_0(1+\lambda\rho)}{(1-\lambda^2)(1-\lambda\rho)},$$

and the ratio gives $b_1 = \rho(1+\lambda)/(1+\lambda\rho)$.

```
rng = np.random.default_rng(0)
λ, θ, U_star, μ, σ_e, σ_1, T = 0.7, 1.0, 5.0, 4.0, 1.0, 0.5, 200_000
burn = 2_000

for ρ in [0.0, 0.5, 0.9, 0.99]:
    e = σ_e * rng.standard_normal(T)
    v1 = σ_1 * rng.standard_normal(T)
    y = μ + lfilter([1.0], [1.0, -ρ], e)                    # AR(1) around μ
    U = U_star - θ * e + v1                                  # y_t - x_t = e_t
    z = lfilter([0.0, 1 - λ], [1.0, -λ], y)                 # (1-λ) Σ λ^{i-1} y_{t-i}
    X = np.column_stack([np.ones(T - burn), z[burn:], U[burn:]])
    b0, b1, b2 = np.linalg.lstsq(X, y[burn:], rcond=None)[0]
    print(f"ρ = {ρ:<4}:  b1 = {b1:.3f} (formula {ρ * (1 + λ) / (1 + λ * ρ):.3f}),"
          f"  b2 = {b2:.3f} (formula {-θ * σ_e**2 / (θ**2 * σ_e**2 + σ_1**2):.3f})
↪")
```

```
ρ = 0.0 :  b1 = -0.003 (formula 0.000),  b2 = -0.799 (formula -0.800)
ρ = 0.5 :  b1 = 0.633 (formula 0.630),  b2 = -0.801 (formula -0.800)
ρ = 0.9 :  b1 = 0.940 (formula 0.939),  b2 = -0.800 (formula -0.800)
ρ = 0.99:  b1 = 0.994 (formula 0.994),  b2 = -0.800 (formula -0.800)
```

The estimates match the formulas.

In every case $b_1 < 1$, so the Solow–Tobin test rejects the natural-rate hypothesis even though it is true here.

The induction hypothesis builds in weights that sum to one, but rational expectations of a stationary process do not.

As $\rho \to 1$ the bias vanishes, which is the King–Watson reading of why later tests, run on data in which inflation had a unit root, stopped rejecting.

The coefficient b_2 is the slope that a *Keynesian* regression of inflation on unemployment recovers.

It is the slope β_1 of the Keynesian self-confirming equilibrium in *Self-Confirming Equilibria*, with σ_e in the role of σ_2.

Exercise 101.8.3

The sacrifice ratio (101.12) does not depend on the policy.

Fix $\delta = 0.96$ and take $\lambda \in \{0.7, 0.9, 0.95, 0.99\}$, starting from $x = 12$.

1. Compute cumulative excess unemployment per point of disinflation along the optimal path.
2. Do the same for a "cold turkey" policy that sets $y_t = 0$ forever, and for a gradual policy that lowers inflation by one point per period, starting from 11, until it reaches zero.
3. Compare the three with $\theta/(1-\lambda)$, and explain why the optimal policy nonetheless differs from cold turkey.

Solution

```

↪00
```

All three policies cost $\theta/(1-\lambda)$ points of unemployment per point of disinflation, as (101.12) says they must.

The policies differ in how far they disinflate and in how they spread the unemployment over time.

Cold turkey takes inflation all the way to zero, and front-loads the recession.

The optimal discounted policy stops at $y_\infty > 0$ for the reason given after (101.5): near the steady state, the discounted benefit of the last point of disinflation, $y_\infty/(1-\delta)$, just equals its discounted unemployment cost, $\theta U^*/(1-\delta\lambda)$.

As $\lambda \to 1$ that cost rises toward $\theta U^*/(1-\delta)$, so y_∞ rises toward θU^*.

With a quadratic loss, the government also prefers to spread the unemployment out rather than take it all at once.

102.1 Overview

This lecture continues the study of Phillips curve tradeoffs.

It follows chapter 6 of Sargent [1999].

In *Adaptive Expectations and the Phelps Problem* the public forecast inflation with a fixed adaptive rule whose parameter λ we simply chose.

That was unsatisfying in a way the *vindication* story of *The Rise and Fall of U.S. Inflation* cannot afford: a free parameter describing expectations is exactly what rational expectations was meant to eliminate.

Here we take the first step toward earning that parameter, by letting agents choose it to fit the data their own beliefs generate.

We describe three conceptual issues that recur throughout this suite of lectures:

1. how to formulate equilibria in which agents share a common *misspecified* least squares forecasting model,
2. how expectations can contribute independent dynamics within equilibria, and
3. how the classic adaptive expectations scheme can use second moments to approximate a first moment.

To expose these issues we temporarily set aside the Phillips curve and work with Bray [1982]'s simple model of the price of a single good, a workhorse for studying bounded rationality.

From relaxation to learning: Bray's market presents Bray's model as the relaxation algorithm with a gain of $1/t$, and *Least Squares Learning in Self-Referential Models* studies least squares learning in it.

We alter Bray's model to illustrate an equilibrium concept that merges aspects of rational and adaptive expectations in a new way, and that we apply to the Phillips curve in *Self-Confirming Equilibria*.

The focus is on **market equilibrium with optimal but misspecified forecasts**.

- *Optimal* means the free parameters of the forecasting scheme are chosen by (nonlinear) least squares.
- *Misspecified* means the forecasting model is wrong in functional form, or uses too small an information set.

A distinctive feature is that the true model *depends on* how the agents' model is misspecified: agents' beliefs affect their behavior, which shapes the data they then fit.

We will also see that the equilibrium depends on a detail of the agents' model, a root ρ that they place just below one, and that the forecasting gain it delivers vanishes as $\rho \to 1$.

We work in the frequency domain, so let's import what we need:

```
import matplotlib.pyplot as plt
import numpy as np
from scipy.optimize import minimize_scalar
from scipy.signal import lfilter
```

102.2 An experiment in Bray's lab

Following Bray [1982], assume that

$$p_t = a + b\, p^e_{t+1} + u_t, \tag{102.1}$$

where u_t is IID with mean zero and variance σ_u^2, $a > 0$, $b \in (0, 1)$, p_t is the market price, and p^e_{t+1} is the market's expectation of next period's price.

In the notation of *From relaxation to learning: Bray's market*, Bray's b is the feedback coefficient h'.

The rational expectations equilibrium has $p^e_{t+1} = \frac{a}{1-b}$ and $p_t = \frac{a}{1-b} + u_t$.

Bray posited that p^e_{t+1} is the empirical average of past prices, and showed that when $0 < b < 1$ this decreasing-gain scheme converges almost surely to the rational expectation $\frac{a}{1-b}$.

During the transition, the state variable p^e_t contributes dynamics and makes the price serially correlated, but these dynamics are transitory: at the rational expectations equilibrium, p_t is a constant plus a serially uncorrelated shock.

102.2.1 Constant-gain adaptive expectations

To let expectations impart *persistent* serial correlation, we depart from Bray and assume that the market has **constant-gain** adaptive expectations,

$$p^e_{t+1} = C p_t + (1 - C) p^e_t, \qquad |C| < 1. \tag{102.2}$$

Bray's scheme replaces C by $\frac{1}{t}$, so that p^e_{t+1} becomes a sample average.

Fixing C instead *discounts* past observations, which arrests convergence to rational expectations and prevents p^e_{t+1} from converging to a constant.

Written as a distributed lag,

$$p^e_{t+1} = \frac{C}{1 - (1 - C)L} p_t, \tag{102.3}$$

where L is the lag operator.

Equation (102.2) would be the linear least squares forecast if the price followed the integrated moving-average process

$$p_t = p_{t-1} + \epsilon_t - (1-C)\epsilon_{t-1}, \tag{102.4}$$

so the market perceives the price as composed of purely permanent and transitory components.

This is the answer to Muth [1960]'s inverse optimal-prediction problem in *A Peculiar Definition of Bounded Rationality*, with Muth's moving-average coefficient equal to $1-C$.

Equivalently, the perceived model is a *local-level* model, a random walk observed with white noise.

For it, (102.2) is the steady-state Kalman filter of *Convergence*, and the gain C is tied to the ratio q/r of the variance of the random-walk innovation to that of the noise by $q/r = C^2/(1-C)$ (Exercise 102.7.4).

Muth asked for which process a given smoothing rule is optimal.

Here the process is generated by the rule, and agents choose the rule to fit the process.

102.2.2 The actual law of motion

Substituting the belief (102.3) into (102.1) shows that when the market forecasts this way, its actions make the *actual* law of motion for the price

$$p_t = \frac{a}{1-b} + \frac{1}{1-bC}\left[\frac{1-(1-C)L}{1-\frac{1-C}{1-bC}L}\right] u_t = \nu + f(L)u_t, \tag{102.5}$$

where $\nu = \frac{a}{1-b}$ and $f(L)$ is defined to match.

The price has mean ν and spectral density

$$F(\omega) = f(e^{i\omega})f(e^{-i\omega})\,\sigma_u^2, \qquad \omega \in [-\pi, \pi].$$

Notice that F depends on C through f.

Let's encode the true process.

```
class BrayModel:
    """
    Bray's price model with constant-gain adaptive expectations.

    ρ is the root of the agents' perceived ARMA(1,1) model, which stands in
    for the unit root of the integrated moving-average model (see below).
    """

    def __init__(self, a=1.0, b=0.5, σ_u=1.0, ρ=0.995, N=1024):
        self.a, self.b, self.σ_u, self.ρ, self.N = a, b, σ_u, ρ, N
        self.ν = a / (1 - b)
        ω = 2 * np.pi * np.arange(N) / N
        self.ω = ω
        self.z = np.exp(1j * ω)

    def true_spectrum(self, C):
        "Spectral density F(ω) of the actual price process, given belief C."
        b, z = self.b, self.z
        ψ = (1 - C) / (1 - b * C)
        scale = 1 / (1 - b * C)
```

(continues on next page)

(continued from previous page)

```
        f = scale * (1 - (1 - C) * z) / (1 - ψ * z)
        return np.abs(f)**2 * self.σ_u**2

    def approx_spectrum(self, c, σ_ε2=1.0):
        "Spectral density G(ω) of the agent's approximating model."
        g = (1 - (1 - c) * self.z) / (1 - self.ρ * self.z)
        return np.abs(g)**2 * σ_ε2
```

102.3 Optimal misspecification

Two facts about the actual law (102.5) motivate an equilibrium restriction on C:

1. Given that the price obeys (102.5), the true linear least squares one-step forecasting rule is *not* a geometric distributed lag like (102.2).
2. Even restricting the forecast to the form (102.2), the *best* such rule would make C solve a forecast-error-minimization problem, so C is an outcome, not a free parameter.

