Intermediate Quantitative Economics with Python

Thomas J. Sargent & John Stachurski

Nov 10, 2026

CONTENTS

I Tools and Techniques **7**

1 Modeling COVID-19 **9**
- 1.1 Overview . . . 9
- 1.2 The SEIR model . . . 10
- 1.3 Implementation . . . 11
- 1.4 Experiments . . . 12
- 1.5 Ending lockdown . . . 17

2 Linear Algebra **21**
- 2.1 Overview . . . 21
- 2.2 Vectors . . . 22
- 2.3 Matrices . . . 29
- 2.4 Solving systems of equations . . . 31
- 2.5 Eigenvalues and eigenvectors . . . 36
- 2.6 Further topics . . . 39
- 2.7 Exercises . . . 41

3 QR Decomposition **45**
- 3.1 Overview . . . 45
- 3.2 Matrix factorization . . . 45
- 3.3 Gram-Schmidt process . . . 45
- 3.4 Some code . . . 47
- 3.5 Example . . . 48
- 3.6 Using QR decomposition to compute eigenvalues . . . 50
- 3.7 QR and PCA . . . 51

4 Circulant Matrices **55**
- 4.1 Overview . . . 55
- 4.2 Constructing a Circulant Matrix . . . 55
- 4.3 Connection to Permutation Matrix . . . 57
- 4.4 Examples with Python . . . 58
- 4.5 Associated Permutation Matrix . . . 62
- 4.6 Discrete Fourier Transform . . . 64

5 Singular Value Decomposition (SVD) **71**
- 5.1 Overview . . . 71
- 5.2 The setting . . . 71
- 5.3 Singular value decomposition . . . 72
- 5.4 Four fundamental subspaces . . . 73
- 5.5 Eckart-Young theorem . . . 76

5.6 Full and reduced SVD's . . . 77
5.7 Polar decomposition . . . 80
5.8 Application: principal components analysis (PCA) . . . 81
5.9 Relationship of PCA to SVD . . . 83
5.10 PCA with eigenvalues and eigenvectors . . . 83
5.11 Connections . . . 85
5.12 Exercises . . . 90

6 VARs and DMDs **97**
6.1 Overview . . . 97
6.2 First-order vector autoregressions . . . 98
6.3 A reduced-rank VAR . . . 100
6.4 The DMD algorithm . . . 102
6.5 Right eigenvectors: DMD modes . . . 103
6.6 Left eigenvectors and a modal representation . . . 104
6.7 Long-run responses . . . 106
6.8 A simulated example . . . 106
6.9 Source for some Python code . . . 111
6.10 Exercises . . . 111

7 Using Newton's Method to Solve Economic Models **115**
7.1 Overview . . . 115
7.2 Fixed point computation using Newton's method . . . 116
7.3 Root-Finding in one dimension . . . 123
7.4 Multivariate Newton's method . . . 124
7.5 Exercises . . . 133

II Elementary Statistics **139**

8 Elementary Probability with Matrices **141**
8.1 Sketch of basic concepts . . . 142
8.2 What does probability mean? . . . 142
8.3 Representing probability distributions . . . 144
8.4 Univariate probability distributions . . . 144
8.5 Bivariate probability distributions . . . 146
8.6 Marginal probability distributions . . . 146
8.7 Conditional probability distributions . . . 147
8.8 Transition probability matrix . . . 147
8.9 Application: forecasting a time series . . . 148
8.10 Statistical independence . . . 148
8.11 Means and variances . . . 149
8.12 Matrix representations of some bivariate distributions . . . 149
8.13 A continuous bivariate random vector . . . 156
8.14 Sum of two independently distributed random variables . . . 165
8.15 Coupling . . . 166
8.16 Copula functions . . . 167
8.17 Exercises . . . 174

9 Some Probability Distributions **181**
9.1 Some Discrete Probability Distributions . . . 181
9.2 Geometric distribution . . . 181
9.3 Pascal (negative binomial) distribution . . . 182
9.4 Newcomb–Benford distribution . . . 183
9.5 Univariate Gaussian distribution . . . 185

9.6 Uniform Distribution . . . 185
9.7 A Mixed Discrete-Continuous Distribution . . . 186
9.8 Drawing a Random Number from a Particular Distribution . . . 187

10 LLN and CLT **195**
10.1 Overview . . . 195
10.2 Relationships . . . 196
10.3 LLN . . . 196
10.4 CLT . . . 200
10.5 Exercises . . . 206

11 Two Meanings of Probability **213**
11.1 Overview . . . 213
11.2 Frequentist Interpretation . . . 214
11.3 Bayesian Interpretation . . . 220
11.4 Comparing the two interpretations . . . 228
11.5 Role of a Conjugate Prior . . . 229

12 Multivariate Hypergeometric Distribution **231**
12.1 Overview . . . 231
12.2 The administrator's problem . . . 231
12.3 Usage . . . 235

13 Multivariate Normal Distribution **241**
13.1 Overview . . . 241
13.2 The multivariate normal distribution . . . 242
13.3 Bivariate example . . . 245
13.4 Trivariate example . . . 249
13.5 One dimensional intelligence (IQ) . . . 250
13.6 Information as surprise . . . 254
13.7 Cholesky factor magic . . . 256
13.8 Math and verbal intelligence . . . 256
13.9 Univariate time series analysis . . . 259
13.10 Stochastic difference equation . . . 264
13.11 Application to stock price model . . . 265
13.12 Filtering foundations . . . 267
13.13 Classic factor analysis model . . . 271
13.14 PCA and factor analysis . . . 274
13.15 Exercises . . . 279

14 Fault Tree Uncertainties **289**
14.1 Overview . . . 289
14.2 The lognormal distribution . . . 290
14.3 The convolution theorem . . . 291
14.4 Approximating continuous distributions . . . 292
14.5 Discretizing the lognormal distribution . . . 296
14.6 Convolving probability mass functions . . . 298
14.7 Fault tree analysis . . . 301
14.8 Failure rates unknown . . . 302
14.9 Application: waste hoist failure rate . . . 304
14.10 Exercises . . . 309

15 Introduction to Artificial Neural Networks **317**
15.1 Overview . . . 318
15.2 A Deep (but not Wide) Artificial Neural Network . . . 318

15.3 Calibrating Parameters . . . 319
15.4 Back Propagation and the Chain Rule . . . 320
15.5 Training Set . . . 321
15.6 Example 1 . . . 324
15.7 How Deep? . . . 325
15.8 Example 2 . . . 326

16 Randomized Response Surveys **329**
16.1 Overview . . . 329
16.2 Warner's Strategy . . . 329
16.3 Comparing Two Survey Designs . . . 331
16.4 Concluding Remarks . . . 337

17 Expected Utilities of Random Responses **339**
17.1 Overview . . . 339
17.2 Privacy measures . . . 339
17.3 Zoo of concepts . . . 340
17.4 Respondent's expected utility . . . 341
17.5 Utilitarian view of survey design . . . 345
17.6 Criticisms of proposed privacy measures . . . 348
17.7 Concluding remarks . . . 352

III Bayes Law 355

18 Non-Conjugate Priors **357**
18.1 Overview . . . 357
18.2 The coin-flipping model . . . 358
18.3 MCMC reproduces the conjugate posterior . . . 360
18.4 Non-conjugate priors . . . 362
18.5 Variational inference . . . 367
18.6 Where to next . . . 371

19 Posterior Distributions for AR(1) Parameters **373**
19.1 Overview . . . 373
19.2 Estimation . . . 375
19.3 Conclusion . . . 385

20 Forecasting an AR(1) Process **387**
20.1 A Univariate First-Order Autoregressive Process . . . 388
20.2 Implementation . . . 389
20.3 Predictive Distributions of Path Properties . . . 394
20.4 A Wecker-Like Algorithm . . . 395
20.5 Using Simulations to Approximate a Posterior Distribution . . . 395
20.6 Calculating Sample Path Statistics . . . 396
20.7 Original Wecker Method . . . 398
20.8 Extended Wecker Method . . . 399
20.9 Comparison . . . 401
20.10 Conclusion . . . 403

IV Statistics and Information 405

21 Statistical Divergence Measures **407**
21.1 Overview . . . 407

21.2 Primer on entropy, cross-entropy, KL divergence . . . 408
21.3 Two Beta distributions: running example . . . 409
21.4 Kullback–Leibler divergence . . . 410
21.5 Jensen-Shannon divergence . . . 412
21.6 Chernoff entropy . . . 414
21.7 Comparing divergence measures . . . 415
21.8 KL divergence and maximum-likelihood estimation . . . 418
21.9 Related lectures . . . 419
21.10 Exercises . . . 420

22 Likelihood Ratio Processes **427**
22.1 Overview . . . 427
22.2 Likelihood Ratio Process . . . 428
22.3 Nature permanently draws from density g . . . 430
22.4 Peculiar property . . . 433
22.5 Nature permanently draws from density f . . . 433
22.6 Likelihood ratio test . . . 436
22.7 Hypothesis testing and classification . . . 445
22.8 Markov chains . . . 458
22.9 Related lectures . . . 461
22.10 Exercises . . . 461

23 Heterogeneous Beliefs and Financial Markets **469**
23.1 Overview . . . 469
23.2 Review: likelihood ratio processes . . . 470
23.3 Blume and Easley's setting . . . 471
23.4 Nature and agents' beliefs . . . 472
23.5 A socialist risk-sharing arrangement . . . 472
23.6 Social planner's allocation problem . . . 473
23.7 If you're so smart, ... 475
23.8 Competitive equilibrium prices . . . 476
23.9 Simulations . . . 480
23.10 Related lectures . . . 487
23.11 Exercises . . . 487

24 Likelihood Processes For VAR Models **515**
24.1 Overview . . . 515
24.2 VAR model setup . . . 516
24.3 Likelihood ratio process . . . 519
24.4 Example 1: two AR(1) processes . . . 520
24.5 Example 2: bivariate VAR models . . . 521
24.6 KL divergence rate . . . 526
24.7 Application: Samuelson multiplier-accelerator . . . 528
24.8 Exercises . . . 535

25 Mean of a Likelihood Ratio Process **543**
25.1 Overview . . . 543
25.2 Mathematical expectation of likelihood ratio . . . 544
25.3 Importance sampling . . . 547
25.4 Approximating a cumulative likelihood ratio . . . 548
25.5 Distribution of sample mean . . . 551
25.6 Choosing a sampling distribution . . . 554
25.7 Exercises . . . 558

26 A Problem that Stumped Milton Friedman **565**

26.1 Overview . . . 565
26.2 Source of the Problem . . . 566
26.3 Neyman-Pearson formulation . . . 567
26.4 Wald's sequential formulation . . . 569
26.5 Links between A, B and α, β . . . 571
26.6 Simulations . . . 573
26.7 Related lectures . . . 584
26.8 Exercises . . . 584

27 A Bayesian Formulation of Friedman and Wald's Problem **599**
27.1 Overview . . . 599
27.2 A Dynamic Programming Approach . . . 601
27.3 Implementation . . . 606
27.4 Analysis . . . 609
27.5 Exercises . . . 616

28 Exchangeability and Bayesian Updating **621**
28.1 Overview . . . 621
28.2 Independently and identically distributed . . . 622
28.3 A setting in which past observations are informative . . . 623
28.4 Relationship between IID and exchangeable . . . 624
28.5 Exchangeability . . . 625
28.6 Bayes' Law . . . 626
28.7 More details about Bayesian updating . . . 627
28.8 Appendix . . . 635
28.9 Sequels . . . 643
28.10 Exercises . . . 644

29 Likelihood Ratio Processes and Bayesian Learning **653**
29.1 Overview . . . 653
29.2 The setting . . . 654
29.3 Likelihood ratio processes and Bayes' law . . . 655
29.4 Another timing protocol . . . 661
29.5 Behavior of posterior probability $\{\pi_t\}$ under subjective probability distribution . . . 663
29.6 Initial prior is verified by paths drawn from subjective conditional densities . . . 671
29.7 Drilling down a little bit . . . 672
29.8 Related lectures . . . 674
29.9 Exercises . . . 674

30 Blackwell's Theorem on Comparing Experiments **681**
30.1 Overview . . . 681
30.2 Experiments and stochastic transformations . . . 683
30.3 Three equivalent criteria . . . 685
30.4 The main theorem . . . 687
30.5 Kihlstrom's Bayesian interpretation . . . 688
30.6 Simulating the Blackwell order with many states . . . 695
30.7 The DeGroot uncertainty function . . . 697
30.8 Application 1: demand for information about product quality . . . 700
30.9 Application 2: sequential experimental design . . . 702
30.10 The Data Processing Inequality and Coarse-Graining . . . 705
30.11 Relation to Bayesian likelihood-ratio learning . . . 708
30.12 Summary . . . 709
30.13 Exercises . . . 710

31 Incentives for Information Transfer **715**

31.1 Overview . . . 715
31.2 A statistical decision problem . . . 717
31.3 A planner and an agent . . . 718
31.4 Economies with two actions . . . 721
31.5 Dominated actions as threats . . . 723
31.6 Truthful but coarse reports . . . 726
31.7 Comparing experiments . . . 727
31.8 Better information can hurt the planner . . . 729
31.9 What the discussants added . . . 735
31.10 Relation to other lectures . . . 736
31.11 Concluding remarks . . . 737
31.12 Exercises . . . 737

32 Information and Market Equilibrium **753**
32.1 Overview . . . 753
32.2 Setup . . . 755
32.3 Price revelation . . . 756
32.4 Invertibility and the elasticity of substitution . . . 758
32.5 Bayesian price expectations in a dynamic economy . . . 764
32.6 Simulating Bayesian learning from prices . . . 767
32.7 Exercises . . . 774

33 Incorrect Models **789**
33.1 Overview . . . 789
33.2 Sampling from compound lottery H . . . 792
33.3 Type 1 agent . . . 794
33.4 What a type 1 agent learns when mixture H generates data . . . 794
33.5 Kullback-Leibler divergence governs limit of π_t . . . 798
33.6 Type 2 agent . . . 803
33.7 Concluding remarks . . . 804
33.8 Exercises . . . 806

34 Bayesian versus Frequentist Decision Rules **817**
34.1 Overview . . . 817
34.2 Setup . . . 818
34.3 Frequentist Decision Rule . . . 821
34.4 Bayesian Decision Rule . . . 828
34.5 Was the Navy Captain's Hunch Correct? . . . 836
34.6 More Details . . . 838
34.7 Distribution of Bayesian Decision Rule's Time to Decide . . . 838
34.8 Probability of Making Correct Decision . . . 843
34.9 Distribution of Likelihood Ratios at Neyman-Pearson's t . . . 846
34.10 Exercises . . . 848

35 Merging of Opinions: The Blackwell–Dubins Theorem **855**
35.1 Overview . . . 855
35.2 Probability measures on sequence spaces . . . 856
35.3 The likelihood-ratio martingale . . . 858
35.4 The Blackwell–Dubins theorem . . . 860
35.5 The Beta–Bernoulli model . . . 861
35.6 Failure of merging: mutual singularity . . . 872
35.7 Kakutani's theorem: when does merging hold? . . . 874
35.8 Extension to continuous time . . . 878
35.9 Applications . . . 879
35.10 The rate of merging . . . 881

35.11 Summary and extensions . . . 883
35.12 Exercises . . . 884

36 Survival and Long-Run Dynamics under Recursive Preferences **891**
36.1 Overview . . . 891
36.2 Environment . . . 892
36.3 Planner's problem . . . 894
36.4 Survival conditions . . . 897
36.5 Wealth dynamics decomposition . . . 897
36.6 Survival regions . . . 905
36.7 Three survival channels . . . 909
36.8 Varying the IES . . . 911
36.9 Asymptotic results . . . 912
36.10 The separable case . . . 915
36.11 Asset pricing implications . . . 917
36.12 Optimistic and pessimistic distortions . . . 918
36.13 Long-run consumption distribution . . . 920
36.14 Summary . . . 922

37 The Design and Price of Information **923**
37.1 Overview . . . 923
37.2 The decision problem . . . 924
37.3 Experiments and their value . . . 925
37.4 Blackwell's order is only partial . . . 927
37.5 The seller's problem . . . 929
37.6 Two types . . . 929
37.7 A continuum of types . . . 932
37.8 Concluding remarks . . . 939
37.9 Exercises . . . 940

38 Market Diffusion with Two-Sided Learning **951**
38.1 Overview . . . 951
38.2 The market . . . 952
38.3 Two-sided learning . . . 953
38.4 Efficient experimentation . . . 955
38.5 Equilibrium . . . 957
38.6 Too much experimentation, then too little . . . 960
38.7 Diffusion over time . . . 961
38.8 Martingale properties . . . 964
38.9 Concluding remarks . . . 965
38.10 Exercises . . . 965

39 Which Moments to Match? **977**
39.1 Overview . . . 977
39.2 The estimation problem . . . 979
39.3 The auxiliary model and its score . . . 979
39.4 The estimator . . . 980
39.5 Why the score is the right thing to match . . . 981
39.6 Efficiency . . . 982
39.7 Comparison with matching the auxiliary parameters . . . 983
39.8 Choosing the score generator . . . 983
39.9 A first example: an AR(1) inside an AR(2) . . . 984
39.10 A second example: stochastic volatility . . . 988
39.11 Testing the structural model . . . 992
39.12 Applications . . . 993

39.13 Recovering the latent state . . . 994
39.14 Related lectures . . . 994
39.15 Exercises . . . 994

V Linear Programming 1005

40 Optimal Transport 1007
40.1 Overview . . . 1007
40.2 The Optimal Transport Problem . . . 1008
40.3 The Linear Programming Approach . . . 1009
40.4 The Dual Problem . . . 1016
40.5 The Python Optimal Transport Package . . . 1018

41 Von Neumann Growth Model (and a Generalization) 1023
41.1 Notation . . . 1028
41.2 Model Ingredients and Assumptions . . . 1029
41.3 Dynamic Interpretation . . . 1031
41.4 Duality . . . 1032
41.5 Interpretation as Two-player Zero-sum Game . . . 1033

VI Introduction to Dynamics 1041

42 Finite Markov Chains 1043
42.1 Overview . . . 1043
42.2 Definitions . . . 1044
42.3 Simulation . . . 1046
42.4 Marginal Distributions . . . 1048
42.5 Irreducibility and Aperiodicity . . . 1050
42.6 Stationary Distributions . . . 1053
42.7 Ergodicity . . . 1057
42.8 Computing Expectations . . . 1058
42.9 Exercises . . . 1059

43 Inventory Dynamics 1067
43.1 Overview . . . 1067
43.2 Sample paths . . . 1068
43.3 Marginal distributions . . . 1071
43.4 Exercises . . . 1074

44 Linear State Space Models 1079
44.1 Overview . . . 1079
44.2 The Linear State Space Model . . . 1080
44.3 Distributions and Moments . . . 1086
44.4 Stationarity and Ergodicity . . . 1093
44.5 Noisy Observations . . . 1098
44.6 Prediction . . . 1099
44.7 Code . . . 1100
44.8 Exercises . . . 1100

45 Samuelson Multiplier-Accelerator 1103
45.1 Overview . . . 1103
45.2 Details . . . 1105
45.3 Implementation . . . 1108

45.4 Stochastic shocks . . . 1117
45.5 Government spending . . . 1119
45.6 Wrapping everything into a class . . . 1121
45.7 Using the LinearStateSpace class . . . 1126
45.8 Pure multiplier model . . . 1133
45.9 Summary . . . 1136

46 The Acceleration Principle and the Nature of Business Cycles 1137
46.1 Overview . . . 1137
46.2 Empirical foundation for the acceleration principle . . . 1139
46.3 Acceleration enables oscillations . . . 1140
46.4 A linear system with shocks . . . 1143
46.5 From autocovariances to spectra . . . 1144
46.6 Spectral peaks in the Hansen-Samuelson model . . . 1145
46.7 Real roots can produce peaks in general models . . . 1149
46.8 A calibrated model in the frequency domain . . . 1152
46.9 Summary . . . 1162
46.10 Exercises . . . 1163

47 Kesten Processes and Firm Dynamics 1171
47.1 Overview . . . 1171
47.2 Kesten processes . . . 1172
47.3 Heavy tails . . . 1175
47.4 Application: firm dynamics . . . 1177
47.5 Exercises . . . 1178

48 Wealth Distribution Dynamics 1185
48.1 Overview . . . 1185
48.2 Lorenz Curves and the Gini Coefficient . . . 1186
48.3 A Model of Wealth Dynamics . . . 1189
48.4 Implementation . . . 1190
48.5 Applications . . . 1193
48.6 Exercises . . . 1197

49 A First Look at the Kalman Filter 1201
49.1 Overview . . . 1201
49.2 The basic idea . . . 1202
49.3 Convergence . . . 1210
49.4 Implementation . . . 1210
49.5 Exercises . . . 1211

50 Another Look at the Kalman Filter 1219
50.1 A worker's output . . . 1220
50.2 A firm's wage-setting policy . . . 1221
50.3 A state-space representation . . . 1221
50.4 An innovations representation . . . 1222
50.5 Some computational experiments . . . 1225
50.6 Future extensions . . . 1235

51 The Kalman Filter and Vector Autoregressions 1237
51.1 Overview . . . 1237
51.2 The state space system . . . 1238
51.3 The Kalman filter . . . 1238
51.4 The Gram-Schmidt process . . . 1241
51.5 Hidden Markov model . . . 1241

51.6 Estimation . . . 1241
51.7 Vector autoregressions and the Kalman filter . . . 1242
51.8 Spectral factorization identity . . . 1243
51.9 Python implementation . . . 1245
51.10 Where this leads . . . 1250
51.11 Summary . . . 1251
51.12 Exercises . . . 1251

52 Vector Autoregressions for Subsets of Variables 1257
52.1 Overview . . . 1257
52.2 The large system . . . 1258
52.3 The small system . . . 1259
52.4 Four representations . . . 1259
52.5 Two cases where nothing is lost . . . 1262
52.6 Code . . . 1263
52.7 Example 1: a bivariate VAR(2) . . . 1266
52.8 Example 2: an omitted interest rate . . . 1273
52.9 Summary . . . 1275
52.10 Exercises . . . 1275

53 Organization Capital 1279
53.1 Overview . . . 1279
53.2 The basic idea . . . 1280
53.3 Personnel information as organization capital . . . 1280
53.4 Industry equilibrium . . . 1287
53.5 Bayesian screening simulation . . . 1289
53.6 Team information . . . 1291
53.7 Firm-specific human capital . . . 1293
53.8 Costs of transferring organization capital . . . 1294
53.9 Summary and implications . . . 1296

54 Two Models of Measurements and the Investment Accelerator 1299
54.1 Overview . . . 1299
54.2 The economic model . . . 1301
54.3 Measurement errors . . . 1305
54.4 A classical model of measurements initially collected by an agency . . . 1307
54.5 A model of optimal estimates reported by an agency . . . 1314
54.6 Simulation . . . 1319
54.7 Summary . . . 1325
54.8 Exercises . . . 1326

VII Search 1331

55 Job Search I: The McCall Search Model 1333
55.1 Overview . . . 1334
55.2 The McCall Model . . . 1334
55.3 Computing the Optimal Policy: Take 1 . . . 1337
55.4 Computing an Optimal Policy: Take 2 . . . 1344
55.5 Continuous Offer Distribution . . . 1346
55.6 Volatility . . . 1348
55.7 Exercises . . . 1353

56 Job Search II: Search and Separation 1357
56.1 Overview . . . 1358

56.2 The model . . . 1358
56.3 Solving the model . . . 1359
56.4 Code . . . 1360
56.5 A simplifying transformation . . . 1364
56.6 Implementation . . . 1365
56.7 Impact of parameters . . . 1366
56.8 Exercises . . . 1369

57 Job Search III: Search with Separation and Markov Wages 1373
57.1 Model setup . . . 1374
57.2 Code . . . 1375
57.3 Improving efficiency . . . 1379
57.4 Sensitivity analysis . . . 1381
57.5 Employment simulation . . . 1382
57.6 Ergodic property . . . 1385
57.7 Cross-sectional analysis . . . 1386
57.8 Lower unemployment compensation (c=0.5) . . . 1390
57.9 Exercises . . . 1390

58 Job Search IV: Fitted Value Function Iteration 1393
58.1 Overview . . . 1393
58.2 Model . . . 1394
58.3 Solution method . . . 1394
58.4 Implementation . . . 1397
58.5 Simulation . . . 1402
58.6 Exercises . . . 1409

59 Job Search V: Risk-Sensitive Preferences 1413
59.1 Overview . . . 1413
59.2 Outline . . . 1414
59.3 Introduction to risk-sensitivity . . . 1414
59.4 Back to job search . . . 1421

60 Job Search VI: Persistent and Transitory Wage Shocks 1429
60.1 Overview . . . 1429
60.2 The model . . . 1430
60.3 Implementation . . . 1431
60.4 Unemployment duration . . . 1435
60.5 Exercises . . . 1437

61 Job Search VII: Modeling Career Choice 1439
61.1 Overview . . . 1439
61.2 Model . . . 1440
61.3 Implementation . . . 1442
61.4 Exercises . . . 1447

62 Job Search VIII: On-the-Job Search 1453
62.1 Overview . . . 1453
62.2 Model . . . 1454
62.3 Implementation . . . 1456
62.4 Solving for Policies . . . 1458
62.5 Exercises . . . 1461

63 Job Search IX: Search with Learning 1467
63.1 Overview . . . 1467

63.2 Model . . . 1468
63.3 Take 1: Solution by VFI . . . 1472
63.4 Take 2: A More Efficient Method . . . 1477
63.5 Another Functional Equation . . . 1477
63.6 Solving the RWFE . . . 1477
63.7 Implementation . . . 1478
63.8 Exercises . . . 1479
63.9 Solutions . . . 1479
63.10 Appendix A . . . 1481
63.11 Appendix B . . . 1483
63.12 Examples . . . 1487

VIII Reinforcement Learning 1499

64 Inventory Management via Q-Learning 1501
64.1 Introduction . . . 1501
64.2 The Model . . . 1502
64.3 Solving via Value Function Iteration . . . 1503
64.4 Q-Learning . . . 1507

65 Risk-Sensitive Inventory Management via Q-Learning 1515
65.1 Introduction . . . 1515
65.2 The Model . . . 1516
65.3 Solving via Value Function Iteration . . . 1516
65.4 Interpreting the Outcomes . . . 1521
65.5 Q-Learning . . . 1522
65.6 Conclusion . . . 1529

66 Job Search X: Search with Q-Learning 1531
66.1 Overview . . . 1531
66.2 Review of McCall model . . . 1532
66.3 Implied quality function Q . . . 1535
66.4 From probabilities to samples . . . 1536
66.5 Q-learning . . . 1537
66.6 Employed worker can't quit . . . 1545
66.7 Possible extensions . . . 1546

IX Introduction to Optimal Savings 1547

67 Optimal Savings I: Cake Eating 1549
67.1 Overview . . . 1549
67.2 The model . . . 1550
67.3 The value function . . . 1551
67.4 The optimal policy . . . 1553
67.5 The Euler equation . . . 1554
67.6 Exercises . . . 1557

68 Optimal Savings II: Numerical Cake Eating 1561
68.1 Overview . . . 1561
68.2 Reviewing the Model . . . 1562
68.3 Value Function Iteration . . . 1562
68.4 Exercises . . . 1571

69 Optimal Savings III: Stochastic Returns **1577**
69.1 Overview . . . 1577
69.2 The Model . . . 1578
69.3 Computation . . . 1582
69.4 Exercises . . . 1590

70 Optimal Savings IV: Time Iteration **1593**
70.1 Overview . . . 1593
70.2 The Euler Equation . . . 1594
70.3 Implementation . . . 1596
70.4 Exercises . . . 1602

71 Optimal Savings V: The Endogenous Grid Method **1605**
71.1 Overview . . . 1605
71.2 Key Idea . . . 1606
71.3 Implementation . . . 1607

72 Optimal Savings VI: EGM with JAX **1613**
72.1 Overview . . . 1613
72.2 Implementation . . . 1614
72.3 Exercises . . . 1618

X Household Problems **1623**

73 The Income Fluctuation Problem I: Discretization and VFI **1625**
73.1 Overview . . . 1625
73.2 Set Up . . . 1626
73.3 Code . . . 1627
73.4 Exercises . . . 1631

74 The Income Fluctuation Problem II: Optimistic Policy Iteration **1635**
74.1 Overview . . . 1635
74.2 Model and Primitives . . . 1636
74.3 Operators and Policies . . . 1636
74.4 Value Function Iteration . . . 1638
74.5 Optimistic Policy Iteration . . . 1639
74.6 Timing Comparison . . . 1640
74.7 Exercises . . . 1643

75 The Income Fluctuation Problem III: The Endogenous Grid Method **1647**
75.1 Overview . . . 1647
75.2 The Household Problem . . . 1648
75.3 Computation . . . 1650
75.4 NumPy Implementation . . . 1651
75.5 JAX Implementation . . . 1654
75.6 Simulation . . . 1662

76 The Income Fluctuation Problem IV: Transient Income Shocks **1665**
76.1 Overview . . . 1665
76.2 The Household Problem . . . 1666
76.3 NumPy Implementation . . . 1667
76.4 JAX Implementation . . . 1671
76.5 Simulation . . . 1678
76.6 Wealth Inequality . . . 1680

76.7 Exercises . . . 1683

77 The Income Fluctuation Problem V: Stochastic Returns on Assets 1687
77.1 Overview . . . 1688
77.2 The Model . . . 1688
77.3 Solution Algorithm . . . 1690
77.4 Implementation . . . 1691
77.5 Simulation . . . 1694
77.6 Wealth Inequality . . . 1697
77.7 Exercises . . . 1698

XI LQ Control 1703

78 LQ Control: Foundations 1705
78.1 Overview . . . 1705
78.2 Introduction . . . 1706
78.3 Optimality – finite horizon . . . 1709
78.4 Implementation . . . 1711
78.5 Extensions and comments . . . 1716
78.6 Further applications . . . 1718
78.7 Exercises . . . 1726

79 Lagrangian for LQ Control 1735
79.1 Overview . . . 1735
79.2 Undiscounted LQ DP Problem . . . 1736
79.3 Lagrangian . . . 1737
79.4 State-Costate Dynamics . . . 1738
79.5 Reciprocal Pairs Property . . . 1738
79.6 Schur decomposition . . . 1739
79.7 Application . . . 1740
79.8 Other Applications . . . 1745
79.9 Discounted Problems . . . 1745

80 Eliminating Cross Products 1749
80.1 Overview . . . 1749
80.2 Undiscounted Dynamic Programming Problem . . . 1749
80.3 Kalman Filter . . . 1750
80.4 Duality table . . . 1751

81 The Permanent Income Model 1753
81.1 Overview . . . 1753
81.2 The Savings Problem . . . 1754
81.3 Alternative Representations . . . 1761
81.4 Two Classic Examples . . . 1764
81.5 Further Reading . . . 1767
81.6 Appendix: The Euler Equation . . . 1768

82 Permanent Income II: LQ Techniques 1769
82.1 Overview . . . 1769
82.2 Setup . . . 1770
82.3 The LQ Approach . . . 1772
82.4 Implementation . . . 1773
82.5 Two Example Economies . . . 1776

83 Robust Permanent Income and Pricing **1787**
83.1 Overview . . . 1787
83.2 Risk-sensitive recursive preferences . . . 1788
83.3 A preference for robustness . . . 1791
83.4 The permanent income economy . . . 1791
83.5 Observational equivalence . . . 1792
83.6 Estimation . . . 1795
83.7 Asset pricing and the market price of risk . . . 1798
83.8 A risk-sensitive regulator . . . 1800
83.9 Exercises . . . 1803
83.10 Related lectures . . . 1806

84 Certainty Equivalence **1807**
84.1 Overview . . . 1807
84.2 A central problem of empirical economics . . . 1808
84.3 A formal setup . . . 1808
84.4 Estimated rules are not enough . . . 1809
84.5 An optimization problem . . . 1809
84.6 A linear-quadratic DP problem and certainty equivalence . . . 1810
84.7 A trouble with ad hoc expectations . . . 1813
84.8 Exercises . . . 1813
84.9 Concluding remarks . . . 1814

85 Certainty Equivalence and Model Uncertainty **1815**
85.1 Overview . . . 1815
85.2 Recap: ordinary certainty equivalence . . . 1816
85.3 Model uncertainty and robustness . . . 1818
85.4 Value function under robustness . . . 1820
85.5 Risk-sensitive preferences . . . 1821
85.6 Application: permanent income model . . . 1821
85.7 Summary . . . 1826
85.8 Exercises . . . 1826

86 The LQ Permanent Income Model **1831**
86.1 Overview . . . 1831
86.2 The standard LQ permanent income model . . . 1832
86.3 Exercises . . . 1838

87 Consumption Smoothing with Incomplete and Complete Markets **1845**
87.1 Overview . . . 1845
87.2 A brief review . . . 1846
87.3 Spreading consumption cross sections . . . 1847
87.4 A borrowers and lenders economy . . . 1849
87.5 Consumption smoothing with complete markets . . . 1851
87.6 Exercises . . . 1853

88 Robust Consumption Smoothing and Precautionary Savings **1859**
88.1 Overview . . . 1859
88.2 A brief review . . . 1860
88.3 A robust permanent income model . . . 1862
88.4 Observational equivalence . . . 1865
88.5 The scalar worst-case model . . . 1870
88.6 Frequency domain interpretation . . . 1874
88.7 Detection error probabilities . . . 1876
88.8 Robustness of decision rules . . . 1879

88.9 Concluding remarks . . . 1879
88.10 Exercises . . . 1880
88.11 Related lectures . . . 1883

89 A Robust LQ Bewley Model **1885**
89.1 Overview . . . 1885
89.2 Mapping the Bewley economy into the HST framework . . . 1886
89.3 The robustness scalar for this economy . . . 1887
89.4 The Bewley observational-equivalence locus . . . 1887
89.5 Equilibrium with heterogeneous types . . . 1888
89.6 Where the agents genuinely differ . . . 1889
89.7 Computation . . . 1889
89.8 Concluding remarks . . . 1895
89.9 Exercises . . . 1895
89.10 Related lectures . . . 1899

90 Production Smoothing via Inventories **1901**
90.1 Overview . . . 1901
90.2 Example 1 . . . 1906
90.3 Inventories Not Useful . . . 1907
90.4 Inventories Useful but are Hardwired to be Zero Always . . . 1907
90.5 Example 2 . . . 1909
90.6 Example 3 . . . 1910
90.7 Example 4 . . . 1911
90.8 Example 5 . . . 1913
90.9 Example 6 . . . 1914
90.10 Exercises . . . 1917

XII Bounded Rationality in Macroeconomics 1923

91 A Peculiar Definition of Bounded Rationality **1925**
91.1 Overview . . . 1925
91.2 Rational expectations as a fixed point . . . 1930
91.3 One recursion, many learners . . . 1935
91.4 Money and prices . . . 1939
91.5 Two currencies . . . 1942
91.6 Where this leaves us . . . 1943
91.7 Exercises . . . 1944

92 Adaptive Agents in an Overlapping Generations Monetary Economy **1951**
92.1 Overview . . . 1951
92.2 The environment . . . 1952
92.3 Part 1: a stochastic deficit . . . 1953
92.4 Part 2: a constant deficit and two steady states . . . 1959
92.5 A government learning the Phillips curve . . . 1970
92.6 Concluding remarks . . . 1974
92.7 Exercises . . . 1974

93 Learning, Approximation, and Equilibrium Computation **1989**
93.1 Overview . . . 1989
93.2 A continuous-state functional equation . . . 1990
93.3 A benchmark solution . . . 1993
93.4 Parameterized expectations . . . 1995
93.5 Learning is equilibrium computation . . . 1998

93.6 Learning without a functional form . . . 2002
93.7 Concluding remarks . . . 2005
93.8 Exercises . . . 2006

94 Exchange Rate Indeterminacy, Learning, and Experiments 2015
94.1 Overview . . . 2015
94.2 The two-currency economy . . . 2016
94.3 Newton–Raphson learning . . . 2018
94.4 Evidence from the laboratory . . . 2025
94.5 A genetic algorithm economy . . . 2026
94.6 Concluding remarks . . . 2032
94.7 Exercises . . . 2033

95 Networks, Genetic Algorithms, and Classifier Systems 2043
95.1 Overview . . . 2043
95.2 The perceptron: an agent as a discriminant function . . . 2044
95.3 Associative memory: the Hopfield network . . . 2047
95.4 The genetic algorithm . . . 2050
95.5 Classifier systems . . . 2057
95.6 Evolutionary programming . . . 2062
95.7 Concluding remarks . . . 2063
95.8 Exercises . . . 2064

96 Money as a Medium of Exchange among Artificially Intelligent Agents 2075
96.1 Overview . . . 2075
96.2 The Kiyotaki-Wright environment . . . 2077
96.3 Classifier systems for the Kiyotaki-Wright environment . . . 2080
96.4 Implementation . . . 2084
96.5 Economy A1.1: does a medium of exchange emerge? . . . 2091
96.6 Economy A2.1: when theory predicts speculation . . . 2094
96.7 The bucket brigade's discount factor . . . 2098
96.8 Economy B.1: selecting between two equilibria . . . 2101
96.9 The genetic algorithm . . . 2103
96.10 Economy A1.2: learning from random rules . . . 2105
96.11 Economy C: fiat money . . . 2107
96.12 Economy D: five goods, five types . . . 2110
96.13 Concluding remarks . . . 2113
96.14 Exercises . . . 2114

97 1993 Prospects for Bounded Rationality in Macroeconomics 2121
97.1 Overview . . . 2121
97.2 The quest, restated . . . 2122
97.3 The debit side: how much we must hard-wire . . . 2122
97.4 Why the econometricians have not returned the compliment . . . 2124
97.5 The credit side: selection, computation, and a returned gift . . . 2130
97.6 Reading the ledger against the quest . . . 2132
97.7 Postscript: what became of the program . . . 2133
97.8 Exercises . . . 2138

XIII Phillips Curve Tradeoffs 2147

98 The Rise and Fall of U.S. Inflation 2149
98.1 Overview . . . 2149
98.2 Facts . . . 2150

98.3 The Phillips curve in the data . . . 2152
98.4 Two interpretations . . . 2156
98.5 Ignoring the Lucas Critique . . . 2157
98.6 A premature summary: triumph or vindication? . . . 2159
98.7 Data patterns after 1999 . . . 2162
98.8 A note on notation . . . 2168
98.9 Exercises . . . 2171

99 The Credibility Problem 2179
99.1 Overview . . . 2179
99.2 A one-period economy . . . 2180
99.3 Nash and Ramsey outcomes . . . 2181
99.4 Best response dynamics . . . 2184
99.5 Least squares learning converges to Nash . . . 2186
99.6 More foresight . . . 2189
99.7 Appendix: stochastic approximation . . . 2189
99.8 Exercises . . . 2190

100 Credible Government Policies 2199
100.1 Overview . . . 2199
100.2 The repeated economy . . . 2201
100.3 Recursive strategies and promised values . . . 2204
100.4 The Abreu–Pearce–Stacchetti method . . . 2205
100.5 The best and the worst equilibrium . . . 2207
100.6 Examples of recursive equilibria . . . 2211
100.7 Multiplicity . . . 2214
100.8 Numerical example . . . 2216
100.9 Interpretations . . . 2217
100.10 Exercises . . . 2219

101 Adaptive Expectations and the Phelps Problem 2229
101.1 Overview . . . 2229
101.2 Adaptive expectations . . . 2230
101.3 The Phelps problem . . . 2232
101.4 Disinflation paths . . . 2234
101.5 The general Phelps problem . . . 2236
101.6 Testing the natural-rate hypothesis . . . 2238
101.7 Sacrifice ratios and the subversion of the Phelps model . . . 2239
101.8 Exercises . . . 2241

102 Optimal Misspecified Beliefs 2245
102.1 Overview . . . 2245
102.2 An experiment in Bray's lab . . . 2246
102.3 Optimal misspecification . . . 2248
102.4 Comparing the true and forecasting models . . . 2252
102.5 How the equilibrium depends on ρ . . . 2254
102.6 Lessons . . . 2255
102.7 Exercises . . . 2256

103 Self-Confirming Equilibria 2261
103.1 Overview . . . 2261
103.2 Objects in the Phelps problem . . . 2262
103.3 The actual Phillips curve . . . 2263
103.4 Self-confirming equilibria . . . 2263
103.5 The special case solved by hand . . . 2264

103.6 Uniqueness and E-stability . . . 2267
103.7 Equilibrium with misspecified beliefs . . . 2270
103.8 Exercises . . . 2278

104 Adaptive Learning and Escape Dynamics 2285
104.1 Overview . . . 2285
104.2 A primer on recursive algorithms . . . 2287
104.3 The adaptive model . . . 2293
104.4 Mean dynamics near the self-confirming equilibrium . . . 2296
104.5 Least squares learning: a decreasing gain . . . 2298
104.6 Constant gain and escape dynamics . . . 2302
104.7 The escape route and the induction hypothesis . . . 2304
104.8 Relation to equilibria under forecast misspecification . . . 2307
104.9 Role of the discount factor . . . 2307
104.10 Anticipated utility . . . 2309
104.11 Conclusions . . . 2309
104.12 Exercises . . . 2310

105 Escaping Nash Inflation 2317
105.1 Overview . . . 2317
105.2 The model . . . 2318
105.3 The self-confirming equilibrium . . . 2320
105.4 Adaptation and the mean dynamics . . . 2322
105.5 Escape dynamics as a control problem . . . 2323
105.6 The changed-measure escape path . . . 2325
105.7 The race of four ODEs . . . 2327
105.8 Mean dynamics reinforce the escape . . . 2329
105.9 The experimentation trap . . . 2330
105.10 Simulating escapes . . . 2331
105.11 Escape frequency and model richness . . . 2334
105.12 Escaping volatile inflation . . . 2334
105.13 Exercises . . . 2336

106 Priors, Escapes, and Learning Cycles 2347
106.1 Overview . . . 2347
106.2 The static model . . . 2348
106.3 The self-confirming equilibrium . . . 2350
106.4 Drifting beliefs and the Kalman filter . . . 2350
106.5 Mean dynamics and E-stability . . . 2352
106.6 Learning cycles . . . 2354
106.7 Escape dynamics and the direction of escape . . . 2358
106.8 Sims's nonconvergence . . . 2358
106.9 Conclusion . . . 2365
106.10 Exercises . . . 2366

107 Econometric Policy Evaluation 2379
107.1 Overview . . . 2379
107.2 The model . . . 2380
107.3 The likelihood function . . . 2381
107.4 Data . . . 2382
107.5 Beliefs and recommendations . . . 2383
107.6 Estimates . . . 2385
107.7 Recommendations and misses . . . 2387
107.8 Misses favor vindication . . . 2392
107.9 What came later . . . 2396

107.10 Exercises . . . 2397

108 Drifts and Volatilities **2403**
108.1 Overview . . . 2403
108.2 Bad policy or bad luck? . . . 2405
108.3 A VAR with drifting coefficients and stochastic volatility . . . 2406
108.4 The data . . . 2408
108.5 Priors . . . 2410
108.6 Simulating the posterior . . . 2411
108.7 What the data say . . . 2413
108.8 Why classical tests missed the drift . . . 2432
108.9 Bad policy or bad luck? A verdict . . . 2433
108.10 Appendix: the sampler in detail . . . 2434
108.11 Exercises . . . 2438

109 Drifts and Volatilities after 2000 **2447**
109.1 Overview . . . 2447
109.2 The model and the sampler . . . 2448
109.3 The extended sample . . . 2448
109.4 Fitting the extended sample . . . 2451
109.5 Did coefficient drift continue? . . . 2452
109.6 Volatility after the Great Moderation . . . 2453
109.7 Core inflation, the natural rate, and persistence . . . 2457
109.8 What the additional observations change . . . 2461
109.9 Exercises . . . 2461

110 The Lost Conquest: Fed Policy in the 2020s **2467**
110.1 Overview . . . 2467
110.2 The three elements . . . 2469
110.3 The Fed's drifting-coefficients beliefs . . . 2470
110.4 The Fed's Phelps problem . . . 2473
110.5 Why the Fed was slow: a counterfactual . . . 2479
110.6 Real-time data and the delay . . . 2480
110.7 How beliefs shape the Phelps rule . . . 2484
110.8 From policy to measured beliefs . . . 2486
110.9 Was the conquest lost? . . . 2492
110.10 Exercises . . . 2493

XIV Optimal Growth 2503

111 Cass-Koopmans Model **2505**
111.1 Overview . . . 2505
111.2 The Model . . . 2506
111.3 Planning Problem . . . 2507
111.4 Shooting Algorithm . . . 2511
111.5 Setting Initial Capital to Steady State Capital . . . 2515
111.6 A Turnpike Property . . . 2517
111.7 A Limiting Infinite Horizon Economy . . . 2520
111.8 Stable Manifold and Phase Diagram . . . 2521
111.9 Concluding Remarks . . . 2523

112 Cass-Koopmans Competitive Equilibrium **2527**
112.1 Overview . . . 2527
112.2 Review of Cass-Koopmans Model . . . 2528

112.3 Competitive Equilibrium . . . 2529
112.4 Market Structure . . . 2530
112.5 Firm Problem . . . 2530
112.6 Household Problem . . . 2531
112.7 Computing a Competitive Equilibrium . . . 2533
112.8 Yield Curves and Hicks-Arrow Prices . . . 2541

113 Cass-Koopmans Model with Distorting Taxes 2543
113.1 Overview . . . 2543
113.2 The Economy . . . 2543
113.3 Equilibrium . . . 2545
113.4 No-arbitrage Condition . . . 2545
113.5 Household's First Order Condition . . . 2546
113.6 Computing Equilibria . . . 2547
113.7 Python Code . . . 2547
113.8 Some functional forms . . . 2551
113.9 Computation . . . 2552
113.10 Exogenous growth . . . 2575

114 Two-Country Model with Distorting Taxes 2587
114.1 Overview . . . 2587
114.2 A Two-Country Cass-Koopmans Model . . . 2587

XV Multiple Agent Models 2601

115 A Lake Model of Employment and Unemployment 2603
115.1 Overview . . . 2603
115.2 The model . . . 2604
115.3 Implementation . . . 2606
115.4 Dynamics of an individual worker . . . 2613
115.5 Exercises . . . 2616

116 Lake Model with an Endogenous Job Finding Rate 2623
116.1 Overview . . . 2623
116.2 Set Up . . . 2624
116.3 Fiscal policy . . . 2629
116.4 Exercises . . . 2633

117 Rational Expectations Equilibrium 2637
117.1 Overview . . . 2637
117.2 Rational expectations equilibrium . . . 2640
117.3 Computing an equilibrium . . . 2643
117.4 Concluding remarks . . . 2645
117.5 Exercises . . . 2646

118 Investment Under Uncertainty 2653
118.1 Overview . . . 2653
118.2 The industry . . . 2654
118.3 The firm and the price of installed capital . . . 2655
118.4 Rational expectations equilibrium . . . 2656
118.5 Equilibrium as a planning problem . . . 2657
118.6 Recursive competitive equilibrium . . . 2658
118.7 A computable version . . . 2659
118.8 Long run behavior with serially independent demand . . . 2662

118.9 Long run behavior with serially correlated demand . . . 2664
118.10 Relation to the rational expectations lecture . . . 2669
118.11 Exercises . . . 2670

119 Equilibrium Search and Unemployment 2675
119.1 Overview . . . 2675
119.2 The economy . . . 2677
119.3 A worker's problem . . . 2678
119.4 Employment, wages, and two thresholds . . . 2679
119.5 A computable version . . . 2681
119.6 Economy-wide equilibrium . . . 2684
119.7 Learning the value of search . . . 2687
119.8 Inside the equilibrium . . . 2689
119.9 Efficiency . . . 2695
119.10 Relation to other lectures . . . 2696
119.11 Exercises . . . 2699

120 Optimal Growth Under Uncertainty and Tobin's q 2719
120.1 Overview . . . 2719
120.2 The Brock-Mirman planning problem . . . 2720
120.3 Long-run behavior . . . 2721
120.4 Irreversible investment and Tobin's q . . . 2722
120.5 Differentiability of the value function . . . 2723
120.6 Computing the model . . . 2726
120.7 Exercises . . . 2731

121 Stability in Linear Rational Expectations Models 2735
121.1 Overview . . . 2735
121.2 Linear Difference Equations . . . 2736
121.3 Illustration: Cagan's Model . . . 2738
121.4 Some Python Code . . . 2739
121.5 Alternative Code . . . 2741
121.6 Another Perspective . . . 2743
121.7 Log money Supply Feeds Back on Log Price Level . . . 2746
121.8 Big P, Little p Interpretation . . . 2749
121.9 Fun with SymPy . . . 2751

122 Markov Perfect Equilibrium 2755
122.1 Overview . . . 2755
122.2 Background . . . 2756
122.3 Linear Markov Perfect Equilibria . . . 2757
122.4 Application . . . 2760
122.5 Exercises . . . 2763

123 Uncertainty Traps 2773
123.1 Overview . . . 2773
123.2 The Model . . . 2774
123.3 Implementation . . . 2777
123.4 Results . . . 2778
123.5 Exercises . . . 2779

124 The Aiyagari Model 2787
124.1 Overview . . . 2787
124.2 The Economy . . . 2788
124.3 Implementation . . . 2790

124.4 Exercises . . . 2800

125 The Aiyagari Model with Endogenous Grid Method 2807
125.1 Overview . . . 2807
125.2 The Economy . . . 2808
125.3 Implementation with EGM . . . 2810
125.4 Computing Aggregate Capital by Simulation . . . 2814
125.5 Computing Equilibrium . . . 2815
125.6 Wealth Distribution . . . 2817
125.7 Summary and Comparison . . . 2819
125.8 Exercises . . . 2820

126 Transitions in an Overlapping Generations Model 2821
126.1 Overview . . . 2821
126.2 Setting . . . 2822
126.3 Production . . . 2823
126.4 Government . . . 2823
126.5 Activities in factor markets . . . 2823
126.6 Representative firm's problem . . . 2824
126.7 Individuals' problems . . . 2825
126.8 Equilibrium . . . 2826
126.9 Next steps . . . 2826
126.10 Closed form solution . . . 2826
126.11 A computational strategy . . . 2839
126.12 Exercises . . . 2849

127 A Long-Lived, Heterogeneous Agents, Overlapping Generations Model 2853
127.1 Overview . . . 2853
127.2 Environment . . . 2854
127.3 Production . . . 2855
127.4 Government . . . 2855
127.5 Activities in factor markets . . . 2856
127.6 Representative firm's problem . . . 2857
127.7 Households' problems . . . 2857
127.8 Population dynamics . . . 2857
127.9 Equilibrium . . . 2858
127.10 Implementation . . . 2858
127.11 Computing a steady state . . . 2862
127.12 Transition dynamics . . . 2868
127.13 Experiment 1: an immediate tax cut . . . 2873
127.14 Experiment 2: a preannounced tax cut . . . 2880
127.15 Exercises . . . 2884

128 Two Computations to Fund Social Security 2889
128.1 Overview . . . 2890
128.2 Model . . . 2891
128.3 Two experiments . . . 2896
128.4 Computation strategy . . . 2897
128.5 Calibration . . . 2900
128.6 Individual optimality . . . 2904
128.7 Transition path computation . . . 2914
128.8 Experiment 1: compensation through debt . . . 2926
128.9 Experiment 2: government capital accumulation . . . 2941
128.10 Distribution surfaces . . . 2948
128.11 Concluding remarks . . . 2954

128.12 Exercises . . . 2954

129 Social Security Trust Fund Depletion **2959**
129.1 Overview . . . 2959
129.2 The institution . . . 2961
129.3 A model we can solve quickly . . . 2962
129.4 Aggregation and the ledger . . . 2972
129.5 The economy before the news . . . 2972
129.6 Solving for the equilibrium payable path . . . 2974
129.7 Claiming and retirement along the transition . . . 2976
129.8 How this compares with the full model . . . 2981
129.9 Exercises . . . 2983

130 Linear Quadratic Mean Field Games **2997**
130.1 Overview . . . 2997
130.2 The environment . . . 2999
130.3 Solving the individual problem . . . 3000
130.4 A state-costate system . . . 3001
130.5 The equilibrium Riccati equation . . . 3002
130.6 Computing equilibria . . . 3004
130.7 The scalar case . . . 3006
130.8 An industry equilibrium with capital accumulation . . . 3009
130.9 Aggregate shocks and identification . . . 3017
130.10 Persistence . . . 3020
130.11 Multiproduct price setting with Kimball demand . . . 3022
130.12 The planner . . . 3027
130.13 Summary . . . 3032
130.14 Exercises . . . 3032
130.15 Further reading . . . 3044

131 Linear Quadratic Mean Field Games: Extensions **3045**
131.1 Overview . . . 3045
131.2 What we need from the previous lecture . . . 3046
131.3 State-action cross terms . . . 3047
131.4 Forcing processes and pass-through . . . 3052
131.5 Coupling through higher moments . . . 3054
131.6 Exercises . . . 3058
131.7 Further reading . . . 3063

XVI Asset Pricing and Finance 3065

132 Asset Pricing: Finite State Models **3067**
132.1 Overview . . . 3067
132.2 Pricing Models . . . 3068
132.3 Prices in the Risk-Neutral Case . . . 3069
132.4 Risk Aversion and Asset Prices . . . 3074
132.5 Exercises . . . 3083

133 Stochastic Consumption, Risk Aversion, and the Temporal Behavior of Asset Returns **3089**
133.1 Overview . . . 3090
133.2 Euler equation . . . 3090
133.3 The Euler equation under lognormality . . . 3091
133.4 The restricted system and its likelihood . . . 3092
133.5 Likelihood implementation . . . 3094

133.6 Preference parameters and likelihood ratio tests . . . 3105
133.7 Predictability and the R-squared restriction . . . 3108
133.8 Return-difference tests . . . 3109
133.9 Empirical MLE estimation . . . 3111
133.10 Residual diagnostics . . . 3115
133.11 Connection to the equity premium puzzle . . . 3117
133.12 Another approach . . . 3118

134 Estimating Euler Equations by Generalized Method of Moments **3119**
134.1 Overview . . . 3119
134.2 The economic model . . . 3120
134.3 From conditional to unconditional moments . . . 3121
134.4 GMM criterion and asymptotic theory . . . 3127
134.5 Covariance estimation and the choice of instruments . . . 3128
134.6 Empirical GMM estimation . . . 3135
134.7 Summary . . . 3137

135 Competitive Equilibria with Arrow Securities **3139**
135.1 Overview . . . 3139
135.2 The setting . . . 3141
135.3 Markov asset prices . . . 3142
135.4 Recursive formulation . . . 3144
135.5 A rational expectations equilibrium . . . 3145
135.6 State variable degeneracy . . . 3147
135.7 Computing a competitive equilibrium . . . 3148
135.8 Finite horizon . . . 3151
135.9 Python code . . . 3152
135.10 Examples . . . 3154
135.11 Concluding remarks . . . 3166
135.12 Related lectures . . . 3167
135.13 Exercises . . . 3168

136 Heterogeneous Beliefs and Bubbles **3181**
136.1 Overview . . . 3181
136.2 Structure of the model . . . 3182
136.3 Solving the model . . . 3184
136.4 Exercises . . . 3189

137 Speculative Behavior with Bayesian Learning **3193**
137.1 Overview . . . 3193
137.2 Structure of the model . . . 3194
137.3 Information and beliefs . . . 3195
137.4 Source of heterogeneous priors . . . 3195
137.5 Beta priors . . . 3196
137.6 Market prices with learning . . . 3197
137.7 Two Traders . . . 3198
137.8 Concluding remarks . . . 3205
137.9 Exercise . . . 3205

138 Rational Learning and Rational Expectations **3209**
138.1 Overview . . . 3209
138.2 The economy . . . 3210
138.3 The rational learning equilibrium . . . 3212
138.4 Computing the equilibrium . . . 3213
138.5 Posterior concentration . . . 3216

138.6 Equilibrium trades and prices . . . 3218
138.7 Convergence of posterior assessments . . . 3219
138.8 Sharpening the convergence result . . . 3220
138.9 Obstacles to convergence . . . 3222
138.10 Learning within versus learning about a rational expectations equilibrium . . . 3223
138.11 Summary . . . 3224
138.12 Exercises . . . 3224

139 Least Squares Learning in Self-Referential Models **3229**
139.1 Overview . . . 3229
139.2 The self-referential structure . . . 3230
139.3 Why a differential equation governs the limit . . . 3231
139.4 The governing ODE . . . 3232
139.5 Five examples . . . 3237
139.6 Example 1: Ordinary linear stochastic difference equations . . . 3237
139.7 Example 2: Bray's cobweb model . . . 3238
139.8 Counterexample: Unstable Bray feedback . . . 3241
139.9 Example 3: Bray-Savin supply-shifter model . . . 3243
139.10 Example 4: Hyperinflation / asset prices . . . 3246
139.11 Example 5: Investment under uncertainty . . . 3249
139.12 Connection to rational learning . . . 3252
139.13 Summary . . . 3252
139.14 Exercises . . . 3252

140 Affine Models of Asset Prices **3259**
140.1 Overview . . . 3259
140.2 The model . . . 3260
140.3 Pricing risky assets . . . 3263
140.4 Affine term structure of yields . . . 3265
140.5 Risk premiums . . . 3274
140.6 Risk-neutral probabilities . . . 3279
140.7 Distorted beliefs . . . 3282
140.8 Concluding remarks . . . 3287

141 The Recovery Theorem **3289**
141.1 Overview . . . 3289
141.2 Model setup . . . 3290
141.3 The recovery theorem . . . 3293
141.4 Numerical example . . . 3296
141.5 Natural vs. risk-neutral distributions . . . 3300
141.6 Effect of risk aversion . . . 3302
141.7 Recovering the discount rate . . . 3304
141.8 Tail risk: natural vs. risk-neutral probabilities of catastrophe . . . 3305
141.9 From option prices to transition prices . . . 3306
141.10 Testing efficient markets . . . 3307
141.11 Limitations and extensions . . . 3308
141.12 Exercises . . . 3309

142 Long-term Risk: An Operator Approach **3315**
142.1 Overview . . . 3315
142.2 Multiplicative functionals . . . 3317
142.3 Semigroups . . . 3319
142.4 The generator . . . 3322
142.5 Principal eigenfunctions . . . 3326
142.6 A finite-state Markov chain . . . 3329

142.7 The affine diffusion example . . . 3337
142.8 Long-run risk prices . . . 3346
142.9 Assumptions behind the scenes . . . 3356
142.10 Summary . . . 3357
142.11 Exercises . . . 3358

143 Misspecified Recovery **3367**
143.1 Overview . . . 3367
143.2 Three transition matrices . . . 3368
143.3 Martingale component . . . 3372
143.4 From matrices to the general framework . . . 3374
143.5 When recovery fails . . . 3381
143.6 Additional state vector . . . 3398
143.7 Measuring the martingale component . . . 3399
143.8 Lessons . . . 3400
143.9 Exercises . . . 3400

XVII Data and Empirics 3403

144 Pandas for Panel Data **3405**
144.1 Overview . . . 3405
144.2 Slicing and Reshaping Data . . . 3406
144.3 Merging Dataframes and Filling NaNs . . . 3411
144.4 Grouping and Summarizing Data . . . 3416
144.5 Final Remarks . . . 3422
144.6 Exercises . . . 3422

145 Linear Regression in Python **3427**
145.1 Overview . . . 3427
145.2 Simple Linear Regression . . . 3428
145.3 Extending the Linear Regression Model . . . 3434
145.4 Endogeneity . . . 3436
145.5 Summary . . . 3440
145.6 Exercises . . . 3440

146 Maximum Likelihood Estimation **3445**
146.1 Overview . . . 3446
146.2 Set up and assumptions . . . 3446
146.3 Conditional distributions . . . 3450
146.4 Maximum likelihood estimation . . . 3451
146.5 MLE with numerical methods . . . 3453
146.6 Maximum likelihood estimation with `statsmodels` . . . 3459
146.7 Summary . . . 3463
146.8 Exercises . . . 3464

147 A Linear Model of Unemployment **3467**
147.1 Overview . . . 3467
147.2 The natural rate versus hysteresis . . . 3468

MODELING COVID-19

Contents

- *Modeling COVID-19*
  - *Overview*
  - *The SEIR model*
  - *Implementation*
  - *Experiments*
  - *Ending lockdown*

1.1 Overview

This is a Python version of the code for analyzing the COVID-19 pandemic provided by Andrew Atkeson.

See, in particular

- NBER Working Paper No. 26867
- COVID-19 Working papers and code

The purpose of his notes is to introduce economists to quantitative modeling of infectious disease dynamics.

Dynamics are modeled using a standard SEIR (Susceptible-Exposed-Infected-Removed) model of disease spread.

The model dynamics are represented by a system of ordinary differential equations.

The main objective is to study the impact of suppression through social distancing on the spread of the infection.

The focus is on US outcomes but the parameters can be adjusted to study other countries.

We will use the following standard imports:

```
import matplotlib.pyplot as plt
import numpy as np
from numpy import exp
```

We will also use SciPy's numerical routine odeint for solving differential equations.

```
from scipy.integrate import odeint
```

This routine calls into compiled code from the FORTRAN library odepack.

1.2 The SEIR model

In the version of the SEIR model we will analyze there are four states.

All individuals in the population are assumed to be in one of these four states.

The states are: susceptible (S), exposed (E), infected (I), and removed (R).

Assumption 1.2.1

- Those in state R have been infected and either recovered or died.
- Those who have recovered are assumed to have acquired immunity.
- Those in the exposed group are not yet infectious.

1.2.1 Time path

The flow across states follows the path $S \to E \to I \to R$.

When the effective reproduction number exceeds one, infections initially increase but eventually decline as the susceptible population falls.

The interest is primarily in

- the number of infections at a given time (which determines whether or not the health care system is overwhelmed) and
- how long the caseload can be deferred (hopefully until a vaccine arrives)

Using lowercase letters for the fraction of the population in each state, the dynamics are

$$\begin{aligned} \dot{s}(t) &= -\beta(t)\, s(t)\, i(t) \\ \dot{e}(t) &= \beta(t)\, s(t)\, i(t) - \sigma e(t) \\ \dot{i}(t) &= \sigma e(t) - \gamma i(t) \end{aligned} \tag{1.1}$$

In these equations,

- $\beta(t)$ is called the **transmission rate** (the rate at which individuals bump into others and expose them to the virus).
- σ is called the **infection rate** (the rate at which those who are exposed become infected).
- γ is called the **removal rate** (the rate at which infected people recover or die).
- The dot symbol $\dot{y}$ represents the time derivative dy/dt.

We do not need to model the fraction r of the population in state R separately because the states form a partition.

In particular, the "removed" fraction of the population is $r = 1 - s - e - i$.

We will also track $c = i + r$, which is the cumulative caseload (i.e., all those who have or have had the infection).

The system (1.1) can be written in vector form as

$$\dot{x} = F(x, t), \qquad x := (s, e, i) \tag{1.2}$$

for a suitable definition of F (see the code below).

1.2.2 Parameters

Both σ and γ are thought of as fixed, biologically determined parameters.

As in Atkeson's note, we set

- $\sigma = 1/5.2$ to reflect an average incubation period of 5.2 days.
- $\gamma = 1/18$ to match an average illness duration of 18 days.

The transmission rate is modeled as

- $\beta(t) := R(t)\gamma$ where $R(t)$ is the **effective reproduction number** at time t.

(The notation is slightly confusing, since $R(t)$ is different to R, the symbol that represents the removed state.)

1.3 Implementation

First we set the population size to match the US.

```
pop_size = 3.3e8
```

Next we fix parameters as described above.

```
γ = 1 / 18
σ = 1 / 5.2
```

Now we construct a function that represents F in (1.2)

```
def F(x, t, R0=1.6):
    """
    Time derivative of the state vector.

        * x is the state vector (array_like)
        * t is time (scalar)
        * R0 is the effective transmission rate, defaulting to a constant

    """
    s, e, i = x

    # New exposure of susceptibles
    β = R0(t) * γ if callable(R0) else R0 * γ
    ne = β * s * i

    # Time derivatives
    ds = - ne
    de = ne - σ * e
    di = σ * e - γ * i

    return ds, de, di
```

Note that `R0` can be either constant or a given function of time.

The initial conditions are calibrated to a population of 330 million.

The value $i_0 = 10^{-7}$ represents 33 initially infected people, while $e_0 = 4i_0$ represents 132 exposed people.

Setting $s_0 = 1 - i_0 - e_0$ assigns the remaining population to the susceptible state and sets the initial removed fraction to zero.

```
# initial conditions of s, e, i
i_0 = 1e-7
e_0 = 4 * i_0
s_0 = 1 - i_0 - e_0
```

In vector form the initial condition is

```
x_0 = s_0, e_0, i_0
```

We solve for the time path numerically using `odeint`, at a sequence of dates `t_vec`.

```
def solve_path(R0, t_vec, x_init=x_0):
    """
    Solve for i(t) and c(t) via numerical integration,
    given the time path for R0.

    """
    G = lambda x, t: F(x, t, R0)
    s_path, e_path, i_path = odeint(G, x_init, t_vec).transpose()

    c_path = 1 - s_path - e_path       # cumulative cases
    return i_path, c_path
```

1.4 Experiments

Let's run some experiments using this code.

The time period we investigate will be 550 days, or around 18 months:

```
t_length = 550
grid_size = 1000
t_vec = np.linspace(0, t_length, grid_size)
```

1.4.1 Experiment 1: constant R0 case

Let's start with the case where `R0` is constant.

We calculate the time path of infected people under different assumptions for `R0`:

```
R0_vals = np.linspace(1.6, 3.0, 6)
labels = [f'$R_0 = {r:.2f}$' for r in R0_vals]
i_paths, c_paths = [], []

for r in R0_vals:
    i_path, c_path = solve_path(r, t_vec)
    i_paths.append(i_path)
    c_paths.append(c_path)
```

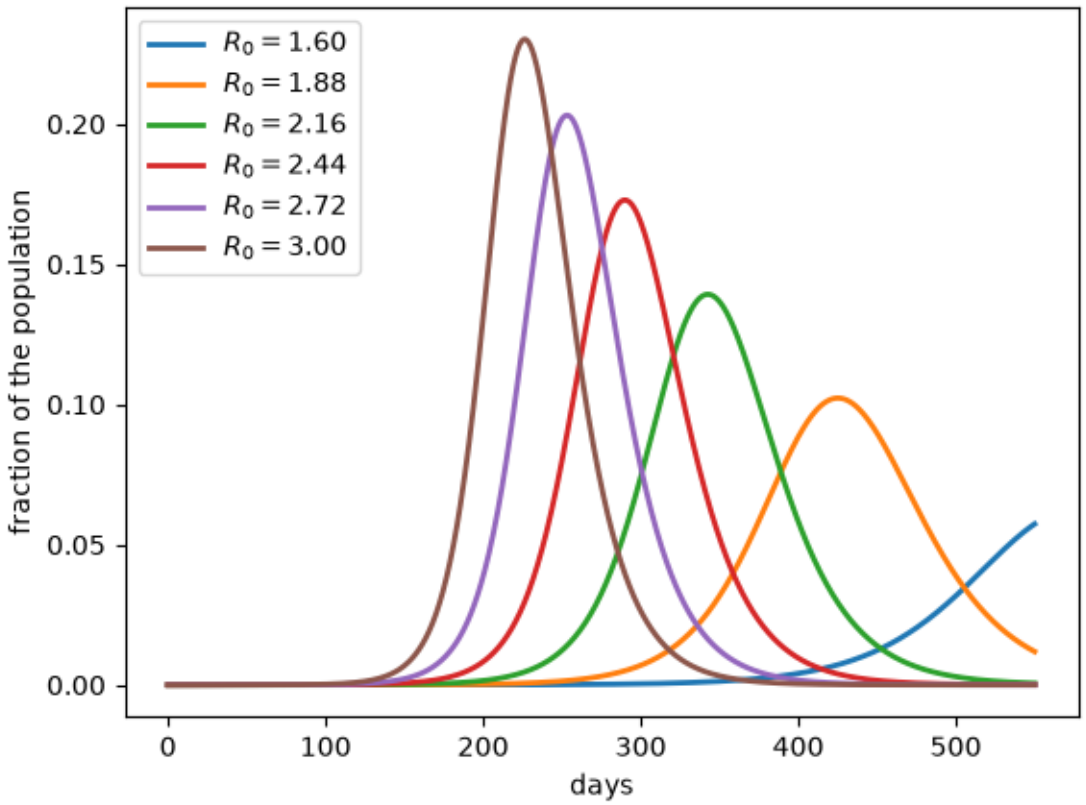
Here's some code to plot the time paths.

```
def plot_paths(paths, labels, ylabel, times=t_vec):

    fig, ax = plt.subplots()
```

(continues on next page)

(continued from previous page)



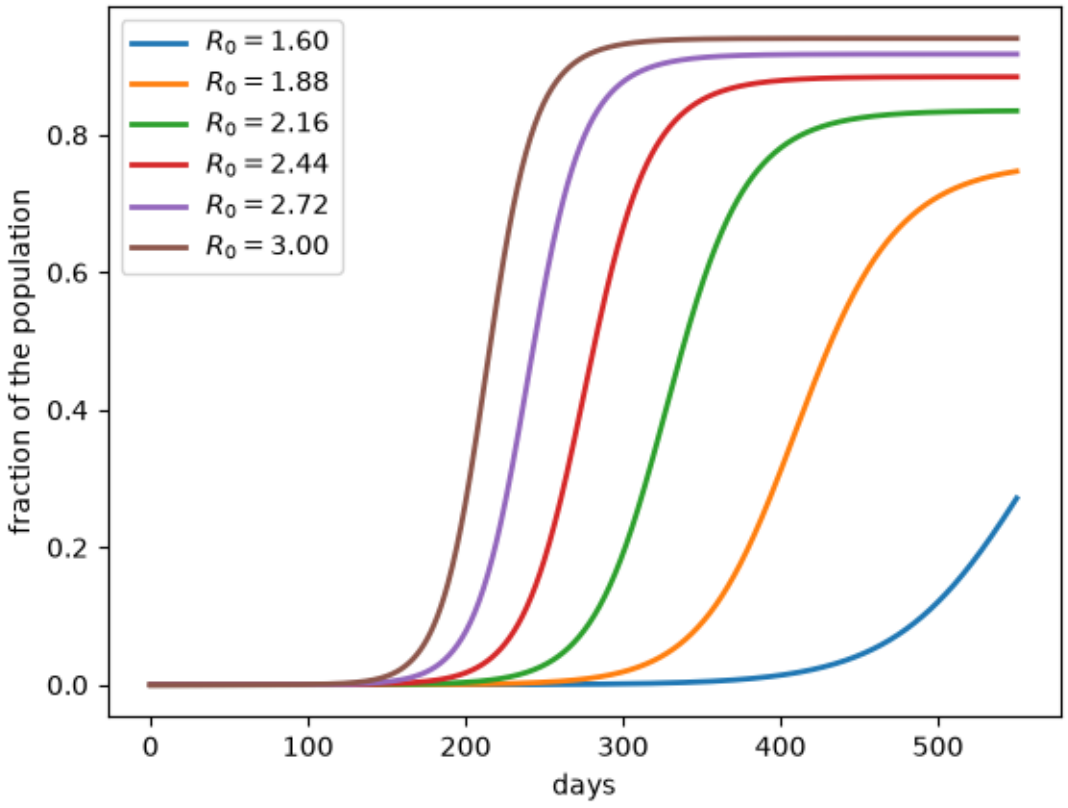
```
    for path, label in zip(paths, labels):
        ax.plot(times, path, lw=2, label=label)

    ax.set_xlabel('days')
    ax.set_ylabel(ylabel)
    ax.legend(loc='upper left')

    plt.show()
```

Let's plot current cases as a fraction of the population.

```
plot_paths(i_paths, labels, ylabel='fraction of the population')
```



As expected, lower effective transmission rates defer the peak of infections.

They also lead to a lower peak in current cases.

Here are cumulative cases, as a fraction of population:

```
plot_paths(c_paths, labels, ylabel='fraction of the population')
```

1.4.2 Experiment 2: changing mitigation

Let's look at a scenario where mitigation (e.g., social distancing) is successively imposed.

Here's a specification for `R0` as a function of time.

```
def R0_mitigating(t, r0=3, η=1, r_bar=1.6):
    R0 = r0 * exp(- η * t) + (1 - exp(- η * t)) * r_bar
    return R0
```

The idea is that `R0` starts off at 3 and falls to 1.6.

This is due to progressive adoption of stricter mitigation measures.

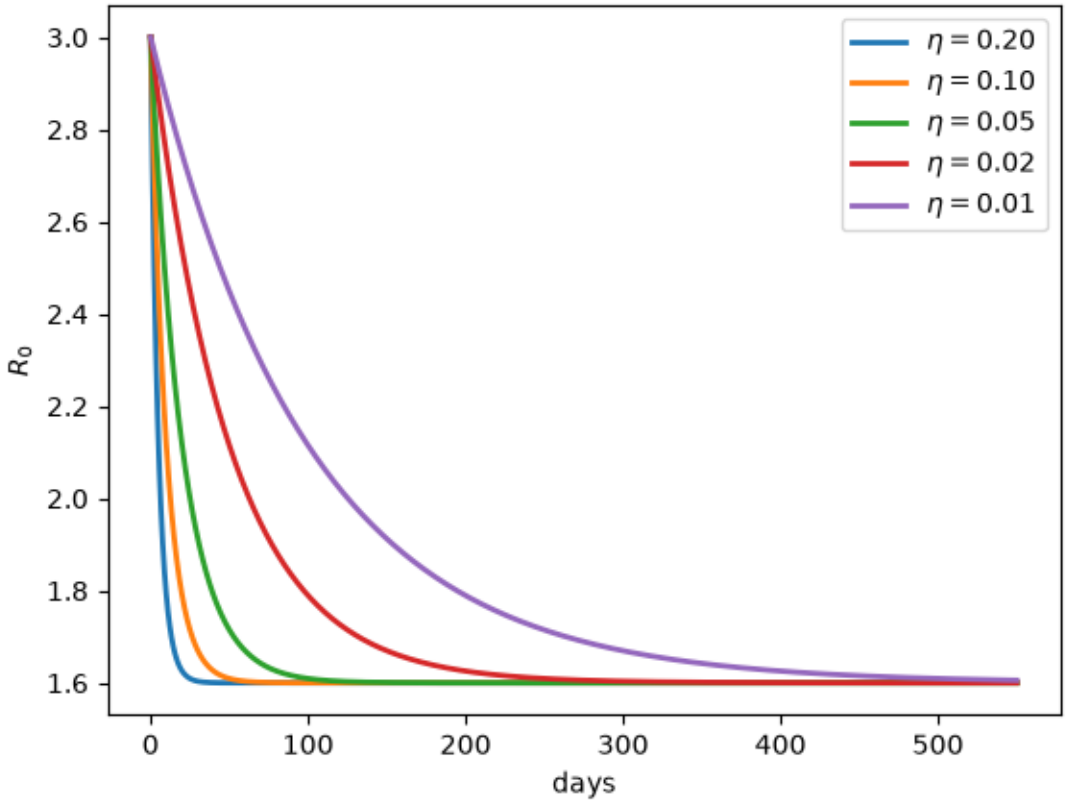
The parameter `η` controls the rate, or the speed at which restrictions are imposed.

Since t is measured in days, η is measured per day, and its reciprocal, $1/\eta$, is the adjustment period.

The values below correspond to adjustment periods of 5, 10, 20, 50, and 100 days:

```
η_vals = 1/5, 1/10, 1/20, 1/50, 1/100
labels = [fr'$\eta = {η:.2f}$' for η in η_vals]
```

This is what the time path of `R0` looks like at these alternative rates:



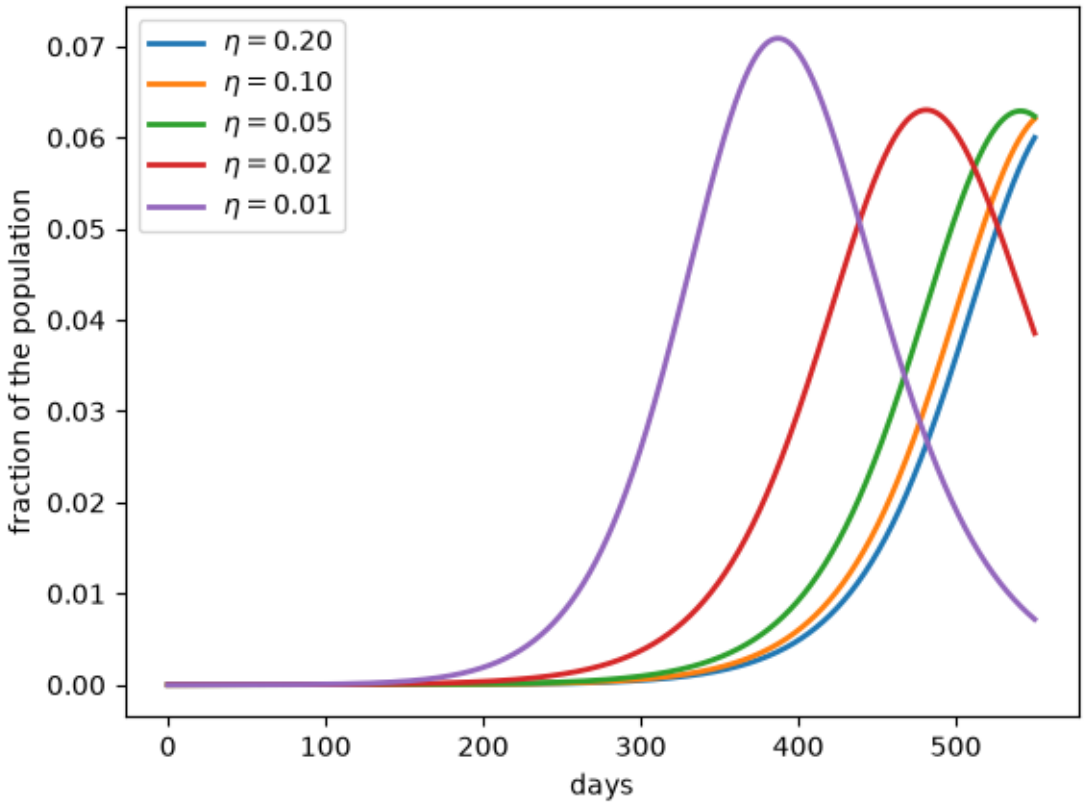
```
fig, ax = plt.subplots()

for η, label in zip(η_vals, labels):
    ax.plot(t_vec, R0_mitigating(t_vec, η=η), lw=2, label=label)
```

(continues on next page)

(continued from previous page)

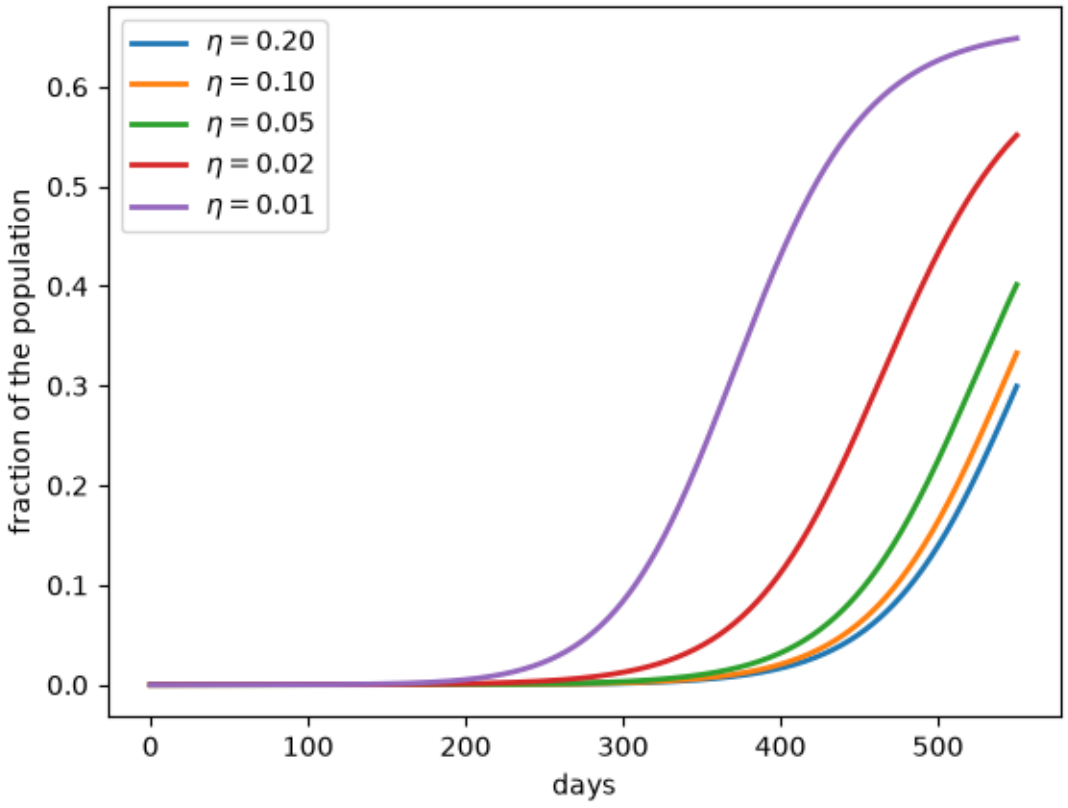
```
ax.set_xlabel('days')
ax.set_ylabel('$R_0$')
ax.legend()
plt.show()
```



Let's calculate the time path of infected people:

```
i_paths, c_paths = [], []

for η in η_vals:
    R0 = lambda t: R0_mitigating(t, η=η)
    i_path, c_path = solve_path(R0, t_vec)
    i_paths.append(i_path)
    c_paths.append(c_path)
```



These are current cases under the different scenarios:

```
plot_paths(i_paths, labels, ylabel='fraction of the population')
```

Here are cumulative cases, as a fraction of population:

```
plot_paths(c_paths, labels, ylabel='fraction of the population')
```

Faster implementation of mitigation mainly delays the infection peak, with a smaller effect on its height.

1.5 Ending lockdown

The following replicates additional results by Andrew Atkeson on the timing of lifting lockdown.

Consider these two mitigation scenarios:

1. $R_t = 0.5$ for 30 days and then $R_t = 2$ for the remaining 17 months. This corresponds to lifting lockdown in 30 days.
2. $R_t = 0.5$ for 120 days and then $R_t = 2$ for the remaining 14 months. This corresponds to lifting lockdown in 4 months.

The parameters considered here start the model with 25,000 active infections and 75,000 agents already exposed to the virus and thus soon to be contagious.

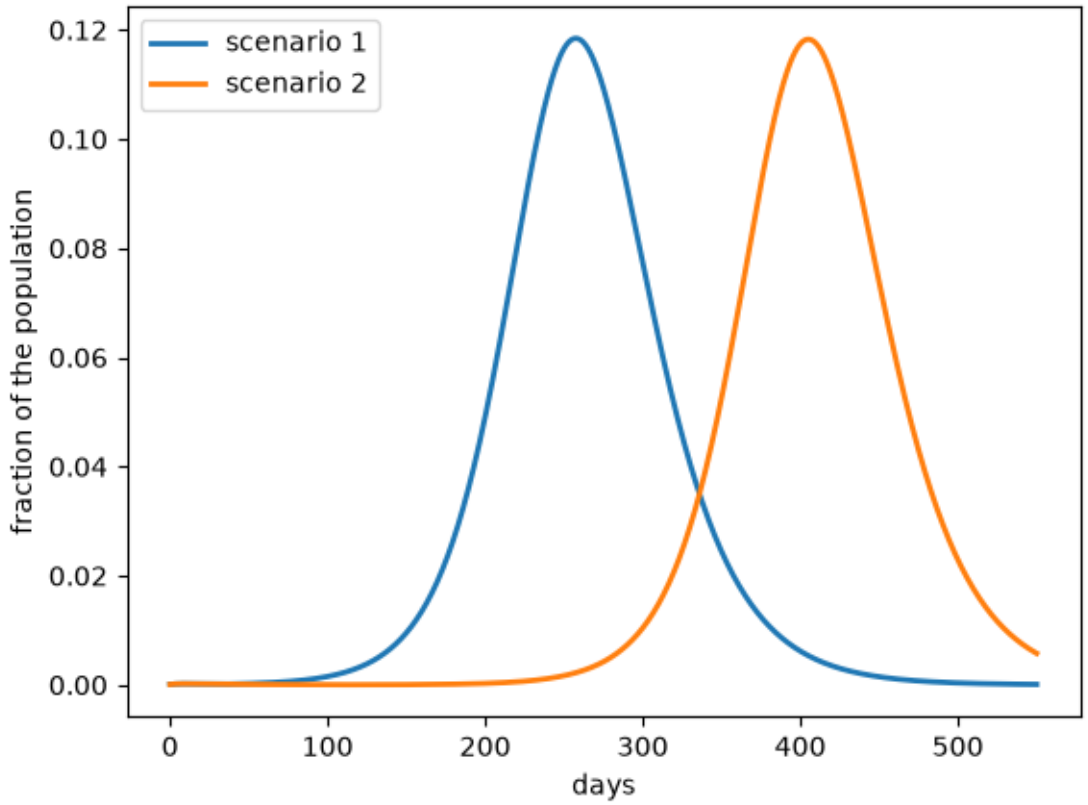
```
# initial conditions
i_0 = 25_000 / pop_size
e_0 = 75_000 / pop_size
s_0 = 1 - i_0 - e_0
x_0 = s_0, e_0, i_0
```

Let's calculate the paths:

```
R0_paths = (lambda t: 0.5 if t < 30 else 2,
            lambda t: 0.5 if t < 120 else 2)
```

(continues on next page)

(continued from previous page)



```
labels = [f'scenario {i}' for i in (1, 2)]

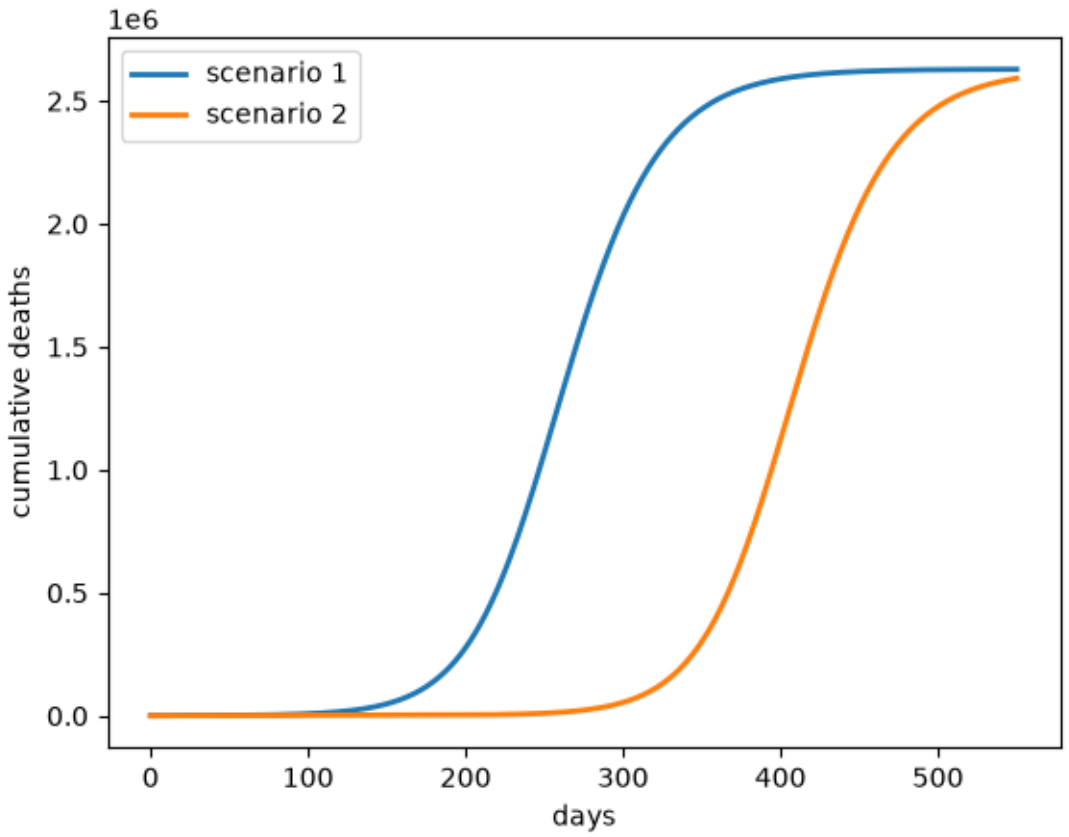
i_paths, c_paths = [], []

for R0 in R0_paths:
    i_path, c_path = solve_path(R0, t_vec, x_init=x_0)
    i_paths.append(i_path)
    c_paths.append(c_path)
```

Here is the fraction of the population with an active infection:

```
plot_paths(i_paths, labels, ylabel='fraction of the population')
```

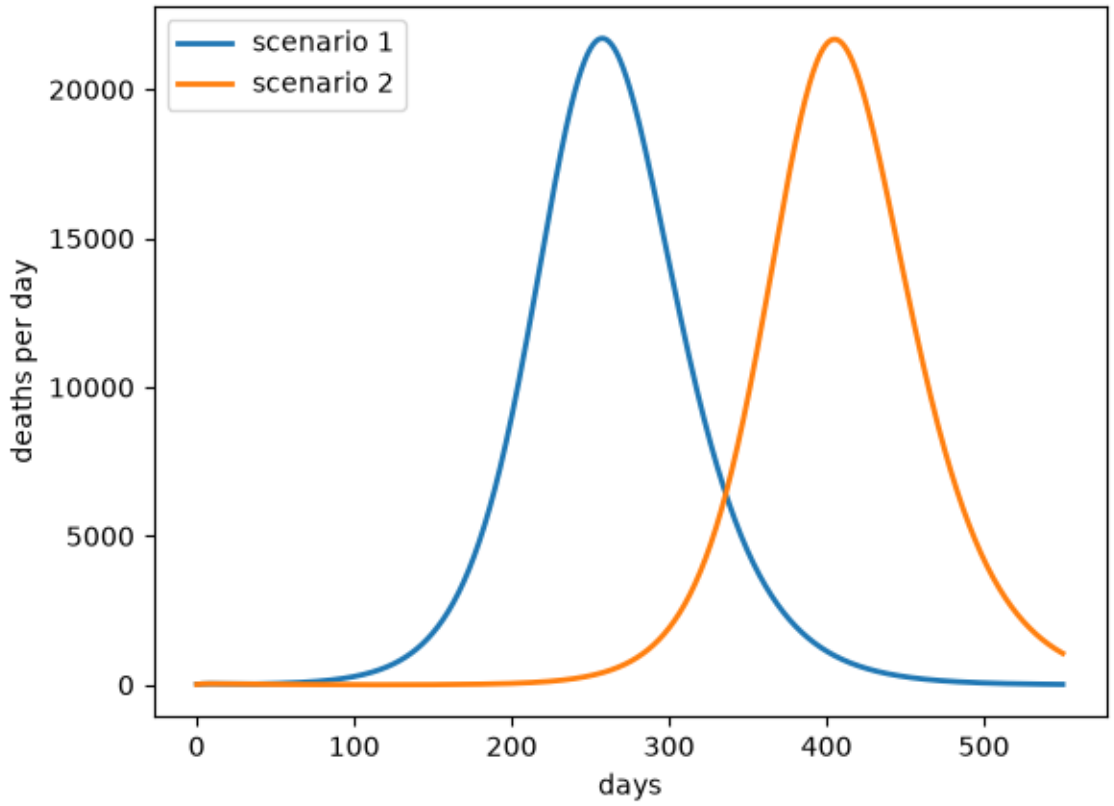
Both scenarios produce approximately the same infection peak, but the longer lockdown delays it.