A rational expectations equilibrium would repair both features.

Chapter 6 of Sargent [1999] softens the equilibrium concept, proceeding "in the spirit (but not the letter)" of Lucas and Prescott [1971] and Brock [1972]: we leave feature 1 untouched (agents keep the wrong functional form) while fixing feature 2 (they choose the best parameter within that form).

Think of putting a single individual into a market where everyone else (the "representative agent") uses C, so the price obeys (102.5).

This "big C, little c" device is the "big Y, little y" trick of *Rational Expectations Equilibrium*, applied to a forecasting rule rather than to a decision rule.

The individual chooses c to fit the best model of the form

$$p_t = \frac{1-(1-c)L}{1-L}\epsilon_t, \tag{102.6}$$

by minimizing the one-step-ahead forecast error variance.

102.3.1 The perceived model and its root ρ

A model with the exact unit root of (102.6) cannot be fitted to data that have a mean, and its spectral density is infinite at frequency zero.

Following Sargent [1999] (chapter 6, footnotes 4 and 5), the agents' perceived model replaces the unit root by a root ρ slightly below one:

$$p_t = \frac{1-(1-c)L}{1-\rho L}\epsilon_t = g(L)\epsilon_t, \qquad 0<\rho<1. \tag{102.7}$$

This is a stationary, mean-zero ARMA(1,1) model.

It has no constant, so it must use the near-unit-root persistence of $1/(1-\rho L)$ to fit the nonzero mean ν of the price.

We treat ρ as a primitive of the perceived model, part of what agents believe, not as a numerical device: the equilibrium depends on it, as *How the equilibrium depends on \rho* shows.

Definition 102.3.1 (Best-estimate map)

Given C and the consequent price process (102.5), the individual's best forecast parameter $c = B(C)$ is the nonlinear least squares estimator of c in (102.7), where the data are generated by (102.5).

Inverting (102.7) gives the perceived model's one-step-ahead forecast error $\epsilon_t = g(L)^{-1} p_t$.

Applied to the actual price, this error has mean $\nu / g(1) = \nu(1-\rho)/c$ and a variance that we can compute from the spectral density F.

Following the frequency-domain method of Hansen and Sargent [Hansen and Sargent, 1993], the best approximating (c, σ_ϵ^2) minimizes

$$A(c, \sigma_\epsilon^2) = \frac{1}{N} \sum_{j=0}^{N-1} \left\{ \log G(\omega_j, c) + \frac{F(\omega_j)}{G(\omega_j, c)} \right\} + \frac{\nu^2}{G(0)}, \tag{102.8}$$

where $\omega_j = \frac{2\pi j}{N}$ and $G(\omega, c) = |g(e^{i\omega})|^2 \sigma_\epsilon^2$ is the spectral density of the perceived model.

The term $\frac{\nu^2}{G(0)} = \frac{\nu^2 (1-\rho)^2}{c^2 \sigma_\epsilon^2}$ charges the perceived model for the squared mean of its forecast errors; this is how the model is made to use its near-unit root to fit the mean.

Concentrating out σ_ϵ^2 sets it equal to the mean square forecast error

$$\sigma_\epsilon^2(c) = \frac{1}{N} \sum_{j=0}^{N-1} \frac{F(\omega_j)}{|g(e^{i\omega_j})|^2} + \frac{\nu^2 (1-\rho)^2}{c^2}. \tag{102.9}$$

The average of $\log |g(e^{i\omega})|^2$ over frequencies is zero, by Kolmogorov's formula for an invertible filter with $g(0) = 1$.

So minimizing (102.8) over c is the same as minimizing $\sigma_\epsilon^2(c)$: the agent chooses the c that minimizes the mean square one-step-ahead forecast error, computed under his model (102.7).

The mean term shows where ρ enters: a larger c shrinks the squared mean $\nu^2 (1-\rho)^2 / c^2$, so the closer ρ is to one, the weaker the pull toward a large c.

Definition 102.3.2 (Equilibrium under forecast misspecification)

An equilibrium under forecast misspecification is a fixed point $C = B(C)$.

At such a fixed point the representative agent is representative: the single individual's best parameter equals the one everyone uses.

```
def forecast_mse(F, ν, c, ρ, z):
    """
    Mean square one-step forecast error σ_ε^2(c) of the perceived model
    g(L) = (1 - (1-c)L)/(1 - ρL), when the true process has mean ν and
    spectral density F on the grid z = exp(iω).  ρ = 1 is allowed.
    """
    W = np.abs((1 - ρ * z) / (1 - (1 - c) * z))**2      # |1/g(e^{iω})|^2
    return np.mean(F * W) + ν**2 * W[0]                 # variance + squared mean

def best_estimate(model, C):
    "The best-estimate map c = B(C)."
    F = model.true_spectrum(C)
    res = minimize_scalar(lambda c: forecast_mse(F, model.ν, c, model.ρ, model.z),
                          bounds=(1e-4, 0.99), method='bounded',
```

(continues on next page)

(continued from previous page)

```
                           options={'xatol': 1e-10})
    return res.x

def solve_equilibrium(model, C0=0.3, tol=1e-10, maxit=500):
    "Iterate the best-estimate map to a fixed point."
    C = C0
    for _ in range(maxit):
        C_new = best_estimate(model, C)
        if abs(C_new - C) < tol:
            break
        C = C_new
    return C_new
```

Now we solve for the equilibrium of the baseline model.

```
bray = BrayModel(a=1.0, b=0.5, σ_u=1.0, ρ=0.995)
C_star = solve_equilibrium(bray)
print(f"equilibrium belief   C = {C_star:.4f}")
```

```
equilibrium belief   C = 0.0805
```

For these parameters the equilibrium belief is $C \approx 0.08$, reproducing the value reported in chapter 6 of Sargent [1999].

102.3.2 Forecast errors

Three standard deviations of one-step-ahead forecast errors describe the equilibrium:

- $\bar{\sigma}_\epsilon$, the root mean square forecast error of the perceived model (102.7) at $c = C$, including the mean of its errors: the square root of the minimized (102.9).
- the root mean square error of the rule (102.2) that agents actually use. Its weights sum to one, so its errors have mean zero; it is σ_ϵ computed with $\rho = 1$.
- $\sigma_u/(1 - bC)$, the standard deviation of the innovation in the true process (102.5), the smallest one-step error that any forecaster who knew the true law could attain.

```
F_star = bray.true_spectrum(C_star)
c_star = best_estimate(bray, C_star)

σ_bar = np.sqrt(forecast_mse(F_star, bray.ν, c_star, bray.ρ, bray.z))
σ_rule = np.sqrt(forecast_mse(F_star, bray.ν, C_star, 1.0, bray.z))
σ_true = bray.σ_u / (1 - bray.b * C_star)

print(f"perceived model (ρ = {bray.ρ}):    {σ_bar:.4f}")
print(f"rule actually used (ρ = 1):     {σ_rule:.4f}")
print(f"true innovation σ_u/(1 - bC):   {σ_true:.4f}")
```

```
perceived model (ρ = 0.995):    1.0579
rule actually used (ρ = 1):     1.0530
true innovation σ_u/(1 - bC):   1.0419
```

The first number is the $\bar{\sigma}_\epsilon$ that chapter 6 of Sargent [1999] reports.

The book gives 1.0208 for the last one, which is the square root of the value printed here.

The forecasts that agents actually make are only slightly worse than the best attainable ones.

102.3.3 What kind of equilibrium is this?

The fixed point $C = B(C)$ has several names in the later literature, each emphasizing a different feature.

- It is a **restricted-perceptions equilibrium** (Evans and Honkapohja [2001], chapter 13): forecasts are optimal within a restricted class of models that excludes the truth.
- For given C, the best estimate c is a **pseudo-true value** in the sense of White [1982], the parameter of a misspecified model that comes closest to the truth. Unlike in White's setting, here the truth itself depends on the agents' parameter, through C.
- Up to constants, criterion (102.8) is the frequency-domain (Whittle) form of the Kullback–Leibler divergence of the perceived model from the true process. So the fixed point is also a **Berk–Nash equilibrium** in the sense of Esponda and Pouzo [2016], with the forecasting rule as the agents' action.

Learning, Approximation, and Equilibrium Computation computes the same kind of object, which it calls an approximate equilibrium, for a saving rule restricted to a polynomial family.

There the agents' fit is a least squares projection onto a basis; here it is a nonlinear fit of an ARMA model across the whole spectrum.

Because B works like a best-response map, we can ask whether agents who nudge their gain toward the best estimate would find the equilibrium.

The associated differential equation $dC/d\tau = B(C) - C$ is the E-stability condition of *One recursion, many learners*: the fixed point is E-stable when $B'(C^*) < 1$.

```
h = 1e-4
B_prime = (best_estimate(bray, C_star + h) - best_estimate(bray, C_star - h)) / (2 *␣
 ↪h)
print(f"B'(C*) = {B_prime:.3f}")
```

```
B'(C*) = 0.148
```

Here $0 < B'(C^*) < 1$, so the equilibrium is E-stable, and iterating B converges to it monotonically, which is how `solve_equilibrium` found it.

Why don't the agents eventually discover that their model is wrong?

Kalai and Lehrer [1993] applied a merging theorem of Blackwell and Dubins [1962] to establish conditions under which forecasts must eventually merge with rational expectations.

The present model shuts off that mechanism at the outset: the agents' model puts zero probability on events that have positive probability under the truth, violating the absolute continuity condition that merging requires.

With enough data, appropriate statistical tests would eventually tell agents how to improve their forecasts.

Kreps [1998] argues that sensible agents would eventually abandon a misspecified model that the data reject; Exercise 102.7.3 estimates how much data that would take here.

The answer lies in how far apart the true and approximating spectral densities are, which we now study.

102.4 Comparing the true and forecasting models

For the equilibrium C, we plot the equilibrium spectral densities of the true and approximating models.

```
G = bray.approx_spectrum(c_star, σ_bar**2)

half = bray.N // 2
fig, ax = plt.subplots(figsize=(8, 5))
ax.plot(bray.ω[:half], np.log(F_star[:half]), 'C0', label='true model', lw=2)
ax.plot(bray.ω[:half], np.log(G[:half]), 'C1--', label='forecasting model', lw=2)
ax.set_xlabel(r'angular frequency $\omega$')
ax.set_ylabel('log spectral density')
ax.legend()
plt.show()
```

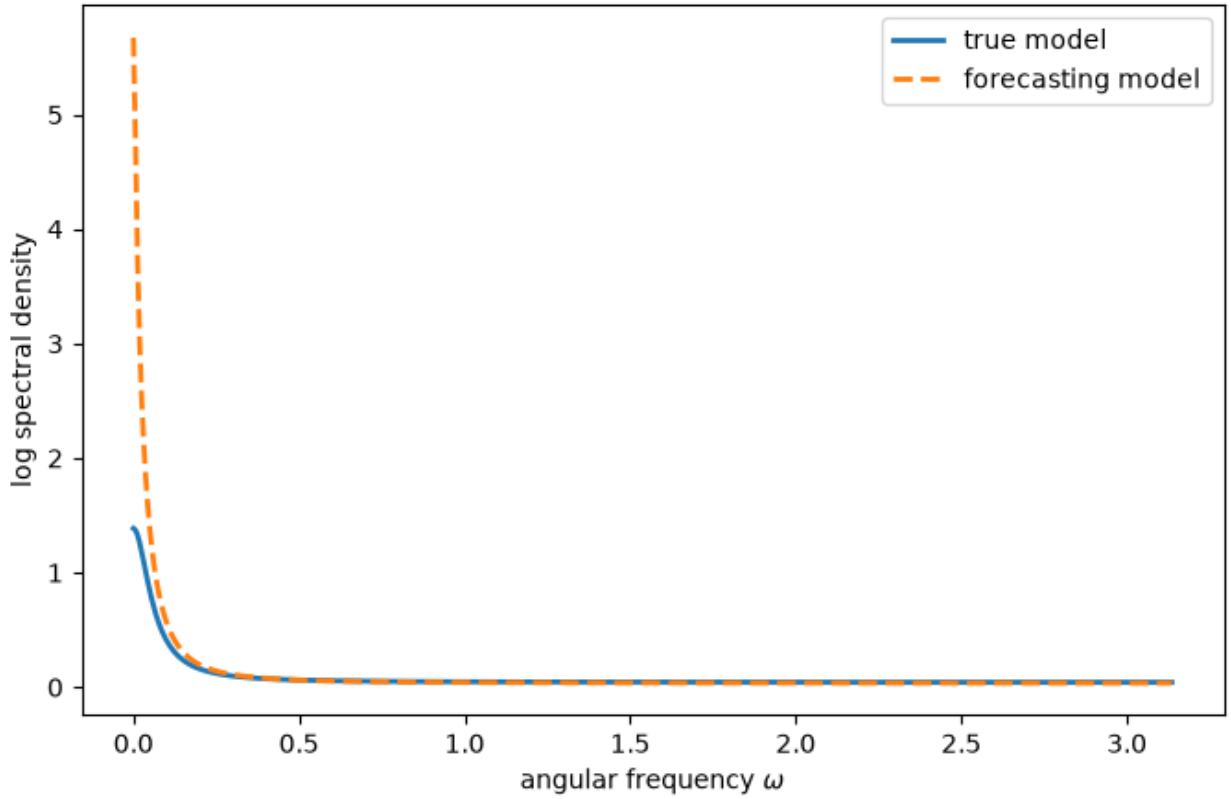

Fig. 102.1: Spectral densities of the true price process and of the agents' approximating model

In minimizing (102.8), the approximating model uses its near-unit-root to fit the mean.

The large gap between the spectral densities at low frequencies reflects how the approximating model fits a *first* moment (the mean ν) with features of *second* moments (a spike in the spectral density at frequency zero).

The true spectral density decreases sharply with frequency — Granger's "typical spectral shape" [Granger, 1966] — revealing substantial positive serial correlation in the price, because agents' belief that the price is subject to permanent shocks makes shocks persist.

102.4.1 Impulse responses

We compare the impulse response functions of the two models by feeding a unit shock through each moving-average representation.

The true process (102.5) and the perceived model (102.7) are driven by different shocks, u_t and ϵ_t.

To compare like with like, we normalize the true response by its impact effect $f(0) = 1/(1 - bC)$, so that both models respond to a unit one-step-ahead forecast error.

```
def impulse_response(num, den, T=25):
    "IRF of (1 - num L)/(1 - den L)."
    h = np.empty(T)
    h[0] = 1.0
    for k in range(1, T):
        h[k] = den * h[k - 1]
    h[1:] -= num * h[:-1]            # apply the numerator (1 - num L)
    return h

ψ = (1 - C_star) / (1 - bray.b * C_star)
irf_true = impulse_response(1 - C_star, ψ)              # f(L) / f(0)
irf_approx = impulse_response(1 - c_star, bray.ρ)       # g(L)

lags = np.arange(len(irf_true))
fig, axes = plt.subplots(1, 2, figsize=(11, 4.5))
for ax, start in zip(axes, [0, 1]):
    ax.plot(lags[start:], irf_true[start:], 'C0o-', ms=4, label='true model', lw=2)
    ax.plot(lags[start:], irf_approx[start:], 'C1s--', ms=4,
            label='approximating model', lw=2)
    ax.set_xlabel('lag')
    ax.set_ylabel('response')
axes[0].set_title('all lags')
axes[1].set_title('lags 1 and beyond')
axes[0].legend()
plt.tight_layout()
plt.show()

print(f"response at lag 1:  true {irf_true[1]:.3f},  approximating {irf_approx[1]:.3f}
 ↪")
```

```
response at lag 1:  true 0.039,  approximating 0.076
```

The impulse response of the true model affirms the serial correlation in the price.

From lag one on, the true response lies below the approximating one: the approximating model over-predicts the effects of a shock at every horizon, and its near unit root makes those effects die out much more slowly, at rate ρ rather than $\phi = (1 - C)/(1 - bC)$.

Chapter 6 of Sargent [1999] says that the approximating model under-predicts short-term consequences; that statement rests on comparing impact effects without the normalization, and so reflects only the different scales of the two shocks.

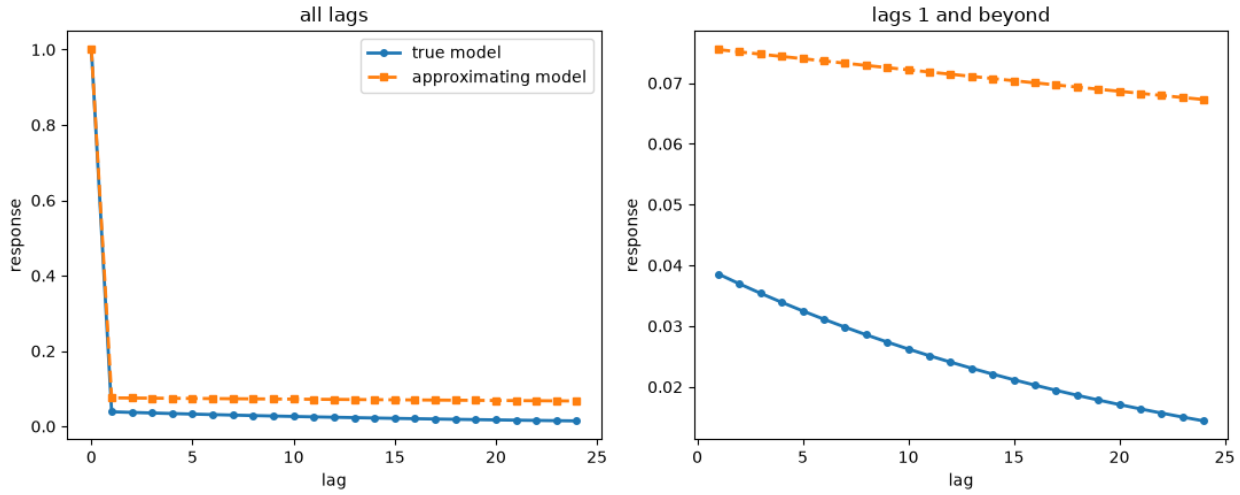

Fig. 102.2: Impulse responses of the true and approximating models to a unit one-step-ahead forecast error

102.5 How the equilibrium depends on ρ

Every number so far was computed with the perceived root $\rho = 0.995$.

The next cell recomputes the equilibrium for values of ρ closer to one, and then for the exact unit root $\rho = 1$ of the rule (102.2) itself.

We use a finer frequency grid, because the perceived spectral density has a spike at frequency zero whose width is about $1 - \rho$.

```
print(f"{'ρ':>7} {'C*':>8} {'weight sum':>11} {'RMSE of rule':>13}")
for ρ in [0.98, 0.99, 0.995, 0.999, 0.9995]:
    m = BrayModel(a=1.0, b=0.5, σ_u=1.0, ρ=ρ, N=2**14)
    C = solve_equilibrium(m, C0=0.1)
    rmse = np.sqrt(forecast_mse(m.true_spectrum(C), m.ν, C, 1.0, m.z))
    print(f"{ρ:>7} {C:>8.4f} {1 - (1 - ρ) / C:>11.3f} {rmse:>13.4f}")

m1 = BrayModel(a=1.0, b=0.5, σ_u=1.0, ρ=1.0, N=2**14)
C_grid = np.linspace(0.005, 0.4, 40)
ratio = max(best_estimate(m1, C) / C for C in C_grid)
print(f"\nρ = 1: largest value of B(C)/C on the grid = {ratio:.3f}")
print(f"ρ = 1: best c given C = {C_star:.4f} is {best_estimate(m1, C_star):.4f}")
```

```
      ρ       C*  weight sum  RMSE of rule
   0.98   0.1901       0.895        1.1352
   0.99   0.1245       0.920        1.0846
  0.995   0.0805       0.938        1.0530
  0.999   0.0284       0.965        1.0181
 0.9995   0.0180       0.972        1.0114

ρ = 1: largest value of B(C)/C on the grid = 0.365
ρ = 1: best c given C = 0.0805 is 0.0274
```

As ρ rises toward one, the equilibrium gain C^* falls toward zero.