What kind of mortality can we expect under these scenarios?

Suppose that 1% of cases result in death.

```
ν = 0.01
```



This is the cumulative number of deaths:

```
paths = [(c_path - i_path) * ν * pop_size
         for c_path, i_path in zip(c_paths, i_paths)]
plot_paths(paths, labels, ylabel='cumulative deaths')
```

This is the number of deaths per day:

```
paths = [path * ν * γ * pop_size for path in i_paths]
plot_paths(paths, labels, ylabel='deaths per day')
```

Pushing the peak of the curve further into the future may reduce cumulative deaths if a vaccine is found.

CHAPTER

LINEAR ALGEBRA

Contents

- *Linear Algebra*
  - *Overview*
  - *Vectors*
  - *Matrices*
  - *Solving systems of equations*
  - *Eigenvalues and eigenvectors*
  - *Further topics*
  - *Exercises*

2.1 Overview

Linear algebra is one of the most useful branches of applied mathematics for economists to invest in.

For example, many applied problems in economics and finance require the solution of a linear system of equations, such as

$$\begin{aligned} y_1 &= ax_1 + bx_2 \\ y_2 &= cx_1 + dx_2 \end{aligned}$$

or, more generally,

$$\begin{aligned} y_1 &= a_{11}x_1 + a_{12}x_2 + \cdots + a_{1k}x_k \\ &\vdots \\ y_n &= a_{n1}x_1 + a_{n2}x_2 + \cdots + a_{nk}x_k \end{aligned} \tag{2.1}$$

The objective here is to solve for the "unknowns" $x_1, \ldots, x_k$ given $a_{11}, \ldots, a_{nk}$ and $y_1, \ldots, y_n$.

When considering such problems, it is essential that we first consider at least some of the following questions

- Does a solution actually exist?
- Are there in fact many solutions, and if so how should we interpret them?
- If no solution exists, is there a best "approximate" solution?

- If a solution exists, how should we compute it?

These are the kinds of topics addressed by linear algebra.

In this lecture we will cover the basics of linear and matrix algebra, treating both theory and computation.

We admit some overlap with NumPy, where operations on NumPy arrays were first explained.

Note that this lecture is more theoretical than most, and contains background material that will be used in applications as we go along.

Let's start with some imports:

```
import matplotlib.pyplot as plt
import numpy as np
from matplotlib import cm
from mpl_toolkits.mplot3d import Axes3D
from scipy.linalg import inv, solve, det, eig
```

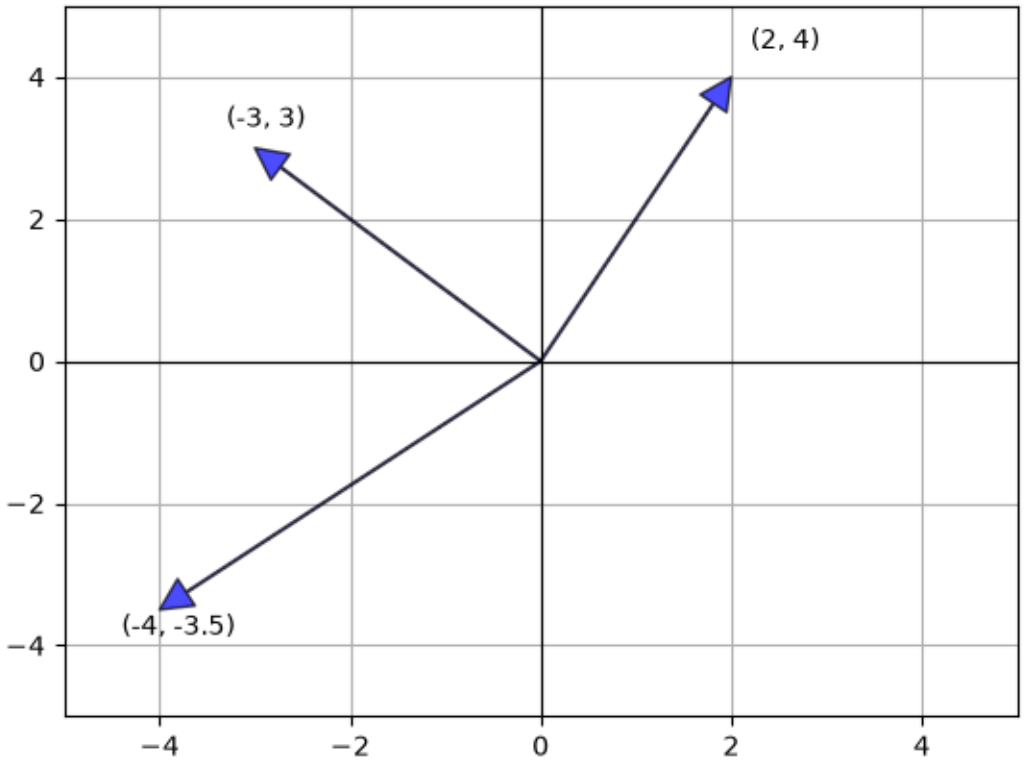
2.2 Vectors

A **vector** of length n is just a sequence (or array, or tuple) of n numbers, which we write as $x = (x_1, \ldots, x_n)$ or $x = [x_1, \ldots, x_n]$.

We will write these sequences either horizontally or vertically as we please.

(Later, when we wish to perform certain matrix operations, it will become necessary to distinguish between the two)

The set of all n-vectors is denoted by $\mathbb{R}^n$.



For example, $\mathbb{R}^2$ is the plane, and a vector in $\mathbb{R}^2$ is just a point in the plane.

Traditionally, vectors are represented visually as arrows from the origin to the point.

The following figure represents three vectors in this manner

```
fig, ax = plt.subplots()
# Draw the axes through the origin
ax.axhline(0, color='black', lw=0.8)
ax.axvline(0, color='black', lw=0.8)

ax.set(xlim=(-5, 5), ylim=(-5, 5))
ax.grid()
vecs = ((2, 4), (-3, 3), (-4, -3.5))
for v in vecs:
    ax.annotate('', xy=v, xytext=(0, 0),
                arrowprops=dict(facecolor='blue',
                shrink=0,
                alpha=0.7,
                width=0.5))
    ax.text(1.1 * v[0], 1.1 * v[1], str(v))
plt.show()
```

2.2.1 Vector operations

The two most common operators for vectors are addition and scalar multiplication, which we now describe.

As a matter of definition, when we add two vectors, we add them element-by-element

$$x + y = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix} + \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_n \end{bmatrix} := \begin{bmatrix} x_1 + y_1 \\ x_2 + y_2 \\ \vdots \\ x_n + y_n \end{bmatrix}$$

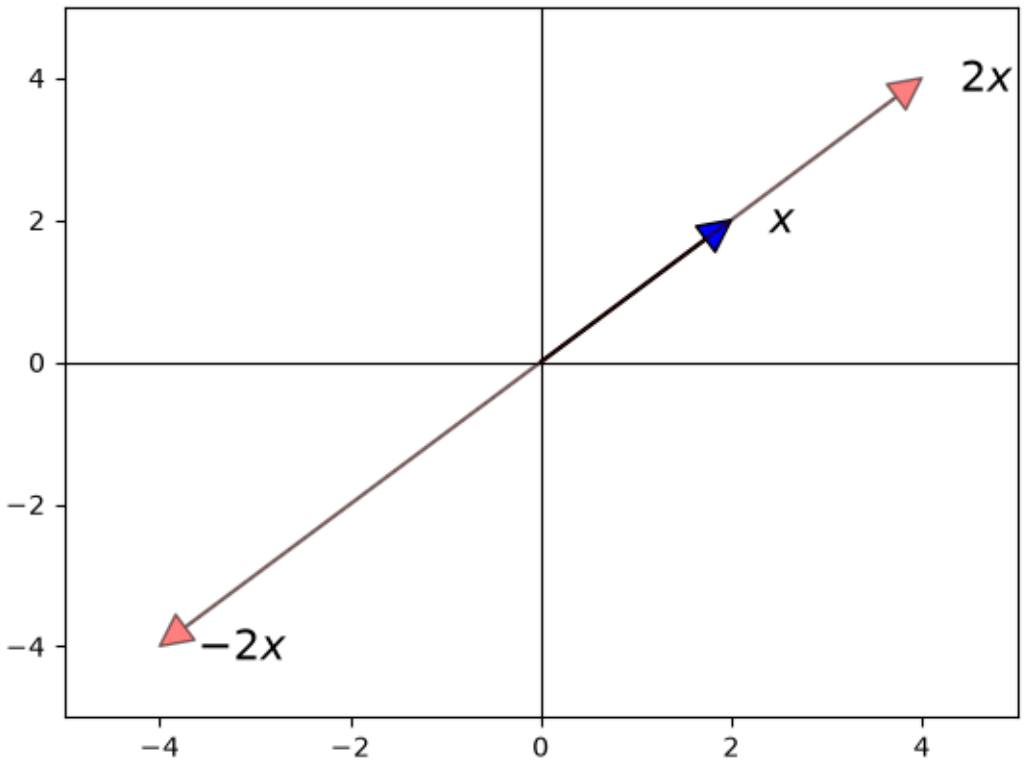
Scalar multiplication is an operation that takes a number γ and a vector x and produces

$$\gamma x := \begin{bmatrix} \gamma x_1 \\ \gamma x_2 \\ \vdots \\ \gamma x_n \end{bmatrix}$$

Scalar multiplication is illustrated in the next figure

```
fig, ax = plt.subplots()
# Draw the axes through the origin
ax.axhline(0, color='black', lw=0.8)
ax.axvline(0, color='black', lw=0.8)

ax.set(xlim=(-5, 5), ylim=(-5, 5))
x = (2, 2)
ax.annotate('', xy=x, xytext=(0, 0),
            arrowprops=dict(facecolor='blue',
```



(continues on next page)

(continued from previous page)

```
            shrink=0,
            alpha=1,
            width=0.5))
ax.text(x[0] + 0.4, x[1] - 0.2, '$x$', fontsize='16')

scalars = (-2, 2)
x = np.array(x)

for s in scalars:
    v = s * x
    ax.annotate('', xy=v, xytext=(0, 0),
                arrowprops=dict(facecolor='red',
                shrink=0,
                alpha=0.5,
                width=0.5))
    ax.text(v[0] + 0.4, v[1] - 0.2, f'${s} x$', fontsize='16')
plt.show()
```

In Python, a vector can be represented as a list or tuple, such as `x = (2, 4, 6)`, but is more commonly represented as a NumPy array.

One advantage of NumPy arrays is that scalar multiplication and addition have very natural syntax

```
x = np.ones(3)             # Vector of three ones
y = np.array((2, 4, 6))    # Converts tuple (2, 4, 6) into array
x + y
```

```
array([3., 5., 7.])
```

```
4 * x
```

```
array([4., 4., 4.])
```

2.2.2 Inner product and norm

The **inner product** of vectors $x, y \in \mathbb{R}^n$ is defined as

$$x^\top y := \sum_{i=1}^n x_i y_i$$

Two vectors are called **orthogonal** if their inner product is zero.

The **norm** of a vector x represents its "length" (i.e., its distance from the zero vector) and is defined as

$$\|x\| := \sqrt{x^\top x} := \left(\sum_{i=1}^n x_i^2 \right)^{1/2}$$

The expression $\|x - y\|$ is thought of as the distance between x and y.

Continuing on from the previous example, the inner product and norm can be computed as follows

```
np.sum(x * y)           # Inner product of x and y, method 1
```

```
np.float64(12.0)
```

```
x @ y                   # Inner product of x and y, method 2 (preferred)
```

```
np.float64(12.0)
```

The `@` operator is preferred because it uses optimized BLAS libraries that implement fused multiply-add operations, providing better performance and numerical accuracy compared to the separate multiply and sum operations.

```
np.sqrt(np.sum(x**2))   # Norm of x, take one
```

```
np.float64(1.7320508075688772)
```

```
np.sqrt(x @ x)          # Norm of x, take two (preferred)
```

```
np.float64(1.7320508075688772)
```

```
np.linalg.norm(x)       # Norm of x, take three
```

```
np.float64(1.7320508075688772)
```

2.2.3 Span

Given a set of vectors $A := \{a_1, \ldots, a_k\}$ in $\mathbb{R}^n$, it's natural to think about the new vectors we can create by performing linear operations.

New vectors created in this manner are called **linear combinations** of A.

In particular, $y \in \mathbb{R}^n$ is a linear combination of $A := \{a_1, \ldots, a_k\}$ if

$$y = \beta_1 a_1 + \cdots + \beta_k a_k \text{ for some scalars } \beta_1, \ldots, \beta_k$$

In this context, the values $\beta_1, \ldots, \beta_k$ are called the **coefficients** of the linear combination.

The set of linear combinations of A is called the **span** of A.

The next figure shows the span of $A = \{a_1, a_2\}$ in $\mathbb{R}^3$.

The span is a two-dimensional plane passing through these two points and the origin.

```
ax = plt.figure().add_subplot(projection='3d')

x_min, x_max = -5, 5
y_min, y_max = -5, 5

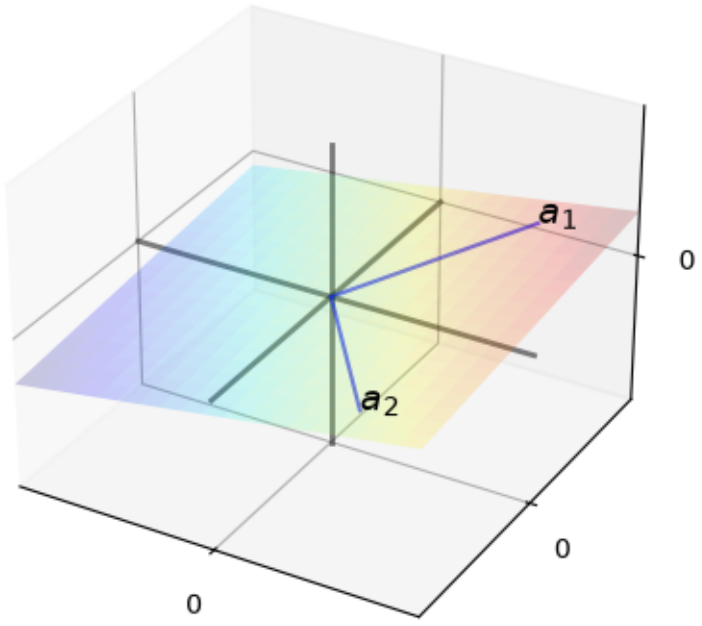
α, β = 0.2, 0.1

ax.set(xlim=(x_min, x_max), ylim=(x_min, x_max), zlim=(x_min, x_max),
       xticks=(0,), yticks=(0,), zticks=(0,))

gs = 3
z = np.linspace(x_min, x_max, gs)
x = np.zeros(gs)
y = np.zeros(gs)
ax.plot(x, y, z, 'k-', lw=2, alpha=0.5)
ax.plot(z, x, y, 'k-', lw=2, alpha=0.5)
ax.plot(y, z, x, 'k-', lw=2, alpha=0.5)

# Fixed linear function, to generate a plane
def f(x, y):
    return α * x + β * y

# Vector locations, by coordinate
x_coords = np.array((3, 3))
y_coords = np.array((4, -4))
z = f(x_coords, y_coords)
for i in (0, 1):
    ax.text(x_coords[i], y_coords[i], z[i], f'$a_{i+1}$', fontsize=14)



# Lines to vectors
for i in (0, 1):
    x = (0, x_coords[i])
    y = (0, y_coords[i])
    z = (0, f(x_coords[i], y_coords[i]))
    ax.plot(x, y, z, 'b-', lw=1.5, alpha=0.6)

# Draw the plane
grid_size = 20
xr2 = np.linspace(x_min, x_max, grid_size)
```

(continues on next page)

(continued from previous page)

```
yr2 = np.linspace(y_min, y_max, grid_size)
x2, y2 = np.meshgrid(xr2, yr2)
z2 = f(x2, y2)
ax.plot_surface(x2, y2, z2, rstride=1, cstride=1, cmap=cm.jet,
                linewidth=0, antialiased=True, alpha=0.2)
plt.show()
```

Examples

If A contains only one nonzero vector $a_1 \in \mathbb{R}^2$, then its span is just the scalar multiples of a_1, which is the unique line passing through both a_1 and the origin.

If $A = \{e_1, e_2, e_3\}$ consists of the **canonical basis vectors** of $\mathbb{R}^3$, that is

$$e_1 := \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}, \quad e_2 := \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}, \quad e_3 := \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix}$$

then the span of A is all of $\mathbb{R}^3$, because, for any $x = (x_1, x_2, x_3) \in \mathbb{R}^3$, we can write

$$x = x_1 e_1 + x_2 e_2 + x_3 e_3$$

Now consider $A_0 = \{e_1, e_2, e_1 + e_2\}$.

If $y = (y_1, y_2, y_3)$ is any linear combination of these vectors, then $y_3 = 0$ (check it).

Hence A_0 fails to span all of $\mathbb{R}^3$.

2.2.4 Linear independence

As we'll see, it's often desirable to find families of vectors with relatively large span, so that many vectors can be described by linear operators on a few vectors.

The condition we need for a set of vectors to have a large span is what's called linear independence.

In particular, a collection of vectors $A := \{a_1, \ldots, a_k\}$ in $\mathbb{R}^n$ is said to be

- **linearly dependent** if some strict subset of A has the same span as A.
- **linearly independent** if it is not linearly dependent.

Put differently, a set of vectors is linearly independent if no vector is redundant to the span and linearly dependent otherwise.

To illustrate the idea, recall *the figure* that showed the span of vectors $\{a_1, a_2\}$ in $\mathbb{R}^3$ as a plane through the origin.

If we take a third vector a_3 and form the set $\{a_1, a_2, a_3\}$, this set will be

- linearly dependent if a_3 lies in the plane
- linearly independent otherwise

As another illustration of the concept, since $\mathbb{R}^n$ can be spanned by n vectors (see the discussion of canonical basis vectors above), any collection of $m > n$ vectors in $\mathbb{R}^n$ must be linearly dependent.

The following statements are equivalent to linear independence of $A := \{a_1, \ldots, a_k\} \subset \mathbb{R}^n$

1. No vector in A can be formed as a linear combination of the other elements.
2. If $\beta_1 a_1 + \cdots + \beta_k a_k = 0$ for scalars $\beta_1, \ldots, \beta_k$, then $\beta_1 = \cdots = \beta_k = 0$.

(The zero in the first expression is the origin of $\mathbb{R}^n$)

2.2.5 Unique representations

Another nice thing about sets of linearly independent vectors is that each element in the span has a unique representation as a linear combination of these vectors.

In other words, if $A := \{a_1, \ldots, a_k\} \subset \mathbb{R}^n$ is linearly independent and

$$y = \beta_1 a_1 + \cdots + \beta_k a_k$$

then no other coefficient sequence $\gamma_1, \ldots, \gamma_k$ will produce the same vector y.

Indeed, if we also have $y = \gamma_1 a_1 + \cdots + \gamma_k a_k$, then

$$(\beta_1 - \gamma_1) a_1 + \cdots + (\beta_k - \gamma_k) a_k = 0$$

Linear independence now implies $\gamma_i = \beta_i$ for all i.

2.3 Matrices

Matrices are a neat way of organizing data for use in linear operations.

An $n \times k$ matrix is a rectangular array A of numbers with n rows and k columns:

$$A = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1k} \\ a_{21} & a_{22} & \cdots & a_{2k} \\ \vdots & \vdots & & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nk} \end{bmatrix}$$

Often, the numbers in the matrix represent coefficients in a system of linear equations, as discussed at the start of this lecture.

For obvious reasons, the matrix A is also called a vector if either $n = 1$ or $k = 1$.

In the former case, A is called a **row vector**, while in the latter it is called a **column vector**.

If $n = k$, then A is called **square**.

The matrix formed by replacing a_{ij} by a_{ji} for every i and j is called the **transpose** of A and denoted A' or $A^\top$.

If $A = A^\top$, then A is called **symmetric**.

For an $n \times n$ matrix A, the n entries $a_{11}, \ldots, a_{nn}$ form the **principal diagonal**.

A is called **diagonal** if the only nonzero entries are on the principal diagonal.

If, in addition to being diagonal, each element along the principal diagonal is equal to 1, then A is called the **identity matrix** and denoted by I.

2.3.1 Matrix operations

Just as was the case for vectors, a number of algebraic operations are defined for matrices.

Scalar multiplication and addition are immediate generalizations of the vector case:

$$\gamma A = \gamma \begin{bmatrix} a_{11} & \cdots & a_{1k} \\ \vdots & \vdots & \vdots \\ a_{n1} & \cdots & a_{nk} \end{bmatrix} := \begin{bmatrix} \gamma a_{11} & \cdots & \gamma a_{1k} \\ \vdots & \vdots & \vdots \\ \gamma a_{n1} & \cdots & \gamma a_{nk} \end{bmatrix}$$

and

$$A + B = \begin{bmatrix} a_{11} & \cdots & a_{1k} \\ \vdots & \vdots & \vdots \\ a_{n1} & \cdots & a_{nk} \end{bmatrix} + \begin{bmatrix} b_{11} & \cdots & b_{1k} \\ \vdots & \vdots & \vdots \\ b_{n1} & \cdots & b_{nk} \end{bmatrix} := \begin{bmatrix} a_{11} + b_{11} & \cdots & a_{1k} + b_{1k} \\ \vdots & \vdots & \vdots \\ a_{n1} + b_{n1} & \cdots & a_{nk} + b_{nk} \end{bmatrix}$$

In the latter case, the matrices must have the same shape in order for the definition to make sense.

We also have a convention for *multiplying* two matrices.

The rule for matrix multiplication generalizes the idea of inner products discussed above and is designed to make multiplication play well with basic linear operations.

If A and B are two matrices, then their product AB is formed by taking as its i, j-th element the inner product of the i-th row of A and the j-th column of B.

There are many tutorials to help you visualize this operation, such as this one, or the discussion on the Wikipedia page.

If A is $n \times k$ and B is $j \times m$, then to multiply A and B we require $k = j$, and the resulting matrix AB is $n \times m$.

As perhaps the most important special case, consider multiplying $n \times k$ matrix A and $k \times 1$ column vector x.

According to the preceding rule, this gives us an $n \times 1$ column vector

$$Ax = \begin{bmatrix} a_{11} & \cdots & a_{1k} \\ \vdots & \vdots & \vdots \\ a_{n1} & \cdots & a_{nk} \end{bmatrix} \begin{bmatrix} x_1 \\ \vdots \\ x_k \end{bmatrix} := \begin{bmatrix} a_{11}x_1 + \cdots + a_{1k}x_k \\ \vdots \\ a_{n1}x_1 + \cdots + a_{nk}x_k \end{bmatrix} \tag{2.2}$$

Note

AB and BA are not generally the same thing.

Another important special case is the identity matrix.

You should check that if A is $n \times k$ and I is the $k \times k$ identity matrix, then $AI = A$.

If I is the $n \times n$ identity matrix, then $IA = A$.

2.3.2 Matrices in NumPy

NumPy arrays are also used as matrices, and have fast, efficient functions and methods for all the standard matrix operations[1].

You can create them manually from tuples of tuples (or lists of lists) as follows

```
A = ((1, 2),
     (3, 4))

type(A)
```

```
tuple
```

```
A = np.array(A)

type(A)
```

```
numpy.ndarray
```

```
A.shape
```

```
(2, 2)
```

The `shape` attribute is a tuple giving the number of rows and columns — see here for more discussion.

To get the transpose of `A`, use `A.transpose()` or, more simply, `A.T`.

There are many convenient functions for creating common matrices (matrices of zeros, ones, etc.) — see here.

Since operations are performed elementwise by default, scalar multiplication and addition have very natural syntax

```
A = np.identity(3)
B = np.ones((3, 3))
2 * A
```

[1] Although there is a specialized matrix data type defined in NumPy, it's more standard to work with ordinary NumPy arrays. See this discussion.

```
array([[2., 0., 0.],
       [0., 2., 0.],
       [0., 0., 2.]])
```

```
A + B
```

```
array([[2., 1., 1.],
       [1., 2., 1.],
       [1., 1., 2.]])
```

To multiply matrices we use the `@` symbol.

In particular, `A @ B` is matrix multiplication, whereas `A * B` is element-by-element multiplication.

See here for more discussion.

2.3.3 Matrices as maps

Each $n \times k$ matrix A can be identified with a function $f(x) = Ax$ that maps $x \in \mathbb{R}^k$ into $y = Ax \in \mathbb{R}^n$.

These kinds of functions have a special property: they are **linear**.

A function $f \colon \mathbb{R}^k \to \mathbb{R}^n$ is called **linear** if, for all $x, y \in \mathbb{R}^k$ and all scalars α, β, we have

$$f(\alpha x + \beta y) = \alpha f(x) + \beta f(y)$$

You can check that this holds for the function $f(x) = Ax + b$ when b is the zero vector and fails when b is nonzero.

In fact, it's known that f is linear if and *only if* there exists a matrix A such that $f(x) = Ax$ for all x.

2.4 Solving systems of equations

Recall again the system of equations (2.1).

If we compare (2.1) and (2.2), we see that (2.1) can now be written more conveniently as

$$y = Ax \tag{2.3}$$

The problem we face is to determine a vector $x \in \mathbb{R}^k$ that solves (2.3), taking y and A as given.

This is a special case of a more general problem: Find an x such that $y = f(x)$.

Given an arbitrary function f and a y, is there always an x such that $y = f(x)$?

If so, is it always unique?

The answer to both these questions is negative, as the next figure shows

```
def f(x):
    return 0.6 * np.cos(4 * x) + 1.4

xmin, xmax = -1, 1
x = np.linspace(xmin, xmax, 160)
y = f(x)
ya, yb = np.min(y), np.max(y)
```

(continues on next page)

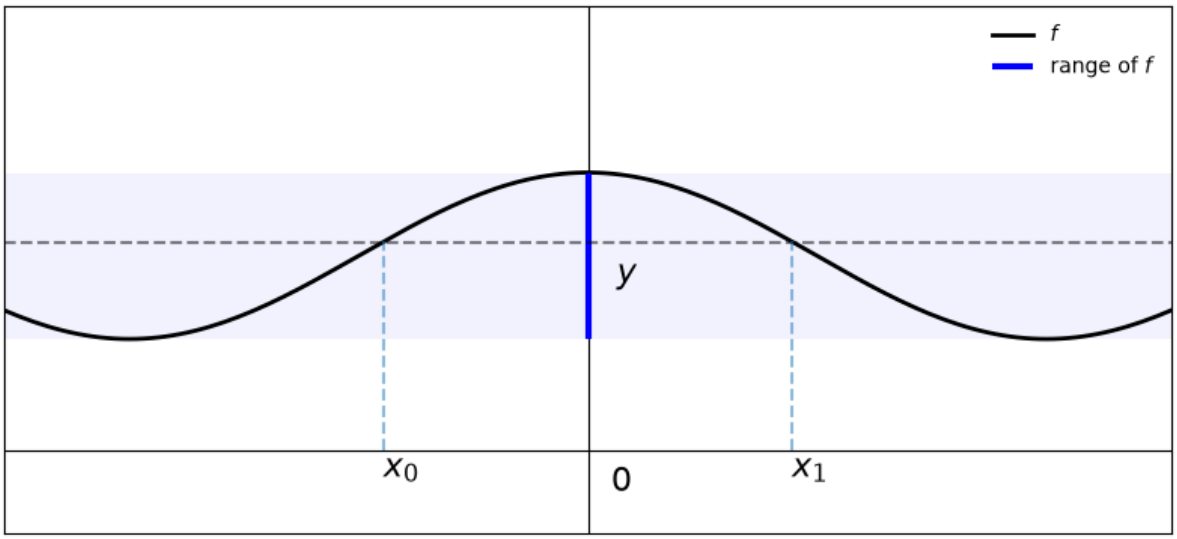
(continued from previous page)

```
# Extra height keeps the labels clear of the axes in both panels.
fig, axes = plt.subplots(2, 1, figsize=(10, 10))

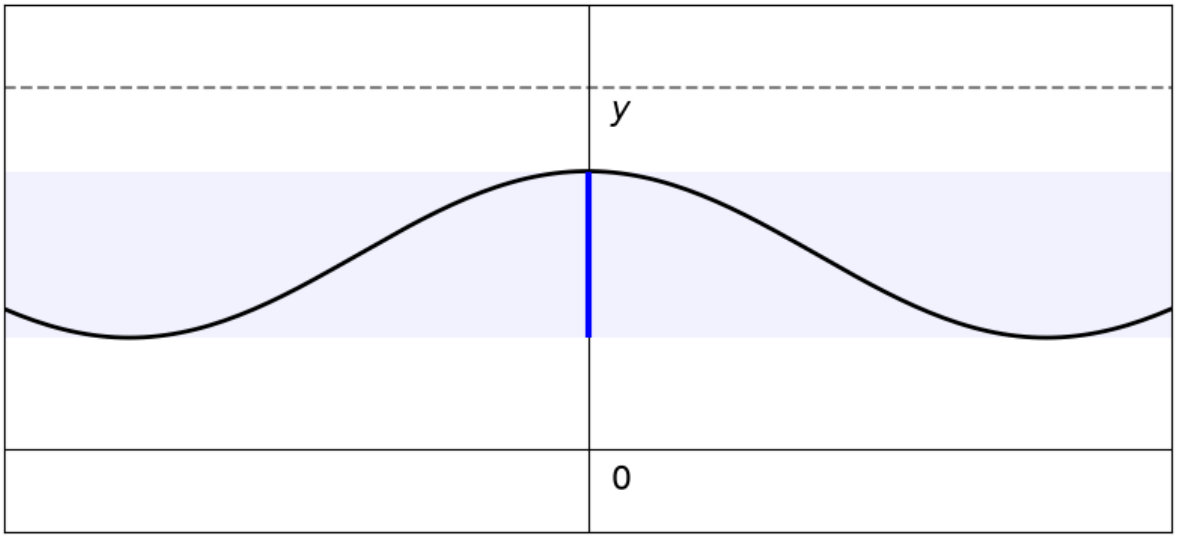
for ax in axes:
    # Draw the axes through the origin
    ax.axhline(0, color='black', lw=0.8)
    ax.axvline(0, color='black', lw=0.8)

    ax.set(ylim=(-0.6, 3.2), xlim=(xmin, xmax),
           yticks=(), xticks=())

    ax.plot(x, y, 'k-', lw=2, label='$f$')
    ax.fill_between(x, ya, yb, facecolor='blue', alpha=0.05)
    ax.vlines([0], ya, yb, lw=3, color='blue', label='range of $f$')
    ax.text(0.04, -0.3, '$0$', fontsize=16)



ax = axes[0]



ax.legend(loc='upper right', frameon=False)
ybar = 1.5
ax.plot(x, x * 0 + ybar, 'k--', alpha=0.5)
ax.text(0.05, 0.8 * ybar, '$y$', fontsize=16)
for i, z in enumerate((-0.35, 0.35)):
    ax.vlines(z, 0, f(z), linestyle='--', alpha=0.5)
    ax.text(z, -0.2, f'$x_{i}$', fontsize=16)

ax = axes[1]

ybar = 2.6
ax.plot(x, x * 0 + ybar, 'k--', alpha=0.5)
ax.text(0.04, 0.91 * ybar, '$y$', fontsize=16)

plt.show()
```

In the first plot, there are multiple solutions, as the function is not one-to-one, while in the second there are no solutions, since y lies outside the range of f.

Can we impose conditions on A in (2.3) that rule out these problems?

In this context, the most important thing to recognize about the expression Ax is that it corresponds to a linear combination of the columns of A.

In particular, if $a_1, \ldots, a_k$ are the columns of A, then

$$Ax = x_1 a_1 + \cdots + x_k a_k$$

Hence the range of $f(x) = Ax$ is exactly the span of the columns of A.

We want the range to be large so that it contains arbitrary y.

As you might recall, the condition that we want for the span to be large is *linear independence*.

A happy fact is that linear independence of the columns of A also gives us uniqueness.

Indeed, it follows from our *earlier discussion* that if $\{a_1, \ldots, a_k\}$ are linearly independent and $y = Ax = x_1 a_1 + \cdots + x_k a_k$, then no $z \neq x$ satisfies $y = Az$.

2.4.1 The square matrix case

Let's discuss some more details, starting with the case where A is $n \times n$.

This is the familiar case where the number of unknowns equals the number of equations.

For arbitrary $y \in \mathbb{R}^n$, we hope to find a unique $x \in \mathbb{R}^n$ such that $y = Ax$.

In view of the observations immediately above, if the columns of A are linearly independent, then their span, and hence the range of $f(x) = Ax$, is all of $\mathbb{R}^n$.

Hence there always exists an x such that $y = Ax$.

Moreover, the solution is unique.

In particular, the following are equivalent

1. The columns of A are linearly independent.
2. For any $y \in \mathbb{R}^n$, the equation $y = Ax$ has a unique solution.

The property of having linearly independent columns is sometimes expressed as having **full column rank**.

Inverse matrices

Can we give some sort of expression for the solution?

If y and A are scalar with $A \neq 0$, then the solution is $x = A^{-1} y$.

A similar expression is available in the matrix case.

In particular, if square matrix A has full column rank, then it possesses a multiplicative **inverse matrix** A^{-1}, with the property that $AA^{-1} = A^{-1}A = I$.

As a consequence, if we pre-multiply both sides of $y = Ax$ by A^{-1}, we get $x = A^{-1} y$.

This is the solution that we're looking for.

Determinants

Another quick comment about square matrices is that to every such matrix we assign a unique number called the **determinant** of the matrix — you can find the expression for it here.

If the determinant of A is not zero, then we say that A is **nonsingular**.

Perhaps the most important fact about determinants is that A is nonsingular if and only if A is of full column rank.

This gives us a useful one-number summary of whether or not a square matrix can be inverted.

2.4.2 More rows than columns

This is the $n \times k$ case with $n > k$.

This case is very important in many settings, not least in the setting of linear regression (where n is the number of observations, and k is the number of explanatory variables).

Given arbitrary $y \in \mathbb{R}^n$, we seek an $x \in \mathbb{R}^k$ such that $y = Ax$.

In this setting, the existence of a solution is highly unlikely.

Without much loss of generality, let's go over the intuition focusing on the case where the columns of A are linearly independent.

It follows that the span of the columns of A is a k-dimensional subspace of $\mathbb{R}^n$.

This span is very "unlikely" to contain arbitrary $y \in \mathbb{R}^n$.

To see why, recall the *figure above*, where $k = 2$ and $n = 3$.

Imagine an arbitrarily chosen $y \in \mathbb{R}^3$, located somewhere in that three-dimensional space.

What's the likelihood that y lies in the span of $\{a_1, a_2\}$ (i.e., the two dimensional plane through these points)?

In a sense, it must be very small, since this plane has zero "thickness".

As a result, in the $n > k$ case we usually give up on existence.

However, we can still seek the best approximation, for example, an x that makes the distance $\|y - Ax\|$ as small as possible.

To solve this problem, one can use either calculus or the theory of orthogonal projections.

The solution is known to be $\hat{x} = (A^\top A)^{-1} A^\top y$ — see for example chapter 3 of these notes.

2.4.3 More columns than rows

This is the $n \times k$ case with $n < k$, so there are fewer equations than unknowns.

In this case there are either no solutions or infinitely many — in other words, uniqueness never holds.

For example, consider the case where $k = 3$ and $n = 2$.

Thus, the columns of A consist of 3 vectors in $\mathbb{R}^2$.

This set can never be linearly independent, since it is possible to find two vectors that span $\mathbb{R}^2$.

(For example, use the canonical basis vectors)

It follows that one column is a linear combination of the other two.

For example, let's say that $a_1 = \alpha a_2 + \beta a_3$.

Then if $y = Ax = x_1 a_1 + x_2 a_2 + x_3 a_3$, we can also write

$$y = x_1(\alpha a_2 + \beta a_3) + x_2 a_2 + x_3 a_3 = (x_1\alpha + x_2)a_2 + (x_1\beta + x_3)a_3$$

In other words, uniqueness fails.

2.4.4 Linear equations with SciPy

Here's an illustration of how to solve linear equations with SciPy's `linalg` submodule.

All of these routines are Python front ends to time-tested and highly optimized FORTRAN code

```
A = ((1, 2), (3, 4))
A = np.array(A)
y = np.ones((2, 1))  # Column vector
det(A)  # Check that A is nonsingular, and hence invertible
```

```
np.float64(-2.0)
```

```
A_inv = inv(A)  # Compute the inverse
A_inv
```

```
array([[-2. ,  1. ],
       [ 1.5, -0.5]])
```

```
x = A_inv @ y  # Solution
A @ x          # Should equal y
```

```
array([[1.],
       [1.]])
```

```
solve(A, y)  # Produces the same solution
```

```
array([[-1.],
       [ 1.]])
```

Observe how we can solve for $x = A^{-1}y$ either via `inv(A) @ y`, or using `solve(A, y)`.

To solve $Ax = y$, we generally prefer `solve(A, y)` because it avoids the unnecessary step of computing the inverse of A.

To obtain the least-squares solution $\hat{x} = (A^\top A)^{-1} A^\top y$, use `scipy.linalg.lstsq(A, y)`.

2.5 Eigenvalues and eigenvectors

Let A be an $n \times n$ square matrix.

If λ is scalar and v is a non-zero vector in $\mathbb{R}^n$ such that

$$Av = \lambda v$$

then we say that λ is an **eigenvalue** of A, and v is an **eigenvector**.

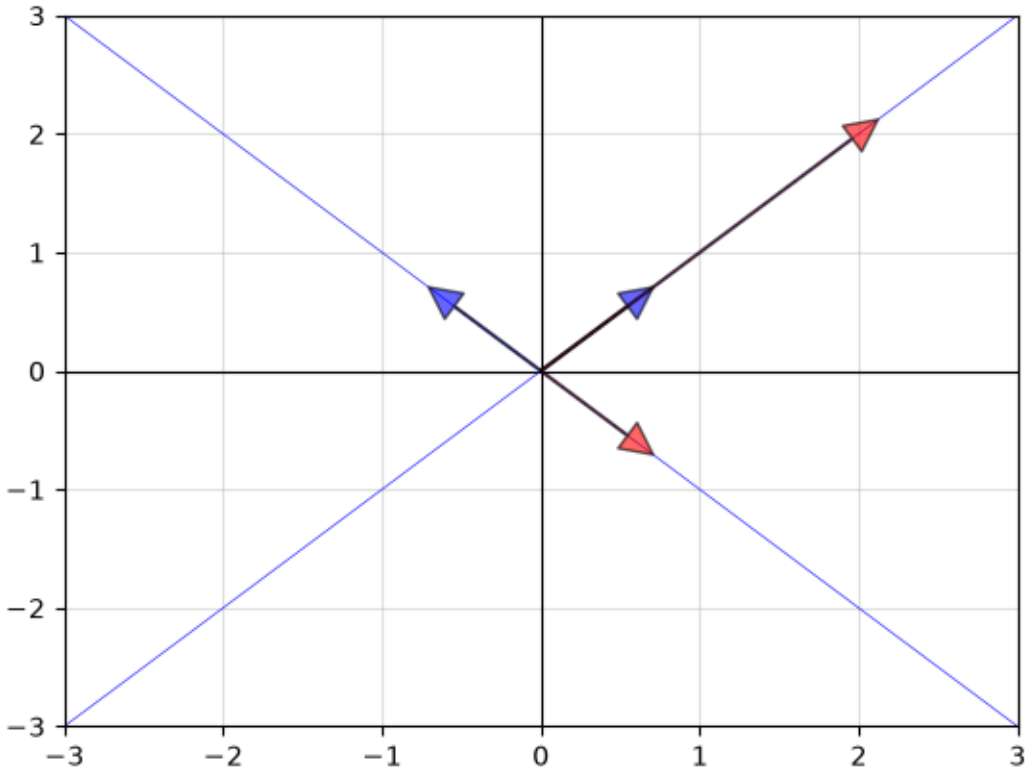
Thus, an eigenvector of A is a vector such that when the map $f(x) = Ax$ is applied, v is merely scaled.

The next figure shows two eigenvectors (blue arrows) and their images under A (red arrows).

As expected, the image Av of each v is just a scaled version of the original

```
A = ((1, 2),
     (2, 1))
A = np.array(A)
evals, evecs = eig(A)
evecs = evecs[:, 0], evecs[:, 1]

fig, ax = plt.subplots()
# Draw the axes through the origin
ax.axhline(0, color='black', lw=0.8)
ax.axvline(0, color='black', lw=0.8)
ax.grid(alpha=0.4)



xmin, xmax = -3, 3
ymin, ymax = -3, 3
ax.set(xlim=(xmin, xmax), ylim=(ymin, ymax))

# Plot each eigenvector
for v in evecs:
    ax.annotate('', xy=v, xytext=(0, 0),
                arrowprops=dict(facecolor='blue',
                shrink=0,
                alpha=0.6,
                width=0.5))

# Plot the image of each eigenvector
for v in evecs:
    v = A @ v
    ax.annotate('', xy=v, xytext=(0, 0),
                arrowprops=dict(facecolor='red',
                shrink=0,
                alpha=0.6,
                width=0.5))

# Plot the lines they run through
x = np.linspace(xmin, xmax, 3)
for v in evecs:
    a = v[1] / v[0]
    ax.plot(x, a * x, 'b-', lw=0.4)

plt.show()
```

The eigenvalue equation is equivalent to $(A - \lambda I)v = 0$, and this has a nonzero solution v only when the columns of $A - \lambda I$ are linearly dependent.

This in turn is equivalent to stating that the determinant is zero.

Hence to find all eigenvalues, we can look for λ such that the determinant of $A - \lambda I$ is zero.

This problem can be expressed as one of solving for the roots of a polynomial in λ of degree n.

This in turn implies the existence of n solutions in the complex plane, although some might be repeated.

Some nice facts about the eigenvalues of a square matrix A are as follows

1. The determinant of A equals the product of the eigenvalues.
2. The trace of A (the sum of the elements on the principal diagonal) equals the sum of the eigenvalues.
3. If A is symmetric, then all of its eigenvalues are real.
4. If A is invertible and $\lambda_1, \ldots, \lambda_n$ are its eigenvalues, then the eigenvalues of A^{-1} are $1/\lambda_1, \ldots, 1/\lambda_n$.

A corollary of the first statement is that a matrix is invertible if and only if all its eigenvalues are nonzero.

Using SciPy, we can solve for the eigenvalues and eigenvectors of a matrix as follows

```
A = ((1, 2),
     (2, 1))

A = np.array(A)
evals, evecs = eig(A)
evals
```

```
array([ 3.+0.j, -1.+0.j])
```

```
evecs
```

```
array([[ 0.70710678, -0.70710678],
       [ 0.70710678,  0.70710678]])
```

Note that the *columns* of `evecs` are the eigenvectors.

Since any nonzero scalar multiple of an eigenvector is an eigenvector with the same eigenvalue (check it), the eig routine normalizes the length of each eigenvector to one.

2.5.1 Generalized eigenvalues

It is sometimes useful to consider the **generalized eigenvalue problem**, which, for given matrices A and B, seeks generalized eigenvalues λ and eigenvectors v such that

$$Av = \lambda Bv$$

This can be solved in SciPy via `scipy.linalg.eig(A, B)`.

Of course, if B is square and invertible, then we can treat the generalized eigenvalue problem as an ordinary eigenvalue problem $B^{-1}Av = \lambda v$, but this is not always the case.