With the exact unit root, $B(C) < C$ for every C on the grid, so iterating B drives C to zero, and the only fixed point is $C = 0$.

That is the rational expectations equilibrium: with $C = 0$ expectations stop moving, and the price is $p_t = \nu + u_t$.

Accordingly, the root mean square error of the rule in the last column falls toward $\sigma_u = 1$ as $\rho \to 1$.

The mechanism is the mean term in (102.9).

A perceived model with $\rho < 1$ forecasts with weights that sum to $1 - (1 - \rho)/c < 1$ (the column "weight sum"), so its errors have mean $\nu(1 - \rho)/c$.

A larger c shrinks that bias, and this pull toward a large c is what keeps C^* away from zero; as $\rho \to 1$ the bias, and the pull, vanish.

There is a tension in the construction.

The price (102.5) is generated by the rule (102.2), whose weights sum to one, but the gain is chosen by fitting the ρ-model.

An agent who chose c to minimize the actual mean square error of the rule he uses would, in effect, set $\rho = 1$, and the last line of output shows that he would pick a gain well below C^* (Exercise 102.7.2 confirms this by simulation).

So the equilibrium with $C^* > 0$, and the persistent serial correlation that comes with it, exists for each fixed $\rho < 1$ and disappears as $\rho \to 1$.

The issue goes back to footnotes 4 and 5 of chapter 6 of Sargent [1999], where $\rho < 1$ is introduced to keep the spectral density well defined.

It matters again in *Self-Confirming Equilibria*, where the better-than-Nash outcomes of an equilibrium with misspecified beliefs rest on it.

102.6 Lessons

The agents in this model are **boundedly rational**, in the sense of *A Peculiar Definition of Bounded Rationality*: *rational* describes their use of least squares, and *bounded* describes their model misspecification.

Under rational expectations there is only one model in play.

Under bounded rationality there must be at least two: the one used by the boundedly rational agents, and the true one.

These mutually influence each other — the boundedly rational agents use their model to approximate the true one, and the true one reflects the decisions of the agents — and both differ from the rational expectations model.

The peculiar way that the adaptive expectations model uses a unit root to mimic a constant foreshadows a version of the Phillips curve model, developed in *Self-Confirming Equilibria*, that will help vindicate econometric policy evaluation, and whose good outcomes also depend on $\rho < 1$.

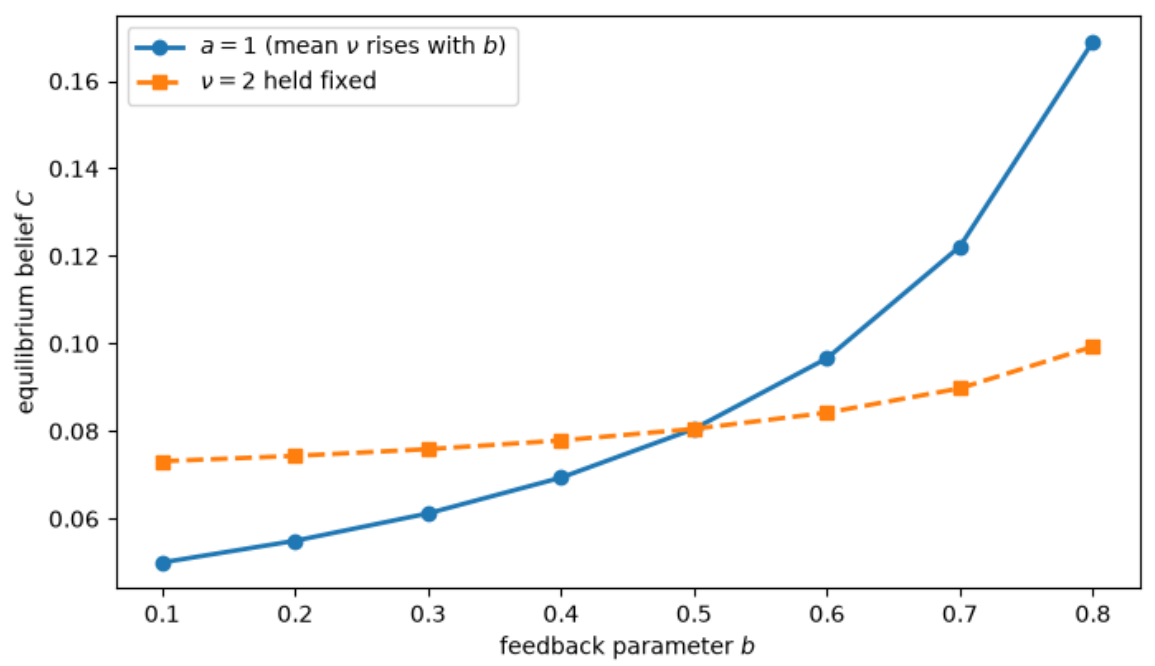
The same trick — using a unit root to approximate a constant — drives the *escape dynamics* of *Adaptive Learning and Escape Dynamics*, where a learning government's estimated distributed-lag Phillips curve drifts toward the induction hypothesis and, believing it, cuts inflation toward Ramsey.

In the static model of *Escaping Nash Inflation*, an escape instead makes the perceived Phillips curve vertical, which trivially satisfies the induction property.

102.7 Exercises

Exercise 102.7.1

The equilibrium belief C depends on the feedback parameter b in (102.1).



1. Compute and plot the equilibrium C as a function of $b \in \{0.1, 0.2, \ldots, 0.8\}$, holding $a = 1$ and $\sigma_u = 1$ fixed.
2. With a fixed, a change in b also changes the mean $\nu = a/(1-b)$ that the perceived model must fit. Repeat the calculation holding $\nu = 2$ fixed, by setting $a = 2(1-b)$.
3. How much of the effect of b works through the mean? How does the persistence $\phi = (1-C)/(1-bC)$ of the actual price change with b?

Solution

```
b_grid = np.arange(0.1, 0.85, 0.1)
C_a1 = np.array([solve_equilibrium(BrayModel(a=1.0, b=b)) for b in b_grid])
C_v2 = np.array([solve_equilibrium(BrayModel(a=2 * (1 - b), b=b)) for b in b_grid])
ψ_a1 = (1 - C_a1) / (1 - b_grid * C_a1)

fig, ax = plt.subplots(figsize=(8, 4.5))
ax.plot(b_grid, C_a1, 'o-', lw=2, label=r'$a = 1$ (mean $\nu$ rises with $b$)')
ax.plot(b_grid, C_v2, 's--', lw=2, label=r'$\nu = 2$ held fixed')
ax.set_xlabel('feedback parameter $b$')
ax.set_ylabel('equilibrium belief $C$')
ax.legend()
plt.show()

print(f"a = 1:   C from {C_a1[0]:.3f} to {C_a1[-1]:.3f},  "
      f"ν from {1 / (1 - b_grid[0]):.2f} to {1 / (1 - b_grid[-1]):.2f}")
print(f"ν = 2:   C from {C_v2[0]:.3f} to {C_v2[-1]:.3f}")
print(f"persistence ψ ranges from {ψ_a1.min():.3f} to {ψ_a1.max():.3f}")
```

```
a = 1:   C from 0.050 to 0.169,  ν from 1.11 to 5.00
ν = 2:   C from 0.073 to 0.099
persistence ψ ranges from 0.955 to 0.961
```

With $a = 1$, stronger feedback raises the equilibrium gain a great deal, but it also raises the mean ν that the perceived model must fit.

Holding ν fixed, the gain rises much less.

Most of the effect of b therefore works through the mean: a larger mean makes the bias $\nu(1-\rho)/c$ of the perceived model costlier, so agents choose a larger gain.

The persistence ϕ of the actual price barely changes, so stronger feedback does not make the price process noticeably less persistent.

Exercise 102.7.2

The best-estimate map is computed in the frequency domain, under the perceived model (102.7).

Check what the equilibrium implies in the time domain.

Simulate the market (102.1)–(102.2) with $C = C^*$ for one million periods.

For a grid of values of c, compute the mean square error of the forecast $p^e_{t+1}(c) = c\,p_t + (1-c)p^e_t(c)$ of p_{t+1}.

Which c minimizes it?

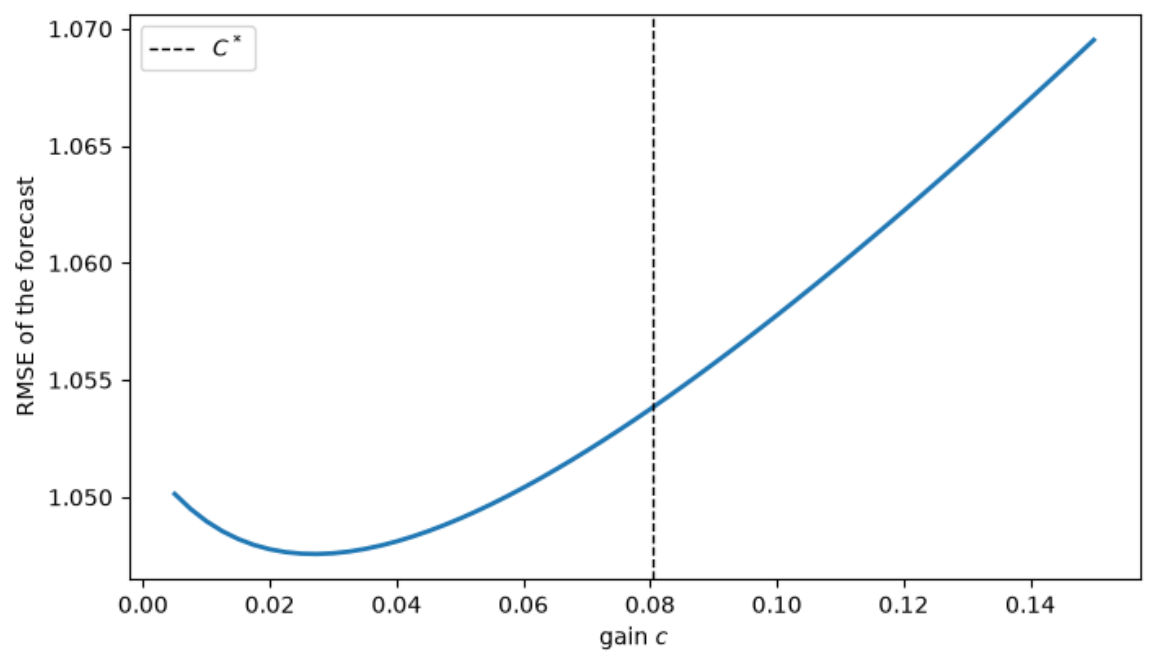
Compare it with C^* and with the exact-unit-root best estimate printed in *How the equilibrium depends on \rho*.