2.6 Further topics

We round out our discussion by briefly mentioning several other important topics.

2.6.1 Series expansions

Recall the usual summation formula for a geometric progression, which states that if $|a| < 1$, then $\sum_{k=0}^{\infty} a^k = (1-a)^{-1}$.

A generalization of this idea exists in the matrix setting.

Matrix norms

Let A be a square matrix, and let

$$\|A\| := \max_{\|x\|=1} \|Ax\|$$

The norms on the right-hand side are ordinary vector norms, while the norm on the left-hand side is a **matrix norm** — in this case, the so-called **spectral norm**.

For example, for a square matrix S, the condition $\|S\| < 1$ means that S is **contractive**, in the sense that it pulls all vectors towards the origin[2].

[2] Suppose that $\|S\| < 1$.
Take any nonzero vector x, and let $r := \|x\|$.
We have $\|Sx\| = r\|S(x/r)\| \leq r\|S\| < r = \|x\|$.
Hence every point is pulled towards the origin.

Neumann's theorem

Let A be a square matrix and let $A^k := AA^{k-1}$ with $A^1 := A$.

In other words, A^k is the k-th power of A.

Neumann's theorem states the following: If $\|A^k\| < 1$ for some $k \in \mathbb{N}$, then $I - A$ is invertible, and

$$(I - A)^{-1} = \sum_{k=0}^{\infty} A^k \tag{2.4}$$

Spectral radius

A result known as Gelfand's formula tells us that, for any square matrix A,

$$\rho(A) = \lim_{k \to \infty} \|A^k\|^{1/k}$$

Here $\rho(A)$ is the **spectral radius**, defined as $\max_i |\lambda_i|$, where $\{\lambda_i\}_i$ is the set of eigenvalues of A.

As a consequence of Gelfand's formula, if all eigenvalues are strictly less than one in modulus, there exists a k with $\|A^k\| < 1$.

In which case (2.4) is valid.

2.6.2 Positive definite matrices

Let A be a symmetric $n \times n$ matrix.

We say that A is

1. **positive definite** if $x^\top Ax > 0$ for every $x \in \mathbb{R}^n \setminus \{0\}$
2. **positive semi-definite** or **nonnegative definite** if $x^\top Ax \geq 0$ for every $x \in \mathbb{R}^n$

Analogous definitions exist for negative definite and negative semi-definite matrices.

It is notable that if A is positive definite, then all of its eigenvalues are strictly positive, and hence A is invertible (with positive definite inverse).

2.6.3 Differentiating linear and quadratic forms

The following formulas are useful in many economic contexts.

Let

- z, x and a all be $n \times 1$ vectors
- A be an $n \times n$ matrix
- B be an $m \times n$ matrix and y be an $m \times 1$ vector

Then

1. $\frac{\partial a^\top x}{\partial x} = a$
2. $\frac{\partial Ax}{\partial x} = A^\top$
3. $\frac{\partial x^\top Ax}{\partial x} = (A + A^\top)x$
4. $\frac{\partial y^\top Bz}{\partial y} = Bz$

5. $\frac{\partial y^\top B z}{\partial B} = y z^\top$

Exercise 2.7.1 below asks you to apply these formulas.

2.6.4 Further reading

The documentation of the `scipy.linalg` submodule can be found here.

Chapters 2 and 3 of A Primer in Econometric Theory contain a discussion of linear algebra along the same lines as above, with solved exercises.

If you don't mind a slightly abstract approach, a nice intermediate-level text on linear algebra is [Jänich, 1994].

2.7 Exercises

Exercise 2.7.1

Let x be a given $n \times 1$ vector and consider the problem

$$v(x) = \max_{y,u} \{-y^\top P y - u^\top Q u\}$$

subject to the linear constraint

$$y = Ax + Bu$$

Here

- P is an $n \times n$ matrix and Q is an $m \times m$ matrix
- A is an $n \times n$ matrix and B is an $n \times m$ matrix
- both P and Q are symmetric and positive semidefinite
- $H := Q + B^\top P B$ is positive definite

(What must the dimensions of y and u be to make this a well-posed problem?)

One way to solve the problem is to form the Lagrangian

$$\mathcal{L} = -y^\top P y - u^\top Q u + \lambda^\top [Ax + Bu - y]$$

where λ is an $n \times 1$ vector of Lagrange multipliers.

Try applying the formulas given above for differentiating quadratic and linear forms to obtain the first-order conditions for maximizing $\mathcal{L}$ with respect to y, u and minimizing it with respect to λ.

Show that these conditions imply that

1. $\lambda = -2Py$.
2. The optimizing choice of u satisfies $u = -(Q + B^\top P B)^{-1} B^\top P A x$.
3. The function v satisfies $v(x) = -x^\top \tilde{P} x$ where $\tilde{P} = A^\top P A - A^\top P B (Q + B^\top P B)^{-1} B^\top P A$.

As we will see, in economic contexts Lagrange multipliers often are shadow prices.

Note

If we don't care about the Lagrange multipliers, we can substitute the constraint into the objective function, and then just maximize $-(Ax + Bu)^\top P(Ax + Bu) - u^\top Qu$ with respect to u.
You can verify that this leads to the same maximizer.

Solution

We have an optimization problem:

$$v(x) = \max_{y,u}\{-y^\top Py - u^\top Qu\}$$

s.t.

$$y = Ax + Bu$$

with primitives

- P is a symmetric and positive semidefinite $n \times n$ matrix
- Q is a symmetric and positive semidefinite $m \times m$ matrix
- A is an $n \times n$ matrix
- B is an $n \times m$ matrix

Assume that $H := Q + B^\top PB$ is positive definite.

The associated Lagrangian is:

$$L = -y^\top Py - u^\top Qu + \lambda^\top [Ax + Bu - y]$$

Step 1.

Differentiating Lagrangian equation w.r.t y and setting its derivative equal to zero yields

$$\frac{\partial L}{\partial y} = -(P + P^\top)y - \lambda = -2Py - \lambda = 0\,,$$

since P is symmetric.

Accordingly, the first-order condition for maximizing L w.r.t. y implies

$$\lambda = -2Py$$

Step 2.

Differentiating Lagrangian equation w.r.t. u and setting its derivative equal to zero yields

$$\frac{\partial L}{\partial u} = -(Q + Q^\top)u + B^\top \lambda = -2Qu + B^\top \lambda = 0$$

Substituting $\lambda = -2Py$ gives

$$Qu + B^\top Py = 0$$

Substituting the linear constraint $y = Ax + Bu$ into the above equation gives

$$Qu + B^\top P(Ax + Bu) = 0$$

$$(Q + B^\top PB)u + B^\top PAx = 0$$

which is the first-order condition for maximizing L w.r.t. u.

Thus, the optimal choice of u must satisfy

$$u = -(Q + B^\top PB)^{-1} B^\top PAx \,,$$

which follows from the definition of the first-order conditions for Lagrangian equation.

Step 3.

Rewriting our problem by substituting the constraint into the objective function, we get

$$v(x) = \max_u \{-(Ax + Bu)^\top P(Ax + Bu) - u^\top Qu\}$$

Since we know the optimal choice of u satisfies $u = -(Q + B^\top PB)^{-1} B^\top PAx$, then

$$v(x) = -(Ax + Bu)^\top P(Ax + Bu) - u^\top Qu \quad \text{with} \quad u = -(Q + B^\top PB)^{-1} B^\top PAx$$

To evaluate the function

$$\begin{aligned} v(x) &= -(Ax + Bu)^\top P(Ax + Bu) - u^\top Qu \\ &= -(x^\top A^\top + u^\top B^\top)P(Ax + Bu) - u^\top Qu \\ &= -x^\top A^\top PAx - u^\top B^\top PAx - x^\top A^\top PBu - u^\top B^\top PBu - u^\top Qu \\ &= -x^\top A^\top PAx - 2u^\top B^\top PAx - u^\top (Q + B^\top PB)u \end{aligned}$$

For simplicity, set $S := (Q + B^\top PB)^{-1} B^\top PA$, so that $u = -Sx$.

Regarding the second term $-2u^\top B^\top PAx$,

$$\begin{aligned} -2u^\top B^\top PAx &= +2x^\top S^\top B^\top PAx \\ &= 2x^\top A^\top PB(Q + B^\top PB)^{-1} B^\top PAx \end{aligned}$$

Notice that the term $(Q + B^\top PB)^{-1}$ is symmetric as both P and Q are symmetric.

Regarding the third term $-u^\top (Q + B^\top PB)u$,

$$\begin{aligned} -u^\top (Q + B^\top PB)u &= -x^\top S^\top (Q + B^\top PB)Sx \\ &= -x^\top A^\top PB(Q + B^\top PB)^{-1} B^\top PAx \end{aligned}$$

Hence, the summation of second and third terms is $x^\top A^\top PB(Q + B^\top PB)^{-1} B^\top PAx$.

This implies that

$$\begin{aligned} v(x) &= -x^\top A^\top PAx - 2u^\top B^\top PAx - u^\top (Q + B^\top PB)u \\ &= -x^\top A^\top PAx + x^\top A^\top PB(Q + B^\top PB)^{-1} B^\top PAx \\ &= -x^\top [A^\top PA - A^\top PB(Q + B^\top PB)^{-1} B^\top PA]x \end{aligned}$$

Therefore, the solution to the optimization problem $v(x) = -x^\top \tilde{P} x$ follows the above result by denoting $\tilde{P} := A^\top PA - A^\top PB(Q + B^\top PB)^{-1} B^\top PA$

CHAPTER

THREE

QR DECOMPOSITION

3.1 Overview

This lecture describes the QR decomposition and how it relates to

- Orthogonal projection and least squares
- A Gram-Schmidt process
- Eigenvalues and eigenvectors

We'll write some Python code to help consolidate our understandings.

3.2 Matrix factorization

In this lecture, we consider a real matrix $A \in \mathbb{R}^{n \times m}$ with $m \geq n$.

A QR decomposition (also called a QR factorization) of A takes the form

$$A = QR, \qquad Q \in \mathbb{R}^{n \times n}, \qquad R \in \mathbb{R}^{n \times m}, \qquad Q^\top Q = I_n.$$

The matrix R has zeros below its main diagonal.

Hence, R is upper triangular when $m = n$ and upper trapezoidal when $m > n$.

We'll use a *Gram-Schmidt process* to compute a QR decomposition.

Because doing so is so educational, we'll write our own Python code to do the job.

3.3 Gram-Schmidt process

We'll start with a *square* matrix A.

If a square matrix A is nonsingular, then a QR factorization is unique up to signs.

We'll deal with a rectangular matrix A later.

Actually, our algorithm will work with a rectangular A that is not square.

3.3.1 Gram-Schmidt process for square A

Here we apply a Gram-Schmidt process to the *columns* of matrix A.

In particular, let

$$A = \begin{bmatrix} a_1 & a_2 & \cdots & a_n \end{bmatrix}$$

Let $||\cdot||$ denote the L2 norm.

The Gram-Schmidt algorithm repeatedly combines the following two steps in a particular order

- **normalize** a vector to have unit norm
- **orthogonalize** the next vector

To begin, we set $u_1 = a_1$ and then *normalize*:

$$u_1 = a_1, \quad e_1 = \frac{u_1}{||u_1||}$$

We *orthogonalize* first to compute u_2 and then *normalize* to create e_2:

$$u_2 = a_2 - (a_2 \cdot e_1)e_1, \quad e_2 = \frac{u_2}{||u_2||}$$

We invite the reader to verify that e_1 is orthogonal to e_2 by checking that $e_1 \cdot e_2 = 0$.

The Gram-Schmidt procedure continues iterating.

Thus, for $k = 2, \ldots, n-1$ we construct

$$u_{k+1} = a_{k+1} - (a_{k+1} \cdot e_1)e_1 - \cdots - (a_{k+1} \cdot e_k)e_k, \quad e_{k+1} = \frac{u_{k+1}}{||u_{k+1}||}$$

Here $(a_j \cdot e_i)$ can be interpreted as the linear least squares *regression coefficient* of a_j on e_i

- it is the inner product of a_j and e_i divided by the inner product of e_i where $e_i \cdot e_i = 1$, as *normalization* has assured us.
- this regression coefficient has an interpretation as being a *covariance* divided by a *variance*

It can be verified that

$$A = \begin{bmatrix} a_1 & a_2 & \cdots & a_n \end{bmatrix} = \begin{bmatrix} e_1 & e_2 & \cdots & e_n \end{bmatrix} \begin{bmatrix} a_1 \cdot e_1 & a_2 \cdot e_1 & \cdots & a_n \cdot e_1 \\ 0 & a_2 \cdot e_2 & \cdots & a_n \cdot e_2 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & a_n \cdot e_n \end{bmatrix}$$

Thus, we have constructed the decomposition

$$A = QR$$

where

$$Q = \begin{bmatrix} e_1 & e_2 & \cdots & e_n \end{bmatrix}$$

and

$$R = \begin{bmatrix} a_1 \cdot e_1 & a_2 \cdot e_1 & \cdots & a_n \cdot e_1 \\ 0 & a_2 \cdot e_2 & \cdots & a_n \cdot e_2 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & a_n \cdot e_n \end{bmatrix}$$

3.3.2 A not square

Now suppose that A is an $n \times m$ matrix where $m > n$.

Then a QR decomposition is

$$A = \begin{bmatrix} a_1 & a_2 & \cdots & a_m \end{bmatrix} = \begin{bmatrix} e_1 & e_2 & \cdots & e_n \end{bmatrix} \begin{bmatrix} a_1 \cdot e_1 & a_2 \cdot e_1 & \cdots & a_n \cdot e_1 & a_{n+1} \cdot e_1 & \cdots & a_m \cdot e_1 \\ 0 & a_2 \cdot e_2 & \cdots & a_n \cdot e_2 & a_{n+1} \cdot e_2 & \cdots & a_m \cdot e_2 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & a_n \cdot e_n & a_{n+1} \cdot e_n & \cdots & a_m \cdot e_n \end{bmatrix}$$

Here, R is an $n \times m$ upper trapezoidal matrix.

This implies that

$$\begin{aligned} a_1 &= (a_1 \cdot e_1)e_1 \\ a_2 &= (a_2 \cdot e_1)e_1 + (a_2 \cdot e_2)e_2 \\ &\vdots \quad \vdots \\ a_n &= (a_n \cdot e_1)e_1 + (a_n \cdot e_2)e_2 + \cdots + (a_n \cdot e_n)e_n \\ a_{n+1} &= (a_{n+1} \cdot e_1)e_1 + (a_{n+1} \cdot e_2)e_2 + \cdots + (a_{n+1} \cdot e_n)e_n \\ &\vdots \quad \vdots \\ a_m &= (a_m \cdot e_1)e_1 + (a_m \cdot e_2)e_2 + \cdots + (a_m \cdot e_n)e_n \end{aligned}$$

3.4 Some code

Now let's write some homemade Python code to implement a QR decomposition by deploying the Gram-Schmidt process described above.

```
import numpy as np
from scipy.linalg import qr

rng = np.random.default_rng(1234)
```

The `qr_decomposition` function below illustrates the square case and its extension to wide $n \times m$ matrices with $m \geq n$, assuming that the first n columns are linearly independent.

```
def qr_decomposition(A):
    n, m = A.shape # get the shape of A

    Q = np.empty((n, n)) # initialize matrix Q
    u = np.empty((n, n)) # initialize matrix u

    u[:, 0] = A[:, 0]
    Q[:, 0] = u[:, 0] / np.linalg.norm(u[:, 0])

    for i in range(1, n):

        u[:, i] = A[:, i]
        for j in range(i):
            u[:, i] -= (A[:, i] @ Q[:, j]) * Q[:, j] # get each u vector

        Q[:, i] = u[:, i] / np.linalg.norm(u[:, i]) # compute each e vector
```

(continues on next page)

(continued from previous page)

```
    R = np.zeros((n, m))
    for i in range(n):
        for j in range(i, m):
            R[i, j] = A[:, j] @ Q[:, i]

    return Q, R
```

The preceding code is fine but can benefit from some further housekeeping.

We want to do this because later in this notebook we want to compare results from using our homemade code above with the code for a QR that the Python SciPy package delivers.

There can be sign differences between the Q and R matrices produced by different numerical algorithms.

All of these are valid QR decompositions because of how the sign differences cancel out when we compute QR.

To make the results from our homemade function and the QR module in SciPy comparable, we'll require the diagonal entries of R to be nonnegative.

We do this by adjusting the signs of the columns in Q and the corresponding rows in R appropriately.

To accomplish this we'll define a pair of functions.

```
def diag_sign(A):
    """Compute a diagonal sign matrix, mapping zero signs to one."""

    signs = np.where(np.diag(A) < 0, -1.0, 1.0)
    D = np.diag(signs)

    return D

def adjust_sign(Q, R):
    """
    Adjust the signs of the columns of Q and rows of R
    so that R has a nonnegative diagonal.
    """

    D = diag_sign(R)

    Q[:, :] = Q @ D
    R[:, :] = D @ R

    return Q, R
```

3.5 Example

Now let's do an example.

```
A = np.array([[1.0, 1.0, 0.0], [1.0, 0.0, 1.0], [0.0, 1.0, 1.0]])
# A = np.array([[1.0, 0.5, 0.2], [0.5, 0.5, 1.0], [0.0, 1.0, 1.0]])
# A = np.array([[1.0, 0.5, 0.2], [0.5, 0.5, 1.0]])

A
```

```
array([[1., 1., 0.],
       [1., 0., 1.],
       [0., 1., 1.]])
```

```
Q, R = adjust_sign(*qr_decomposition(A))
```

```
Q
```

```
array([[ 0.70710678,  0.40824829, -0.57735027],
       [ 0.70710678, -0.40824829,  0.57735027],
       [ 0.        ,  0.81649658,  0.57735027]])
```

```
R
```

```
array([[1.41421356, 0.70710678, 0.70710678],
       [0.        , 1.22474487, 0.40824829],
       [0.        , 0.        , 1.15470054]])
```

Let's compare outcomes with what the SciPy package produces

```
Q_scipy, R_scipy = adjust_sign(*qr(A))
```

```
print('Our Q: \n', Q)
print('\n')
print('SciPy Q: \n', Q_scipy)
```

```
Our Q:
 [[ 0.70710678  0.40824829 -0.57735027]
 [ 0.70710678 -0.40824829  0.57735027]
 [ 0.          0.81649658  0.57735027]]

SciPy Q:
 [[ 0.70710678  0.40824829 -0.57735027]
 [ 0.70710678 -0.40824829  0.57735027]
 [ 0.          0.81649658  0.57735027]]
```

```
print('Our R: \n', R)
print('\n')
print('SciPy R: \n', R_scipy)
```

```
Our R:
 [[1.41421356 0.70710678 0.70710678]
 [0.         1.22474487 0.40824829]
 [0.         0.         1.15470054]]

SciPy R:
 [[1.41421356 0.70710678 0.70710678]
 [0.         1.22474487 0.40824829]
 [0.         0.         1.15470054]]
```

The above outcomes give us the good news that our homemade function agrees with what SciPy produces.

Now let's do a QR decomposition for a rectangular matrix A that is $n \times m$ with $m > n$.

```
A = np.array([[1, 3, 4], [2, 0, 9]])
```

```
Q, R = adjust_sign(*qr_decomposition(A))
Q, R
```

```
(array([[ 0.4472136 ,  0.89442719],
        [ 0.89442719, -0.4472136 ]]),
 array([[ 2.23606798,  1.34164079,  9.8386991 ],
        [ 0.        ,  2.68328157, -0.4472136 ]]))
```

```
Q_scipy, R_scipy = adjust_sign(*qr(A))
Q_scipy, R_scipy
```

```
(array([[ 0.4472136 ,  0.89442719],
        [ 0.89442719, -0.4472136 ]]),
 array([[ 2.23606798,  1.34164079,  9.8386991 ],
        [ 0.        ,  2.68328157, -0.4472136 ]]))
```

3.6 Using QR decomposition to compute eigenvalues

Now for a useful fact about the QR algorithm.

The following iterations on the QR decomposition can be used to compute *eigenvalues* of a *square* matrix A.

Here is the algorithm:

1. Set $A_0 = A$ and form $A_0 = Q_0 R_0$
2. Form $A_1 = R_0 Q_0$. Note that A_1 is similar to A_0 (easy to verify) and so has the same eigenvalues.
3. Form $A_1 = Q_1 R_1$ (i.e., form the QR decomposition of A_1).
4. Form $A_2 = R_1 Q_1$ and then $A_2 = Q_2 R_2$.
5. Iterate to convergence.
6. Compute eigenvalues of A and compare them to the diagonal values of the limiting A_n found from this process.

Remark 3.6.1

This algorithm is close to one of the most efficient ways of computing eigenvalues!

Let's write some Python code to try out the algorithm

```
def qr_eigvals(A, tol=1e-12, maxiter=1000):
    "Find the eigenvalues of A using QR decomposition."

    A_old = np.array(A, dtype=float, copy=True)
    A_new = np.array(A, dtype=float, copy=True)

    diff = np.inf
    i = 0
    while (diff > tol) and (i < maxiter):
        A_old[:, :] = A_new
```

(continues on next page)

(continued from previous page)

```
        Q, R = qr_decomposition(A_old)

        A_new[:, :] = R @ Q

        diff = np.abs(A_new - A_old).max()
        i += 1

    eigvals = np.diag(A_new)

    return eigvals
```

Now let's try the code and compare the results with `np.linalg.eigvals`.

Here goes

```
# experiment this with one random A matrix
A = rng.random((3, 3))
```

```
sorted(qr_eigvals(A))
```

```
[np.float64(0.3056734729625916),
 np.float64(0.3842419370857368),
 np.float64(1.5699606602423861)]
```

Compare with NumPy's implementation.

```
sorted(np.linalg.eigvals(A))
```

```
[np.float64(0.3056734729643013),
 np.float64(0.38424193708402865),
 np.float64(1.569960660242386)]
```

3.7 QR and PCA

There are interesting connections between the QR decomposition and principal components analysis (PCA).

Here are some.

1. Let $X^\top$ be a $k \times n$ random matrix where the jth column is a random draw from $N(\mu, \Sigma)$ where μ is $k \times 1$ vector of means and Σ is a $k \times k$ covariance matrix. We want $n \gg k$ – this is an "econometrics example".
2. Form $X^\top = QR$ where Q is $k \times k$ and R is $k \times n$.
3. Form the eigenvalues of $RR^\top$, i.e., we'll compute $RR^\top = \tilde{P}\Lambda\tilde{P}^\top$.
4. Form $X^\top X = Q\tilde{P}\Lambda\tilde{P}^\top Q^\top$ and compare it with the eigen decomposition $X^\top X = P\hat{\Lambda}P^\top$.
5. It will turn out that $\Lambda = \hat{\Lambda}$ and that $P = Q\tilde{P}$.

Let's verify conjecture 5 with some Python code.

Start by simulating a random (n, k) matrix X.

```
k = 5
n = 1000
```

(continues on next page)

(continued from previous page)

```
# generate some random moments
μ = rng.random(size=k)
C = rng.random((k, k))
Σ = C.T @ C
```

```
# Each row of X is a draw from the multivariate normal distribution
X = rng.multivariate_normal(μ, Σ, size=n)
```

```
X.shape
```

```
(1000, 5)
```

Let's apply the QR decomposition to $X^\top$.

```
Q, R = adjust_sign(*qr_decomposition(X.T))
```

Check the shapes of Q and R.

```
Q.shape, R.shape
```

```
((5, 5), (5, 1000))
```

Now we can construct $RR^\top = \tilde{P}\Lambda\tilde{P}^\top$ and form an eigen decomposition.

```
RR = R @ R.T

λ, P_tilde = np.linalg.eigh(RR)
Λ = np.diag(λ)
```

We can also apply the decomposition to $X^\top X = P\hat{\Lambda}P^\top$.

```
XX = X.T @ X

λ_hat, P = np.linalg.eigh(XX)
Λ_hat = np.diag(λ_hat)
```

Compare the eigenvalues that are on the diagonals of Λ and $\hat{\Lambda}$.

```
λ, λ_hat
```

```
(array([  56.69677761,  225.16561049,  667.8151515 , 1413.45780269,
        8882.27383225]),
 array([  56.69677761,  225.16561049,  667.8151515 , 1413.45780269,
        8882.27383225]))
```

Let's compare P and $Q\tilde{P}$.

Again we need to be careful about sign differences between the columns of P and $Q\tilde{P}$.

```
QP_tilde = Q @ P_tilde

np.abs(P @ diag_sign(P) - QP_tilde @ diag_sign(QP_tilde)).max()
```

```
np.float64(5.162537064506978e-15)
```

Let's verify that $X^\top X$ can be decomposed as $Q\tilde{P}\Lambda\tilde{P}^\top Q^\top$.

```
QPΛPQ = Q @ P_tilde @ Λ @ P_tilde.T @ Q.T
```

```
np.abs(QPΛPQ - XX).max()
```

```
np.float64(2.091837814077735e-11)
```

CHAPTER

FOUR

CIRCULANT MATRICES

4.1 Overview

This lecture describes circulant matrices and some of their properties.

Circulant matrices are useful because multiplying by them is closely connected to convolution, and their eigenvectors can be constructed using the Discrete Fourier Transform.

We use circulant matrices to connect several useful concepts, including

- convolution
- Fourier transforms
- permutation matrices

For background on eigenvalues and eigenvectors, see *Linear Algebra*; for another use of Fourier transforms and convolution, see *Fault Tree Uncertainties*.

Circulant matrices are also widely used in machine learning, for example, in image processing.

We begin by importing some Python packages

```
import numpy as np
import matplotlib.pyplot as plt
```

```
np.set_printoptions(precision=3, suppress=True)
```

4.2 Constructing a Circulant Matrix

To construct an $N \times N$ circulant matrix, we need only the first row, say,

$$\begin{bmatrix} c_0 & c_1 & c_2 & c_3 & c_4 & \cdots & c_{N-1} \end{bmatrix}.$$

After setting entries in the first row, the remaining rows of a circulant matrix are determined as follows:

$$C = \begin{bmatrix} c_0 & c_1 & c_2 & c_3 & c_4 & \cdots & c_{N-1} \\ c_{N-1} & c_0 & c_1 & c_2 & c_3 & \cdots & c_{N-2} \\ c_{N-2} & c_{N-1} & c_0 & c_1 & c_2 & \cdots & c_{N-3} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ c_3 & c_4 & c_5 & c_6 & c_7 & \cdots & c_2 \\ c_2 & c_3 & c_4 & c_5 & c_6 & \cdots & c_1 \\ c_1 & c_2 & c_3 & c_4 & c_5 & \cdots & c_0 \end{bmatrix} \tag{4.1}$$

This pattern can be formalized as follows.

Definition 4.2.1 (Circulant matrix)

An $N \times N$ matrix C is **circulant** if there are numbers $c_0, \dots, c_{N-1}$ such that

$$C_{ij} = c_{(j-i) \bmod N}, \qquad 0 \leq i, j \leq N-1.$$

Equivalently, each row is obtained from the previous row by shifting entries one step to the right.

It is also possible to construct a circulant matrix by creating the transpose of the above matrix, in which case only the first column needs to be specified.

Let's write some Python code to generate a circulant matrix.

```
def construct_circulant(row):

    N = row.size

    C = np.empty((N, N))

    for i in range(N):

        C[i, i:] = row[:N-i]
        C[i, :i] = row[N-i:]

    return C
```

```
# a simple case when N = 3
construct_circulant(np.array([1., 2., 3.]))
```

```
array([[1., 2., 3.],
       [3., 1., 2.],
       [2., 3., 1.]])
```

4.2.1 Some Properties of Circulant Matrices

Here are some useful properties:

Suppose that A and B are both circulant matrices of the same order and constructed using the same cyclic shift convention.

Then it can be verified that

- The transpose of a circulant matrix is a circulant matrix.
- $A + B$ is a circulant matrix
- AB is a circulant matrix
- $AB = BA$

Now consider a circulant matrix with first row

$$c = \begin{bmatrix} c_0 & c_1 & \cdots & c_{N-1} \end{bmatrix}$$

and consider a vector

$$a = \begin{bmatrix} a_0 & a_1 & \cdots & a_{N-1} \end{bmatrix}$$

The **convolution** of vectors c and a is defined as the vector $b = c * a$ with components

$$b_k = \sum_{i=0}^{N-1} c_{k-i} a_i \tag{4.2}$$

Here and below, indices such as $k - i$ are interpreted modulo N.

We use $*$ to denote **convolution** via the calculation described in equation (4.2).

It can be verified that the vector b satisfies

$$b = C^\top a$$

where $C^\top$ is the transpose of the circulant matrix defined in equation (4.1).

4.3 Connection to Permutation Matrix

A good way to construct a circulant matrix is to use a **permutation matrix**.

Before defining a permutation **matrix**, we'll define a **permutation**.

A **permutation** of a set of the set of non-negative integers $\{0, 1, 2, ...\}$ is a one-to-one mapping of the set into itself.

A permutation of a set $\{1, 2, ..., n\}$ rearranges the n integers in the set.

A permutation matrix is obtained by permuting the rows of an $n \times n$ identity matrix according to a permutation of the numbers 1 to n.

Thus, every row and every column contain precisely a single 1 with 0 everywhere else.

Every permutation corresponds to a unique permutation matrix.

For example, the $N \times N$ matrix

$$P = \begin{bmatrix} 0 & 1 & 0 & 0 & \cdots & 0 \\ 0 & 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \cdots & 1 \\ 1 & 0 & 0 & 0 & \cdots & 0 \end{bmatrix} \tag{4.3}$$

serves as a **cyclic shift** operator that, when applied to an $N \times 1$ vector h, shifts entries in rows 2 through N up one row and shifts the entry in row 1 to row N.

Eigenvalues of the cyclic shift permutation matrix P defined in equation (4.3) can be computed by constructing

$$P - \lambda I = \begin{bmatrix} -\lambda & 1 & 0 & 0 & \cdots & 0 \\ 0 & -\lambda & 1 & 0 & \cdots & 0 \\ 0 & 0 & -\lambda & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \cdots & 1 \\ 1 & 0 & 0 & 0 & \cdots & -\lambda \end{bmatrix}$$

and solving

$$\det(P - \lambda I) = (-1)^N (\lambda^N - 1) = 0$$

Eigenvalues λ_i can be complex.

Magnitudes $\mid \lambda_i \mid$ of these eigenvalues λ_i all equal 1.

Thus, **singular values** of the permutation matrix P defined in equation (4.3) all equal 1.

It can be verified that permutation matrices are orthogonal matrices:

$$PP^\top = I$$

4.4 Examples with Python

Let's write some Python code to illustrate these ideas.

```
def construct_cyclic_shift_matrix(N):

    P = np.zeros((N, N))

    for i in range(N-1):
        P[i, i+1] = 1
    P[-1, 0] = 1

    return P
```

```
P4 = construct_cyclic_shift_matrix(4)
P4
```

```
array([[0., 1., 0., 0.],
       [0., 0., 1., 0.],
       [0., 0., 0., 1.],
       [1., 0., 0., 0.]])
```

```
# compute the eigenvalues and eigenvectors
λ, Q = np.linalg.eig(P4)
```

```
for i in range(4):
    print(f'λ{i} = {λ[i]:.1f} \nvec{i} = {Q[:, i]}\n')
```

```
λ0 = -1.0+0.0j
vec0 = [-0.5+0.j  0.5+0.j -0.5+0.j  0.5+0.j]

λ1 = 0.0+1.0j
vec1 = [-0. -0.5j  0.5+0.j   0. +0.5j -0.5-0.j ]

λ2 = 0.0-1.0j
vec2 = [-0. +0.5j  0.5-0.j   0. -0.5j -0.5+0.j ]

λ3 = 1.0+0.0j
vec3 = [-0.5+0.j -0.5+0.j -0.5+0.j -0.5+0.j]
```

In graphs below, we shall portray eigenvalues of a shift permutation matrix in the complex plane.

These eigenvalues are uniformly distributed along the unit circle.

They are the n **roots of unity**, meaning they are the n numbers z that solve $z^n = 1$, where z is a complex number.

In particular, the n roots of unity are

$$z = \exp\left(\frac{2\pi jk}{N}\right), \quad k = 0, \ldots, N-1$$

where j denotes the purely imaginary unit number.

```
fig, ax = plt.subplots(2, 2, figsize=(10, 10))

for i, N in enumerate([3, 4, 6, 8]):

    row_i = i // 2
    col_i = i % 2

    P = construct_cyclic_shift_matrix(N)
    λ, Q = np.linalg.eig(P)

    circ = plt.Circle((0, 0), radius=1, edgecolor='b', facecolor='None')
    ax[row_i, col_i].add_patch(circ)

    for j in range(N):
        ax[row_i, col_i].scatter(λ[j].real, λ[j].imag, c='b')

    ax[row_i, col_i].set_title(f'N = {N}')
    ax[row_i, col_i].set_xlabel('real')
    ax[row_i, col_i].set_ylabel('imaginary')

plt.show()
```

For a vector of coefficients $\{c_i\}_{i=0}^{n-1}$, eigenvectors of P are also eigenvectors of

$$C = c_0 I + c_1 P + c_2 P^2 + \cdots + c_{N-1} P^{N-1}.$$

Consider an example in which $N = 8$ and let $w = e^{-2\pi j/N}$.

It can be verified that the matrix F_8 of eigenvectors of P_8 is

$$F_8 = \begin{bmatrix} 1 & 1 & 1 & \cdots & 1 \\ 1 & w & w^2 & \cdots & w^7 \\ 1 & w^2 & w^4 & \cdots & w^{14} \\ 1 & w^3 & w^6 & \cdots & w^{21} \\ 1 & w^4 & w^8 & \cdots & w^{28} \\ 1 & w^5 & w^{10} & \cdots & w^{35} \\ 1 & w^6 & w^{12} & \cdots & w^{42} \\ 1 & w^7 & w^{14} & \cdots & w^{49} \end{bmatrix}$$

The matrix F_8 defines a Discrete Fourier Transform.

To convert it into an orthogonal eigenvector matrix, we can simply normalize it by dividing every entry by $\sqrt{8}$.

- stare at the first column of F_8 above to convince yourself of this fact

The eigenvalues corresponding to each eigenvector are $\{w^j\}_{j=0}^7$ in order.

```
def construct_F(N):

    w = np.e ** (-complex(0, 2*np.pi/N))

    F = np.ones((N, N), dtype=complex)
    for i in range(1, N):
        F[i, 1:] = w ** (i * np.arange(1, N))

    return F, w
```

```
F8, w = construct_F(8)
```

```
w
```

```
(0.7071067811865476-0.7071067811865475j)
```

```
F8
```

```
array([[ 1.   +0.j   ,  1.   +0.j   ,  1.   +0.j   ,  1.   +0.j   ,
         1.   +0.j   ,  1.   +0.j   ,  1.   +0.j   ,  1.   +0.j   ],
       [ 1.   +0.j   ,  0.707-0.707j,  0.   -1.j   , -0.707-0.707j,
        -1.   -0.j   , -0.707+0.707j, -0.   +1.j   ,  0.707+0.707j],
       [ 1.   +0.j   ,  0.   -1.j   , -1.   -0.j   , -0.   +1.j   ,
         1.   +0.j   ,  0.   -1.j   , -1.   -0.j   , -0.   +1.j   ],
       [ 1.   +0.j   , -0.707-0.707j, -0.   +1.j   ,  0.707-0.707j,
        -1.   -0.j   ,  0.707+0.707j,  0.   -1.j   , -0.707+0.707j],
       [ 1.   +0.j   , -1.   -0.j   ,  1.   +0.j   , -1.   -0.j   ,
         1.   +0.j   , -1.   -0.j   ,  1.   +0.j   , -1.   -0.j   ],
       [ 1.   +0.j   , -0.707+0.707j,  0.   -1.j   ,  0.707+0.707j,
        -1.   -0.j   ,  0.707-0.707j, -0.   +1.j   , -0.707-0.707j],
       [ 1.   +0.j   , -0.   +1.j   , -1.   -0.j   ,  0.   -1.j   ,
         1.   +0.j   , -0.   +1.j   , -1.   -0.j   ,  0.   -1.j   ],
       [ 1.   +0.j   ,  0.707+0.707j, -0.   +1.j   , -0.707+0.707j,
        -1.   -0.j   , -0.707-0.707j,  0.   -1.j   ,  0.707-0.707j]])
```

```
# normalize
Q8 = F8 / np.sqrt(8)
```

```
# verify the orthogonality (unitarity)
Q8 @ np.conjugate(Q8)
```

```
array([[ 1.+0.j, -0.+0.j, -0.+0.j, -0.+0.j, -0.+0.j,  0.+0.j,  0.+0.j,
         0.+0.j],
       [-0.-0.j,  1.+0.j, -0.+0.j, -0.+0.j, -0.+0.j, -0.+0.j,  0.+0.j,

         1.+0.j]])
```

Let's verify that kth column of Q_8 is an eigenvector of P_8 with an eigenvalue w^k.

```
P8 = construct_cyclic_shift_matrix(8)
```

```
diff_arr = np.empty(8, dtype=complex)
for j in range(8):
    diff = P8 @ Q8[:, j] - w ** j * Q8[:, j]
    diff_arr[j] = diff @ diff.T
```

```
diff_arr
```

```
array([ 0.+0.j, -0.+0.j, -0.+0.j, -0.+0.j, -0.+0.j, -0.+0.j, -0.+0.j,
       -0.+0.j])
```

4.5 Associated Permutation Matrix

Next, we execute calculations to verify that the circulant matrix C defined in equation (4.1) can be written as

$$C = c_0 I + c_1 P + \cdots + c_{N-1} P^{N-1}$$

and that every eigenvector of P is also an eigenvector of C.

We illustrate this for $N = 8$ case.

```
rng = np.random.default_rng()
c = rng.random(8)
```

```
c
```

```
array([0.962, 0.236, 0.113, 0.437, 0.198, 0.586, 0.435, 0.318])
```

```
C8 = construct_circulant(c)
```

Compute $c_0 I + c_1 P + \cdots + c_{N-1} P^{N-1}$.

```
N = 8

C = np.zeros((N, N))
P = np.eye(N)

for i in range(N):
    C += c[i] * P
    P = P8 @ P
```

```
C
```

```
array([[0.962, 0.236, 0.113, 0.437, 0.198, 0.586, 0.435, 0.318],
       [0.318, 0.962, 0.236, 0.113, 0.437, 0.198, 0.586, 0.435],
       [0.435, 0.318, 0.962, 0.236, 0.113, 0.437, 0.198, 0.586],
       [0.586, 0.435, 0.318, 0.962, 0.236, 0.113, 0.437, 0.198],
       [0.198, 0.586, 0.435, 0.318, 0.962, 0.236, 0.113, 0.437],
       [0.437, 0.198, 0.586, 0.435, 0.318, 0.962, 0.236, 0.113],
       [0.113, 0.437, 0.198, 0.586, 0.435, 0.318, 0.962, 0.236],
       [0.236, 0.113, 0.437, 0.198, 0.586, 0.435, 0.318, 0.962]])
```

```
C8
```

```
array([[0.962, 0.236, 0.113, 0.437, 0.198, 0.586, 0.435, 0.318],
       [0.318, 0.962, 0.236, 0.113, 0.437, 0.198, 0.586, 0.435],
       [0.435, 0.318, 0.962, 0.236, 0.113, 0.437, 0.198, 0.586],
       [0.586, 0.435, 0.318, 0.962, 0.236, 0.113, 0.437, 0.198],
       [0.198, 0.586, 0.435, 0.318, 0.962, 0.236, 0.113, 0.437],
       [0.437, 0.198, 0.586, 0.435, 0.318, 0.962, 0.236, 0.113],
       [0.113, 0.437, 0.198, 0.586, 0.435, 0.318, 0.962, 0.236],
       [0.236, 0.113, 0.437, 0.198, 0.586, 0.435, 0.318, 0.962]])
```

Now let's compute the difference between two circulant matrices that we have constructed in two different ways.

```
np.abs(C - C8).max()
```

```
np.float64(0.0)
```

The jth column of Q_8 is an eigenvector of C_8 associated with eigenvalue $\sum_{k=0}^{7} c_k w^{jk}$.

```
λ_C8 = np.zeros(8, dtype=complex)

for j in range(8):
    for k in range(8):
        λ_C8[j] += c[k] * w ** (j * k)
```

```
λ_C8
```

```
array([3.285+0.j   , 0.433+0.486j, 0.612-0.068j, 1.096-0.159j,
       0.131-0.j   , 1.096+0.159j, 0.612+0.068j, 0.433-0.486j])
```

We can verify this by comparing `C8 @ Q8[:, j]` with `λ_C8[j] * Q8[:, j]`.

```
# verify
for j in range(8):
    diff = C8 @ Q8[:, j] - λ_C8[j] * Q8[:, j]
    print(diff)
```

```
[-0.+0.j -0.+0.j -0.+0.j -0.+0.j -0.+0.j -0.+0.j -0.+0.j -0.+0.j]

4.6 Discrete Fourier Transform

The **Discrete Fourier Transform** (DFT) allows us to represent a discrete time sequence as a weighted sum of complex sinusoids.

Consider a sequence of N real numbers $\{x_j\}_{j=0}^{N-1}$.

The **Discrete Fourier Transform** maps $\{x_j\}_{j=0}^{N-1}$ into a sequence of complex numbers $\{X_k\}_{k=0}^{N-1}$

where

$$X_k = \sum_{n=0}^{N-1} x_n e^{-2\pi \frac{kn}{N} i}$$

```
def DFT(x):
    "The discrete Fourier transform."

    N = len(x)
    w = np.e ** (-complex(0, 2*np.pi/N))

    X = np.zeros(N, dtype=complex)
    for k in range(N):
        for n in range(N):
            X[k] += x[n] * w ** (k * n)

    return X
```

Consider the following example.

$$x_n = \begin{cases} 1/2 & n = 0, 1 \\ 0 & \text{otherwise} \end{cases}$$

```
x = np.zeros(10)
x[0:2] = 1/2
```

```
x
```

```
array([0.5, 0.5, 0. , 0. , 0. , 0. , 0. , 0. , 0. , 0. ])
```

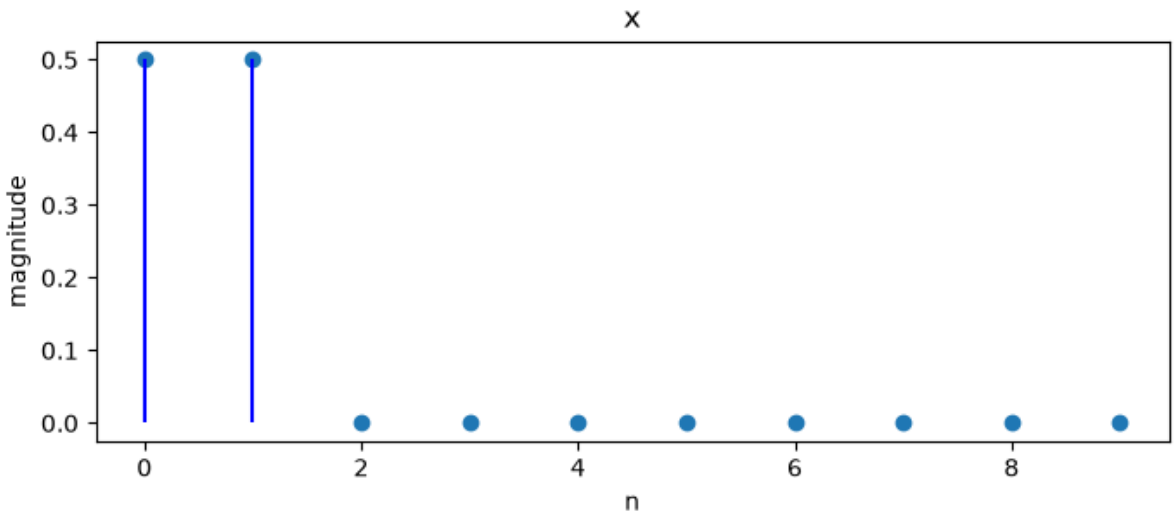
Apply a discrete Fourier transform.

```
X = DFT(x)
```

```
X
```

```
array([ 1.   +0.j   ,  0.905-0.294j,  0.655-0.476j,  0.345-0.476j,
        0.095-0.294j, -0.   +0.j   ,  0.095+0.294j,  0.345+0.476j,
        0.655+0.476j,  0.905+0.294j])
```

We can plot magnitudes of a sequence of numbers and the associated discrete Fourier transform.



```
def plot_magnitude(x=None, X=None):

    data = []
    names = []
    xs = []
    if (x is not None):
        data.append(x)
        names.append('x')
        xs.append('n')
    if (X is not None):
        data.append(X)
        names.append('X')
        xs.append('k')

    num = len(data)
    for i in range(num):
        n = data[i].size
        plt.figure(figsize=(8, 3))
        plt.scatter(range(n), np.abs(data[i]))
        plt.vlines(range(n), 0, np.abs(data[i]), color='b')

        plt.xlabel(xs[i])
        plt.ylabel('magnitude')
        plt.title(names[i])
        plt.show()
```

```
plot_magnitude(x=x, X=X)
```

The **inverse Fourier transform** transforms a Fourier transform X of x back to x.

The inverse Fourier transform is defined as

$$x_n = \sum_{k=0}^{N-1} \frac{1}{N} X_k e^{2\pi(\frac{kn}{N})i}, \quad n = 0, 1, \dots, N-1$$

```
def inverse_DFT(X):

    N = len(X)
    w = np.e ** (complex(0, 2*np.pi/N))

    x = np.zeros(N, dtype=complex)
    for n in range(N):
        for k in range(N):
            x[n] += X[k] * w ** (k * n) / N

    return x
```

```
inverse_DFT(X)
```

```
array([ 0.5+0.j,  0.5-0.j, -0. -0.j, -0. -0.j, -0. -0.j, -0. -0.j, -0. -0.j,
       -0. +0.j, -0. +0.j, -0. +0.j, -0. +0.j])
```

Another example is

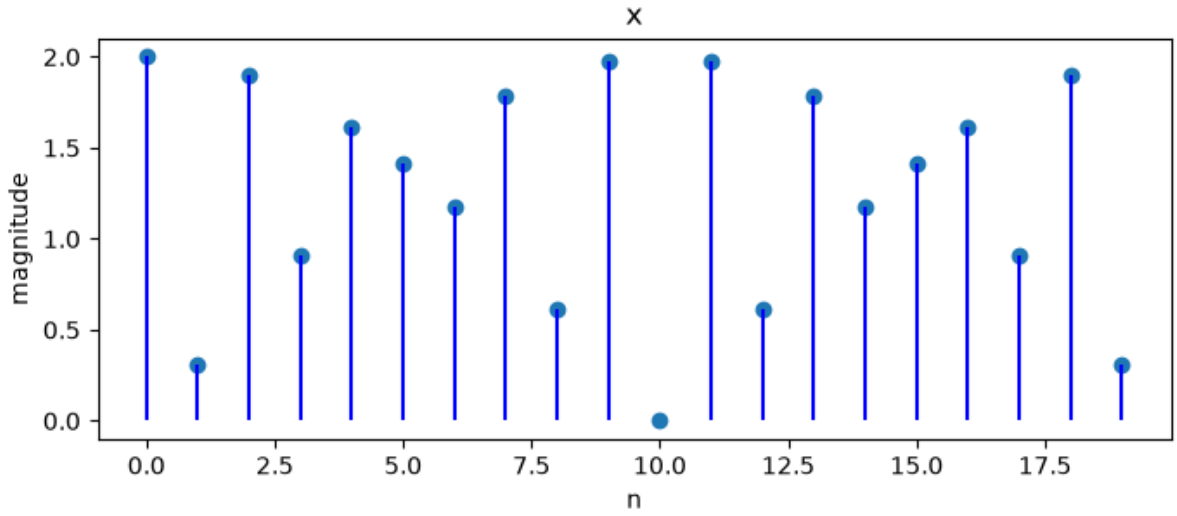
$$x_n = 2\cos\left(2\pi \frac{11}{40} n\right), \; n = 0, 1, 2, \cdots 19$$

Since $N = 20$, we cannot use an integer multiple of $\frac{1}{20}$ to represent a frequency $\frac{11}{40}$.

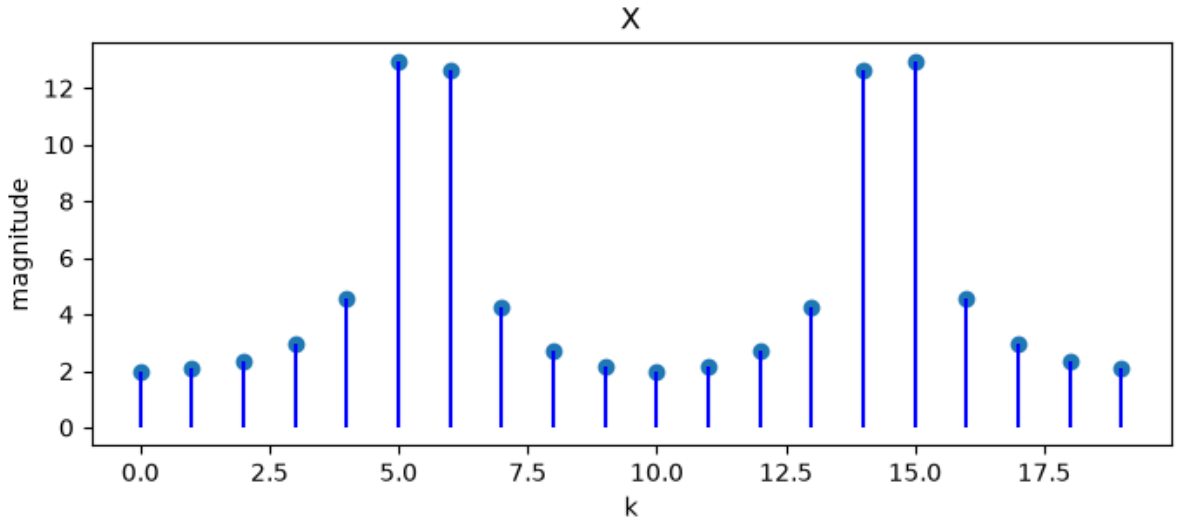
To handle this, we shall end up using all N of the available frequencies in the DFT.

Since $\frac{11}{40}$ is in between $\frac{10}{40}$ and $\frac{12}{40}$ (each of which is an integer multiple of $\frac{1}{20}$), the complex coefficients in the DFT have their largest magnitudes at $k = 5, 6, 15, 16$, not just at a single frequency.

```
N = 20
x = np.empty(N)
```



(continues on next page)



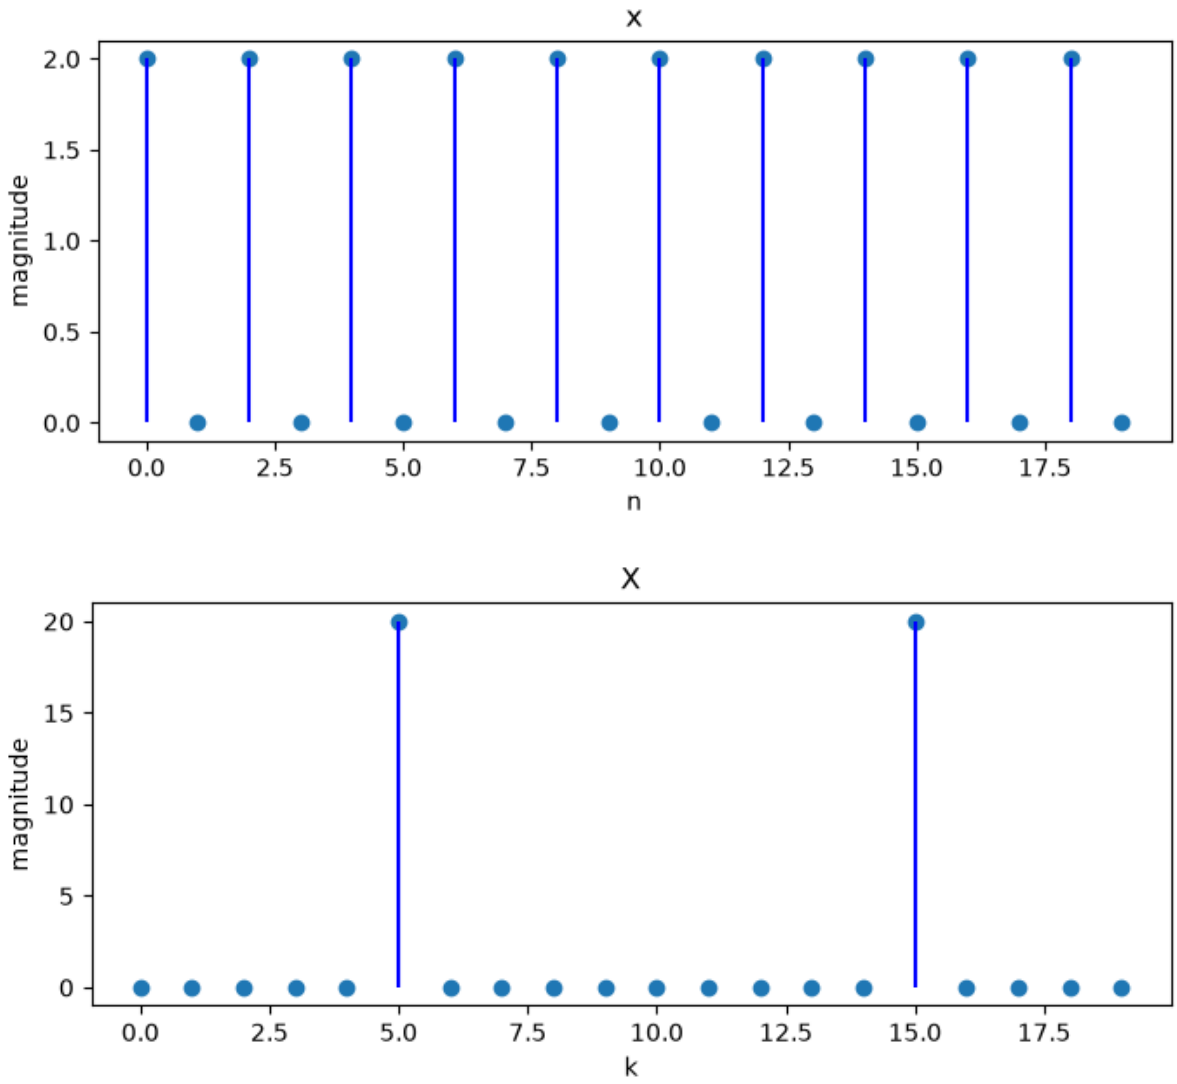
(continued from previous page)

```
for j in range(N):
    x[j] = 2 * np.cos(2 * np.pi * 11 * j / 40)
```

```
X = DFT(x)
```

```
plot_magnitude(x=x, X=X)
```

What happens if we change the last example to $x_n = 2\cos\left(2\pi\frac{10}{40}n\right)$?



Note that $\frac{10}{40}$ is an integer multiple of $\frac{1}{20}$.

```
N = 20
x = np.empty(N)

for j in range(N):
    x[j] = 2 * np.cos(2 * np.pi * 10 * j / 40)
```

```
X = DFT(x)
```

```
plot_magnitude(x=x, X=X)
```

If we represent the discrete Fourier transform as a matrix, we discover that it equals the matrix F_N of eigenvectors of the permutation matrix P_N.

We can use the example where $x_n = 2\cos\left(2\pi\frac{11}{40}n\right),\ n = 0, 1, 2, \cdots 19$ to illustrate this.

```
N = 20
x = np.empty(N)

for j in range(N):
    x[j] = 2 * np.cos(2 * np.pi * 11 * j / 40)
```

```
x
```

```
array([ 2.   , -0.313, -1.902,  0.908,  1.618, -1.414, -1.176,  1.782,
        0.618, -1.975, -0.   ,  1.975, -0.618, -1.782,  1.176,  1.414,
       -1.618, -0.908,  1.902,  0.313])
```

First use the summation formula to transform x to X.

```
X = DFT(x)
X
```

```
array([2. +0.j   , 2. +0.558j, 2. +1.218j, 2. +2.174j, 2. +4.087j,
       2.+12.785j, 2.-12.466j, 2. -3.751j, 2. -1.801j, 2. -0.778j,
       2. -0.j   , 2. +0.778j, 2. +1.801j, 2. +3.751j, 2.+12.466j,
       2.-12.785j, 2. -4.087j, 2. -2.174j, 2. -1.218j, 2. -0.558j])
```

Now let's evaluate the outcome of postmultiplying the eigenvector matrix F_{20} by the vector x, a product that we claim should equal the Fourier transform of the sequence $\{x_n\}_{n=0}^{N-1}$.

```
F20, _ = construct_F(20)
```

```
F20 @ x
```

```
array([2. +0.j   , 2. +0.558j, 2. +1.218j, 2. +2.174j, 2. +4.087j,
       2.+12.785j, 2.-12.466j, 2. -3.751j, 2. -1.801j, 2. -0.778j,
       2. -0.j   , 2. +0.778j, 2. +1.801j, 2. +3.751j, 2.+12.466j,
       2.-12.785j, 2. -4.087j, 2. -2.174j, 2. -1.218j, 2. -0.558j])
```

Similarly, the inverse DFT can be expressed as an inverse DFT matrix F_{20}^{-1}.

```
F20_inv = np.linalg.inv(F20)
F20_inv @ X
```

```
array([ 2.   -0.j, -0.313-0.j, -1.902+0.j,  0.908-0.j,  1.618-0.j,
       -1.414+0.j, -1.176+0.j,  1.782+0.j,  0.618-0.j, -1.975-0.j,
       -0.   +0.j,  1.975-0.j, -0.618-0.j, -1.782+0.j,  1.176+0.j,
        1.414-0.j, -1.618-0.j, -0.908+0.j,  1.902+0.j,  0.313-0.j])
```

CHAPTER

FIVE

SINGULAR VALUE DECOMPOSITION (SVD)

5.1 Overview

The **singular value decomposition** (SVD) is a work-horse in applications of least squares projection that form foundations for many statistical and machine learning methods.

After defining the SVD, we'll describe how it connects to

- **four fundamental spaces** of linear algebra
- **low-rank approximations** of matrices
- under-determined and over-determined **least squares regressions** (see the exercises)
- **principal components analysis** (PCA)

In a sequel to this lecture, *VARs and DMDs*, we'll describe how SVDs provide ways rapidly to compute reduced-rank approximations to first-order vector autoregressions (VARs) by means of a **dynamic mode decomposition** (DMD).

Like principal components analysis, DMD can be thought of as a data-reduction procedure that represents salient patterns by projecting data onto a limited set of factors.

5.2 The setting

Let X be an $m \times n$ matrix of rank p.

Necessarily, $p \leq \min(m, n)$.

In much of this lecture, we'll think of X as a matrix of data in which

- each column is an **individual** – a time period or person, depending on the application
- each row is a **random variable** describing an attribute of a time period or a person, depending on the application

We'll be interested in two situations

- A **short and fat** case in which $m \ll n$, so that there are many more columns (individuals) than rows (attributes).
- A **tall and skinny** case in which $m \gg n$, so that there are many more rows (attributes) than columns (individuals).

We'll apply a **singular value decomposition** of X in both situations.

In the $m \ll n$ case in which there are many more individuals n than attributes m, we can calculate sample moments of a joint distribution by taking averages across observations of functions of the observations.

In this $m \ll n$ case, we'll look for patterns by using a singular value decomposition to do a principal components analysis (PCA).

In the $m \gg n$ case in which there are many more attributes m than individuals n and when we are in a time-series setting in which n equals the number of time periods covered in the data set X, we'll proceed in a different way.

In the sequel *VARs and DMDs*, we'll again use a singular value decomposition, but now to construct a **dynamic mode decomposition** (DMD).

5.3 Singular value decomposition

A **singular value decomposition** of an $m \times n$ matrix X of rank $p \leq \min(m, n)$ is

$$X = U\Sigma V^\top \tag{5.1}$$

where

$$\begin{aligned} UU^\top &= I \qquad U^\top U = I \\ VV^\top &= I \qquad V^\top V = I \end{aligned}$$

and

- U is an $m \times m$ orthogonal matrix of **left singular vectors** of X
- Columns of U are eigenvectors of $XX^\top$
- V is an $n \times n$ orthogonal matrix of **right singular vectors** of X
- Columns of V are eigenvectors of $X^\top X$
- Σ is an $m \times n$ matrix in which the first p places on its main diagonal are positive numbers $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_p$ called **singular values**; remaining entries of Σ are all zero
- The p singular values are positive square roots of the nonzero eigenvalues of the $m \times m$ matrix $XX^\top$ and also of the $n \times n$ matrix $X^\top X$
- We adopt a convention that when U is a complex valued matrix, $U^\top$ denotes the **conjugate-transpose** or **Hermitian-transpose** of U, meaning that $U^\top_{ij}$ is the complex conjugate of U_{ji}.
- Similarly, when V is a complex valued matrix, $V^\top$ denotes the **conjugate-transpose** or **Hermitian-transpose** of V

The matrices U, Σ, V entail linear transformations that reshape vectors in the following ways:

- multiplying vectors by the unitary matrices U and V **rotates** them, but leaves **angles between vectors** and **lengths of vectors** unchanged.
- multiplying vectors by the diagonal matrix Σ **rescales** each coordinate by a singular value (and adds or drops coordinates when $m \neq n$); in general this changes both lengths of vectors and angles between them.

Thus, representation (5.1) asserts that multiplying an $n \times 1$ vector y by the $m \times n$ matrix X amounts to performing the following three multiplications of y sequentially:

- **rotating** y by computing $V^\top y$
- **rescaling** $V^\top y$ by multiplying it by Σ
- **rotating** $\Sigma V^\top y$ by multiplying it by U

This structure of the $m \times n$ matrix X opens the door to constructing systems of data **encoders** and **decoders**.

Thus,

- $V^\top$ is an encoder
- Σ is an operator to be applied to the encoded data

- U is a decoder to be applied to the output from applying operator Σ to the encoded data

We'll apply this circle of ideas in the sequel *VARs and DMDs* when we study dynamic mode decompositions.

Road ahead

What we have described above is called a **full** SVD.

In a **full** SVD, the shapes of U, Σ, and V are (m, m), (m, n), (n, n), respectively.

Later we'll also describe an **economy** or **reduced** SVD.

Before we study a **reduced** SVD we'll say a little more about properties of a **full** SVD.

5.4 Four fundamental subspaces

Let $\mathcal{C}$ denote a column space, $\mathcal{N}$ denote a null space, and $\mathcal{R}$ denote a row space.

Let's start by recalling the four fundamental subspaces of an $m \times n$ matrix X of rank p.

- The **column space** of X, denoted $\mathcal{C}(X)$, is the span of the columns of X, i.e., all vectors y that can be written as linear combinations of columns of X. Its dimension is p.
- The **null space** of X, denoted $\mathcal{N}(X)$ consists of all vectors y that satisfy $Xy = 0$. Its dimension is $n - p$.
- The **row space** of X, denoted $\mathcal{R}(X)$ is the column space of $X^\top$. It consists of all vectors z that can be written as linear combinations of rows of X. Its dimension is p.
- The **left null space** of X, denoted $\mathcal{N}(X^\top)$, consists of all vectors z such that $X^\top z = 0$. Its dimension is $m - p$.

For a full SVD of a matrix X, the matrix U of left singular vectors and the matrix V of right singular vectors contain orthogonal bases for all four subspaces.

They form two pairs of orthogonal subspaces that we'll describe now.

Let $u_i, i = 1, \ldots, m$ be the m column vectors of U and let $v_i, i = 1, \ldots, n$ be the n column vectors of V.

Let's write the full SVD of X as

$$X = \begin{bmatrix} U_L & U_R \end{bmatrix} \begin{bmatrix} \Sigma_p & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} V_L & V_R \end{bmatrix}^\top \tag{5.2}$$

where Σ_p is a $p \times p$ diagonal matrix with the p singular values on the diagonal and

$$\begin{aligned} U_L &= \begin{bmatrix} u_1 & \cdots & u_p \end{bmatrix}, \quad U_R = \begin{bmatrix} u_{p+1} & \cdots & u_m \end{bmatrix} \\ V_L &= \begin{bmatrix} v_1 & \cdots & v_p \end{bmatrix}, \quad V_R = \begin{bmatrix} v_{p+1} & \cdots & v_n \end{bmatrix} \end{aligned}$$

Representation (5.2) implies that

$$X \begin{bmatrix} V_L & V_R \end{bmatrix} = \begin{bmatrix} U_L & U_R \end{bmatrix} \begin{bmatrix} \Sigma_p & 0 \\ 0 & 0 \end{bmatrix}$$

or

$$\begin{aligned} XV_L &= U_L \Sigma_p \\ XV_R &= 0 \end{aligned} \tag{5.3}$$

or

$$\begin{aligned} Xv_i &= \sigma_i u_i, \quad i = 1, \ldots, p \\ Xv_i &= 0, \quad i = p+1, \ldots, n \end{aligned} \tag{5.4}$$

Equations (5.4) tell how the transformation X maps a pair of orthonormal vectors v_i, v_j for i and j both less than or equal to the rank p of X into a pair of orthogonal vectors $\sigma_i u_i, \sigma_j u_j$ with lengths σ_i and σ_j.

Equations (5.3) assert that

$$\begin{aligned}\mathcal{C}(X) &= \mathcal{C}(U_L)\\ \mathcal{N}(X) &= \mathcal{C}(V_R)\end{aligned}$$

Taking transposes on both sides of representation (5.2) implies

$$X^\top \begin{bmatrix} U_L & U_R \end{bmatrix} = \begin{bmatrix} V_L & V_R \end{bmatrix} \begin{bmatrix} \Sigma_p & 0 \\ 0 & 0 \end{bmatrix}$$

or

$$\begin{aligned}X^\top U_L &= V_L \Sigma_p\\ X^\top U_R &= 0\end{aligned} \tag{5.5}$$

or

$$\begin{aligned}X^\top u_i &= \sigma_i v_i, \quad i = 1, \ldots, p\\ X^\top u_i &= 0 \quad i = p+1, \ldots, m\end{aligned} \tag{5.6}$$

Notice how equations (5.6) assert that the transformation $X^\top$ maps a pair of distinct orthonormal vectors u_i, u_j for i and j both less than or equal to the rank p of X into a pair of orthogonal vectors $\sigma_i v_i, \sigma_j v_j$.

Equations (5.5) assert that

$$\begin{aligned}\mathcal{R}(X) \equiv \mathcal{C}(X^\top) &= \mathcal{C}(V_L)\\ \mathcal{N}(X^\top) &= \mathcal{C}(U_R)\end{aligned}$$

Thus, taken together, the systems of equations (5.3) and (5.5) describe the four fundamental subspaces of X in the following ways:

$$\begin{aligned}\mathcal{C}(X) &= \mathcal{C}(U_L)\\ \mathcal{N}(X^\top) &= \mathcal{C}(U_R)\\ \mathcal{R}(X) \equiv \mathcal{C}(X^\top) &= \mathcal{C}(V_L)\\ \mathcal{N}(X) &= \mathcal{C}(V_R)\end{aligned} \tag{5.7}$$

Since U and V are both orthonormal matrices, collection (5.7) asserts that

- U_L is an orthonormal basis for the column space of X
- U_R is an orthonormal basis for the null space of $X^\top$
- V_L is an orthonormal basis for the row space of X
- V_R is an orthonormal basis for the null space of X

We have verified the four claims in (5.7) simply by performing the multiplications called for by the right side of (5.2) and reading them.

The claims in (5.7) and the fact that U and V are both unitary (i.e., orthonormal) matrices imply that

- the column space of X is orthogonal to the null space of $X^\top$
- the null space of X is orthogonal to the row space of X

Sometimes these properties are described with the following two pairs of orthogonal complement subspaces:

- $\mathcal{C}(X)$ is the orthogonal complement of $\mathcal{N}(X^\top)$

- $\mathcal{R}(X)$ is the orthogonal complement of $\mathcal{N}(X)$

Let's do an example.

```
import numpy as np
import numpy.linalg as LA
import matplotlib.pyplot as plt

rng = np.random.default_rng(1234)
```

Having imported these modules, let's do the example.

We use a 4×5 matrix of rank 2, so that the four subspaces have dimensions 2, 2, 2, and 3.

Note that `np.linalg.svd` returns $V^\top$, not V, as its third output.

So the row space and the null space are spanned by rows of that output.

```
np.set_printoptions(precision=2, suppress=True)

# Define the matrix
A = np.array([[1, 2, 3, 4, 5],
              [2, 3, 4, 5, 6],
              [3, 4, 5, 6, 7],
              [4, 5, 6, 7, 8]])

# Compute the SVD of the matrix; the third output is V^T
U, S, VT = np.linalg.svd(A, full_matrices=True)

# Compute the rank of the matrix
rank = np.linalg.matrix_rank(A)

print("Rank of matrix:\n", rank)
print("S: \n", S)

# Orthonormal bases for the four fundamental subspaces
col_space = U[:, :rank]            # C(A),   a subspace of R^4
left_null_space = U[:, rank:]      # N(A^T), a subspace of R^4
row_space = VT[:rank, :].T         # R(A),   a subspace of R^5
null_space = VT[rank:, :].T        # N(A),   a subspace of R^5

print("Column space:\n", col_space)
print("Left null space:\n", left_null_space)
print("Row space:\n", row_space)
print("Null space:\n", null_space)
```

```
Rank of matrix:
 2
S:
 [21.63  1.46  0.    0.  ]
Column space:
 [[ 0.34  0.76]
 [ 0.44  0.33]
 [ 0.54 -0.11]
 [ 0.64 -0.54]]
Left null space:
 [[-0.27  0.48]
 [ 0.71 -0.44]
 [-0.62 -0.56]
```

(continues on next page)

(continued from previous page)

```
 [ 0.18  0.52]]
Row space:
 [[ 0.25 -0.73]
 [ 0.34 -0.43]
 [ 0.43 -0.13]
 [ 0.52  0.18]
 [ 0.61  0.48]]
Null space:
 [[ 0.62 -0.08  0.08]
 [-0.71 -0.05  0.45]
 [-0.24 -0.18 -0.84]
 [ 0.11  0.83  0.03]
 [ 0.21 -0.52  0.29]]
```

Let's verify that the bases have the properties that (5.7) asserts.

```
print("A @ null_space = 0:         ", np.allclose(A @ null_space, 0))
print("A.T @ left_null_space = 0: ", np.allclose(A.T @ left_null_space, 0))
print("col_space ⊥ left_null_space:", np.allclose(col_space.T @ left_null_space, 0))
print("row_space ⊥ null_space:     ", np.allclose(row_space.T @ null_space, 0))
```

```
A @ null_space = 0:         True
A.T @ left_null_space = 0:  True
col_space ⊥ left_null_space: True
row_space ⊥ null_space:     True
```

5.5 Eckart-Young theorem

Suppose that we want to construct the best rank r approximation of an $m \times n$ matrix X.

By best, we mean a matrix X_r of rank $r < p$ that, among all rank r matrices of dimension $m \times n$, minimizes

$$||X - X_r||$$

where $||\cdot||$ denotes a norm of a matrix.

Three popular **matrix norms** of an $m \times n$ matrix X can be expressed in terms of the singular values of X

- the **spectral** or l^2 norm $||X||_2 = \max_{||y||\neq 0} \frac{||Xy||}{||y||} = \sigma_1$
- the **Frobenius** norm $||X||_F = \sqrt{\sigma_1^2 + \cdots + \sigma_p^2}$
- the **nuclear** norm $||X||_N = \sigma_1 + \cdots + \sigma_p$

The Eckart-Young theorem states that for each of these three norms, the same rank r matrix is best and that it equals

$$\hat{X}_r = \sigma_1 u_1 v_1^\top + \sigma_2 u_2 v_2^\top + \cdots + \sigma_r u_r v_r^\top = U_r \Sigma_r V_r^\top \tag{5.8}$$

where U_r and V_r consist of the first r columns of U and V, respectively, and Σ_r is the $r \times r$ diagonal matrix of the r largest singular values.

The resulting approximation errors are

$$\begin{aligned}
||X - \hat{X}_r||_2 &= \sigma_{r+1} \\
||X - \hat{X}_r||_F &= \sqrt{\sigma_{r+1}^2 + \cdots + \sigma_p^2} \\
||X - \hat{X}_r||_N &= \sigma_{r+1} + \cdots + \sigma_p
\end{aligned}$$

This is a very powerful theorem.

It says that we can approximate an $m \times n$ matrix X of rank p by an $m \times n$ matrix of rank $r < p$ built from the r largest singular values of X and their singular vectors, and that the singular values that we discard measure the approximation error.

If a few singular values are much larger than the others, a low-rank approximation captures most of X while requiring us to store only $r(m + n + 1)$ numbers instead of mn.

You can read about the Eckart-Young theorem and some of its uses here.

We'll make use of this theorem when we discuss principal components analysis (PCA) below.

It also underlies the sequel *VARs and DMDs*, where the pseudo-inverse

$$\hat{X}_r^+ = V_r \Sigma_r^{-1} U_r^\top$$

of the approximation $\hat{X}_r$ is a key ingredient of a dynamic mode decomposition.

Exercise 5.12.2 and Exercise 5.12.3 explore these ideas.

5.6 Full and reduced SVD's

Up to now we have described properties of a **full** SVD in which shapes of U, Σ, and V are (m, m), (m, n), (n, n), respectively.

There is an alternative bookkeeping convention called an **economy** or **reduced** SVD in which the shapes of U, Σ and V are different from what they are in a full SVD.

Because we assume that X has rank p, there are only p nonzero singular values, where $p = \text{rank}(X) \leq \min(m, n)$.

A **reduced** SVD uses this fact to express U, Σ, and V as matrices with shapes (m, p), (p, p), (n, p).

You can read about reduced and full SVD here https://numpy.org/doc/stable/reference/generated/numpy.linalg.svd.html

(With the option `full_matrices=False`, `numpy` returns $\min(m, n)$ columns of U and V; when $p < \min(m, n)$, we drop the columns that correspond to zero singular values to obtain a reduced SVD in the sense used here.)

For a full SVD,

$$\begin{aligned} UU^\top = I \qquad & U^\top U = I \\ VV^\top = I \qquad & V^\top V = I \end{aligned}$$

But not all these properties hold for a **reduced** SVD.

For a reduced SVD, $U^\top U = I_{p \times p}$ and $V^\top V = I_{p \times p}$ always hold, but $UU^\top = I_{m \times m}$ holds only if $p = m$ and $VV^\top = I_{n \times n}$ holds only if $p = n$.

Which properties hold thus depends on whether we are in a **tall-skinny** case or a **short-fat** case.

- In a **tall-skinny** case in which $m \gg n$ and X has full column rank $p = n$, for a **reduced** SVD

$$\begin{aligned} UU^\top \neq I \qquad & U^\top U = I \\ VV^\top = I \qquad & V^\top V = I \end{aligned}$$

- In a **short-fat** case in which $m \ll n$ and X has full row rank $p = m$, for a **reduced** SVD

$$\begin{aligned} UU^\top = I \qquad & U^\top U = I \\ VV^\top \neq I \qquad & V^\top V = I \end{aligned}$$

When we study dynamic mode decompositions in the sequel *VARs and DMDs*, we shall want to remember these properties because we will use a reduced SVD in a tall-skinny case.

Let's do an example to compare **full** and **reduced** SVD's.

To review,

- in a **full** SVD
  - U is $m \times m$
  - Σ is $m \times n$
  - V is $n \times n$
- in a **reduced** SVD
  - U is $m \times p$
  - Σ is $p \times p$
  - V is $n \times p$

First, let's study a case in which $m = 5 > n = 2$.

(This is a small example of the **tall-skinny** case that will concern us when we study dynamic mode decompositions in the sequel.)

```
X = rng.random((5, 2))
U, S, V = np.linalg.svd(X, full_matrices=True)  # full SVD
Uhat, Shat, Vhat = np.linalg.svd(X, full_matrices=False) # economy SVD
print('U, S, V =')
U, S, V
```

```
U, S, V =
```

```
(array([[-0.58,  0.17, -0.2 , -0.67, -0.38],
        [-0.53, -0.23, -0.05,  0.68, -0.45],
        [-0.19,  0.03,  0.98, -0.09, -0.04],
        [-0.18,  0.92, -0.03,  0.29,  0.19],
        [-0.55, -0.27, -0.07, -0.01,  0.78]]),
 array([1.8 , 0.24]),
 array([[-0.95, -0.33],
        [-0.33,  0.95]]))
```

```
print('Uhat, Shat, Vhat = ')
Uhat, Shat, Vhat
```

```
Uhat, Shat, Vhat =
```

```
(array([[-0.58,  0.17],
        [-0.53, -0.23],
        [-0.19,  0.03],
        [-0.18,  0.92],
        [-0.55, -0.27]]),
 array([1.8 , 0.24]),
 array([[-0.95, -0.33],
        [-0.33,  0.95]]))
```

```
rr = np.linalg.matrix_rank(X)
print(f'rank of X = {rr}')
```

```
rank of X = 2
```

Properties:

- Where U is constructed via a full SVD, $U^\top U = I_{m\times m}$ and $UU^\top = I_{m\times m}$
- Where $\hat{U}$ is constructed via a reduced SVD, although $\hat{U}^\top\hat{U} = I_{p\times p}$, it happens that $\hat{U}\hat{U}^\top \neq I_{m\times m}$

We illustrate these properties for our example with the following code cells.

```
UTU = U.T@U
UUT = U@U.T
print('UUT, UTU = ')
UUT, UTU
```

```
UUT, UTU =
```

```
(array([[ 1.,  0., -0., -0., -0.],
        [ 0.,  1., -0.,  0., -0.],
        [-0., -0.,  1., -0., -0.],
        [-0.,  0., -0.,  1.,  0.],
        [-0., -0., -0.,  0.,  1.]]),
 array([[ 1., -0., -0.,  0., -0.],
        [-0.,  1., -0.,  0., -0.],
        [-0., -0.,  1.,  0., -0.],
        [ 0.,  0.,  0.,  1.,  0.],
        [-0., -0., -0.,  0.,  1.]]))
```

```
UhatUhatT = Uhat@Uhat.T
UhatTUhat = Uhat.T@Uhat
print('UhatUhatT, UhatTUhat= ')
UhatUhatT, UhatTUhat
```

```
UhatUhatT, UhatTUhat=
```

```
(array([[ 0.37,  0.27,  0.12,  0.26,  0.28],
        [ 0.27,  0.33,  0.09, -0.11,  0.36],
        [ 0.12,  0.09,  0.04,  0.06,  0.1 ],
        [ 0.26, -0.11,  0.06,  0.88, -0.15],
        [ 0.28,  0.36,  0.1 , -0.15,  0.38]]),
 array([[ 1., -0.],
        [-0.,  1.]]))
```

Remarks:

The cells above illustrate the application of the `full_matrices=True` and `full_matrices=False` options.

Using `full_matrices=False` returns a reduced singular value decomposition.

The **full** and **reduced** SVD's both accurately decompose an $m \times n$ matrix X.

When we study dynamic mode decompositions in the sequel, it will be important for us to remember the preceding properties of full and reduced SVD's in such tall-skinny cases.

Now let's turn to a short-fat case.

To illustrate this case, we'll set $m = 2 < 5 = n$ and compute both full and reduced SVD's.

```
X = rng.random((2, 5))
U, S, V = np.linalg.svd(X, full_matrices=True)  # full SVD
Uhat, Shat, Vhat = np.linalg.svd(X, full_matrices=False) # economy SVD
print('U, S, V = ')
U, S, V
```

```
U, S, V =
```

```
(array([[ 0.78, -0.63],
        [ 0.63,  0.78]]),
 array([1.97, 0.68]),
 array([[ 0.39,  0.48,  0.41,  0.4 ,  0.55],
        [ 0.35,  0.28, -0.55, -0.61,  0.37],
        [-0.52,  0.45,  0.49, -0.54, -0.  ],
        [-0.52,  0.51, -0.54,  0.43,  0.02],
        [-0.44, -0.49, -0.02, -0.  ,  0.75]]))
```

```
print('Uhat, Shat, Vhat = ')
Uhat, Shat, Vhat
```

```
Uhat, Shat, Vhat =
```

```
(array([[ 0.78, -0.63],
        [ 0.63,  0.78]]),
 array([1.97, 0.68]),
 array([[ 0.39,  0.48,  0.41,  0.4 ,  0.55],
        [ 0.35,  0.28, -0.55, -0.61,  0.37]]))
```

Let's verify that our reduced SVD accurately represents X

```
SShat=np.diag(Shat)
np.allclose(X, Uhat@SShat@Vhat)
```

```
True
```

5.7 Polar decomposition

A **reduced** singular value decomposition (SVD) of X is related to a **polar decomposition** of X

$$X = SQ$$

where

$$S = U\Sigma U^\top$$
$$Q = UV^\top$$

and in our reduced SVD

- U is an $m \times p$ orthonormal matrix
- Σ is a $p \times p$ diagonal matrix
- V is an $n \times p$ orthonormal matrix

Because $U^\top U = I$, we have $SQ = U\Sigma U^\top UV^\top = U\Sigma V^\top = X$.

Here

- S is an $m \times m$ **symmetric positive semidefinite** matrix
- Q is an $m \times n$ matrix with $QQ^\top = UU^\top$; so when $p = m$, as for a short-fat X with full row rank, $QQ^\top = I$ and Q has orthonormal rows

5.8 Application: principal components analysis (PCA)

Let's begin with a case in which $n \gg m$, so that we have many more individuals n than attributes m.

The matrix X is **short and fat** in an $n \gg m$ case as opposed to a **tall and skinny** case with $m \gg n$ to be discussed in the sequel.

We regard X as an $m \times n$ matrix of **data**:

$$X = \begin{bmatrix} X_1 \mid X_2 \mid \cdots \mid X_n \end{bmatrix}$$

where for $j = 1, \ldots, n$ the column vector $X_j = \begin{bmatrix} x_{1j} \\ x_{2j} \\ \vdots \\ x_{mj} \end{bmatrix}$ is a vector of observations on variables $1, 2, \ldots, m$.

In a **time series** setting, we would think of columns j as indexing different **times** at which random variables are observed, while rows index different random variables.

In a **cross-section** setting, we would think of columns j as indexing different **individuals** for which random variables are observed, while rows index different **attributes**.

As we have seen before, the SVD is a way to decompose a matrix into useful components, just like polar decomposition, eigendecomposition, and many others.

PCA, on the other hand, is a method that builds on the SVD to analyze data.

Its goal is to find a few linear combinations of the variables that capture the most important patterns of variation in the data.

Step 1: Center the data:

Because we are interested in variation of the data around their means, we first subtract sample means.

(Because our data matrix may hold variables of different units and scales, we might also **standardize** the data by dividing each row by its sample standard deviation.)

We first compute the average of each row of X

$$\bar{X}_i = \frac{1}{n} \sum_{j=1}^{n} x_{ij}$$

We then create a matrix of these means:

$$\bar{X} = \begin{bmatrix} \bar{X}_1 \\ \bar{X}_2 \\ \vdots \\ \bar{X}_m \end{bmatrix} \begin{bmatrix} 1 \mid 1 \mid \cdots \mid 1 \end{bmatrix}$$

and subtract it from the original matrix to create a mean-centered matrix:

$$B = X - \bar{X}$$

Step 2: Compute the covariance matrix:

Because we want to extract relationships between variables rather than just their magnitudes – in other words, we want to know how they can explain each other – we compute the sample covariance matrix of B.

$$C = \frac{1}{n} BB^\top$$

Step 3: Decompose the covariance matrix and arrange the singular values:

Since the matrix C is symmetric and positive semidefinite, we can eigendecompose it, find its eigenvalues, and arrange the eigenvalue and eigenvector matrices in decreasing order.

The eigendecomposition of C can be found by decomposing B instead. Since B is not a square matrix, we obtain an SVD of B:

$$\begin{aligned} BB^\top &= U\Sigma V^\top (U\Sigma V^\top)^\top \\ &= U\Sigma V^\top V \Sigma^\top U^\top \\ &= U\Sigma\Sigma^\top U^\top \end{aligned}$$

so that

$$C = \frac{1}{n} U\Sigma\Sigma^\top U^\top$$

Singular values are conventionally arranged in decreasing order, as `numpy` does.

Step 4: Select singular values, (optional) truncate the rest:

We can now decide how many singular values to keep, based on how much variance we want to retain (e.g., retaining 95% of the total variance).

We can obtain the percentage by calculating the variance contained in the leading r factors divided by the total variance:

$$\frac{\sum_{i=1}^{r} \sigma_i^2}{\sum_{i=1}^{p} \sigma_i^2}$$

By the Eckart-Young theorem, one minus this ratio is also the squared relative Frobenius-norm error $||B - \hat{B}_r||_F^2 / ||B||_F^2$ of the best rank r approximation $\hat{B}_r$ of B.

Step 5: Create the score matrix:

The matrix of **principal components** (or **scores**) is

$$\begin{aligned} T &= U^\top B \\ &= U^\top U \Sigma V^\top \\ &= \Sigma V^\top \end{aligned}$$

Its kth row is the sequence, across observations $j = 1, \ldots, n$, of the kth principal component.

Keeping only the first r rows gives the $r \times n$ matrix $T_r = U_r^\top B$ of the first r principal components, and $U_r T_r = U_r \Sigma_r V_r^\top = \hat{B}_r$ is the Eckart-Young approximation of B.

In the sequel *VARs and DMDs*, the vector $U_r^\top X_t$ of the first r principal components of a time t cross section serves as the regressor in a **principal components regression** that forecasts next period's cross section.

5.9 Relationship of PCA to SVD

To relate an SVD to a PCA of data set X, first construct the SVD of the data matrix X.

Let's assume that sample means of all variables are zero, so we don't need to center our matrix.

$$X = U\Sigma V^\top = \sigma_1 U_1 V_1^\top + \sigma_2 U_2 V_2^\top + \cdots + \sigma_p U_p V_p^\top \tag{5.9}$$

where

$$U = [U_1|U_2|...|U_m]$$

$$V^\top = \begin{bmatrix} V_1^\top \\ V_2^\top \\ \vdots \\ V_n^\top \end{bmatrix}$$

In equation (5.9), each of the $m \times n$ matrices $U_j V_j^\top$ is evidently of rank 1.

Thus, we have

$$X = \sigma_1 \begin{bmatrix} U_{11}V_1^\top \\ U_{21}V_1^\top \\ \cdots \\ U_{m1}V_1^\top \end{bmatrix} + \sigma_2 \begin{bmatrix} U_{12}V_2^\top \\ U_{22}V_2^\top \\ \cdots \\ U_{m2}V_2^\top \end{bmatrix} + ... + \sigma_p \begin{bmatrix} U_{1p}V_p^\top \\ U_{2p}V_p^\top \\ \cdots \\ U_{mp}V_p^\top \end{bmatrix} \tag{5.10}$$

Here is how we would interpret the objects in the matrix equation (5.10) in a time series context:

- for each $k = 1, ..., p$, the object $\{V_{jk}\}_{j=1}^n$ (the kth column of V) is a time series for the kth **principal component**, normalized to have unit length; the unnormalized principal component is $\sigma_k V_k^\top = U_k^\top X$
- $U_k = \begin{bmatrix} U_{1k} \\ U_{2k} \\ \vdots \\ U_{mk} \end{bmatrix}$, $k = 1, ..., p$, is a vector of **loadings** of variables X_i on the kth principal component, $i = 1, ..., m$
- σ_k for each $k = 1, ..., p$ is the strength of the kth **principal component**, where strength means contribution to the overall covariance of X: the kth principal component contributes σ_k^2/n to the sum of the sample variances of the m variables

5.10 PCA with eigenvalues and eigenvectors

We now use an eigen decomposition of a sample covariance matrix to do PCA.

Let $X_{m\times n}$ be our $m \times n$ data matrix.

Let's assume that sample means of all variables are zero.

We can assure this by **pre-processing** the data by subtracting sample means.

Define a matrix Ω that is proportional to the sample covariance matrix (it equals n times it) as

$$\Omega = XX^\top$$

Then use an eigen decomposition to represent Ω as follows:

$$\Omega = P\Lambda P^\top$$

Here

- P is an $m \times m$ orthogonal matrix of eigenvectors of Ω
- Λ is a diagonal matrix of eigenvalues of Ω

We can then represent X as

$$X = P\epsilon$$

where

$$\epsilon = P^{-1}X = P^{\top}X$$

and

$$\epsilon\epsilon^{\top} = \Lambda.$$

We can verify that

$$XX^{\top} = P\Lambda P^{\top}. \tag{5.11}$$

It follows that we can represent the data matrix X as

$$X = [P_1|P_2|...|P_m] \begin{bmatrix} \epsilon_1 \\ \epsilon_2 \\ \vdots \\ \epsilon_m \end{bmatrix} = P_1\epsilon_1 + P_2\epsilon_2 + ... + P_m\epsilon_m$$

where P_j is the jth column of P and ϵ_j is the $1 \times n$ jth row of ϵ.

To reconcile the preceding representation with the PCA that we had obtained earlier through the SVD, we first note that $\epsilon_j\epsilon_j^{\top} = \lambda_j \equiv \sigma_j^2$.

Now for each j with $\lambda_j > 0$ define $\tilde{\epsilon}_j = \frac{\epsilon_j}{\sqrt{\lambda_j}}$, which implies that $\tilde{\epsilon}_j\tilde{\epsilon}_j^{\top} = 1$.

Terms with $\lambda_j = 0$ vanish because then $\epsilon_j = 0$.

Therefore

$$\begin{aligned} X &= \sqrt{\lambda_1}P_1\tilde{\epsilon}_1 + \sqrt{\lambda_2}P_2\tilde{\epsilon}_2 + ... + \sqrt{\lambda_p}P_p\tilde{\epsilon}_p \\ &= \sigma_1P_1\tilde{\epsilon}_1 + \sigma_2P_2\tilde{\epsilon}_2 + ... + \sigma_pP_p\tilde{\epsilon}_p, \end{aligned}$$

which agrees with

$$X = \sigma_1U_1{V_1}^{\top} + \sigma_2U_2{V_2}^{\top} + ... + \sigma_pU_p{V_p}^{\top}$$

provided that we set

- $U_j = P_j$ (a vector of loadings of variables on principal component j)
- ${V_k}^{\top} = \tilde{\epsilon}_k$ (the kth principal component)

Because there are alternative algorithms for computing P and U for a given data matrix X, depending on the algorithms used, we might have sign differences or different orders of eigenvectors.

We can resolve such ambiguities about U and P by

1. sorting eigenvalues and singular values in descending order
2. imposing positive diagonals on P and U and adjusting signs in $V^{\top}$ accordingly

5.11 Connections

To pull things together, it is useful to assemble and compare some formulas presented above.

First, consider an SVD of an $m \times n$ matrix:

$$X = U\Sigma V^\top$$

Compute:

$$\begin{aligned} XX^\top &= U\Sigma V^\top V\Sigma^\top U^\top \\ &= U\Sigma\Sigma^\top U^\top \\ &\equiv U\Lambda U^\top \end{aligned} \tag{5.12}$$

Compare representation (5.12) with equation (5.11) above.

Evidently, U in the SVD is the matrix P of eigenvectors of $XX^\top$ and $\Sigma\Sigma^\top$ is the matrix Λ of eigenvalues.

Second, let's compute

$$\begin{aligned} X^\top X &= V\Sigma^\top U^\top U\Sigma V^\top \\ &= V\Sigma^\top\Sigma V^\top \end{aligned}$$

Thus, the matrix V in the SVD is the matrix of eigenvectors of $X^\top X$.

Summarizing and fitting things together, we have the eigen decomposition of the sample covariance matrix

$$XX^\top = P\Lambda P^\top$$

where P is an orthogonal matrix.

Further, from the SVD of X, we know that

$$XX^\top = U\Sigma\Sigma^\top U^\top$$

where U is an orthogonal matrix.

Thus, $P = U$ (up to the ordering and signs of columns) and we have the representation of X

$$X = P\epsilon = U\Sigma V^\top$$

It follows that

$$U^\top X = \Sigma V^\top = \epsilon$$

so that ϵ is the matrix of principal components (scores) that we constructed in Step 5 above.

Note that the preceding implies that

$$\epsilon\epsilon^\top = \Sigma V^\top V\Sigma^\top = \Sigma\Sigma^\top = \Lambda,$$

so that everything fits together.

Below we define a class `DecomAnalysis` that wraps PCA and SVD for a given data matrix `X`.