Solution

Substituting (102.2) into (102.1) gives $p_t = [a + b(1-C)p^e_t + u_t]/(1-bC)$, and then $p^e_{t+1} = \phi\,p^e_t + C(a +$

$u_t)/(1-bC)$ with $\phi = (1-C)/(1-bC)$.

```
rng = np.random.default_rng(0)
T, burn = 1_000_000, 10_000
a, b, C = bray.a, bray.b, C_star
u = rng.standard_normal(T)



ψ = (1 - C) / (1 - b * C)
pe_next = lfilter([C / (1 - b * C)], [1, -ψ], a + u, zi=[ψ * bray.v])[0]
pe = np.concatenate([[bray.v], pe_next[:-1]])                    # p^e_t
p = (a + b * (1 - C) * pe + u) / (1 - b * C)

def rmse(c):
    "Root mean square error of the forecast c p_t + (1-c) p^e_t of p_{t+1}."
    f = lfilter([c], [1, -(1 - c)], p, zi=[(1 - c) * bray.v])[0]
    return np.sqrt(np.mean((p[burn + 1:] - f[burn:-1])**2))

c_grid = np.linspace(0.005, 0.15, 59)
errors = np.array([rmse(c) for c in c_grid])

fig, ax = plt.subplots(figsize=(8, 4.5))
ax.plot(c_grid, errors, lw=2)
ax.axvline(C_star, color='k', ls='--', lw=1, label='$C^*$')
ax.set_xlabel('gain $c$')
ax.set_ylabel('RMSE of the forecast')
ax.legend()
plt.show()

print(f"RMSE-minimizing c = {c_grid[errors.argmin()]:.3f},  C* = {C_star:.4f}")
```

```
RMSE-minimizing c = 0.027,  C* = 0.0805
```

The gain that minimizes the actual forecast error is far below C^* and close to the exact-unit-root best estimate of *How the equilibrium depends on \rho*.

An individual who judged the rule (102.2) by its actual forecast errors would not choose C^*.

C^* is a best response only within the perceived model (102.7), whose mean penalty does not apply to the rule that agents actually use, because that rule's errors have mean zero.

Exercise 102.7.3

How much data would agents need to detect that their model is wrong?

For Gaussian processes, the expected log-likelihood ratio per observation of the true model (102.5) against the perceived model (102.7) (at $c = B(C^*)$ and the fitted $\bar{\sigma}_\epsilon^2$) is the Kullback–Leibler divergence rate.

1. Using the concentrated criterion and Kolmogorov's formula, show that this rate equals $\log(\bar{\sigma}_\epsilon/\sigma_{\text{true}})$, with $\sigma_{\text{true}} = \sigma_u/(1 - bC^*)$.
2. Compute it, and the number of observations it takes for the expected log-likelihood ratio to reach 3 (a likelihood ratio of about 20).
3. Confirm the rate by simulating the log-likelihood ratio.

Solution

The Kullback–Leibler divergence rate of a mean-zero Gaussian model with spectral density G from a Gaussian process with mean ν and spectral density F is

$$\frac{1}{2}\left\{\frac{1}{N}\sum_j\left[\frac{F(\omega_j)}{G(\omega_j)} - 1 - \log\frac{F(\omega_j)}{G(\omega_j)}\right] + \frac{\nu^2}{G(0)}\right\}.$$

At the fitted $\bar{\sigma}_\epsilon^2$, the terms $\frac{1}{N}\sum_j F/G + \nu^2/G(0)$ add up to one.

By Kolmogorov's formula, the average of $\log G$ is $\log\bar{\sigma}_\epsilon^2$ and the average of $\log F$ is $\log\sigma_{\text{true}}^2$, the log one-step prediction variance of the true process.

So the rate is $\frac{1}{2}\log(\bar{\sigma}_\epsilon^2/\sigma_{\text{true}}^2) = \log(\bar{\sigma}_\epsilon/\sigma_{\text{true}})$.

```
kl = np.log(σ_bar / σ_true)
print(f"KL rate = {kl:.4f} nats per observation")
print(f"observations for an expected log-likelihood ratio of 3: {3 / kl:.0f}")

# simulate: true one-step errors are u_t/(1-bC); the perceived model's are g(L)^{-
↪1} p_t
rng = np.random.default_rng(1)
T, burn = 200_000, 10_000
a, b, C = bray.a, bray.b, C_star
u = rng.standard_normal(T)
ψ = (1 - C) / (1 - b * C)
pe_next = lfilter([C / (1 - b * C)], [1, -ψ], a + u, zi=[ψ * bray.v])[0]
pe = np.concatenate([[bray.v], pe_next[:-1]])
p = (a + b * (1 - C) * pe + u) / (1 - b * C)

e_true = u / (1 - b * C)
e_model = lfilter([1, -bray.ρ], [1, -(1 - c_star)], p)
llr = (-np.log(σ_true) - e_true**2 / (2 * σ_true**2)) \
    - (-np.log(σ_bar) - e_model**2 / (2 * σ_bar**2))
print(f"simulated mean log-likelihood ratio = {llr[burn:].mean():.4f}")
```

```
KL rate = 0.0152 nats per observation
observations for an expected log-likelihood ratio of 3: 198
simulated mean log-likelihood ratio = 0.0153
```

The divergence is about 0.015 nats per observation, so it takes roughly two hundred observations before the data favor the true model by a likelihood ratio of about 20, and that is for a statistician who already knows which alternative to test.

Exercise 102.7.4

Muth [1960] showed that the rule (102.2) is optimal for a random walk observed with noise.

Consider the local-level model $p_t = \mu_t + \eta_t$, $\mu_t = \mu_{t-1} + w_t$, with $\mathbb{V}[w_t] = q$ and $\mathbb{V}[\eta_t] = r$.

1. Show that the steady-state Kalman gain K for this model satisfies $q/r = K^2/(1-K)$, and that the Kalman filter's forecast of p_{t+1} then has the form (102.2) with $C = K$.
2. Set $q/r = C^{*2}/(1-C^*)$, iterate the Riccati equation of *Convergence* to its fixed point, and confirm that $K = C^*$.
3. What does the implied signal-to-noise ratio say about how agents perceive the price?

Solution

With $A = G = 1$, $Q = q$, and $R = r$, the Riccati equation of *A First Look at the Kalman Filter* for the one-step-ahead prediction variance Σ of μ_t is $\Sigma_{t+1} = \Sigma_t - \Sigma_t^2/(\Sigma_t + r) + q$.

At its fixed point, $\Sigma r/(\Sigma + r) = \Sigma - q$, and the gain is $K = \Sigma/(\Sigma + r)$.

Hence $(1-K)\Sigma = \Sigma - q$, so $\Sigma = q/K$, and substituting into $K = \Sigma/(\Sigma + r)$ gives $q/r = K^2/(1-K)$.

The forecast of p_{t+1} is the forecast of μ_{t+1}, which equals the filtered estimate of μ_t: $\hat{\mu}_{t+1} = \hat{\mu}_t + K(p_t - \hat{\mu}_t) = Kp_t + (1-K)\hat{\mu}_t$, which is (102.2) with $C = K$.

```
r = 1.0
q = r * C_star**2 / (1 - C_star)
Σ = 1.0
for _ in range(10_000):
    Σ = Σ - Σ**2 / (Σ + r) + q
K = Σ / (Σ + r)
print(f"q/r = {q / r:.5f},  steady-state Kalman gain K = {K:.4f},  C* = {C_star:.
↪4f}")
```

```
q/r = 0.00705,  steady-state Kalman gain K = 0.0805,  C* = 0.0805
```

The equilibrium beliefs imply a signal-to-noise ratio of less than one percent.

Agents perceive the price as almost entirely transitory noise around a level that drifts very slowly, and that slowly drifting level is how their model mimics the constant mean ν.

```

103.1 Overview

This lecture completes the *equilibrium* half of the study begun in *The Credibility Problem*.

It follows chapter 7 of Sargent [1999], after which the suite turns from fixed beliefs to beliefs that are learned in real time.

We seek models that depart minimally from the basic Kydland and Prescott [1977] model of *The Credibility Problem* but that also let a government's *beliefs* be shaped by the data its own policies generate.

The key equilibrium concept is a **self-confirming equilibrium**: the government has a possibly *wrong* model of the Phillips curve, but it fits that model to the data by least squares, and the data it observes confirm its beliefs.

Fudenberg and Levine [1993] use the term self-confirming equilibrium for a related idea in game theory.

We combine ideas from two literatures:

- King and Watson [1994] document how inferences about the Phillips curve depend on the *direction of fit* — whether one regresses unemployment on inflation (a *classical* identification) or inflation on unemployment (a *Keynesian* identification).

- A literature going back to Muth, Lucas, and Prescott [Lucas and Prescott, 1971, Muth, 1961], and exploited by Marcet and Sargent [1989] and Evans and Honkapohja [2001], formulates rational expectations equilibria as fixed points of mappings from beliefs to the population moments of statistical models; *Rational Expectations Equilibrium* describes the fixed-point view.

We build two self-confirming equilibria that are identical except for the direction of fit, and we find that the direction of minimization affects outcomes.

Both equilibria are unique and E-stable.

We then study an **equilibrium with misspecified beliefs**, combining the Phelps problem of *Adaptive Expectations and the Phelps Problem* with the optimal-misspecification machinery of *Optimal Misspecified Beliefs*.

It delivers outcomes better than Nash, approaching Ramsey as the government becomes patient, provided that the public's perceived model keeps the root ρ of *Optimal Misspecified Beliefs* strictly below one.

In the self-confirming equilibria only the government's model is wrong; in the equilibrium with misspecified beliefs only the public's is.

Let's import what we need:

```
import matplotlib.pyplot as plt
import numpy as np
import quantecon as qe
from scipy.optimize import minimize_scalar
```

103.2 Objects in the Phelps problem

Recall from *Adaptive Expectations and the Phelps Problem* the ingredients of the general Phelps problem.

The government believes in a reduced-form Phillips curve that it can fit in either direction:

$$\text{Classical:} \quad U_t = \gamma^\top X_{C,t} + \varepsilon_{C,t}, \qquad X_{C,t} = \begin{bmatrix} y_t & X_{t-1}^\top \end{bmatrix}^\top,$$

$$\text{Keynesian:} \quad y_t = \beta^\top X_{K,t} + \varepsilon_{K,t}, \qquad X_{K,t} = \begin{bmatrix} U_t & X_{t-1}^\top \end{bmatrix}^\top,$$

where X_{t-1} collects lagged U's, lagged y's, and a constant.

We partition $\gamma = \begin{bmatrix} \gamma_1 & \gamma_{-1}^\top \end{bmatrix}^\top$, where γ_1 is the coefficient on y_t and γ_{-1} collects the coefficients on X_{t-1}, and partition β the same way.

Solving the Phelps problem takes the government's beliefs γ as given and delivers a decision rule $h(\gamma)$ for inflation, $\hat{y}_t = h(\gamma) X_{t-1}$.

The two parameterizations are related by the inversion formulas

$$\gamma_1 = \beta_1^{-1}, \qquad \gamma_{-1} = -\beta_{-1}/\beta_1. \tag{103.1}$$

103.3 The actual Phillips curve

The *actual* Phillips curve extends the one used in earlier lectures to allow for serially correlated shocks:

$$U_t = U^* - \frac{\theta}{1-\rho_2 L}(y_t - x_t) + \frac{v_{1t}}{1-\rho_1 L}, \tag{103.2}$$

with $|\rho_1| < 1$ and $|\rho_2| < 1$.

Here $v_t = (v_{1t}, v_{2t})^\top$ is a vector white noise with a *diagonal* covariance matrix: the Phillips curve shock v_{1t}, with variance σ_1^2, is uncorrelated with the surprise in inflation $v_{2t} \equiv y_t - x_t$, with variance σ_2^2.

For much of this lecture we set $\rho_1 = \rho_2 = 0$ to make theoretical points, which reduces (103.2) to

$$U_t = U^* - \theta(y_t - x_t) + v_{1t}.$$

103.4 Self-confirming equilibria

A self-confirming equilibrium reconciles the government's beliefs with the environment those beliefs generate.

Definition (Self-confirming equilibrium)

A self-confirming equilibrium is a fixed belief vector γ, a government decision rule $h = h(\gamma)$, and a stationary process for (y_t, U_t, x_t) such that

(a) inflation solves the Phelps problem, $y_t = hX_{t-1} + v_{2t}$;

(b) the public optimally forecasts inflation, $x_t = hX_{t-1}$;

© unemployment is generated by the actual Phillips curve (103.2); and

(d) the government's beliefs satisfy the least squares orthogonality conditions $\mathbb{E}\left[\left(U_t - \gamma^\top X_{C,t}\right) X_{C,t}^\top\right] = 0$ (the **classical** direction of fit).

Condition (d) makes the government's beliefs depend on moment matrices that, through (a)–©, themselves depend on the government's beliefs.

The government's beliefs imply behavior that produces data whose moments *confirm* those beliefs.

A distinct self-confirming equilibrium results from replacing (d) with the **Keynesian** direction of fit:

> (d′) the government fits the Keynesian Phillips curve, $\mathbb{E}\left[\left(y_t - \beta^\top X_{K,t}\right) X_{K,t}^\top\right] = 0$, then recovers γ from the inversion formulas (103.1).

Because the government's beliefs affect the whole probability distribution of the data, the direction of minimization affects outcomes.

Note

Computing a self-confirming equilibrium in general means finding a fixed point of a map $\gamma = T(h(\gamma))$ (classical) or $\beta = S(h(\gamma(\beta)))$ (Keynesian).

The moments in the orthogonality conditions are obtained from the state-space representation of the system by solving a discrete Lyapunov equation.

In practice one iterates a relaxation algorithm $\beta_{j+1} = \kappa\beta_j + (1-\kappa)S(\beta_j)$, the damped iteration of *A Peculiar Definition of Bounded Rationality*, which resembles the least squares learning recursion of *The Credibility Problem*; *Uniqueness and E-stability* uses it.

103.5 The special case solved by hand

When $\rho_1 = \rho_2 = 0$, the government's problem collapses to a sequence of static problems, and each self-confirming equilibrium can be computed by hand.

We take $X_{t-1} = 1$, so the government believes $U_t = \gamma_{-1} + \gamma_1 y_t + \varepsilon_{C,t}$; *Uniqueness and E-stability* shows that adding lags of U and y to X_{t-1} changes nothing.

Minimizing $\mathbb{E}\left[U_t^2 + y_t^2\right]$ under this belief gives the static Phelps rule

$$\hat{y} = h(\gamma) = -\frac{\gamma_1\gamma_{-1}}{1+\gamma_1^2}. \tag{103.3}$$

The actual Phillips curve and the diagonal covariance matrix of v_t imply the second moments

$$\mathbb{V}[U_t] = \theta^2\sigma_2^2 + \sigma_1^2, \qquad \mathbb{V}[y_t] = \sigma_2^2, \qquad \operatorname{cov}(U_t, y_t) = -\theta\sigma_2^2. \tag{103.4}$$

Classical direction of fit (U on y): the slope is

$$\gamma_1 = \frac{\operatorname{cov}(U_t, y_t)}{\mathbb{V}[y_t]} = -\theta.$$

Mean unemployment is U^* and mean inflation is $\bar{x} = h(\gamma)$, and the requirement that the means lie on the regression line, $U^* = \gamma_{-1} + \gamma_1\bar{x}$, gives the intercept $\gamma_{-1} = (\gamma_1^2 + 1)U^*$.

Keynesian direction of fit (y on U): the slope is

$$\beta_1 = \frac{\operatorname{cov}(U_t, y_t)}{\mathbb{V}[U_t]} = \frac{-\theta\sigma_2^2}{\sigma_1^2 + \theta^2\sigma_2^2},$$

with intercept $\beta_{-1} = -\frac{\beta_1^2+1}{\beta_1}U^*$, from which the implied classical coefficients follow by inversion, $\gamma_1 = \beta_1^{-1}$ and $\gamma_{-1} = \frac{\beta_1^2+1}{\beta_1^2}U^*$.

```
class SelfConfirmingStatic:
    """
    The two static self-confirming equilibria (ρ1 = ρ2 = 0), one for
    each direction of fit.  γ1 is the slope; γ_int is the intercept γ_{-1}.
    """

    def __init__(self, θ=1.0, U_star=5.0, σ1=0.3, σ2=0.3):
        self.θ, self.U_star, self.σ1, self.σ2 = θ, U_star, σ1, σ2

    def classical(self):
        "Perceived Phillips curve U = γ_{-1} + γ_1 y under classical fit."
        θ, U_star = self.θ, self.U_star
        γ1 = -θ
        γ_int = (γ1**2 + 1) * U_star
        y_bar = -γ_int * γ1 / (γ1**2 + 1)       # mean (= Nash) inflation
        return γ1, γ_int, y_bar
```

(continues on next page)

(continued from previous page)

```
    def keynesian(self):
        "Perceived Phillips curve under Keynesian fit, inverted to y."
        θ, U_star, σ1, σ2 = self.θ, self.U_star, self.σ1, self.σ2
        β1 = -θ * σ2**2 / (σ1**2 + θ**2 * σ2**2)
        β_int = -(β1**2 + 1) / β1 * U_star
        y1 = 1 / β1
        y_int = (β1**2 + 1) / β1**2 * U_star
        y_bar = β_int / (β1**2 + 1)             # mean inflation
        return y1, y_int, y_bar
```

We compute both equilibria for the parameters of chapter 7 of Sargent [1999].

```
sce = SelfConfirmingStatic(θ=1.0, U_star=5.0, σ1=0.3, σ2=0.3)

y1_C, y0_C, y_C = sce.classical()
y1_K, y0_K, y_K = sce.keynesian()

print("Classical direction of fit")
print(f"  y_1 = {y1_C:.1f},  y_(-1) = {y0_C:.1f},  mean inflation = {y_C:.1f}")
print("Keynesian direction of fit")
print(f"  y_1 = {y1_K:.1f},  y_(-1) = {y0_K:.1f},  mean inflation = {y_K:.1f}")
```

```
Classical direction of fit
  y_1 = -1.0,  y_(-1) = 10.0,  mean inflation = 5.0
Keynesian direction of fit
  y_1 = -2.0,  y_(-1) = 25.0,  mean inflation = 10.0
```

These reproduce the numerical example of chapter 7 of Sargent [1999].

Under the classical direction of fit, mean inflation is the Nash value $\theta U^* = 5$.

Under the Keynesian direction of fit, the government estimates a *flatter* Phillips curve and believes the tradeoff is more favorable than it is.

Its mean inflation is

$$\bar{y}_K = -\frac{U^*}{\beta_1} = \theta U^* \left(1 + \frac{\sigma_1^2}{\theta^2 \sigma_2^2}\right), \tag{103.5}$$

which exceeds the Nash rate whenever $\sigma_1 > 0$.

With $\sigma_1 = \theta \sigma_2$, as here, it is twice the Nash rate, 10.

Let's draw the two self-confirming Phillips curves, reproducing Figure 7.1.

```
fig, ax = plt.subplots(figsize=(7, 6))

U_grid = np.linspace(0, 12, 100)

# perceived Phillips curves U = y_{-1} + y_1 y  =>  y = (U - y_{-1}) / y_1
ax.plot(U_grid, (U_grid - y0_C) / y1_C, 'C0', label='P: classical fit', lw=2)

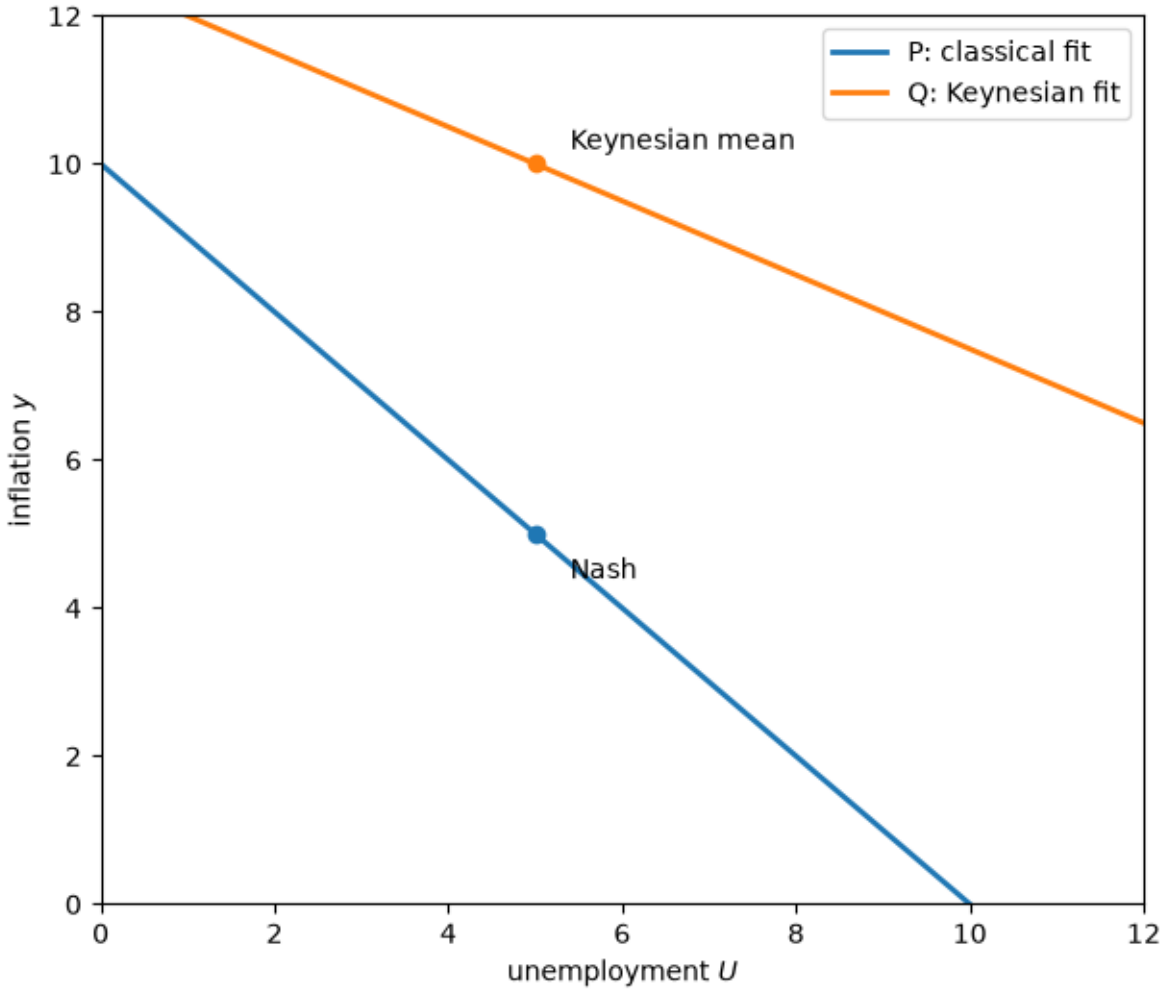

Fig. 103.1: The two self-confirming Phillips curves, one for each direction of fit

Curve P is the self-confirming Phillips curve estimated with the classical direction of fit; curve Q with the Keynesian direction.

Because the Keynesian fit makes the government believe the tradeoff is more exploitable, average inflation is higher.

103.5.1 Why the classical equilibrium is Nash

The classical self-confirming equilibrium reproduces the Nash outcome of *The Credibility Problem* for a simple reason.

Its perceived intercept is $\gamma_{-1} = (1 + \theta^2)U^* = U^* + \theta\bar{x}$, with $\bar{x} = \theta U^*$.

So the perceived curve $U_t = U^* + \theta\bar{x} - \theta y_t$ is the true Phillips curve evaluated at $x_t = \bar{x}$.

The government's model is right about everything it sees in equilibrium.

Its only mistake is to treat $\bar{x}$ as invariant to its own rule, which is exactly the assumption that defines the Nash government, which takes the public's expectations as given.

That is why the time-consistent, or "consistent", equilibrium of Kydland and Prescott [1977] is a self-confirming equilibrium (*A government learning the Phillips curve*).

Readers of Kalai and Lehrer [1993] might have foreseen this.

Learning converges to the truth when decision makers' probability models encompass the Nash equilibrium, and the classical identification scheme satisfies that encompassing condition.

The Keynesian scheme does not: it gives the government a mistaken interpretation of the contemporaneous covariance between innovations to inflation and unemployment, and that worsens outcomes relative to Nash.

Both conclusions rest on the orthogonality conditions in the actual Phillips curve: v_{1t} is uncorrelated with v_{2t}, and v_{2t} is orthogonal to $\widehat{y}_t$.

Different orthogonality conditions would change the quality of the outcomes in both equilibria, which is how, though our model of the government differs from theirs, we join King and Watson's inquiry.

103.5.2 Why not Ramsey?

Both self-confirming equilibria give a mean outcome *worse* than the Ramsey outcome.

This signifies a breakdown of the hypotheses of the proposition in *Adaptive Expectations and the Phelps Problem* that solving the Phelps problem eventually sustains nearly the Ramsey outcome.

What fails is the **induction hypothesis**.

Because $\rho_1 = \rho_2 = 0$, the self-confirming equilibria are serially uncorrelated, so lagged inflation drops out of the empirical Phillips curves.

Deactivating the induction hypothesis makes the government in effect solve a one-period problem and shuts down the intertemporal channel that promotes better outcomes.

The two equilibria illustrate the assertion of Lucas [1972] and Sargent [1971], discussed in *Testing the natural-rate hypothesis*, that rational expectations and the natural-rate hypothesis do not imply the induction hypothesis: both hold here, and the induction hypothesis fails.

103.6 Uniqueness and E-stability

Two properties of these equilibria matter for the lectures that follow: each is unique, and each is E-stable, so that least squares learning can converge to it.

Both are easy to establish in the static case.

Uniqueness. In the classical fit, the slope $T_1 = \text{cov}(U_t, y_t)/\mathbb{V}[y_t] = -\theta$ comes from moments (103.4) that do not depend on policy: the government's beliefs move the mean of inflation, but not its variance or its covariance with unemployment.

Given the slope, the intercept must satisfy

$$\gamma_{-1} = T_{-1}(\gamma) = U^* + \theta h(\gamma) = U^* + \frac{\theta^2}{1+\theta^2}\gamma_{-1},$$

a linear equation with slope $\theta^2/(1+\theta^2) < 1$, and so with a unique solution.

The Keynesian case is the same, with slope $1/(1+\beta_1^2)$ in the equation for the intercept.

E-stability. Write the classical equilibrium as a fixed point $\gamma = T(\gamma)$ of the map from beliefs to the population regression coefficients they generate.

The associated differential equation $d\gamma/d\tau = T(\gamma) - \gamma$ is the E-stability condition of *One recursion, many learners*, and *Least Squares Learning in Self-Referential Models* shows that its stability governs whether least squares learning converges.

Because T_1 does not depend on beliefs, the Jacobian of $T - I$ at the equilibrium is triangular, with eigenvalues -1 (slope) and $\theta^2/(1+\theta^2) - 1 = -1/(1+\theta^2)$ (intercept).

For the Keynesian fit $\beta = S(\beta)$, the eigenvalues are -1 and $1/(1+\beta_1^2) - 1 = -\beta_1^2/(1+\beta_1^2)$.

Let's confirm these by differentiating the two maps numerically.

```
def T_classical(γ, θ=1.0, U_star=5.0):
    "Static classical T-map: beliefs (γ_1, γ_{-1}) ↦ regression of U on (y, 1)."
    γ1, γ_int = γ
    y_hat = -γ1 * γ_int / (1 + γ1**2)
    return np.array([-θ, U_star + θ * y_hat])

def S_keynesian(β, θ=1.0, U_star=5.0, σ1=0.3, σ2=0.3):
    "Static Keynesian S-map: beliefs (β_1, β_{-1}) ↦ regression of y on (U, 1)."
    β1, β_int = β
    y_hat = β_int / (1 + β1**2)
    slope = -θ * σ2**2 / (σ1**2 + θ**2 * σ2**2)
    return np.array([slope, y_hat - slope * U_star])

def jacobian(f, x, ε=1e-6):
    "Central-difference Jacobian of f at x."
    J = np.empty((len(x), len(x)))
    for j in range(len(x)):
        dx = np.zeros(len(x))
        dx[j] = ε
        J[:, j] = (f(x + dx) - f(x - dx)) / (2 * ε)
    return J

for θ in [0.5, 1.0, 2.0]:
    γ_sce = np.array([-θ, (1 + θ**2) * 5.0])
    eig = np.linalg.eigvals(jacobian(lambda g: T_classical(g, θ), γ_sce) - np.eye(2))
    print(f"classical, θ = {θ}:  eigenvalues {np.sort(eig).round(4)},"
          f"  -1/(1+θ²) = {-1 / (1 + θ**2):.4f}")

β1 = -0.3**2 / (0.3**2 + 0.3**2)
β_sce = np.array([β1, -(β1**2 + 1) / β1 * 5.0])
eig = np.linalg.eigvals(jacobian(S_keynesian, β_sce) - np.eye(2))
print(f"Keynesian, θ = 1:  eigenvalues {np.sort(eig).round(4)},"
      f"  -β1²/(1+β1²) = {-β1**2 / (1 + β1**2):.4f}")
```

```
classical, θ = 0.5:  eigenvalues [-1.  -0.8],  -1/(1+θ²) = -0.8000
classical, θ = 1.0:  eigenvalues [-1.  -0.5],  -1/(1+θ²) = -0.5000
classical, θ = 2.0:  eigenvalues [-1.  -0.2],  -1/(1+θ²) = -0.2000
Keynesian, θ = 1:  eigenvalues [-1.  -0.2],  -β1²/(1+β1²) = -0.2000
```

Both equilibria are E-stable.