```
class DecomAnalysis:
    """
    A class for conducting PCA and SVD.
    X: data matrix
    r_component: chosen rank for best approximation
    """

    def __init__(self, X, r_component=None):

        self.X = X

        self.Ω = (X @ X.T)

        self.m, self.n = X.shape
        self.r = LA.matrix_rank(X)

        if r_component:
            self.r_component = r_component
        else:
            self.r_component = min(self.m, self.n)

    def pca(self):

        λ, P = LA.eigh(self.Ω)     # columns of P are eigenvectors

        ind = sorted(range(λ.size), key=lambda x: λ[x], reverse=True)

        # sort by eigenvalues
        self.λ = λ[ind]
        P = P[:, ind]
        self.P = P @ diag_sign(P)

        self.Λ = np.diag(self.λ)

        self.explained_ratio_pca = np.cumsum(self.λ) / self.λ.sum()

        # compute the m by n matrix of principal components
        self.ϵ = self.P.T @ self.X

        P = self.P[:, :self.r_component]
        ϵ = self.ϵ[:self.r_component, :]

        # transform data
        self.X_pca = P @ ϵ

    def svd(self):

        U, σ, VT = LA.svd(self.X)

        ind = sorted(range(σ.size), key=lambda x: σ[x], reverse=True)

        # sort by eigenvalues
        d = min(self.m, self.n)

        self.σ = σ[ind]
        U = U[:, ind]
        D = diag_sign(U)
```

(continues on next page)

(continued from previous page)

```
        self.U = U @ D
        VT[:d, :] = D @ VT[ind, :]
        self.VT = VT

        self.Σ = np.zeros((self.m, self.n))
        self.Σ[:d, :d] = np.diag(self.σ)

        σ_sq = self.σ ** 2
        self.explained_ratio_svd = np.cumsum(σ_sq) / σ_sq.sum()

        # slicing matrices by the number of components to use
        U = self.U[:, :self.r_component]
        Σ = self.Σ[:self.r_component, :self.r_component]
        VT = self.VT[:self.r_component, :]

        # transform data
        self.X_svd = U @ Σ @ VT

    def fit(self, r_component):

        # pca
        P = self.P[:, :r_component]
        ϵ = self.ϵ[:r_component, :]

        # transform data
        self.X_pca = P @ ϵ

        # svd
        U = self.U[:, :r_component]
        Σ = self.Σ[:r_component, :r_component]
        VT = self.VT[:r_component, :]

        # transform data
        self.X_svd = U @ Σ @ VT

def diag_sign(A):
    "Compute the signs of the diagonal of matrix A"

    D = np.diag(np.sign(np.diag(A)))

    return D
```

We also define a function that prints out information so that we can compare decompositions obtained by different algorithms.

```
def compare_pca_svd(da):
    """

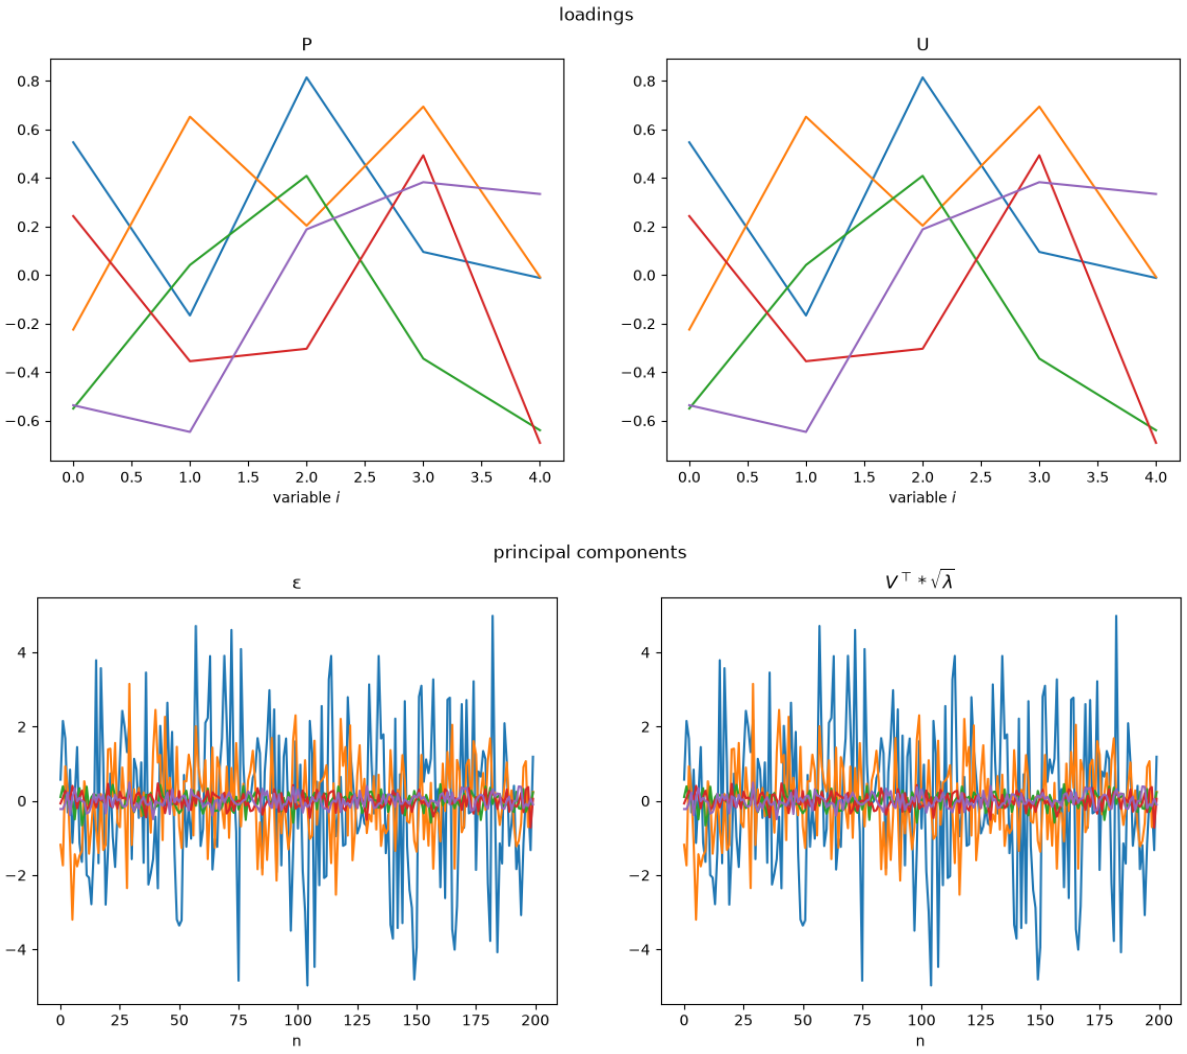
    axs[1].plot(da.VT[:k, :].T * np.sqrt(da.λ[:k]))
    axs[1].set_title(r'$V^\top *\sqrt{\lambda}$')
    axs[1].set_xlabel('n')
    plt.show()
```

Let's apply these tools to a short-fat data matrix with $m = 5$ variables and $n = 200$ observations that is generated by two factors plus noise.



```
m, n = 5, 200
G = rng.normal(size=(m, 2))               # loadings on two factors
Z = rng.normal(size=(2, n))               # factors
X = G @ Z + 0.2 * rng.normal(size=(m, n))
X = X - X.mean(axis=1, keepdims=True)     # subtract sample means

da = DecomAnalysis(X)
compare_pca_svd(da)
```

```
Eigenvalues and Singular values

λ = [884.59 233.75   9.36   8.13   6.41]

σ^2 = [884.59 233.75   9.36   8.13   6.41]
```

The two algorithms produce the same loadings and the same principal components.

The cumulative fractions of variance explained reveal that two principal components account for almost all of the variation in X, which is consistent with how we generated the data.

```
print("explained ratio (PCA):", da.explained_ratio_pca)
print("explained ratio (SVD):", da.explained_ratio_svd)
```

```
explained ratio (PCA): [0.77 0.98 0.99 0.99 1.  ]
explained ratio (SVD): [0.77 0.98 0.99 0.99 1.  ]
```

For an example of PCA applied to analyzing the structure of intelligence tests see the lecture *Multivariate Normal Distribution*.

Look at parts of that lecture that describe and illustrate the classic factor analysis model.

As mentioned earlier, in a sequel to this lecture, *VARs and DMDs*, we'll describe how SVD's provide ways rapidly to compute reduced-order approximations to first-order Vector Autoregressions (VARs).

5.12 Exercises

Exercise 5.12.1

In ordinary least squares (OLS), we learn to compute $\hat{\beta} = (X^\top X)^{-1} X^\top y$, where the matrix X of regressors has one row for each observation and one column for each regressor.

But the matrix $X^\top X$ is not invertible (its determinant is zero) when regressors are perfectly collinear or when there are more regressors than observations, so that X is **short and fat** and the system $X\beta = y$ is underdetermined.

And $X^\top X$ is **ill-conditioned** when regressors are nearly collinear, meaning that the ratio of its largest to its smallest eigenvalue is very large.

What we can do instead is to use what is called a pseudoinverse X^+ of X in place of $(X^\top X)^{-1} X^\top$.

1. Use an SVD of X to build the pseudoinverse matrix X^+ and use it to compute $\hat{\beta} = X^+ y$.
2. Show that when X has linearly independent columns (an **over-determined** system), $X^+ = (X^\top X)^{-1} X^\top$, so that $\hat{\beta}$ is the usual OLS estimator.
3. Show that when X has linearly independent rows (an **under-determined** system), $\hat{\beta}$ solves $X\beta = y$ exactly and has the smallest norm among all solutions.
4. Verify these claims numerically for a 5×8 matrix X of random numbers.

Solution

We can use an SVD to compute the pseudoinverse.

Starting from a reduced SVD

$$X = U \Sigma V^\top$$

in which Σ is the $p \times p$ diagonal matrix of positive singular values, the pseudoinverse is

$$X^+ = V \Sigma^{-1} U^\top$$

Equivalently, in terms of a full SVD, $X^+ = V \Sigma^+ U^\top$, where the $n \times m$ matrix Σ^+ is formed by transposing Σ and replacing each positive singular value σ_j by $1/\sigma_j$:

$$\Sigma^+ = \begin{bmatrix} \frac{1}{\sigma_1} & 0 & \cdots & 0 & 0 \\ 0 & \frac{1}{\sigma_2} & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & \frac{1}{\sigma_p} & 0 \\ 0 & 0 & \cdots & 0 & 0 \end{bmatrix}$$

and finally:

$$\hat{\beta} = X^+ y = V \Sigma^{-1} U^\top y$$

When X has linearly independent columns, V is a square orthogonal matrix, so

$$(X^\top X)^{-1} X^\top = (V \Sigma^2 V^\top)^{-1} V \Sigma U^\top = V \Sigma^{-2} V^\top V \Sigma U^\top = V \Sigma^{-1} U^\top = X^+.$$

When X has linearly independent rows, U is a square orthogonal matrix, so

$$X \hat{\beta} = U \Sigma V^\top V \Sigma^{-1} U^\top y = U U^\top y = y.$$

Every other solution of $X\beta = y$ has the form $\beta = \hat{\beta} + \eta$ with $X\eta = 0$.

The vector $\hat{\beta} = V(\Sigma^{-1}U^\top y)$ lies in the row space of X, which is spanned by the columns of V, while η lies in the null space of X.

These two subspaces are orthogonal, so $\|\beta\|^2 = \|\hat{\beta}\|^2 + \|\eta\|^2 \geq \|\hat{\beta}\|^2$.

Here is a numerical check.

```
n_obs, k = 5, 8
X = rng.normal(size=(n_obs, k))
y = rng.normal(size=n_obs)

U, σ, VT = np.linalg.svd(X, full_matrices=False)
X_plus = VT.T @ np.diag(1 / σ) @ U.T
β_hat = X_plus @ y

print("X_plus equals np.linalg.pinv(X):", np.allclose(X_plus, np.linalg.pinv(X)))
print("X β_hat = y:                     ", np.allclose(X @ β_hat, y))

# another exact solution: add an element of the null space of X
β_other = β_hat + (np.eye(k) - X_plus @ X) @ rng.normal(size=k)
print("X β_other = y:                   ", np.allclose(X @ β_other, y))
print(f"norms: |β_hat| = {LA.norm(β_hat):.3f}, |β_other| = {LA.norm(β_other):.3f}")

# over-determined case: pseudo-inverse reproduces OLS
X_tall = rng.normal(size=(8, 5))
print("pinv equals (X^T X)^{-1} X^T:   ",
      np.allclose(np.linalg.pinv(X_tall), LA.inv(X_tall.T @ X_tall) @ X_tall.T))
```

```
X_plus equals np.linalg.pinv(X): True
X β_hat = y:                     True
X β_other = y:                   True
norms: |β_hat| = 1.099, |β_other| = 1.175
pinv equals (X^T X)^{-1} X^T:    True
```

Exercise 5.12.2

This exercise verifies the Eckart-Young theorem numerically.

Construct a 60×40 matrix X equal to a rank-4 matrix plus noise, for example

```
X = rng.normal(size=(60, 4)) @ rng.normal(size=(4, 40)) + 0.3 * rng.
normal(size=(60, 40))
```

For $r = 1, 2, 4, 8$

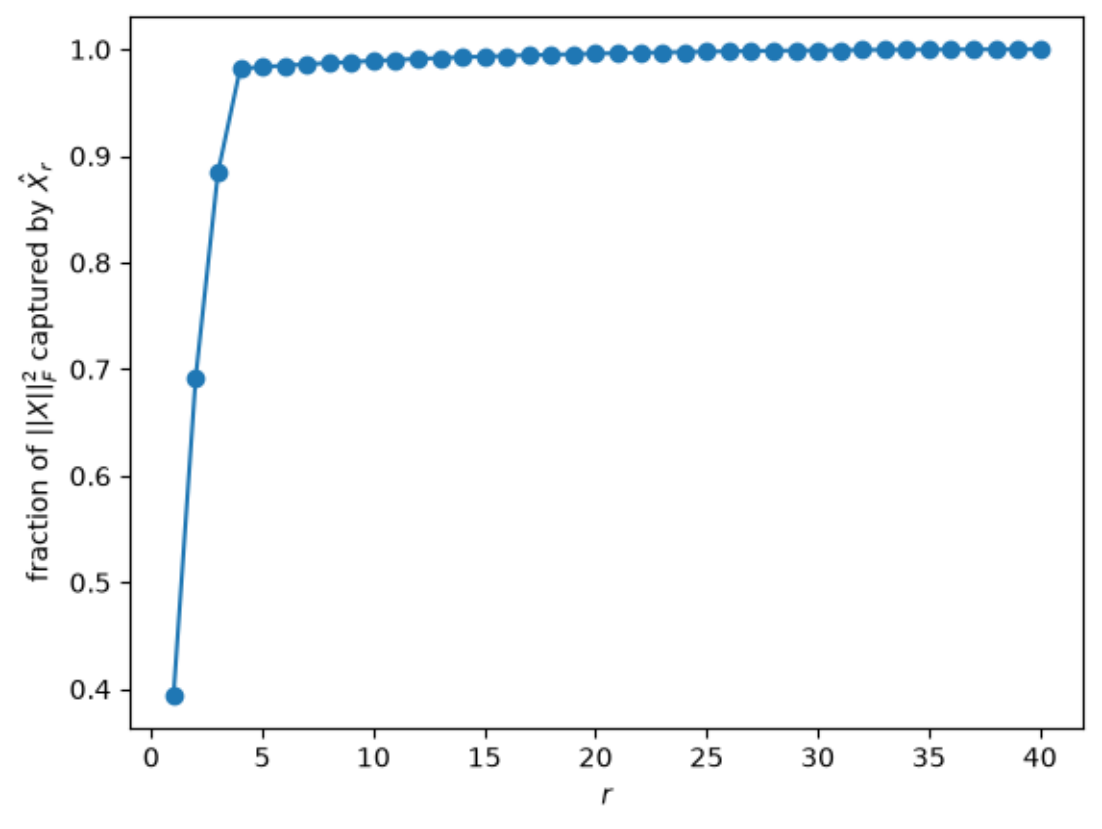
1. compute the Eckart-Young approximation $\hat{X}_r$ and verify the formulas for $||X - \hat{X}_r||$ in the spectral, Frobenius, and nuclear norms
2. compare $||X - \hat{X}_r||_F$ with $||X - QQ^\top X||_F$ for 500 matrices Q with r orthonormal columns that span randomly drawn subspaces (for each Q, $QQ^\top X$ is the best approximation of X whose columns lie in the column space of Q)

Finally, plot the fraction $\sum_{i \leq r} \sigma_i^2 / \sum_i \sigma_i^2$ against r and relate it to Step 4 of the PCA recipe above.

Solution

Here is one solution.

```
m, n = 60, 40
X = rng.normal(size=(m, 4)) @ rng.normal(size=(4, n)) + 0.3 * rng.normal(size=(m,␣
↪n))
U, σ, VT = np.linalg.svd(X, full_matrices=False)



print(" r   spectral  Frobenius  nuclear   |X - X_r|_F   best random |X - QQ'X|_F")
for r in (1, 2, 4, 8):
    X_r = U[:, :r] @ np.diag(σ[:r]) @ VT[:r, :]
    E = X - X_r
    checks = (np.isclose(LA.norm(E, 2), σ[r]),
              np.isclose(LA.norm(E, 'fro'), np.sqrt(np.sum(σ[r:]**2))),
              np.isclose(LA.norm(E, 'nuc'), np.sum(σ[r:])))
    best_random = np.inf
    for _ in range(500):
        Q = LA.qr(rng.normal(size=(m, r)))[0]
        best_random = min(best_random, LA.norm(X - Q @ Q.T @ X, 'fro'))
    print(f"{r:2d}   {str(checks[0]):8s}  {str(checks[1]):9s}  {str(checks[2]):8s}"
          f"  {LA.norm(E, 'fro'):10.2f}   {best_random:10.2f}")
```

```
r   spectral  Frobenius  nuclear   |X - X_r|_F   best random |X - QQ'X|_F
1   True      True       True           77.46        96.00
2   True      True       True           55.16        94.62
4   True      True       True           13.41        91.33
8   True      True       True           11.27        84.75
```

All three error formulas hold, and no randomly drawn rank-r approximation comes close to the Eckart-Young approximation.

```
share = np.cumsum(σ**2) / np.sum(σ**2)

fig, ax = plt.subplots()
ax.plot(np.arange(1, len(σ) + 1), share, 'o-')
ax.set_xlabel('$r$')
ax.set_ylabel('fraction of $||X||_F^2$ captured by $\\hat X_r$')
plt.show()
```

The fraction rises steeply until $r = 4$, the rank of the signal part of X, and then flattens out.

This fraction is exactly the "fraction of variance retained" that Step 4 of the PCA recipe uses to choose how many principal components to keep, and one minus it is the squared relative Frobenius error of $\hat{X}_r$.

Exercise 5.12.3

This exercise builds a bridge to the sequel *VARs and DMDs*.

Simulate a **tall and skinny** time series data set $\tilde{X}$ with $m = 100$ variables and 61 periods in which

$$\tilde{X}_t = Gz_t + 0.5v_t, \qquad z_{t+1} = \begin{bmatrix} 0.9 & 0 \\ 0 & 0.6 \end{bmatrix} z_t + w_{t+1}$$

where G is a 100×2 matrix of standard normal random numbers and v_t and w_{t+1} are standard normal random vectors.

Subtract the sample mean of each variable, then use the first 41 periods to form $X = \left[\tilde{X}_1 \mid \cdots \mid \tilde{X}_{40}\right]$ and $X' = \left[\tilde{X}_2 \mid \cdots \mid \tilde{X}_{41}\right]$.

1. Compute the least squares estimator $\hat{A} = X'X^+$ of the matrix A in the first-order VAR $\tilde{X}_{t+1} = A\tilde{X}_t + \epsilon_{t+1}$ and verify that it fits perfectly: $\hat{A}X = X'$.
2. Let $\hat{X}_2$ be the Eckart-Young rank-2 approximation of X. Verify numerically that $\hat{X}_2^+ = V_2\Sigma_2^{-1}U_2^\top$ and compute the rank-2 estimator $\hat{A}_2 = X'\hat{X}_2^+$.
3. Let $F = U_2^\top X$ be the 2×40 matrix of the first two principal components of X. Verify that $\hat{A}_2 =$

$X' F^\top (FF^\top)^{-1} U_2^\top$, i.e., that $\hat{A}_2 \tilde{X}_t$ equals the fitted value from a regression of $\tilde{X}_{t+1}$ on the first two principal components of $\tilde{X}_t$.

4. Use the remaining 20 periods to compare one-step-ahead out-of-sample forecast errors $\|X'_{\text{out}} - \check{A} X_{\text{out}}\|_F / \|X'_{\text{out}}\|_F$ for $\check{A} = \hat{A}$ and $\check{A} = \hat{A}_2$. Repeat for a few random seeds.

Solution

Here is one solution.

```
def simulate_tall(m=100, T=61, σ_v=0.5, seed=1):
    rng = np.random.default_rng(seed)
    G = rng.normal(size=(m, 2))
    a = np.array([0.9, 0.6])
    z = np.zeros((2, T))
    for t in range(T - 1):
        z[:, t+1] = a * z[:, t] + rng.normal(size=2)
    X_tilde = G @ z + σ_v * rng.normal(size=(m, T))
    return X_tilde - X_tilde.mean(axis=1, keepdims=True)

def rel_error(A, X, X_prime):
    return LA.norm(X_prime - A @ X) / LA.norm(X_prime)

X_tilde = simulate_tall()
X, X_prime = X_tilde[:, :40], X_tilde[:, 1:41]           # estimation sample

seed 4:  A_hat 0.704,  A_r 0.680
seed 5:  A_hat 0.627,  A_r 0.530
seed 6:  A_hat 0.979,  A_r 0.789
```

The minimum-norm estimator $\hat{A}$ fits the estimation sample perfectly but forecasts poorly out of sample, because the pseudo-inverse $X^+ = V\Sigma^{-1}U^\top$ puts large weights $1/\sigma_j$ on directions with small singular values that mostly contain noise.

The rank-2 estimator $\hat{A}_2$ discards those directions and forecasts better out of sample.

The estimator $\hat{A}_2 = X'\hat{X}_2^+$ is exactly the estimator that a **dynamic mode decomposition** computes; the sequel *VARs and DMDs* studies it in detail.

CHAPTER

SIX

VARS AND DMDS

6.1 Overview

This lecture applies computational methods that we learned about in the lecture *Singular Value Decomposition* to

- first-order vector autoregressions (VARs)
- dynamic mode decompositions (DMDs)
- connections between DMDs and first-order VARs

[Sargent *et al.*, 2026] study these connections in detail.

We are especially interested in **tall and skinny** data sets in which the number of variables m exceeds the number of time periods n.

Such data sets are common.

For example, [Sargent *et al.*, 2026] study quarterly Consumer Expenditure Survey data on 100 quantiles of each of three cross sections – private income, post-tax-and-transfer income, and consumption – together with aggregate income growth.

That gives them $m = 301$ variables but only $n = 133$ quarterly observations.

They use a DMD to estimate a first-order VAR of rank 3 for these 301 variables.

Along the way, we'll learn that

- a DMD computes a reduced-rank estimator of the coefficient matrix of a first-order VAR
- that estimator is a **principal components regression**: compress the cross section into a few principal components, then regress next period's data on them
- DMD **modes** are right eigenvectors of the estimated coefficient matrix
- matching **left** eigenvectors can be computed cheaply, and together with the modes they give an exact modal representation of the estimated VAR that is useful for forecasting and for computing long-run responses

We'll use the following imports.

```
import numpy as np
import matplotlib.pyplot as plt
```

6.2 First-order vector autoregressions

We want to fit a **first-order vector autoregression**

$$X_{t+1} = AX_t + C\epsilon_{t+1}, \quad \epsilon_{t+1} \perp X_t \tag{6.1}$$

where ϵ_{t+1} is the time $t+1$ component of a sequence of IID $m \times 1$ random vectors with mean vector zero and identity covariance matrix and where the $m \times 1$ vector X_t is

$$X_t = \begin{bmatrix} X_{1,t} & X_{2,t} & \cdots & X_{m,t} \end{bmatrix}^\top \tag{6.2}$$

Here $\cdot^\top$ denotes matrix transposition and $X_{i,t}$ is variable i at time t.

Equation (6.1) has no constant term.

That is because we assume that each variable has already been transformed – for example, by taking differences, by subtracting a common trend, and by subtracting its time-series mean – so that $\{X_t\}$ can be regarded as a mean-zero, covariance-stationary process.

For example, [Sargent *et al.*, 2026] subtract a cross-section mean of log private income from every log quantile, use the growth rate of that mean as an additional variable, and then subtract time-series means from all variables.

Our data are organized in an $m \times (n+1)$ matrix $\tilde{X}$

$$\tilde{X} = \begin{bmatrix} X_1 \mid X_2 \mid \cdots \mid X_n \mid X_{n+1} \end{bmatrix}$$

where for $t = 1, \ldots, n+1$, the $m \times 1$ vector X_t is given by (6.2).

From $\tilde{X}$, we form two $m \times n$ matrices

$$X = \begin{bmatrix} X_1 \mid X_2 \mid \cdots \mid X_n \end{bmatrix}$$

and

$$X' = \begin{bmatrix} X_2 \mid X_3 \mid \cdots \mid X_{n+1} \end{bmatrix}$$

Here $'$ is part of the name of the matrix X' and does not indicate matrix transposition.

In forming X and X', we have in each case dropped a column from $\tilde{X}$, the last column in the case of X, and the first column in the case of X'.

We want to estimate a system (6.1) that consists of m least squares regressions of **everything** on one lagged value of **everything**.

The ith equation of (6.1) is a regression of $X_{i,t+1}$ on the vector X_t.

So the ith row of an estimator $\hat{A}$ is a $1 \times m$ vector of regression coefficients of $X_{i,t+1}$ on $X_{j,t}, j = 1, \ldots, m$.

A least squares estimator $\hat{A}$ solves

$$\min_{\check{A}} \|X' - \check{A}X\|_F \tag{6.3}$$

where $\|\cdot\|_F$ denotes the Frobenius norm of a matrix

$$\|B\|_F = \sqrt{\sum_i \sum_j |B_{ij}|^2}.$$

We denote the rank of X by $p \leq \min(m, n)$.

The **minimum-norm** solution of (6.3) is

$$\hat{A} = X' X^+ \tag{6.4}$$

where X^+ is the Moore-Penrose pseudo-inverse of X.

Two cases interest us

- $n \gg m$, so that we have many more time series observations n than variables m
- $m \gg n$, so that we have many more variables m than time series observations n

Short-Fat Case:

When $n \gg m$ and X has linearly independent **rows**, $XX^\top$ has an inverse and the pseudo-inverse X^+ is

$$X^+ = X^\top (XX^\top)^{-1}$$

Here X^+ is a **right-inverse** that verifies $XX^+ = I_{m \times m}$.

In this case, problem (6.3) has a unique solution and formula (6.4) becomes

$$\hat{A} = X' X^\top (XX^\top)^{-1} \tag{6.5}$$

This formula for least-squares regression coefficients is widely used in econometrics to estimate vector autoregressions.

The right side of formula (6.5) is proportional to the empirical cross second moment matrix of X_{t+1} and X_t times the inverse of the second moment matrix of X_t.

Tall-Skinny Case:

When $m \gg n$ and X has linearly independent **columns**, $X^\top X$ has an inverse and the pseudo-inverse X^+ is

$$X^+ = (X^\top X)^{-1} X^\top$$

Here X^+ is a **left-inverse** that verifies $X^+ X = I_{n \times n}$.

In this case, formula (6.4) becomes

$$\hat{A} = X' (X^\top X)^{-1} X^\top \tag{6.6}$$

If we use formula (6.6) to calculate $\hat{A}X$ we find that

$$\hat{A} X = X'$$

so that the regression equation **fits perfectly**.

This is a typical outcome in an **underdetermined least-squares** model.

In fact, every matrix $\check{A} = \hat{A} + N$ with $NX = 0$ also fits perfectly, so problem (6.3) has infinitely many solutions.

Formula (6.6) selects the one with the smallest Frobenius norm.

A perfect in-sample fit is a warning sign: with more coefficients than observations, the estimator $\hat{A}$ is tracking noise as well as signal.

We'll respond by constructing a **reduced-rank** estimator that no longer fits perfectly.

6.2.1 Computing X^+ with an SVD

An efficient way to compute the pseudo-inverse X^+ is to start with a **reduced** singular value decomposition

$$X = U\Sigma V^\top \tag{6.7}$$

where U is an $m \times p$ matrix, Σ is a $p \times p$ diagonal matrix of positive singular values $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_p > 0$, and V is an $n \times p$ matrix.

As we saw in *Singular Value Decomposition*, for a reduced SVD

- $U^\top U = I_{p\times p}$ and $V^\top V = I_{p\times p}$, but
- $UU^\top \neq I_{m\times m}$ unless $p = m$, and $VV^\top \neq I_{n\times n}$ unless $p = n$.

For any rank p, the Moore-Penrose pseudo-inverse of X is

$$X^+ = V\Sigma^{-1}U^\top \tag{6.8}$$

When X has linearly independent columns, so that $p = n$ and V is a square orthogonal matrix, we can confirm that formula (6.8) agrees with our earlier formula:

$$\begin{aligned}(X^\top X)^{-1}X^\top &= (V\Sigma U^\top U\Sigma V^\top)^{-1}V\Sigma U^\top \\ &= (V\Sigma^2 V^\top)^{-1}V\Sigma U^\top \\ &= V\Sigma^{-2}V^\top V\Sigma U^\top \\ &= V\Sigma^{-1}U^\top\end{aligned}$$

where the third line uses $V^{-1} = V^\top$.

Substituting formula (6.8) into formula (6.4) gives

$$\hat{A} = X'V\Sigma^{-1}U^\top \tag{6.9}$$

Formula (6.9) shows a weakness of $\hat{A}$.

Small singular values σ_j enter through $1/\sigma_j$.

So directions in which the data X vary very little receive very large weights, which amplifies noise.

6.3 A reduced-rank VAR

A remedy is to keep only the $r < p$ largest singular values.

Let U_r be the $m \times r$ matrix consisting of the first r columns of U, let Σ_r be the $r \times r$ upper-left block of Σ, and let V_r be the $n \times r$ matrix consisting of the first r columns of V.

Our **rank-r estimator** of A is

$$\hat{A}_r = X'V_r\Sigma_r^{-1}U_r^\top \tag{6.10}$$

The $m \times m$ matrix $\hat{A}_r$ has rank at most r.

Notice that $V_r\Sigma_r^{-1}U_r^\top$ is the pseudo-inverse of $\hat{X}_r = U_r\Sigma_r V_r^\top$, the best rank-$r$ approximation of X described by the Eckart-Young theorem in *Singular Value Decomposition*.

So $\hat{A}_r = X'\hat{X}_r^+$: we obtain the rank-$r$ estimator by replacing X with its Eckart-Young approximation in the least squares formula $\hat{A} = X'X^+$.

This is the estimator that a **dynamic mode decomposition** computes.

Dynamic mode decomposition was introduced by [Schmid, 2010].

You can read about it in [Kutz *et al.*, 2016] and [Brunton and Kutz, 2019] (section 7.2).

Associated with $\hat{A}_r$ are fitted residuals and their covariance matrix

$$\hat{a}_{t+1} = X_{t+1} - \hat{A}_r X_t, \qquad \hat{\Omega} = \frac{1}{n}\sum_{t=1}^{n} \hat{a}_{t+1}\hat{a}_{t+1}^\top = \frac{1}{n}(X' - \hat{A}_r X)(X' - \hat{A}_r X)^\top \tag{6.11}$$

Thus, our estimated rank-r VAR is

$$X_{t+1} = \hat{A}_r X_t + \hat{a}_{t+1} \tag{6.12}$$

With $r < p$, the regression no longer fits perfectly and $\hat{\Omega}$ is not zero.

In applications, r is often very small, e.g., three or fewer.

A common way to choose r is to plot the singular values $\sigma_1, \sigma_2, \ldots$ and to truncate where they stop falling rapidly and level off – an "elbow rule."

[Sargent *et al.*, 2026] used this rule to choose $r = 3$.

6.3.1 Interpretation as a principal components regression

We can interpret formula (6.10) statistically.

Define the $r \times 1$ vector

$$f_t = U_r^\top X_t$$

whose components are the first r **principal components** of the cross section X_t (see the discussion of principal components analysis in *Singular Value Decomposition*).

Stacking them gives the $r \times n$ matrix $F = U_r^\top X = \Sigma_r V_r^\top$.

The least-squares regression of X_{t+1} on f_t has coefficient matrix

$$X' F^\top (F F^\top)^{-1} = X' V_r \Sigma_r (\Sigma_r^2)^{-1} = X' V_r \Sigma_r^{-1}$$

so that

$$\hat{A}_r X_t = \left(X' V_r \Sigma_r^{-1}\right) f_t.$$

Similarly, the least-squares regression of $f_{t+1} = U_r^\top X_{t+1}$ on f_t has $r \times r$ coefficient matrix

$$\tilde{A} = U_r^\top X' V_r \Sigma_r^{-1} \tag{6.13}$$

So $\tilde{A}$ is the first-order VAR coefficient matrix for the r principal components.

Note that $\tilde{A} = U_r^\top \hat{A}_r U_r$.

Thus, a DMD proceeds in two steps:

1. it compresses the cross section X_t into r principal components f_t, using only the variation in X
2. it regresses next period's data X_{t+1} on those principal components

Statisticians call this a **principal components regression**.

It resembles the "diffusion index" forecasting method of [Stock and Watson, 2002].

Note

The estimator $\hat{A}_r$ is **not** the matrix of rank r that minimizes $\|X' - \breve{A}X\|_F$.

That minimizer is the **reduced-rank regression** estimator of [Anderson, 1951].

It chooses the r directions that best *predict* X_{t+1}, while $\hat{A}_r$ uses the r directions that best *describe* X_t.

Exercise 6.10.2 compares the two estimators.

6.4 The DMD algorithm

Here is the DMD algorithm.

1. Compute the reduced SVD $X = U\Sigma V^\top$.
2. Retain the r largest singular values to form U_r, Σ_r, and V_r.
3. Form the $r \times r$ matrix $\tilde{A} = U_r^\top X' V_r \Sigma_r^{-1}$ and compute its eigendecomposition

$$\tilde{A}W = W\Lambda \tag{6.14}$$

   where Λ is a diagonal matrix of eigenvalues $\lambda_1, \ldots, \lambda_r$ and the columns of W are corresponding eigenvectors.
4. Form the $m \times r$ matrix Φ and the $r \times m$ matrix Ψ

$$\Phi = X' V_r \Sigma_r^{-1} W, \qquad \Psi = (W\Lambda)^{-1} U_r^\top \tag{6.15}$$

The eigenvalues λ_i on the diagonal of Λ are **DMD eigenvalues** and the columns ϕ_i of Φ are **DMD modes**.

We'll see below that the rows ψ_i of Ψ are matching **left** eigenvectors.

Notice that the heavy lifting consists of an SVD of the $m \times n$ matrix X and an eigendecomposition of the small $r \times r$ matrix $\tilde{A}$.

We never have to form or decompose an $m \times m$ matrix.

Throughout, we assume that $\tilde{A}$ has r linearly independent eigenvectors and nonzero eigenvalues, which is the generic case.

The matrix $\tilde{A}$ is real but not symmetric, so some eigenvalues can come in complex-conjugate pairs.

In that case, the corresponding columns of Φ and rows of Ψ also come in complex-conjugate pairs, while products such as $\Phi\Lambda^j\Psi$ are real.

For complex matrices, we use $\cdot^*$ to denote the conjugate transpose.

Note

[Tu *et al.*, 2014] scale the modes differently, defining them as the columns of $\Phi\Lambda^{-1}$.

With that scaling, the matching left eigenvectors are the rows of $\Lambda\Psi = W^{-1}U_r^\top$.

Rescaling a mode and its left eigenvector in opposite directions changes none of the formulas below.

6.5 Right eigenvectors: DMD modes

The following result of [Tu *et al.*, 2014] explains why the columns of Φ are called modes.

Proposition 6.5.1

The columns of Φ are eigenvectors of $\hat{A}_r$:

$$\hat{A}_r \Phi = \Phi \Lambda$$

Proof. Using formulas (6.10), (6.13), and (6.15),

$$\begin{aligned} \hat{A}_r \Phi &= (X' V_r \Sigma_r^{-1} U_r^\top)(X' V_r \Sigma_r^{-1} W) \\ &= X' V_r \Sigma_r^{-1} \tilde{A} W \\ &= X' V_r \Sigma_r^{-1} W \Lambda \\ &= \Phi \Lambda \end{aligned}$$

Equating columns gives $\hat{A}_r \phi_i = \lambda_i \phi_i$ for $i = 1, \ldots, r$.

We can say more.

Write $\hat{A}_r = B U_r^\top$, where $B = X' V_r \Sigma_r^{-1}$ is $m \times r$.

Because the nonzero eigenvalues of $B U_r^\top$ coincide with those of $U_r^\top B = \tilde{A}$, the eigenvalues of $\hat{A}_r$ are $\lambda_1, \ldots, \lambda_r$ together with $m - r$ zeros.

So the estimated VAR (6.12) is stable if and only if $\max_i |\lambda_i| < 1$, a condition we can check with an $r \times r$ matrix.

(Also see [Brunton and Kutz, 2022], p. 238.)

6.5.1 Projected modes

[Schmid, 2010] originally worked with the **projected modes** $U_r W$ instead of Φ.

Because $U_r^\top \Phi = \tilde{A} W = W \Lambda$, we have

$$U_r U_r^\top \Phi = U_r W \Lambda$$

so, up to scale, the projected modes are orthogonal projections of the modes Φ onto the column space of U_r.

The projected modes are eigenvectors of $\hat{A}_r$ only when $\Phi = U_r W \Lambda$, that is, when the columns of Φ lie in the column space of U_r.

That need not be true, because $\hat{A}_r U_r W = \Phi$.

The construction $\Phi = \hat{A}_r U_r W$ of [Tu *et al.*, 2014] delivers eigenvectors of $\hat{A}_r$ in all cases.

6.6 Left eigenvectors and a modal representation

Now we come to the rows of Ψ.

Proposition 6.6.1

Let $\Psi = (W\Lambda)^{-1}U_r^\top$. Then

1. $\Psi\Phi = I_{r\times r}$
2. $\Psi\hat{A}_r = \Lambda\Psi$, so that the rows of Ψ are left eigenvectors of $\hat{A}_r$
3. $\hat{A}_r = \Phi\Lambda\Psi = \sum_{i=1}^r \lambda_i\phi_i\psi_i$

Proof. For the first claim,

$$\Psi\Phi = \Lambda^{-1}W^{-1}U_r^\top X'V_r\Sigma_r^{-1}W = \Lambda^{-1}W^{-1}\tilde{A}W = \Lambda^{-1}\Lambda = I.$$

For the second claim, since $U_r^\top\hat{A}_r = U_r^\top X'V_r\Sigma_r^{-1}U_r^\top = \tilde{A}U_r^\top$,

$$\Psi\hat{A}_r = \Lambda^{-1}W^{-1}\tilde{A}U_r^\top = \Lambda^{-1}\Lambda W^{-1}U_r^\top = W^{-1}U_r^\top = \Lambda\Psi.$$

For the third claim,

$$\Phi\Lambda\Psi = X'V_r\Sigma_r^{-1}W\Lambda\Lambda^{-1}W^{-1}U_r^\top = X'V_r\Sigma_r^{-1}U_r^\top = \hat{A}_r.$$

Define the $r\times 1$ vector of **modal coordinates**

$$b_t = \Psi X_t = (W\Lambda)^{-1}U_r^\top X_t \tag{6.16}$$

Computing b_t requires only the principal components $f_t = U_r^\top X_t$ and an $r\times r$ matrix.

Because $\Psi\Phi = I$, iterating $\hat{A}_r = \Phi\Lambda\Psi$ gives

$$\hat{A}_r^j = \Phi\Lambda^j\Psi, \quad j\geq 1 \tag{6.17}$$

Consequently, the estimated VAR (6.12) implies

$$b_{t+1} = \Lambda b_t + \Psi\hat{a}_{t+1}$$

and the j-step-ahead forecast of X_{t+j} conditional on X_t is

$$\hat{A}_r^j X_t = \Phi\Lambda^j b_t = \sum_{i=1}^r \phi_i\lambda_i^j b_{i,t} \tag{6.18}$$

Each mode ϕ_i contributes a component whose amplitude decays geometrically at rate λ_i.

The matrix $\Phi\Psi$ is an oblique projection onto the column space of Φ.

It splits X_t into Φb_t plus a remainder $(I-\Phi\Psi)X_t$ that $\hat{A}_r$ sends to zero, because $\hat{A}_r(I-\Phi\Psi) = \Phi\Lambda\Psi - \Phi\Lambda\Psi\Phi\Psi = 0$.

6.6.1 A tempting alternative that does not work

The Moore-Penrose pseudo-inverse $\Phi^+ = (\Phi^*\Phi)^{-1}\Phi^*$ also satisfies $\Phi^+\Phi = I$.

The vector $\check{b}_t = \Phi^+ X_t$ is a vector of least squares regression coefficients of X_t on the columns of Φ, and $\Phi\check{b}_t$ is the orthogonal projection of X_t onto the column space of Φ.

That makes $\check{b}_t$ a natural **descriptive** summary of how much each mode is present in X_t.

But in general

$$\Phi\Lambda\Phi^+ \neq \hat{A}_r$$

so $\check{b}_t$ does **not** evolve according to $\check{b}_{t+1} = \Lambda\check{b}_t$ under the estimated VAR, and $\Phi\Lambda^j\Phi^+ X_t$ is not the VAR forecast $\hat{A}_r^j X_t$.

The reason is that Φ^+ and Ψ are both left inverses of Φ, but their rows span different spaces:

- the rows of Φ^+ span the same space as the rows of Φ^*
- the rows of Ψ span the same space as the rows of $U_r^\top$

The two left inverses coincide if and only if the column spaces of Φ and U_r are the same.

The column space of Φ is the column space of $X'V_r$, which describes where the data go **next** period.

The column space of U_r is spanned by the r directions in which the **current** data X vary most.

These two spaces coincide in special cases, for example when noise-free data are driven by exactly r factors (see Exercise 6.10.1), but not in general.

Note

The formula $(W\Lambda)^{-1}U_r^\top X_1$ appears in [Brunton and Kutz, 2022] (p. 240), where it is presented as a computationally cheap approximation to $\Phi^+ X_1$.

Proposition 6.6.1 shows that it is exactly the vector of coordinates that is consistent with the dynamics of the estimated VAR.

6.6.2 A state-space representation

The modal representation lets us write the estimated VAR as a linear state-space system with an $r \times 1$ state vector.

Define

$$\hat{x}_t = \Lambda\Psi X_{t-1} = W^{-1}U_r^\top X_{t-1} = W^{-1}f_{t-1}$$

Then $X_t = \hat{A}_r X_{t-1} + \hat{a}_t = \Phi\Lambda\Psi X_{t-1} + \hat{a}_t$ and $\hat{x}_{t+1} = \Lambda\Psi X_t$ imply

$$\begin{aligned} \hat{x}_{t+1} &= \Lambda\hat{x}_t + \Lambda\Psi\hat{a}_t \\ X_t &= \Phi\hat{x}_t + \hat{a}_t \end{aligned} \tag{6.19}$$

where we have used $\Psi\Phi = I$.

In representation (6.19)

- the state $\hat{x}_t$ is the vector of lagged principal components expressed in the eigenvector basis of the principal-component VAR $\tilde{A}$
- the transition matrix Λ is diagonal, so the r components of the state evolve independently, apart from correlated shocks

- the columns of Φ are **loadings** of the m observed variables on the r components of the state
- a single $m \times 1$ vector of residuals $\hat{a}_t$ drives both equations; by the least squares normal equations, it is orthogonal in sample to f_{t-1} and therefore to $\hat{x}_t$

[Sargent *et al.*, 2026] connect DMDs to linear state-space models of this form.

6.7 Long-run responses

Modal representation (6.17) also simplifies calculations of long-run responses.

If $|\lambda_i| < 1$ for all i, then

$$\sum_{j=1}^{\infty} \hat{A}_r^j = \Phi\Lambda(I - \Lambda)^{-1}\Psi$$

and

$$(I - \hat{A}_r)^{-1} = I + \Phi\Lambda(I - \Lambda)^{-1}\Psi \tag{6.20}$$

The matrix $\Lambda(I - \Lambda)^{-1}$ is diagonal with entries $\lambda_i/(1 - \lambda_i)$.

So long-run responses are dominated by the most persistent modes.

For example, the rank-3 VAR of [Sargent *et al.*, 2026] has DMD eigenvalues 0.963, 0.865, and 0.547, with long-run weights of roughly 26, 6.4, and 1.2.

Formulas like (6.20) appear in **additive functionals**, which are studied in Additive and Multiplicative Functionals.

Suppose that the first component of X_t is the growth rate of the logarithm Y_t of some aggregate, measured as a deviation from its mean ν, so that $Y_{t+1} - Y_t - \nu = e_1 X_{t+1}$ where $e_1 = \begin{bmatrix} 1 & 0 & \cdots & 0 \end{bmatrix}$.

If X_t obeys the VAR (6.12), then Y_t can be decomposed into a deterministic trend $t\nu$, a martingale $\sum_{j=1}^{t} H\hat{a}_j$, and a stationary component $-gX_t$, plus a constant, where

$$g = e_1\hat{A}_r(I - \hat{A}_r)^{-1}, \qquad H = e_1(I - \hat{A}_r)^{-1} = e_1 + g$$

[Sargent *et al.*, 2026] use this decomposition for aggregate income and for all 300 CEX quantiles.

Formula (6.20) implies

$$g = e_1\Phi\Lambda(I - \Lambda)^{-1}\Psi$$

so computing g and H requires no inversion of an $m \times m$ matrix.

6.8 A simulated example

To see these objects at work, we simulate a tall-skinny data set that shares some features with the CEX data of [Sargent *et al.*, 2026].

There are $m = 300$ cross-section variables, which we can think of as quantiles indexed by $q \in [0, 1]$, and $n + 1 = 134$ quarterly observations.

The cross section is driven by three latent factors z_t that obey a first-order VAR with a diagonal transition matrix

$$z_{t+1} = Dz_t + w_{t+1}, \qquad D = \text{diag}(0.95, 0.80, 0.50)$$

and the observed data are

$$X_t = G z_t + \sigma_v v_t$$

where w_{t+1} and v_t are standard normal random vectors.

The three columns of G are shaped like a **level** factor that moves all quantiles together, a **slope** factor that moves low and high quantiles in opposite directions, and a **curvature** factor that moves the tails relative to the middle.

Here is code that simulates the data.

```
def simulate_data(m=300, T=134, D_diag=(0.95, 0.80, 0.50), σ_v=0.5, seed=1234):
    """
    Simulate an m x T data matrix driven by three latent AR(1) factors.
    """
    rng = np.random.default_rng(seed)
    q = np.linspace(0, 1, m)
    G = np.column_stack([np.ones(m),                # level
                         2 * (q - 0.5),             # slope
                         6 * (q - 0.5)**2 - 0.5])   # curvature
    d = np.array(D_diag)
    k = len(d)
    z = np.zeros((k, T))
    z[:, 0] = rng.normal(size=k) / np.sqrt(1 - d**2)
    for t in range(T - 1):
        z[:, t+1] = d * z[:, t] + rng.normal(size=k)
    X_tilde = G @ z + σ_v * rng.normal(size=(m, T))
    return X_tilde, G, z, q

X_tilde, G, z, q = simulate_data()
X_tilde = X_tilde - X_tilde.mean(axis=1, keepdims=True)    # demean each variable
X_tilde.shape
```

```
(300, 134)
```

The next function implements the DMD algorithm.

```
def dmd(X_tilde, r):
    """
    Rank-r DMD of the m x (n+1) data matrix X_tilde.
    """
    X, X_prime = X_tilde[:, :-1], X_tilde[:, 1:]
    U, σ, Vt = np.linalg.svd(X, full_matrices=False)
    U_r, σ_r, V_r = U[:, :r], σ[:r], Vt[:r, :].T

    B = X_prime @ V_r / σ_r          # X' V_r Σ_r^{-1}
    A_tilde = U_r.T @ B              # r x r VAR for principal components
    λ, W = np.linalg.eig(A_tilde)
    order = np.argsort(-np.abs(λ))   # most persistent modes first
    λ, W = λ[order], W[:, order]

    Φ = B @ W                                # DMD modes (right eigenvectors)
    Ψ = np.linalg.solve(W * λ, U_r.T)        # (W Λ)^{-1} U_r^T (left eigenvectors)
    A_hat = B @ U_r.T                        # rank-r estimator of A
    a_hat = X_prime - A_hat @ X              # residuals
    Ω_hat = a_hat @ a_hat.T / X.shape[1]

    return dict(λ=λ, Φ=Φ, Ψ=Ψ, W=W, A_tilde=A_tilde, A_hat=A_hat,
                Ω_hat=Ω_hat, σ=σ, U_r=U_r)
```

To choose r, we plot the largest singular values of X.

```
σ = np.linalg.svd(X_tilde[:, :-1], compute_uv=False)

fig, ax = plt.subplots()
ax.plot(np.arange(1, 21), σ[:20], 'o')
ax.set_xlabel('index $j$')
ax.set_ylabel(r'singular value $\sigma_j$')
plt.show()
```

The singular values fall rapidly for $j = 1, 2, 3$ and then level off, so the elbow rule tells us to set $r = 3$.

```
r = 3
res = dmd(X_tilde, r)
λ, Φ, Ψ, A_hat = res['λ'], res['Φ'], res['Ψ'], res['A_hat']

print("DMD eigenvalues:  ", np.round(λ, 3))
print("true eigenvalues: ", np.array([0.95, 0.80, 0.50]))
```

```
DMD eigenvalues:   [0.93  0.82  0.337]
true eigenvalues:  [0.95 0.8  0.5 ]
```

The two most persistent eigenvalues are estimated well.

The least persistent one is biased toward zero.

That is because the data are noisy measurements of the factors, so $\{X_t\}$ is not exactly a first-order VAR; errors in the principal components f_t attenuate the estimated coefficients, most visibly for the least persistent mode.

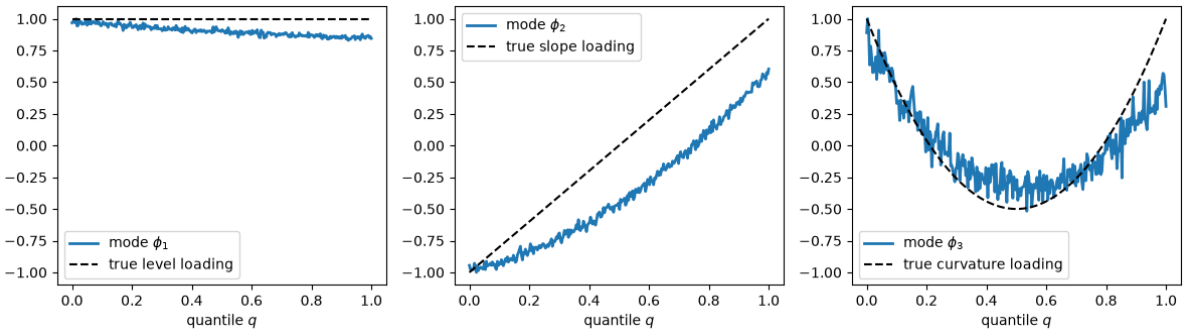
Next we verify *Proposition 6.5.1* and *Proposition 6.6.1*, and check whether $\Phi\Lambda\Phi^+$ equals $\hat{A}_r$.

```
Φ_pinv = np.linalg.pinv(Φ)
rel = lambda M: np.linalg.norm(M) / np.linalg.norm(A_hat)

print("max |A_hat Φ - Φ Λ|         =", np.abs(A_hat @ Φ - Φ * λ).max())
print("max |Ψ Φ - I|               =", np.abs(Ψ @ Φ - np.eye(r)).max())
print("max |Ψ A_hat - Λ Ψ|         =", np.abs(Ψ @ A_hat - λ[:, None] * Ψ).max())
print("relative error, Φ Λ Ψ       =", rel(A_hat - (Φ * λ) @ Ψ))
print("relative error, Φ Λ Φ^+     =", rel(A_hat - (Φ * λ) @ Φ_pinv))
```

```
max |A_hat Φ - Φ Λ|         = 1.1796119636642288e-16
max |Ψ Φ - I|               = 1.7763568394002505e-15
max |Ψ A_hat - Λ Ψ|         = 2.7755575615628914e-16
relative error, Φ Λ Ψ       = 1.9407620402191376e-16
relative error, Φ Λ Φ^+     = 0.07337622086364687
```

The first four numbers are zero up to rounding error, while $\Phi\Lambda\Phi^+$ misses $\hat{A}_r$ by several percent.



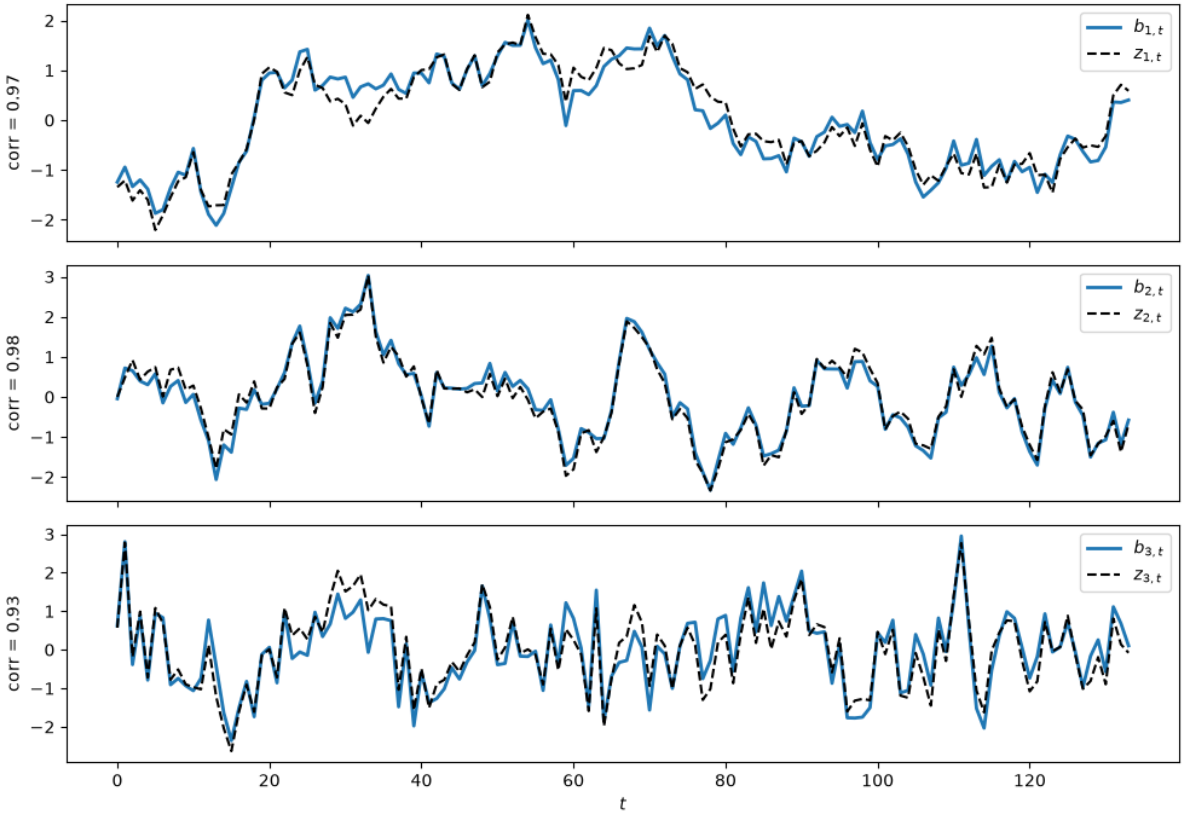
Now let's look at the modes.

Modes are determined only up to scale, so we normalize each mode to have maximum absolute value one and choose its sign to line up with the corresponding column of G, which we normalize in the same way.

```
def normalize(v):
    return v / np.abs(v).max()

labels = ['level', 'slope', 'curvature']
Φ_real = np.real_if_close(Φ)

fig, axes = plt.subplots(1, 3, figsize=(12, 3.5))
for i, ax in enumerate(axes):
    g_i = normalize(G[:, i])
    ψ_i = normalize(Φ_real[:, i])
    ψ_i *= np.sign(ψ_i @ g_i)
    ax.plot(q, ψ_i, lw=2, label=rf'mode $\phi_{i+1}$')
    ax.plot(q, g_i, 'k--', label=f'true {labels[i]} loading')
    ax.set_ylim(-1.1, 1.1)
    ax.set_xlabel('quantile $q$')
    ax.legend()
plt.tight_layout()
plt.show()
```



Each mode is close to one of the true loading patterns, but not identical to it.

Because of sampling error, the estimated eigenvectors mix the true factors a little, most visibly for the second mode.

Next we compare the modal coordinates $b_t = \Psi X_t$ with the true factors z_t, after standardizing both.

```
b = np.real_if_close(Ψ @ X_tilde)
standardize = lambda x: (x - x.mean()) / x.std()

fig, axes = plt.subplots(3, 1, figsize=(10, 7), sharex=True)
for i, ax in enumerate(axes):
    corr = np.corrcoef(b[i], z[i])[0, 1]
    ax.plot(np.sign(corr) * standardize(b[i]), lw=2, label=rf'$b_{{{i+1},t}}$')
    ax.plot(standardize(z[i]), 'k--', label=rf'$z_{{{i+1},t}}$')
    ax.set_ylabel(f'corr = {abs(corr):.2f}')
    ax.legend(loc='upper right')
axes[-1].set_xlabel('$t$')
plt.tight_layout()
plt.show()
```

The DMD recovers the latent factors well.

Finally, we compare j-step-ahead forecasts computed in three ways:

- directly from $\hat{A}_r^j X_t$
- from the modal representation (6.18) with $b_t = \Psi X_t$
- from the tempting alternative $\Phi \Lambda^j \Phi^+ X_t$

```
X = X_tilde[:, :-1]
for j in (1, 4, 12):
    direct = np.linalg.matrix_power(A_hat, j) @ X
    via_Ψ = np.real_if_close((Φ * λ**j) @ Ψ @ X)
    via_pinv = np.real_if_close((Φ * λ**j) @ Φ_pinv @ X)
```

(continues on next page)

(continued from previous page)

```
    err = lambda F: np.linalg.norm(F - direct) / np.linalg.norm(direct)
    print(f"j = {j:2d}:  error with Ψ = {err(via_Ψ):.1e},  "
          f"error with Φ^+ = {err(via_pinv):.3f}")
```

```
j =  1:  error with Ψ = 1.7e-16,  error with Φ^+ = 0.004
j =  4:  error with Ψ = 2.8e-15,  error with Φ^+ = 0.001
j = 12:  error with Ψ = 1.0e-14,  error with Φ^+ = 0.001
```

Forecasts built from Ψ reproduce the VAR forecasts exactly, while those built from Φ^+ do not.

In this example the forecast discrepancy from using Φ^+ is small, but, as Exercise 6.10.1 shows, it grows with the amount of noise in the data.

6.9 Source for some Python code

You can find a Python implementation of DMD in the PyDMD package.

6.10 Exercises

Exercise 6.10.1

In this lecture we saw that $\Phi^+ = \Psi$ if and only if the column spaces of Φ and U_r are the same.

1. Simulate data with `simulate_data(σ_v=0.0)`, so that the data are exact linear combinations of three factors, and compute a rank-3 DMD. Verify numerically that $\Phi^+ = \Psi$ and that $\Phi \Lambda \Phi^+ = \hat{A}_r$.
2. Explain why the column spaces of Φ and U_r coincide in this case.
3. Repeat part 1 with $\sigma_v = 0.1, 0.5, 1.0$ and report how far $\Phi \Lambda \Phi^+$ is from $\hat{A}_r$.

Solution

Here is one solution.

```
for σ_v in (0.0, 0.1, 0.5, 1.0):
    X_sim = simulate_data(σ_v=σ_v)[0]
    X_sim = X_sim - X_sim.mean(axis=1, keepdims=True)
    out = dmd(X_sim, 3)
    Φ_s, Ψ_s, λ_s, A_s = out['Φ'], out['Ψ'], out['λ'], out['A_hat']
    Φ_s_pinv = np.linalg.pinv(Φ_s)
    gap_left = np.linalg.norm(Φ_s_pinv - Ψ_s) / np.linalg.norm(Ψ_s)
    gap_A = np.linalg.norm(A_s - (Φ_s * λ_s) @ Φ_s_pinv) / np.linalg.norm(A_s)
    print(f"σ_v = {σ_v:.1f}:  |Φ^+ - Ψ|/|Ψ| = {gap_left:.1e},  "
          f"|A_hat - Φ Λ Φ^+|/|A_hat| = {gap_A:.1e}")
```

```
σ_v = 0.0:  |Φ^+ - Ψ|/|Ψ| = 9.0e-16,  |A_hat - Φ Λ Φ^+|/|A_hat| = 1.1e-15
σ_v = 0.1:  |Φ^+ - Ψ|/|Ψ| = 4.2e-02,  |A_hat - Φ Λ Φ^+|/|A_hat| = 1.5e-02
σ_v = 0.5:  |Φ^+ - Ψ|/|Ψ| = 2.1e-01,  |A_hat - Φ Λ Φ^+|/|A_hat| = 7.3e-02
σ_v = 1.0:  |Φ^+ - Ψ|/|Ψ| = 4.0e-01,  |A_hat - Φ Λ Φ^+|/|A_hat| = 1.4e-01
```

When $\sigma_v = 0$, $X_t = Gz_t$ for every t, so every column of both X and X' lies in the three-dimensional column space of G.

Because X has rank three, the column space of U_3 equals the column space of G.

The columns of $\Phi = X'V_3\Sigma_3^{-1}W$ are linear combinations of columns of X', so they also lie in the column space of G.

Since Φ has three linearly independent columns, its column space is the column space of G, which is the column space of U_3.

Then the rows of Ψ lie in the space spanned by the rows of Φ^*.

So the rows of $\Psi - \Phi^+$ can be written as $C\Phi^*$ for some matrix C.

Because $(\Psi - \Phi^+)\Phi = I - I = 0$, we get $C\Phi^*\Phi = 0$, and since $\Phi^*\Phi$ is invertible, $C = 0$.

With measurement noise, X' has components outside the column space of U_3, the two left inverses differ, and the gap between $\Phi\Lambda\Phi^+$ and $\hat{A}_r$ grows with σ_v.

Exercise 6.10.2

This exercise compares the DMD estimator $\hat{A}_r$ with the reduced-rank regression estimator of [Anderson, 1951].

The reduced-rank regression estimator is the rank-r matrix that minimizes $\|X' - \check{A}X\|_F$.

It can be computed as $\hat{A}_r^{RRR} = P_r\hat{A}$, where $\hat{A} = X'X^+$ is the minimum-norm least squares estimator and $P_r = Q_rQ_r^\top$, where the columns of Q_r are the first r left singular vectors of the fitted values $\hat{A}X$.

Using data from `simulate_data()`, estimate both rank-3 estimators on the first 100 periods, then

1. compute the relative in-sample residual norm $\|X' - \check{A}X\|_F / \|X'\|_F$ for each estimator
2. compute the same statistic out of sample, using one-step-ahead forecasts for the remaining periods
3. repeat for several random seeds and comment on the results

Solution

Here is one solution.

```
def rrr(X, X_prime, r):
    "Reduced-rank regression estimator of rank r."
    A_full = X_prime @ np.linalg.pinv(X)
    Q = np.linalg.svd(A_full @ X, full_matrices=False)[0][:, :r]
    return Q @ Q.T @ A_full

def rel_resid(A, X, X_prime):
    return np.linalg.norm(X_prime - A @ X) / np.linalg.norm(X_prime)

n_est = 100
print("seed   DMD in   DMD out   RRR in   RRR out")
for seed in range(5):
    X_sim = simulate_data(seed=seed)[0]
    X_sim = X_sim - X_sim.mean(axis=1, keepdims=True)
    X_in, Xp_in = X_sim[:, :n_est-1], X_sim[:, 1:n_est]
    X_out, Xp_out = X_sim[:, n_est-1:-1], X_sim[:, n_est:]
```

```
A_dmd = dmd(X_sim[:, :n_est], 3)['A_hat']
A_rrr = rrr(X_in, Xp_in, 3)
print(f"{seed:4d}   {rel_resid(A_dmd, X_in, Xp_in):.3f}     "
      f"{rel_resid(A_dmd, X_out, Xp_out):.3f}      "
      f"{rel_resid(A_rrr, X_in, Xp_in):.3f}     "
      f"{rel_resid(A_rrr, X_out, Xp_out):.3f}")
```

```
seed   DMD in   DMD out   RRR in   RRR out
   0   0.515    0.616     0.185    0.709
   1   0.570    0.578     0.228    0.638
   2   0.463    0.788     0.165    0.901
   3   0.429    0.786     0.155    0.946
   4   0.405    0.384     0.155    0.430
```

By construction, reduced-rank regression has the smaller in-sample residuals.

But in these samples it forecasts worse out of sample than the DMD estimator.

Reduced-rank regression starts from $\hat{A} = X'V\Sigma^{-1}U^\top$, which uses **all** singular values of X, including tiny ones that amplify noise, and then chooses the three directions that best fit X' in sample.

The DMD estimator instead discards the small singular values before it regresses, which acts as a form of regularization.

Exercise 6.10.3

Using the rank-3 DMD of the simulated data from the lecture,

1. prove formula (6.17) and use it to derive formula (6.20)
2. verify formula (6.20) numerically by comparing it with a direct computation of $(I - \hat{A}_r)^{-1}$
3. treating the first component of X_t as the growth-rate variable, compute $g = e_1 \hat{A}_r (I - \hat{A}_r)^{-1}$ both directly and with the modal formula $g = e_1 \Phi \Lambda (I - \Lambda)^{-1} \Psi$, and report the contribution of each mode to g
4. compute the modal formula again with Φ^+ in place of Ψ and report how much the answer changes

Solution

For part 1, *Proposition 6.6.1* gives $\hat{A}_r = \Phi \Lambda \Psi$ and $\Psi \Phi = I$.

So $\hat{A}_r^2 = \Phi \Lambda (\Psi \Phi) \Lambda \Psi = \Phi \Lambda^2 \Psi$, and induction gives $\hat{A}_r^j = \Phi \Lambda^j \Psi$ for $j \geq 1$.

When $|\lambda_i| < 1$ for all i,

$$\sum_{j=1}^{\infty} \hat{A}_r^j = \Phi \left(\sum_{j=1}^{\infty} \Lambda^j \right) \Psi = \Phi \Lambda (I - \Lambda)^{-1} \Psi$$

and since all eigenvalues of $\hat{A}_r$ are inside the unit circle, $(I - \hat{A}_r)^{-1} = I + \sum_{j=1}^{\infty} \hat{A}_r^j$.

Here is code for parts 2–4.

```
m = A_hat.shape[0]
I = np.eye(m)
weights = λ / (1 - λ)

LR_direct = np.linalg.inv(I - A_hat)
```

```
LR_modal = np.real_if_close(I + (Φ * weights) @ Ψ)
print("max |direct - modal| for (I - A_hat)^{-1}:",
      np.abs(LR_direct - LR_modal).max())

e1 = np.zeros(m)
e1[0] = 1.0
g_direct = e1 @ A_hat @ LR_direct
g_modal = np.real_if_close(e1 @ (Φ * weights) @ Ψ)
print("max |g_direct - g_modal|:", np.abs(g_direct - g_modal).max())

print("\nlong-run weights λ/(1-λ):", np.round(weights.real, 2))
for i in range(r):
    g_i = np.real_if_close(Φ[0, i] * weights[i] * Ψ[i, :])
    share = np.linalg.norm(g_i) / np.linalg.norm(g_direct)
    print(f"mode {i+1}: |contribution to g| / |g| = {share:.2f}")

g_pinv = np.real_if_close(e1 @ (Φ * weights) @ Φ_pinv)
print("\nrelative error in g using Φ^+:",
      np.linalg.norm(g_pinv - g_direct) / np.linalg.norm(g_direct))
```

```
max |direct - modal| for (I - A_hat)^{-1}: 1.457167719820518e-15
max |g_direct - g_modal|: 1.3183898417423734e-15

long-run weights λ/(1-λ): [13.37  4.57  0.51]
mode 1: |contribution to g| / |g| = 1.29
mode 2: |contribution to g| / |g| = 0.66
mode 3: |contribution to g| / |g| = 0.10

relative error in g using Φ^+: 0.026761234549937188
```

The modal formula reproduces the direct computation up to rounding error, and requires only $r \times r$ operations beyond forming Φ and Ψ.

The most persistent mode, with the largest weight $\lambda_i/(1-\lambda_i)$, contributes the most to g.

The ratios need not sum to one, and one can exceed one, because contributions of different modes partially offset each other.

Replacing Ψ by Φ^+ gives a different, incorrect answer.

CHAPTER

SEVEN

USING NEWTON'S METHOD TO SOLVE ECONOMIC MODELS

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

Contents

- *Using Newton's Method to Solve Economic Models*
  - *Overview*
  - *Fixed point computation using Newton's method*
  - *Root-Finding in one dimension*
  - *Multivariate Newton's method*
  - *Exercises*

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install jax
```

7.1 Overview

Many economic problems involve finding fixed points or zeros (also called "roots") of functions.

For example, in a simple supply and demand model, an equilibrium price is one that makes excess demand zero.

In other words, an equilibrium is a zero of the excess demand function.

There are various computational techniques for solving for fixed points and zeros.

In this lecture we study an important gradient-based technique called Newton's method.

Newton's method does not always work but, in situations where it does, convergence is often fast when compared to other methods.

The lecture will apply Newton's method in one-dimensional and multidimensional settings to solve fixed-point and zero-finding problems.

- When finding the fixed point of a function f, Newton's method updates an existing guess of the fixed point by solving for the fixed point of a linear approximation to the function f.
- When finding the zero of a function f, Newton's method updates an existing guess by solving for the zero of a linear approximation to the function f.

To build intuition, we first consider an easy, one-dimensional fixed point problem where we know the solution and solve it using both successive approximation and Newton's method.

Then we apply Newton's method to multidimensional settings to solve for market equilibria with multiple goods.

At the end of the lecture, we leverage the power of automatic differentiation in `jax` to solve a very high-dimensional equilibrium problem.

We use the following imports in this lecture

```
import matplotlib.pyplot as plt
from typing import NamedTuple
from scipy.optimize import root
import jax.numpy as jnp
import jax

# Enable 64-bit precision
jax.config.update("jax_enable_x64", True)
```

7.2 Fixed point computation using Newton's method

In this section we solve the fixed point of the law of motion for capital in the setting of the Solow growth model.

We will inspect the fixed point visually, solve it by successive approximation, and then apply Newton's method to achieve faster convergence.

7.2.1 The Solow model

In the Solow growth model, assuming Cobb-Douglas production technology and zero population growth, the law of motion for capital is

$$k_{t+1} = g(k_t) \quad \text{where} \quad g(k) := sAk^\alpha + (1-\delta)k \tag{7.1}$$

Here

- k_t is capital stock per worker,
- $A, \alpha > 0$ are production parameters with $\alpha < 1$
- $s > 0$ is a savings rate, and
- $\delta \in (0, 1)$ is a rate of depreciation

In this example, we wish to calculate the unique strictly positive fixed point of g, the law of motion for capital.

In other words, we seek a $k^* > 0$ such that $g(k^*) = k^*$.

- Such a k^* is called a steady state, since $k_t = k^*$ implies $k_{t+1} = k^*$.

Using pencil and paper to solve $g(k) = k$, you will be able to confirm that

$$k^* = \left(\frac{sA}{\delta}\right)^{1/(1-\alpha)}$$

7.2.2 Implementation

Let's store our parameters in `NamedTuple` to help us keep our code clean and concise.

```
class SolowParameters(NamedTuple):
    A: float
    s: float
    α: float
    δ: float
```

This function creates a suitable `SolowParameters` with default parameter values.

```
def create_solow_params(A=2.0, s=0.3, α=0.3, δ=0.4):
    """Creates a Solow model parameterization with default values."""
    return SolowParameters(A=A, s=s, α=α, δ=δ)
```

The next two functions implement the law of motion *(7.2.1)* and store the true fixed point k^*.

```
def g(k, params):
    A, s, α, δ = params
    return A * s * k**α + (1 - δ) * k

def exact_fixed_point(params):
    A, s, α, δ = params
    return ((s * A) / δ) ** (1 / (1 - α))
```

Here is a function to provide a 45 degree plot of the dynamics.

```
def plot_45(params, ax, fontsize=14):

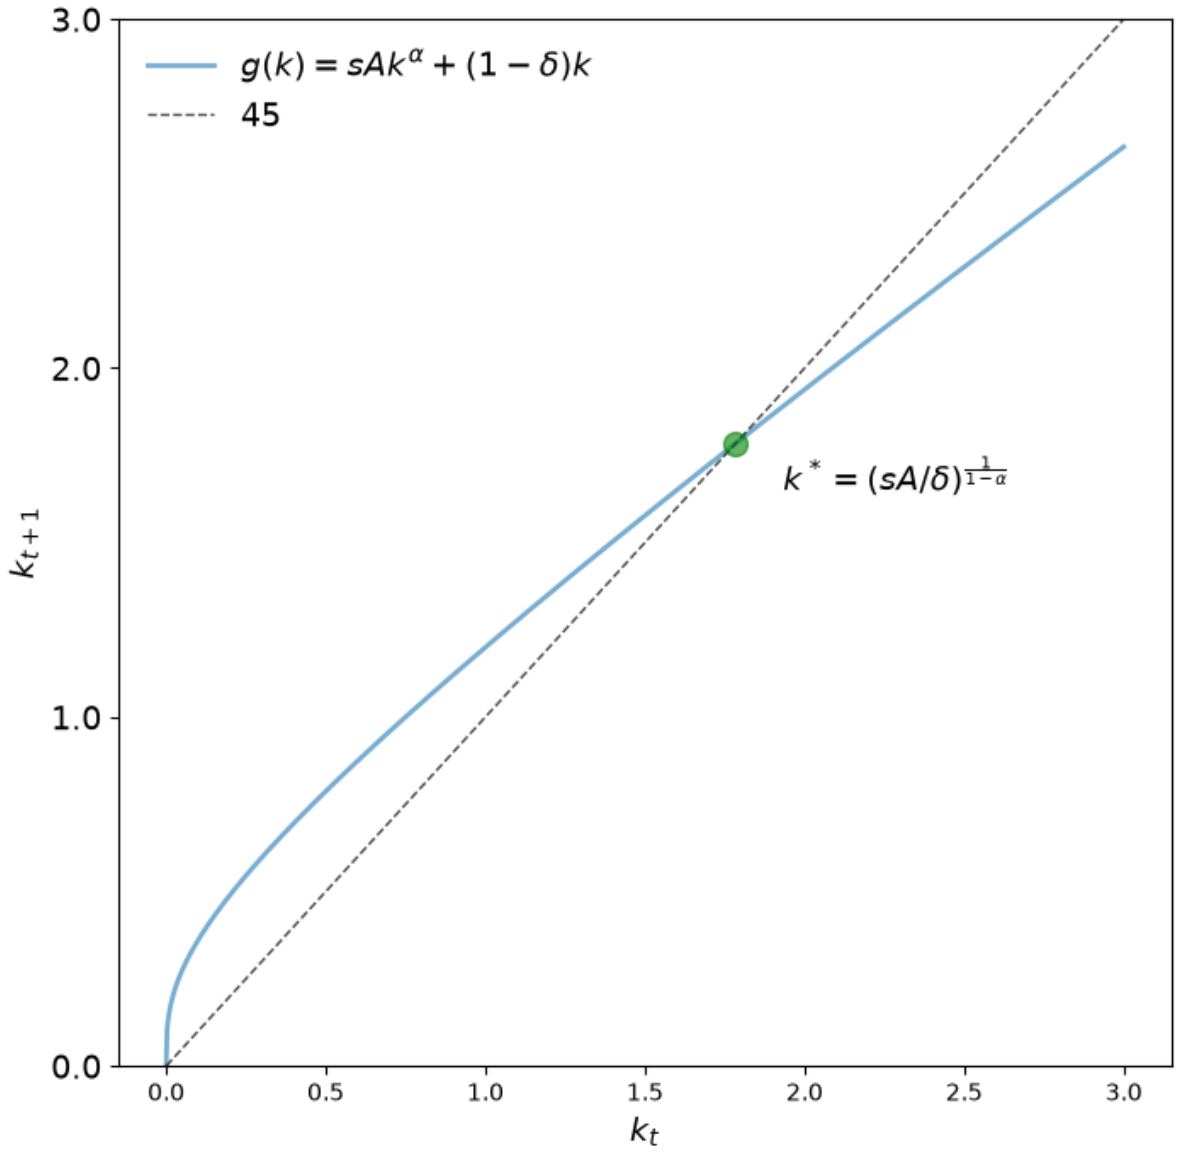
    k_min, k_max = 0.0, 3.0
    k_grid = jnp.linspace(k_min, k_max, 1200)

    # Plot the functions
    lb = r"$g(k) = sAk^{\alpha} + (1 - \delta)k$"
    ax.plot(k_grid, g(k_grid, params), lw=2, alpha=0.6, label=lb)
    ax.plot(k_grid, k_grid, "k--", lw=1, alpha=0.7, label="45")

    # Show and annotate the fixed point
    kstar = exact_fixed_point(params)
    fps = (kstar,)
    ax.plot(fps, fps, "go", ms=10, alpha=0.6)
    ax.annotate(
        r"$k^* = (sA / \delta)^{\frac{1}{1-\alpha}}$",
        xy=(kstar, kstar),
        xycoords="data",
        xytext=(20, -20),
        textcoords="offset points",
        fontsize=fontsize,
```

(continues on next page)

(continued from previous page)



```
    )

    ax.legend(loc="upper left", frameon=False, fontsize=fontsize)

    ax.set_yticks((0, 1, 2, 3))
    ax.set_yticklabels((0.0, 1.0, 2.0, 3.0), fontsize=fontsize)
    ax.set_ylim(0, 3)
    ax.set_xlabel("$k_t$", fontsize=fontsize)
    ax.set_ylabel("$k_{t+1}$", fontsize=fontsize)
```

Let's look at the 45 degree diagram for two parameterizations.

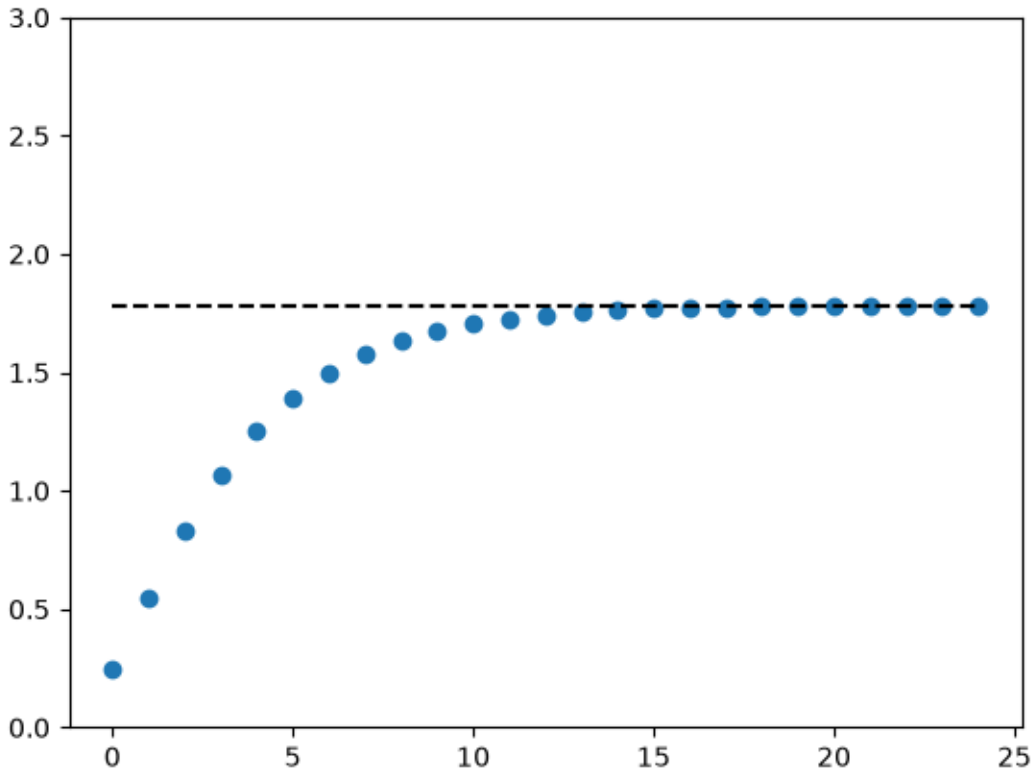
```
params = create_solow_params()
fig, ax = plt.subplots(figsize=(8, 8))
plot_45(params, ax)
plt.show()
```

```
params = create_solow_params(α=0.05, δ=0.5)
fig, ax = plt.subplots(figsize=(8, 8))
plot_45(params, ax)
plt.show()
```

We see that k^* is indeed the unique positive fixed point.

Successive approximation

First let's compute the fixed point using successive approximation.



In this case, successive approximation means repeatedly updating capital from some initial state k_0 using the law of motion.

Here's a time series from a particular choice of k_0.

```
def compute_iterates(k_0, f, params, n=25):
    """Compute time series of length n generated by function f."""
    k = k_0
    k_iterates = []
    for t in range(n):
        k_iterates.append(k)
        k = f(k, params)
    return k_iterates
```

```
params = create_solow_params()
k_0 = 0.25
k_series = compute_iterates(k_0, g, params)
k_star = exact_fixed_point(params)

fig, ax = plt.subplots()
ax.plot(k_series, "o")
ax.plot([k_star] * len(k_series), "k--")
ax.set_ylim(0, 3)
plt.show()
```

Let's see the output for a long time series.

```
k_series = compute_iterates(k_0, g, params, n=10_000)
k_star_approx = k_series[-1]
k_star_approx
```

```
1.7846741842265788
```

This is close to the true value.

```
k_star
```

```
1.7846741842265788
```

Newton's method

In general, when applying Newton's fixed point method to some function g, we start with a guess x_0 of the fixed point and then update by solving for the fixed point of a tangent line at x_0.

To begin with, we recall that the first-order approximation of g at x_0 (i.e., the first order Taylor approximation of g at x_0) is the function

$$\hat{g}(x) \approx g(x_0) + g'(x_0)(x - x_0) \tag{7.2}$$

We solve for the fixed point of $\hat{g}$ by calculating the x_1 that solves

$$x_1 = \frac{g(x_0) - g'(x_0)x_0}{1 - g'(x_0)}$$

Generalising the process above, Newton's fixed point method iterates on

$$x_{t+1} = \frac{g(x_t) - g'(x_t)x_t}{1 - g'(x_t)}, \quad x_0 \text{ given} \tag{7.3}$$

To implement Newton's method we observe that the derivative of the law of motion for capital *(7.2.1)* is

$$g'(k) = \alpha s A k^{\alpha - 1} + (1 - \delta) \tag{7.4}$$

Let's define this:

```
def Dg(k, params):
    A, s, α, δ = params
    return α * A * s * k ** (α - 1) + (1 - δ)
```

Here's a function q representing *(7.2.3)*.

```
def q(k, params):
    return (g(k, params) - Dg(k, params) * k) / (1 - Dg(k, params))
```

Now let's plot some trajectories.

```
def plot_trajectories(
    params,
    k0_a=0.8,  # first initial condition
    k0_b=3.1,  # second initial condition
    n=20,      # length of time series
    fs=14,     # fontsize
```

(continues on next page)

(continued from previous page)

```
):

    fig, axes = plt.subplots(2, 1, figsize=(10, 6))
    ax1, ax2 = axes

    ks1 = compute_iterates(k0_a, g, params, n)
    ax1.plot(ks1, "-o", label="successive approximation")

    ks2 = compute_iterates(k0_b, g, params, n)
    ax2.plot(ks2, "-o", label="successive approximation")

    ks3 = compute_iterates(k0_a, q, params, n)
    ax1.plot(ks3, "-o", label="newton steps")

    ks4 = compute_iterates(k0_b, q, params, n)
    ax2.plot(ks4, "-o", label="newton steps")

    for ax in axes:
        ax.plot(k_star * jnp.ones(n), "k--")
        ax.legend(fontsize=fs, frameon=False)
        ax.set_ylim(0.6, 3.2)
        ax.set_yticks((k_star,))
        ax.set_yticklabels(("$k^*$",), fontsize=fs)
        ax.set_xticks(jnp.linspace(0, 19, 20))

    plt.show()
```

```
params = create_solow_params()
plot_trajectories(params)
```

We can see that Newton's method converges faster than successive approximation.

7.3 Root-Finding in one dimension

In the previous section we computed fixed points.

In fact Newton's method is more commonly associated with the problem of finding zeros of functions.

Let's discuss this "root-finding" problem and then show how it is connected to the problem of finding fixed points.

7.3.1 Newton's method for zeros

Let's suppose we want to find an x such that $f(x) = 0$ for some smooth function f mapping real numbers to real numbers.

Suppose we have a guess x_0 and we want to update it to a new point x_1.

As a first step, we take the first-order approximation of f around x_0:

$$\hat{f}(x) \approx f(x_0) + f'(x_0)(x - x_0)$$

Now we solve for the zero of $\hat{f}$.

In particular, we set $\hat{f}(x_1) = 0$ and solve for x_1 to get

$$x_1 = x_0 - \frac{f(x_0)}{f'(x_0)}, \quad x_0 \text{ given}$$

Generalizing the formula above, for one-dimensional zero-finding problems, Newton's method iterates on

$$x_{t+1} = x_t - \frac{f(x_t)}{f'(x_t)}, \quad x_0 \text{ given} \tag{7.5}$$

The following code implements the iteration *(7.3.1)*

```
def newton(f, x_0, tol=1e-7, max_iter=100_000):
    x = x_0
    Df = jax.grad(f)

    # Implement the zero-finding formula
    @jax.jit
    def q(x):
        return x - f(x) / Df(x)

    error = tol + 1
    n = 0
    while error > tol:
        n += 1
        if n > max_iter:
            raise Exception("Max iteration reached without convergence")
        y = q(x)
        error = jnp.abs(x - y)
        x = y
        print(f"iteration {n}, error = {error:.5f}")
    return x.item()
```

Numerous libraries implement Newton's method in one dimension, including SciPy, so the code is just for illustrative purposes.

(That said, when we want to apply Newton's method using techniques such as automatic differentiation or GPU acceleration, it will be helpful to know how to implement Newton's method ourselves.)

7.3.2 Application to finding fixed points

Now consider again the Solow fixed-point calculation, where we solve for k satisfying $g(k) = k$.

We can convert to this to a zero-finding problem by setting $f(x) := g(x) - x$.

Any zero of f is clearly a fixed point of g.

Let's apply this idea to the Solow problem

```
params = create_solow_params()
k_star_approx_newton = newton(f = lambda x: g(x, params) - x, x_0=0.8)
```

```
iteration 1, error = 1.27209
iteration 2, error = 0.28180
iteration 3, error = 0.00561
iteration 4, error = 0.00000
iteration 5, error = 0.00000
```

```
k_star_approx_newton
```

```
1.7846741842265788
```

The result confirms convergence we saw in the graphs above: a very accurate result is reached with only 5 iterations.