The classical eigenvalue $-1/(1+\theta^2)$ is the slope $\mathcal{M}$ of the mean dynamics in *Least squares learning converges to Nash*, where the public learned expected inflation by least squares.

At the suite's $\theta = 1$ it equals $-1/2$, exactly the boundary below which decreasing-gain least squares converges at the $\sqrt{t}$ rate.

The Keynesian eigenvalue, -0.2 here, lies above that boundary, so least squares converges more slowly, like $t^{-0.2}$.

These rates describe convergence near the equilibrium.

They do not govern how often a learning government escapes from it, which depends instead on the large-deviation analysis of *A primer on recursive algorithms*; Exercise 103.8.2 shows the difference.

Lags. Do these results depend on $X_{t-1} = 1$?

Let the government's regression include one lag of each variable, so that $X_{t-1} = \begin{bmatrix} U_{t-1} & y_{t-1} & 1 \end{bmatrix}^\top$ and $\gamma = \begin{bmatrix} \gamma_1 & \gamma_{-1}^\top \end{bmatrix}^\top$ has four elements.

Now the government's rule $h(\gamma)$ comes from a genuinely dynamic Phelps problem.

With $\rho_1 = \rho_2 = 0$ the population regression is still exact.

Because $x_t = hX_{t-1}$ and v_{1t} is orthogonal to every regressor,

$$U_t = -\theta y_t + \left[\theta h(\gamma) + \begin{bmatrix} 0 & 0 & U^* \end{bmatrix}\right] X_{t-1} + v_{1t},$$

so $T_1(\gamma) = -\theta$ and $T_{-1}(\gamma) = \theta h(\gamma)^\top + \begin{bmatrix} 0 & 0 & U^* \end{bmatrix}^\top$.

We compute $h(\gamma)$ with the general Phelps solver of *Adaptive Expectations and the Phelps Problem*, repeated here so that this lecture runs on its own.

We check that the Nash beliefs $\gamma_N = \begin{bmatrix} -\theta & 0 & 0 & (1+\theta^2)U^* \end{bmatrix}^\top$ are a fixed point, compute the eigenvalues of the Jacobian of $T - I$, and run the relaxation algorithm from random starting beliefs.

```

relaxation from 10 random starts: largest distance of the limit from y_N = 3.0e-10
```

The Nash beliefs are a fixed point for every θ and δ, and the eigenvalues are -1 and $-1/(1+\theta^2)$, the latter repeated three times, whatever the discount factor.

Relaxation from every starting point converges to the Nash beliefs, with zero weights on the lags.

Adding lags gives the government room to discover the induction hypothesis, but in a self-confirming equilibrium the lag weights are zero and the hypothesis stays deactivated.

Adaptive Learning and Escape Dynamics finds the same pair of eigenvalues with two lags of each variable (*Mean dynamics near the self-confirming equilibrium*).

103.7 Equilibrium with misspecified beliefs

To explore how imputing a *different* wrong model might *improve* on the Nash outcome, we now let the *public*, not the government, make a subtle specification error.

This links adaptive expectations, the induction hypothesis, and the Phelps problem.

The government knows the correct model,

$$U_t = U^* - \theta(y_t - x_t) + v_{1t}, \qquad x_t = Cy_{t-1} + (1-C)x_{t-1}, \quad C \in (0,1), \tag{103.6}$$

where the public has constant-gain adaptive expectations with a parameter C that it *tunes to fit the data*.

Taking x_t as a state variable, the government solves the Phelps problem: it maximizes $-\mathbb{E}_0 \sum_{t=0}^{\infty} \delta^t \left[(U^* - \theta(y_t - x_t))^2 + y_t^2\right]$ by choice of a feedback rule $y_t = f_1 + f_2 x_t + v_{2t}$.

This is exactly the LQ Phelps problem of *Adaptive Expectations and the Phelps Problem* with adaptation parameter $\lambda = 1 - C$; the code below repeats it so that this lecture runs on its own.

```
def phelps_policy(C, δ, θ=1.0, U_star=5.0):
    "Government feedback rule y_t = f1 + f2 x_t, with public gain C."
    λ = 1 - C
    a = np.array([[U_star], [θ]])
    R = 0.5 * (a @ a.T)
    Q = np.array([[0.5 * (θ**2 + 1)]])
    N = -0.5 * θ * a.T
    A = np.array([[1.0, 0.0], [0.0, λ]])
    B = np.array([[0.0], [1 - λ]])
    lq = qe.LQ(Q, R, A, B, N=N, beta=min(δ, 1 - 1e-7))
    P, F, d = lq.stationary_values()
    return -F[0, 0], -F[0, 1]
```

The government's behavior makes the *actual* inflation rate

$$y_t = \frac{f_1}{1 - f_2} + \frac{1 - (1 - C)L}{1 - (1 - C(1 - f_2))L} v_{2t} = \nu + f(L) v_{2t}, \tag{103.7}$$

with mean $\nu = f_1/(1 - f_2)$ and spectrum $F(\omega; C) = |f(e^{i\omega})|^2 \sigma_2^2$.

The mean ν is the steady state of the Phelps rule, so the closed form $y_\infty = \theta U^*(1 - \delta)/(1 - \delta\lambda)$ derived in *Adaptive Expectations and the Phelps Problem*, with $\lambda = 1 - C$, gives it:

$$\nu = \theta U^* \frac{1 - \delta}{1 - \delta + \delta C}. \tag{103.8}$$

Mean inflation is below the Nash rate θU^* whenever $C > 0$; it falls toward zero as $\delta \to 1$ with C fixed, and it rises to θU^* as $C \to 0$.

Everything therefore depends on the equilibrium value of C.

Given C, the public seeks the best-fitting misspecified model of the same form as in *Optimal Misspecified Beliefs*, the stationary ARMA(1,1) model

$$y_t = \frac{1 - (1 - c)L}{1 - \rho L} \epsilon_t = g(L) \epsilon_t,$$

whose root ρ slightly below one (not to be confused with the roots ρ_1, ρ_2 of (103.2)) lets it fit the mean ν with near-unit-root persistence.

The induced best-estimate map $c = B(C)$ defines an **equilibrium under forecast misspecification** as a fixed point $C = B(C)$.

This makes both the true and the approximating models equilibrium outcomes, and turns the adaptation parameter C into an outcome rather than a free parameter.

The best-estimate code is the same as in *Optimal Misspecified Beliefs*.

```
def forecast_mse(F, ν, c, ρ, z):
    """
    Mean square one-step forecast error of the perceived model
    g(L) = (1 - (1-c)L)/(1 - ρL) when the true process has mean ν and
    spectral density F on the grid z = exp(iω).  ρ = 1 is allowed.
    """
```

(continues on next page)

        ν, _, (f1, f2) = self.true_process(C_new)
        return C_new, ν, (f1, f2)
```

The size of the inflation surprise.

Chapter 7 of Sargent [1999] states $\sigma_1 = \sigma_2 = 0.3$ for this example.

Its reported numbers are reproduced with $\sigma_2 = 1$, which is also consistent with its statement that the true model's one-step prediction error has standard deviation 1.

We use $\sigma_2 = 1$.

The choice matters because the fitting criterion is not scale-invariant.

The criterion of *Optimal Misspecified Beliefs* equals σ_2^2 times a function of c that depends on σ_2 only through the ratio ν/σ_2 of the mean that the perceived model must fit to the size of the surprises.

A smaller σ_2 makes the mean relatively larger, which pushes the public toward a larger gain and so, by (103.8), lowers mean inflation.

```
mp = MisspecifiedPhillips(δ=0.97)
C_star, ν_star, (f1, f2) = mp.solve()

print(f"equilibrium gain     C = {C_star:.4f}")
print(f"policy rule          y = {f1:.4f} + {f2:.4f} x")
print(f"mean inflation       ν = {ν_star:.3f}   (formula: "
      f"{mp.θ * mp.U_star * (1 - mp.δ) / (1 - mp.δ + mp.δ * C_star):.3f})")
print(f"Nash inflation   θ U*  = {mp.θ * mp.U_star:.3f}")

C_03, ν_03, _ = MisspecifiedPhillips(δ=0.97, σ2=0.3).solve()
print(f"\nwith σ2 = 0.3:  C = {C_03:.4f},  mean inflation = {ν_03:.3f}")
```

```
equilibrium gain     C = 0.0673
policy rule          y = 1.0242 + 0.3495 x
mean inflation       ν = 1.574   (formula: 1.574)
Nash inflation   θ U*  = 5.000

with σ2 = 0.3:  C = 0.1138,  mean inflation = 1.069
```

With $\sigma_2 = 1$, these are the values that chapter 7 of Sargent [1999] reports.

The most important outcome is that the implied mean inflation rate is substantially *below* the Nash value of 5.

The induction hypothesis embedded in the adaptive expectations scheme, together with a high discount factor, delivers this improvement.

Because C is now an equilibrium outcome, the mechanism is sharper than in *Adaptive Expectations and the Phelps Problem*, where $\lambda = 1 - C$ could be manipulated independently of δ.

As in *Optimal Misspecified Beliefs*, the equilibrium is E-stable.

```
h = 1e-4
B_prime = (mp.best_estimate(C_star + h) - mp.best_estimate(C_star - h)) / (2 * h)
print(f"B'(C*) = {B_prime:.3f}")
```

```
B'(C*) = -0.305
```

Here $B'(C^*)$ is negative but greater than -1, so the iteration of B converges, oscillating around C^*.

One reason for the negative slope is that a higher gain makes the government disinflate further, which lowers the mean that the public's model must fit and so lowers the gain the public wants.

103.7.1 Approaching Ramsey

As the government becomes more patient, the equilibrium mean inflation rate falls toward the Ramsey value of zero.

```