7.4 Multivariate Newton's method

In this section, we introduce a two-good problem, present a visualization of the problem, and solve for the equilibrium of the two-good market using both a zero finder in `SciPy` and Newton's method.

We then expand the idea to a larger market with 5,000 goods and compare the performance of the two methods again.

We will see a significant performance gain when using Newton's method.

7.4.1 A two-goods market equilibrium

Let's start by computing the market equilibrium of a two-good problem.

We consider a market for two related products, good 0 and good 1, with price vector $p = (p_0, p_1)$

Supply of good i at price p is

$$q_i^s(p) = b_i \sqrt{p_i}$$

Demand of good i at price p is

$$q_i^d(p) = \exp(-(a_{i0} p_0 + a_{i1} p_1)) + c_i$$

Here c_i, b_i and a_{ij} are parameters.

For example, the two goods might be computer components that are typically used together, in which case they are complements. Hence demand depends on the price of both components.

The excess demand function is

$$e_i(p) = q_i^d(p) - q_i^s(p), \quad i = 0, 1$$

An equilibrium price vector p^* satisfies $e_i(p^*) = 0$.

We set

$$A = \begin{bmatrix} a_{00} & a_{01} \\ a_{10} & a_{11} \end{bmatrix}, \qquad b = \begin{bmatrix} b_0 \\ b_1 \end{bmatrix} \qquad \text{and} \qquad c = \begin{bmatrix} c_0 \\ c_1 \end{bmatrix}$$

for this particular question.

A graphical exploration

Since our problem is only two-dimensional, we can use graphical analysis to visualize and help understand the problem.

Our first step is to define the excess demand function

$$e(p) = \begin{bmatrix} e_0(p) \\ e_1(p) \end{bmatrix}$$

The function below calculates the excess demand for given parameters

```
@jax.jit
def e(p, A, b, c):
    return jnp.exp(-A @ p) + c - b * jnp.sqrt(p)
```

Our default parameter values will be

$$A = \begin{bmatrix} 0.5 & 0.4 \\ 0.8 & 0.2 \end{bmatrix}, \qquad b = \begin{bmatrix} 1 \\ 1 \end{bmatrix} \qquad \text{and} \qquad c = \begin{bmatrix} 1 \\ 1 \end{bmatrix}$$

```
A = jnp.array([[0.5, 0.4], [0.8, 0.2]])
b = jnp.ones(2)
c = jnp.ones(2)
```

At a price level of $p = (1, 0.5)$, the excess demand is

```
p = jnp.array([1, 0.5])
ex_demand = e(p, A, b, c)

print(
    f"The excess demand for good 0 is {ex_demand[0]:.3f} \n"
    f"The excess demand for good 1 is {ex_demand[1]:.3f}"
)
```

```
The excess demand for good 0 is 0.497
The excess demand for good 1 is 0.699
```

To increase the efficiency of computation, we will use the power of vectorization using `jax.vmap`. This is much faster than the python loops.

```
# Create vectorization on the first axis of p.
e_vectorized_p_1 = jax.vmap(e, in_axes=(0, None, None, None))

# Create vectorization on the second axis of p.
e_vectorized = jax.vmap(e_vectorized_p_1, in_axes=(0, None, None, None))
```

Next we plot the two functions e_0 and e_1 on a grid of (p_0, p_1) values, using contour surfaces and lines.

We will use the following function to build the contour plots

```
def plot_excess_demand(ax, good=0, grid_size=100, grid_max=4, surface=True):
    p_grid = jnp.linspace(0, grid_max, grid_size)

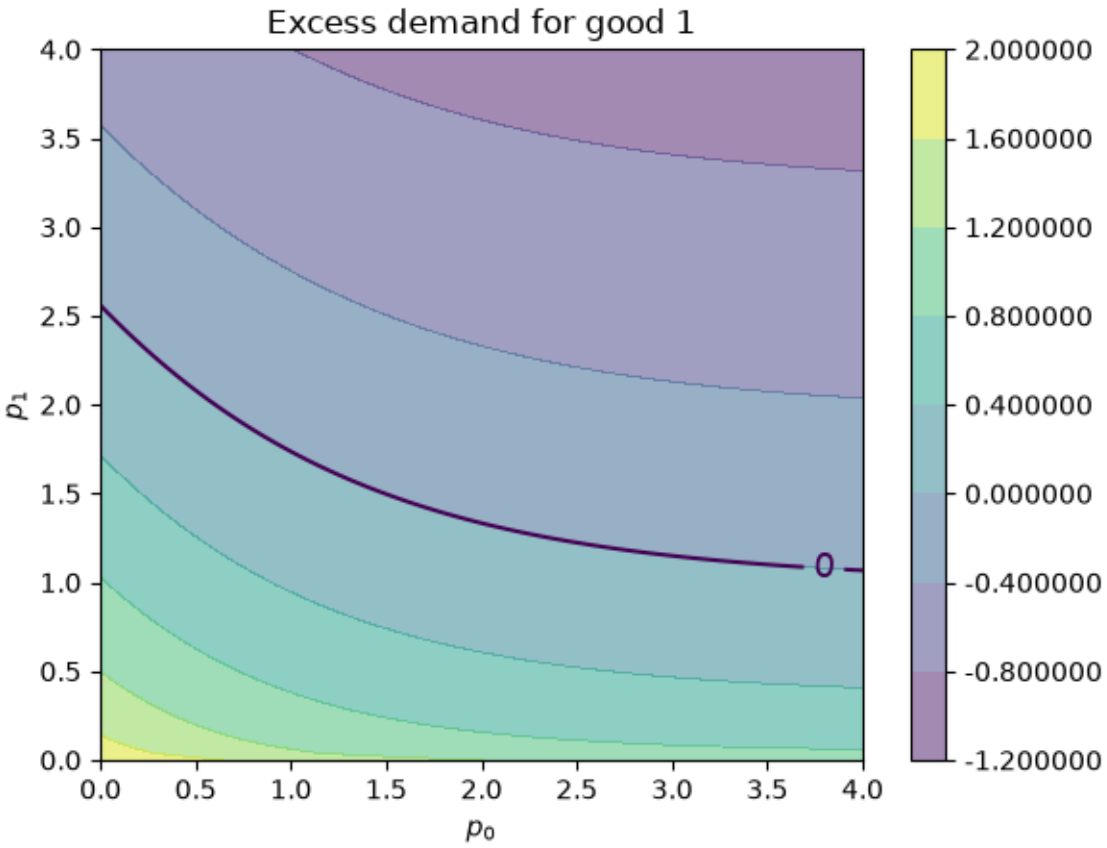
    # Create meshgrid for all combinations of p_1 and p_2
    P1, P2 = jnp.meshgrid(p_grid, p_grid, indexing="ij")

    # Stack to create array of shape (grid_size, grid_size, 2)
    P = jnp.stack([P1, P2], axis=-1)

    # Compute all values at once using vectorized function
    z_full = e_vectorized(P, A, b, c)
    z = z_full[:, :, good]

    if surface:
        cs1 = ax.contourf(p_grid, p_grid, z.T, alpha=0.5)
        plt.colorbar(cs1, ax=ax, format="%.6f")

    ctr1 = ax.contour(p_grid, p_grid, z.T, levels=[0.0])
    ax.set_xlabel("$p_0$")
    ax.set_ylabel("$p_1$")
    ax.set_title(f"Excess demand for good {good}")
    plt.clabel(ctr1, inline=1, fontsize=13)
```

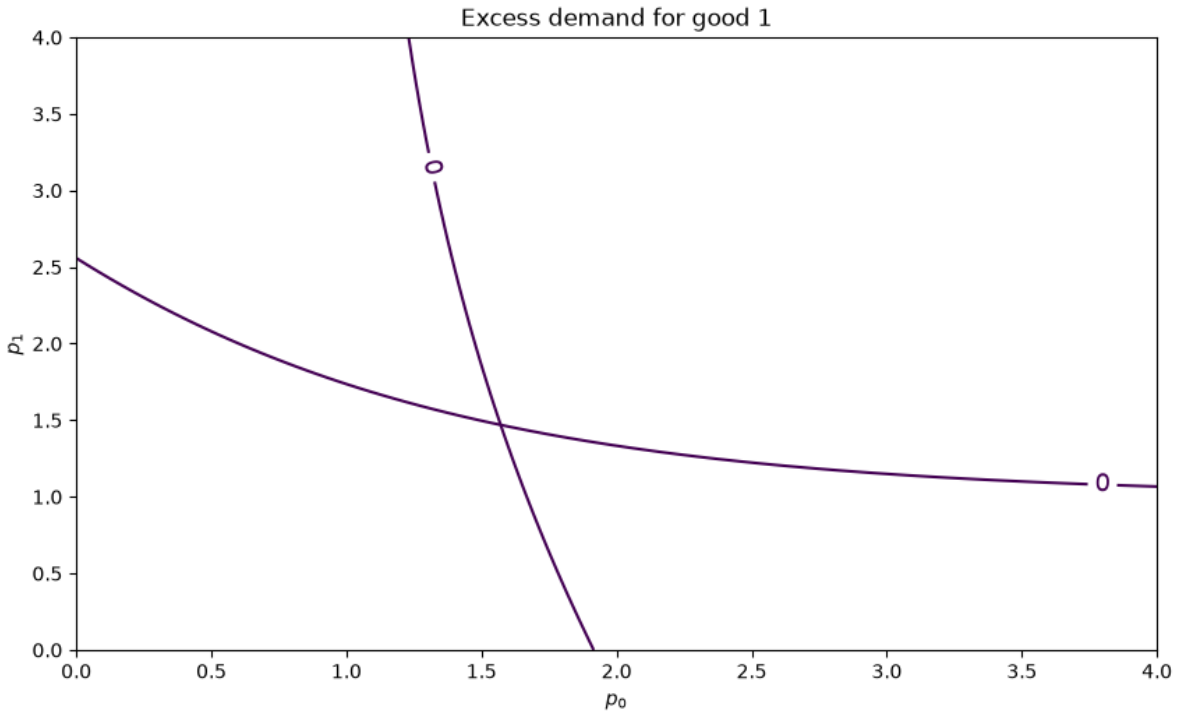


Here's our plot of e_0:

```
fig, ax = plt.subplots()
plot_excess_demand(ax, good=0)
plt.show()
```

Here's our plot of e_1:

```
fig, ax = plt.subplots()
plot_excess_demand(ax, good=1)
plt.show()
```



We see the black contour line of zero, which tells us when $e_i(p) = 0$.

For a price vector p such that $e_i(p) = 0$ we know that good i is in equilibrium (demand equals supply).

If these two contour lines cross at some price vector p^*, then p^* is an equilibrium price vector.

```
fig, ax = plt.subplots(figsize=(10, 5.7))
for good in (0, 1):
    plot_excess_demand(ax, good=good, surface=False)
plt.show()
```

It seems there is an equilibrium close to $p = (1.6, 1.5)$.

Using a multidimensional root finder

To solve for p^* more precisely, we use a zero-finding algorithm from `scipy.optimize`.

We supply $p = (1, 1)$ as our initial guess.

```
init_p = jnp.ones(2)
```

This uses the modified Powell method to find the zero

```
%%time
solution = root(lambda p: e(p, A, b, c), init_p, method="hybr")
```

```
CPU times: user 3.5 ms, sys: 5.69 ms, total: 9.19 ms
Wall time: 6 ms
```

Here's the resulting value:

```
p = solution.x
p
```

```
array([1.57080182, 1.46928838])
```

This looks close to our guess from observing the figure. We can plug it back into e to test that $e(p) \approx 0$:

```
e_p = jnp.max(jnp.abs(e(p, A, b, c)))
e_p.item()
```

```
2.0383694732117874e-13
```

This is indeed a very small error.

Adding gradient information

In many cases, for zero-finding algorithms applied to smooth functions, supplying the Jacobian of the function leads to better convergence properties.

Here, we manually calculate the elements of the Jacobian

$$J(p) = \begin{bmatrix} \frac{\partial e_0}{\partial p_0}(p) & \frac{\partial e_0}{\partial p_1}(p) \\ \frac{\partial e_1}{\partial p_0}(p) & \frac{\partial e_1}{\partial p_1}(p) \end{bmatrix}$$

```
def jacobian_e(p, A, b, c):
    p_0, p_1 = p
    a_00, a_01 = A[0, :]
    a_10, a_11 = A[1, :]
    j_00 = -a_00 * jnp.exp(-a_00 * p_0) - (b[0] / 2) * p_0 ** (-1 / 2)
    j_01 = -a_01 * jnp.exp(-a_01 * p_1)
    j_10 = -a_10 * jnp.exp(-a_10 * p_0)
    j_11 = -a_11 * jnp.exp(-a_11 * p_1) - (b[1] / 2) * p_1 ** (-1 / 2)
    J = [[j_00, j_01], [j_10, j_11]]
    return jnp.array(J)
```

```
%%time
solution = root(
    lambda p: e(p, A, b, c),
    init_p,
    jac = lambda p: jacobian_e(p, A, b, c),
    method="hybr",
)
```

```
CPU times: user 301 ms, sys: 38.1 ms, total: 339 ms
Wall time: 326 ms
```

Now the solution is even more accurate (although, in this low-dimensional problem, the difference is quite small):

```
p = solution.x
e_p = jnp.max(jnp.abs(e(p, A, b, c)))
e_p.item()
```

```
1.3322676295501878e-15
```

Using Newton's method

Now let's use Newton's method to compute the equilibrium price using the multivariate version of Newton's method

$$p_{n+1} = p_n - J_e(p_n)^{-1} e(p_n) \tag{7.6}$$

This is a multivariate version of *(7.3.1)*

(Here $J_e(p_n)$ is the Jacobian of e evaluated at p_n.)

The iteration starts from some initial guess of the price vector p_0.

Here, instead of coding Jacobian by hand, we use the `jacobian()` function in the `jax` library to auto-differentiate and calculate the Jacobian.

With only slight modification, we can generalize *our previous attempt* to multidimensional problems

```
def newton(f, x_0, tol=1e-5, max_iter=10):
    x = x_0
    f_jac = jax.jacobian(f)

    @jax.jit
    def q(x):
        return x - jnp.linalg.solve(f_jac(x), f(x))

    error = tol + 1
    n = 0
    while error > tol:
        n += 1
        if n > max_iter:
            raise Exception("Max iteration reached without convergence")
        y = q(x)
        if any(jnp.isnan(y)):
            raise Exception("Solution not found with NaN generated")
        error = jnp.linalg.norm(x - y)
        x = y
        print(f"iteration {n}, error = {error:.5f}")
    print("\n" + f"Result = {x} \n")
    return x
```

We find the algorithm terminates in 4 steps

```
%%time
p = newton(lambda p: e(p, A, b, c), init_p)
```

```
iteration 1, error = 0.62515
iteration 2, error = 0.11152
iteration 3, error = 0.00258
iteration 4, error = 0.00000

Result = [1.57080182 1.46928838]

CPU times: user 404 ms, sys: 79.8 ms, total: 484 ms
Wall time: 318 ms
```

```
e_p = jnp.max(jnp.abs(e(p, A, b, c)))
e_p.item()
```

```
1.4632739464559563e-13
```

The result is very accurate.

With the larger overhead, the speed is not better than the optimized `scipy` function.

7.4.2 A high-dimensional problem

Our next step is to investigate a large market with 3,000 goods.

The excess demand function is essentially the same, but now the matrix A is 3000×3000 and the parameter vectors b and c are 3000×1.

```
dim = 3000

# Create JAX random key
key = jax.random.key(0)

# Create a random matrix A and normalize the columns to sum to one
A = jax.random.uniform(key, (dim, dim))
s = jnp.sum(A, axis=0)
A = A / s

# Set up b and c
b = jnp.ones(dim)
c = jnp.ones(dim)
```

Here's our initial condition

```
init_p = jnp.ones(dim)
```

```
%%time
p = newton(lambda p: e(p, A, b, c), init_p)
```

```
iteration 1, error = 23.22262
iteration 2, error = 3.94537
iteration 3, error = 0.08500
iteration 4, error = 0.00004
iteration 5, error = 0.00000

Result = [1.50723773 1.51041603 1.50134795 ... 1.49941629 1.49033692 1.49666807]

CPU times: user 5.06 s, sys: 1.77 s, total: 6.82 s
Wall time: 6.87 s
```

```
e_p = jnp.max(jnp.abs(e(p, A, b, c)))
e_p.item()
```

```
4.440892098500626e-16
```

With the same tolerance, we compare the runtime and accuracy of Newton's method to SciPy's `root` function

```
%%time
solution = root(
    lambda p: e(p, A, b, c),
    init_p,
    jac = lambda p: jax.jacobian(e)(p, A, b, c),
    method="hybr",
    tol=1e-5,
)
```

```
CPU times: user 35.1 s, sys: 95.7 ms, total: 35.2 s
Wall time: 35.5 s
```

```
p = solution.x
e_p = jnp.max(jnp.abs(e(p, A, b, c)))
e_p.item()
```

```
9.209231102147442e-07
```

7.5 Exercises

Exercise 7.5.1

Consider a three-dimensional extension of the Solow fixed point problem with

$$A = \begin{bmatrix} 2 & 3 & 3 \\ 2 & 4 & 2 \\ 1 & 5 & 1 \end{bmatrix}, \quad s = 0.2, \quad \alpha = 0.5, \quad \delta = 0.8$$

As before the law of motion is

$$k_{t+1} = g(k_t) \quad \text{where} \quad g(k) := sAk^\alpha + (1 - \delta)k$$

However, k_t is now a 3×1 vector.

Solve for the fixed point using Newton's method with the following initial values:

$$k1_0 = (1, 1, 1)$$
$$k2_0 = (3, 5, 5)$$
$$k3_0 = (50, 50, 50)$$

Hint

- The computation of the fixed point is equivalent to computing k^* such that $g(k^*) - k^* = 0$.
- If you are unsure about your solution, you can start with the solved example:

$$A = \begin{bmatrix} 2 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 2 \end{bmatrix}$$

with $s = 0.3$, $\alpha = 0.3$, and $\delta = 0.4$ and starting value:

$$k_0 = (1, 1, 1)$$

The result should converge to the *analytical solution*.

Solution

Let's first define the parameters for this problem

```
A = jnp.array([[2.0, 3.0, 3.0], [2.0, 4.0, 2.0], [1.0, 5.0, 1.0]])

s = 0.2
α = 0.5
δ = 0.8

initLs = [jnp.ones(3), jnp.array([3.0, 5.0, 5.0]), jnp.repeat(50.0, 3)]
```

Then define the multivariate version of the formula for the *(7.2.1)*

```
@jax.jit
def multivariate_solow(k, A=A, s=s, α=α, δ=δ):
    return s * jnp.dot(A, k**α) + (1 - δ) * k
```

Let's run through each starting value and see the output

```
attempt = 1
for init in initLs:
    print(f'Attempt {attempt}: Starting value is {init} \n')
    %time k = newton(lambda k: multivariate_solow(k) - k, \
                     init)
    print('-'*64)
    attempt += 1
```

```
Attempt 1: Starting value is [1. 1. 1.]
iteration 1, error = 50.49630
iteration 2, error = 41.10937
iteration 3, error = 4.29413
iteration 4, error = 0.38543
iteration 5, error = 0.00544
iteration 6, error = 0.00000

Result = [3.84058108 3.87071771 3.41091933]

CPU times: user 377 ms, sys: 53.2 ms, total: 430 ms
Wall time: 275 ms
----------------------------------------------------------------
Attempt 2: Starting value is [3. 5. 5.]

iteration 1, error = 2.07011
iteration 2, error = 0.12642
iteration 3, error = 0.00060
iteration 4, error = 0.00000

Result = [3.84058108 3.87071771 3.41091933]

CPU times: user 243 ms, sys: 29.8 ms, total: 272 ms
Wall time: 114 ms
----------------------------------------------------------------
Attempt 3: Starting value is [50. 50. 50.]
iteration 1, error = 73.00943
iteration 2, error = 6.49379
iteration 3, error = 0.68070
iteration 4, error = 0.01620
iteration 5, error = 0.00001
iteration 6, error = 0.00000

Result = [3.84058108 3.87071771 3.41091933]

CPU times: user 484 ms, sys: 66 ms, total: 550 ms
Wall time: 259 ms
```

```
----------------------------------------------------------------
```

We find that the results are invariant to the starting values given the well-defined property of this question.

But the number of iterations it takes to converge is dependent on the starting values.

Let's substitute the output back into the formula to check our last result

```
multivariate_solow(k) - k
```

```
Array([0., 0., 0.], dtype=float64)
```

Note the error is very small.

We can also test our results on the known solution

```
A = jnp.array([[2.0, 0.0, 0.0], [0.0, 2.0, 0.0], [0.0, 0.0, 2.0]])

s = 0.3
α = 0.3
δ = 0.4

init = jnp.repeat(1.0, 3)
%%time

k = newton(lambda k: multivariate_solow(k, A=A, s=s, α=α, δ=δ) - k, init)
```

```
iteration 1, error = 1.57459
iteration 2, error = 0.21345
iteration 3, error = 0.00205
iteration 4, error = 0.00000

Result = [1.78467418 1.78467418 1.78467418]

CPU times: user 460 ms, sys: 54.6 ms, total: 515 ms
Wall time: 224 ms
```

The result is very close to the ground truth but still slightly different.

```
%%time

k = newton(
    lambda k: multivariate_solow(k, A=A, s=s, α=α, δ=δ) - k, init, tol=1e-7
)
```

```
iteration 1, error = 1.57459
iteration 2, error = 0.21345
iteration 3, error = 0.00205
iteration 4, error = 0.00000
iteration 5, error = 0.00000

Result = [1.78467418 1.78467418 1.78467418]

CPU times: user 453 ms, sys: 63.9 ms, total: 517 ms
Wall time: 217 ms
```

We can see it steps towards a more accurate solution.

Exercise 7.5.2

In this exercise, let's try different initial values and check how Newton's method responds to different starting points.

Let's define a three-good problem with the following default values:

$$A = \begin{bmatrix} 0.2 & 0.1 & 0.7 \\ 0.3 & 0.2 & 0.5 \\ 0.1 & 0.8 & 0.1 \end{bmatrix}, \qquad b = \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} \qquad \text{and} \qquad c = \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix}$$

For this exercise, use the following extreme price vectors as initial values:

$$p1_0 = (5, 5, 5)$$
$$p2_0 = (1, 1, 1)$$
$$p3_0 = (4.5, 0.1, 4)$$

Set the tolerance to $1e - 15$ for more accurate output.

Solution

Define parameters and initial values

```
A = jnp.array([[0.2, 0.1, 0.7], [0.3, 0.2, 0.5], [0.1, 0.8, 0.1]])
b = jnp.array([1.0, 1.0, 1.0])
c = jnp.array([1.0, 1.0, 1.0])

initLs = [jnp.repeat(5.0, 3), jnp.ones(3), jnp.array([4.5, 0.1, 4.0])]
```

Let's run through each initial guess and check the output

```
for attempt, init in enumerate(initLs, start=1):
    print(f"Attempt {attempt}: Starting value is {init} \n")
    %time p = newton(lambda p: e(p, A, b, c), init, tol=1e-15, max_iter=15)
    print("-" * 64)
```

```
Attempt 1: Starting value is [5. 5. 5.]
iteration 1, error = 9.24381
CPU times: user 417 ms, sys: 74.6 ms, total: 492 ms
Wall time: 218 ms
```

```
---------------------------------------------------------------------------
Exception                                 Traceback (most recent call last)
Cell In[52], line 3
      1 for attempt, init in enumerate(initLs, start=1):
      2     print(f"Attempt {attempt}: Starting value is {init} \n")
----> 3     get_ipython().run_line_magic('time', 'p = newton(lambda p: e(p, A,␣
 ↪b, c), init, tol=1e-15, max_iter=15)')
      4     print("-" * 64)

File <timed exec>:1
----> 1 'Could not get source, probably due dynamically evaluated source code.'

Cell In[35], line 17, in newton(f, x_0, tol, max_iter)
     13         if n > max_iter:
     14             raise Exception("Max iteration reached without convergence")
     15         y = q(x)
     16         if any(jnp.isnan(y)):
---> 17             raise Exception("Solution not found with NaN generated")
     18         error = jnp.linalg.norm(x - y)
     19         x = y
     20         print(f"iteration {n}, error = {error:.5f}")

Exception: Solution not found with NaN generated
```

We can see that Newton's method may fail for some starting values.

Sometimes it may take a few initial guesses to achieve convergence.

Substitute the result back to the formula to check our result using the second initial guess which converges

```
p_solution = newton(lambda p: e(p, A, b, c), initLs[1], tol=1e-15, max_iter=15)
e(p_solution, A, b, c)
```

```
iteration 1, error = 0.73419
iteration 2, error = 0.12472
iteration 3, error = 0.00269
iteration 4, error = 0.00000
iteration 5, error = 0.00000
iteration 6, error = 0.00000

Result = [1.49744442 1.49744442 1.49744442]
```

```
Array([0.00000000e+00, 0.00000000e+00, 2.22044605e-16], dtype=float64)
```

We can see the result is very accurate.

Part II

Elementary Statistics

CHAPTER

EIGHT

ELEMENTARY PROBABILITY WITH MATRICES

This lecture uses matrix algebra to illustrate some basic ideas about probability theory.

After introducing underlying objects, we'll use matrices and vectors to describe probability distributions.

Among concepts that we'll be studying include

- a joint probability distribution
- marginal distributions associated with a given joint distribution
- conditional probability distributions
- statistical independence of two random variables
- joint distributions associated with a prescribed set of marginal distributions
  - couplings
  - copulas
- the probability distribution of a sum of two independent random variables
  - convolution of marginal distributions
- parameters that define a probability distribution
- sufficient statistics as data summaries

We'll use a matrix to represent a bivariate or multivariate probability distribution and a vector to represent a univariate probability distribution

This *companion lecture* describes some popular probability distributions and describes how to use Python to sample from them.

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install prettytable
```

As usual, we'll start with some imports

```
import numpy as np
import matplotlib.pyplot as plt
import prettytable as pt
from scipy import stats
from scipy.special import comb
from mpl_toolkits.mplot3d import Axes3D
from matplotlib_inline.backend_inline import set_matplotlib_formats
set_matplotlib_formats('retina')

rng = np.random.default_rng(0)
```

8.1 Sketch of basic concepts

We'll briefly define what we mean by a **probability space**, a **probability measure**, and a **random variable**.

For most of this lecture, we sweep these objects into the background

> **Note**
>
> Nevertheless, they'll be lurking beneath **induced distributions** of random variables that we'll focus on here.
>
> These deeper objects are essential for defining and analysing the concepts of stationarity and ergodicity that underly laws of large numbers.
>
> For a relatively nontechnical presentation of some of these results see this chapter from Lars Peter Hansen and Thomas J. Sargent's online monograph titled *Risk, Uncertainty, and Values*.

Let Ω be a set of possible underlying outcomes and let $\omega \in \Omega$ be a particular underlying outcome.

Let $\mathcal{F}$ be a collection of subsets of Ω that we call **events**.

(Technically, $\mathcal{F}$ is a σ-algebra.)

A **probability measure** μ maps each event $\mathcal{G} \in \mathcal{F}$ into a scalar number $\mu(\mathcal{G})$ between 0 and 1, with $\mu(\Omega) = 1$.

The triple $\Omega, \mathcal{F}, \mu$ forms our **probability space**.

A **random variable** $X(\omega)$ is a function of the underlying outcome $\omega \in \Omega$ that assigns a value in some set of possible values.

If A is a set of possible values of X, then the event that X lies in A is

$$\mathcal{G} = \{\omega \in \Omega : X(\omega) \in A\}.$$

The random variable $X(\omega)$ has a **probability distribution** induced by the probability measure μ:

$$\text{Prob}(X \in A) = \mu(\mathcal{G}).$$

If μ has a density $p(\omega)$, then we can also write

$$\text{Prob}(X \in A) = \int_{\mathcal{G}} p(\omega)\, d\omega \tag{8.1}$$

We call this the induced probability distribution of random variable X.

Instead of working explicitly with an underlying probability space $\Omega, \mathcal{F}$ and probability measure μ, applied statisticians often proceed simply by specifying a form for an induced distribution for a random variable X.

That is how we'll proceed in this lecture and in many subsequent lectures.

8.2 What does probability mean?

Before diving in, we'll say a few words about what probability theory means and how it connects to statistics.

We also touch on these topics in *Two Meanings of Probability* and *Bayesian versus Frequentist Decision Rules*.

For much of this lecture we'll be discussing fixed "population" probabilities.

These are purely mathematical objects.

To appreciate how statisticians connect probabilities to data, the key is to understand the following concepts:

- A single draw from a probability distribution
- Repeated independently and identically distributed (i.i.d.) draws of "samples" or "realizations" from the same probability distribution
- A **statistic** defined as a function of a sequence of samples
- An **empirical distribution** or **histogram** (a binned empirical distribution) that records observed **relative frequencies**
- The idea that a population probability distribution is what we anticipate **relative frequencies** will be in a long sequence of i.i.d. draws. Here the following mathematical machinery makes precise what is meant by **anticipated relative frequencies**
  - **Law of Large Numbers (LLN)**
  - **Central Limit Theorem (CLT)**

8.2.1 A discrete random variable example

Scalar example

Let X be a scalar random variable that takes on the I possible values $0, 1, 2, \ldots, I-1$ with probabilities

$$\text{Prob}(X = i) = f_i,$$

where

$$f_i \geqslant 0, \quad \sum_i f_i = 1.$$

We sometimes write

$$X \sim \{f_i\}_{i=0}^{I-1}$$

as a short-hand way of saying that the random variable X is described by the probability distribution $\{f_i\}_{i=0}^{I-1}$.

Consider drawing a sample $x_0, x_1, \ldots, x_{N-1}$ of N independent and identically distributed draws of X.

What do "identical" and "independent" mean in IID or iid ("identically and independently distributed")?

- "identical" means that each draw is from the same distribution.
- "independent" means that the joint distribution equals the product of marginal distributions, i.e.,

$$\begin{aligned}\text{Prob}\{x_0 = i_0, x_1 = i_1, \ldots, x_{N-1} = i_{N-1}\} &= \text{Prob}\{x_0 = i_0\} \cdot \cdots \cdot \text{Prob}\{x_{N-1} = i_{N-1}\} \\ &= f_{i_0} f_{i_1} \cdot \cdots \cdot f_{i_{N-1}}\end{aligned}$$

We define an **empirical distribution** as follows.

For each $i = 0, \ldots, I-1$, let

$$\begin{aligned}N_i &= \text{number of times } X = i, \\ N &= \sum_{i=0}^{I-1} N_i \quad \text{total number of draws}, \\ \tilde{f}_i &= \frac{N_i}{N} \sim \text{ frequency of draws for which } X = i\end{aligned}$$

Key concepts that connect probability theory with statistics are laws of large numbers and central limit theorems.

A Law of Large Numbers (LLN) states that $\tilde{f}_i \to f_i$ as $N \to \infty$.

A Central Limit Theorem (CLT) describes a **rate** at which $\tilde{f}_i \to f_i$.

See *LLN and CLT* for a detailed treatment of both results.

8.2.2 Understanding probability: frequentist vs. Bayesian

For "frequentist" statisticians, **anticipated relative frequency** is **all** that a probability distribution means.

But for a Bayesian it means something else – something partly subjective and purely personal.

We say "partly" because a Bayesian also pays attention to relative frequencies.

8.3 Representing probability distributions

A probability distribution $\text{Prob}(X \in A)$ can be described by its **cumulative distribution function (CDF)**

$$F_X(x) = \text{Prob}\{X \leq x\}.$$

Sometimes, but not always, a random variable can also be described by a **density function** $f(x)$ that is related to its CDF by

$$\text{Prob}\{X \in B\} = \int_{t \in B} f(t)dt$$

$$F(x) = \int_{-\infty}^{x} f(t)dt$$

Here B is a set of possible X's whose probability of occurring we want to compute.

When a probability density exists, a probability distribution can be characterized either by its CDF or by its density.

For a **discrete-valued** random variable

- the number of possible values of X is finite or countably infinite
- we replace a **density** with a **probability mass function**, a non-negative sequence that sums to one
- when a density exists, we replace integration with summation in formulas like (8.1)

In this lecture, we mostly discuss discrete random variables.

Doing this enables us to confine our tool set basically to linear algebra.

Later we'll briefly discuss how to approximate a continuous random variable with a discrete random variable.

8.4 Univariate probability distributions

We'll devote most of this lecture to discrete-valued random variables, but we'll say a few things about continuous-valued random variables.

8.4.1 Discrete random variable

Let X be a discrete random variable that takes possible values: $i = 0, 1, \ldots, I-1 = \bar{X}$.

Here, we choose the maximum index $I-1$ because of how this aligns nicely with Python's index convention.

Define $f_i \equiv \text{Prob}\{X = i\}$ and assemble the non-negative vector

$$f = \begin{bmatrix} f_0 \\ f_1 \\ \vdots \\ f_{I-1} \end{bmatrix} \tag{8.2}$$

for which $f_i \in [0,1]$ for each i and $\sum_{i=0}^{I-1} f_i = 1$.

This vector defines a **probability mass function**.

The distribution (8.2) has **parameters** $\{f_i\}_{i=0,1,\cdots,I-2}$ since $f_{I-1} = 1 - \sum_{i=0}^{I-2} f_i$.

These parameters pin down the shape of the distribution.

(Sometimes $I = \infty$.)

Such a "non-parametric" distribution has as many "parameters" as there are possible values of the random variable.

We often work with special distributions that are characterized by a small number parameters.

In these special parametric distributions,

$$f_i = g(i;\theta)$$

where θ is a vector of parameters that is of much smaller dimension than I.

A **statistical model** is a joint probability distribution characterized by a list of **parameters**.

The concept of **parameter** is intimately related to the notion of **sufficient statistic**.

A **statistic** is a nonlinear function of a data set.

Sufficient statistics summarize all **information** that a data set contains about parameters of a statistical model.

Note that a sufficient statistic corresponds to a particular statistical model.

Sufficient statistics are key tools that AI uses to summarize or compress a **big data** set.

R. A. Fisher provided a rigorous definition of **information** – see Fisher information.

An example of a parametric probability distribution is a **geometric distribution**.

It is described by

$$f_i = \text{Prob}\{X = i\} = (1-\lambda)\lambda^i, \quad \lambda \in [0,1), \quad i = 0,1,2,...$$

Evidently, $\sum_{i=0}^{\infty} f_i = 1$.

Let θ be a vector of parameters of the distribution described by f, then

$$f_i(\theta) \geq 0, \sum_{i=0}^{\infty} f_i(\theta) = 1$$

8.4.2 Continuous random variable

Let X be a continuous random variable that takes values in a set $\tilde{X} \subseteq \mathbb{R}$ and whose distribution has parameters θ.

$$\text{Prob}\{X \in A\} = \int_{x \in A} f(x;\theta)\, dx; \quad f(x;\theta) \geq 0$$

where A is a subset of $\tilde{X}$ and

$$\text{Prob}\{X \in \tilde{X}\} = 1$$

8.5 Bivariate probability distributions

We'll now discuss a bivariate **joint distribution**.

To begin, we restrict ourselves to two discrete random variables.

Let X, Y be two discrete random variables that take values:

$$X \in \{0, \ldots, I-1\}$$

$$Y \in \{0, \ldots, J-1\}$$

Then their **joint distribution** is described by a matrix

$$F_{I \times J} = [f_{ij}]_{i \in \{0,\ldots,I-1\}, j \in \{0,\ldots,J-1\}}$$

whose elements are

$$f_{ij} = \text{Prob}\{X = i, Y = j\} \geq 0$$

where

$$\sum_i \sum_j f_{ij} = 1$$

8.6 Marginal probability distributions

The joint distribution induces marginal distributions

$$\text{Prob}\{X = i\} = \sum_{j=0}^{J-1} f_{ij} = \mu_i, \quad i = 0, \ldots, I-1$$

$$\text{Prob}\{Y = j\} = \sum_{i=0}^{I-1} f_{ij} = \nu_j, \quad j = 0, \ldots, J-1$$

For example, let a joint distribution over (X, Y) be

$$F = \begin{bmatrix} .25 & .1 \\ .15 & .5 \end{bmatrix} \tag{8.3}$$

The implied marginal distributions are:

$$\begin{aligned} \text{Prob}\{X = 0\} &= .25 + .1 = .35 \\ \text{Prob}\{X = 1\} &= .15 + .5 = .65 \\ \text{Prob}\{Y = 0\} &= .25 + .15 = .4 \\ \text{Prob}\{Y = 1\} &= .1 + .5 = .6 \end{aligned}$$

As a digression, if two random variables X, Y are continuous and have joint density $f(x, y)$, then marginal distributions can be computed by

$$f(x) = \int_{\mathbb{R}} f(x, y) dy$$

$$f(y) = \int_{\mathbb{R}} f(x, y) dx$$

8.7 Conditional probability distributions

Conditional probabilities are defined according to

$$\text{Prob}\{A \mid B\} = \frac{\text{Prob}\{A \cap B\}}{\text{Prob}\{B\}}$$

where A, B are two events.

For a pair of discrete random variables, we have the **conditional distribution**

$$\text{Prob}\{X = i | Y = j\} = \frac{f_{ij}}{\sum_i f_{ij}} = \frac{\text{Prob}\{X = i, Y = j\}}{\text{Prob}\{Y = j\}}$$

where $i = 0, \ldots, I-1, \quad j = 0, \ldots, J-1.$

Note that

$$\sum_i \text{Prob}\{X = i | Y = j\} = \frac{\sum_i f_{ij}}{\sum_i f_{ij}} = 1$$

The mathematics of conditional probability implies:

$$\text{Prob}\{X = i | Y = j\} = \frac{\text{Prob}\{X = i, Y = j\}}{\text{Prob}\{Y = j\}} = \frac{\text{Prob}\{Y = j | X = i\}\text{Prob}\{X = i\}}{\text{Prob}\{Y = j\}} \tag{8.4}$$

Note

Formula (8.4) is also what a Bayesian calls **Bayes' Law**.

A Bayesian statistician regards marginal probability distribution $\text{Prob}(X = i), i = 0, \ldots, I-1$ as a **prior** distribution that describes his personal subjective beliefs about X.

He then interprets formula (8.4) as a procedure for constructing a **posterior** distribution that describes how he would revise his subjective beliefs after observing that Y equals j.

For the joint distribution (8.3)

$$\text{Prob}\{X = 0 | Y = 1\} = \frac{.1}{.1 + .5} = \frac{.1}{.6}$$

8.8 Transition probability matrix

Consider the following joint probability distribution of two random variables.

Let X, Y be discrete random variables with joint distribution

$$\text{Prob}\{X = i, Y = j\} = \rho_{ij}$$

where $i = 0, \ldots, I-1; j = 0, \ldots, J-1$ and

$$\sum_i \sum_j \rho_{ij} = 1, \quad \rho_{ij} \geqslant 0.$$

An associated conditional distribution is

$$\text{Prob}\{Y = j | X = i\} = \frac{\rho_{ij}}{\sum_j \rho_{ij}} = \frac{\text{Prob}\{Y = j, X = i\}}{\text{Prob}\{X = i\}}$$

We can define a transition probability matrix P with i, j component

$$p_{ij} = \text{Prob}\{Y = j | X = i\} = \frac{\rho_{ij}}{\sum_j \rho_{ij}}$$

where

$$\begin{bmatrix} p_{00} & p_{01} \\ p_{10} & p_{11} \end{bmatrix}$$

The first row is the probability that $Y = j, j = 0, 1$ conditional on $X = 0$.

The second row is the probability that $Y = j, j = 0, 1$ conditional on $X = 1$.

Note that

- $\sum_j p_{ij} = \frac{\sum_j \rho_{ij}}{\sum_j \rho_{ij}} = 1$, so each row of the transition matrix P is a probability distribution (not so for each column).

8.9 Application: forecasting a time series

Suppose that there are two time periods.

- $t = 0$ "today"
- $t = 1$ "tomorrow"

Let $X(0)$ be a random variable to be realized at $t = 0$, $X(1)$ be a random variable to be realized at $t = 1$.

Suppose that

$$\text{Prob}\{X(0) = i, X(1) = j\} = f_{ij} \geq 0, \quad i = 0, \cdots, I-1, \quad j = 0, \cdots, J-1$$
$$\sum_i \sum_j f_{ij} = 1$$

f_{ij} is a joint distribution over $[X(0), X(1)]$.

A conditional distribution is

$$\text{Prob}\{X(1) = j | X(0) = i\} = \frac{f_{ij}}{\sum_j f_{ij}}$$

This formula is a workhorse for applied economic forecasters.

8.10 Statistical independence

Random variables X and Y are statistically **independent** if

$$\text{Prob}\{X = i, Y = j\} = f_i g_j$$

where

$$\text{Prob}\{X = i\} = f_i \geq 0, \quad \sum_i f_i = 1$$
$$\text{Prob}\{Y = j\} = g_j \geq 0, \quad \sum_j g_j = 1$$

Conditional distributions are

$$\text{Prob}\{X = i|Y = j\} = \frac{f_i g_j}{\sum_i f_i g_j} = \frac{f_i g_j}{g_j} = f_i$$
$$\text{Prob}\{Y = j|X = i\} = \frac{f_i g_j}{\sum_j f_i g_j} = \frac{f_i g_j}{f_i} = g_j$$

8.11 Means and variances

The mean and variance of a discrete random variable X are

$$\mu_X \equiv \mathbb{E}[X] = \sum_k k\text{Prob}\{X = k\}$$
$$\sigma_X^2 \equiv \mathbb{D}[X] = \sum_k (k - \mathbb{E}[X])^2 \text{Prob}\{X = k\}$$

A continuous random variable having density $f_X(x)$ has mean and variance

$$\mu_X \equiv \mathbb{E}[X] = \int_{-\infty}^{\infty} x f_X(x) dx$$
$$\sigma_X^2 \equiv \mathbb{D}[X] = \text{E}\left[(X - \mu_X)^2\right] = \int_{-\infty}^{\infty} (x - \mu_X)^2 f_X(x) dx$$

8.12 Matrix representations of some bivariate distributions

Let's use matrices to represent a joint distribution, conditional distribution, marginal distribution, and the mean and variance of a bivariate random variable.

The table below illustrates a probability distribution for a bivariate random variable.

$$F = [f_{ij}] = \begin{bmatrix} 0.3 & 0.2 \\ 0.1 & 0.4 \end{bmatrix}$$

Marginal distributions are

$$\text{Prob}(X = i) = \sum_j f_{ij} = u_i$$

$$\text{Prob}(Y = j) = \sum_i f_{ij} = v_j$$

Let's write some Python code that lets us draw some long samples and compute relative frequencies.

The code lets us check whether the "sampling" distribution agrees with the "population" distribution – confirming that the population distribution correctly tells us the relative frequencies that we should expect in a large sample.

```
# specify parameters
xs = np.array([0, 1])
ys = np.array([10, 20])
f = np.array([[0.3, 0.2], [0.1, 0.4]])
f_cum = np.cumsum(f)

# draw random numbers
```

(continues on next page)

(continued from previous page)

```
p = rng.random(1_000_000)
x = np.vstack([xs[1]*np.ones(p.shape), ys[1]*np.ones(p.shape)])
# map to the bivariate distribution

x[0, p < f_cum[2]] = xs[1]
x[1, p < f_cum[2]] = ys[0]

x[0, p < f_cum[1]] = xs[0]
x[1, p < f_cum[1]] = ys[1]

x[0, p < f_cum[0]] = xs[0]
x[1, p < f_cum[0]] = ys[0]
print(x)
```

```
[[ 1.  0.  0. ...  0.  0.  0.]
 [20. 10. 10. ... 10. 10. 20.]]
```

Note

To generate random draws from the joint distribution F, we use the inverse CDF technique described in *this companion lecture*.

```
# marginal distribution
xp = np.sum(x[0, :] == xs[0])/1_000_000
yp = np.sum(x[1, :] == ys[0])/1_000_000

# print output
print("marginal distribution for x")
xmtb = pt.PrettyTable()
xmtb.field_names = ['x_value', 'x_prob']
xmtb.add_row([xs[0], xp])
xmtb.add_row([xs[1], 1-xp])
print(xmtb)

print("\nmarginal distribution for y")
ymtb = pt.PrettyTable()
ymtb.field_names = ['y_value', 'y_prob']
ymtb.add_row([ys[0], yp])
ymtb.add_row([ys[1], 1-yp])
print(ymtb)
```

```

+---------+--------------------+---------------------+
```

Let's calculate population marginal and conditional probabilities using matrix algebra.

$$
\begin{bmatrix}
 & \vdots & y_1 & y_2 & \vdots & x \\
\cdots & \vdots & \cdots & \cdots & \vdots & \cdots \\
x_1 & \vdots & 0.3 & 0.2 & \vdots & 0.5 \\
x_2 & \vdots & 0.1 & 0.4 & \vdots & 0.5 \\
\cdots & \vdots & \cdots & \cdots & \vdots & \cdots \\
y & \vdots & 0.4 & 0.6 & \vdots & 1
\end{bmatrix}
$$

$\Longrightarrow$

(1) Marginal distribution:

$$\begin{bmatrix} var & \vdots & var_1 & var_2 \\ \cdots & \vdots & \cdots & \cdots \\ x & \vdots & 0.5 & 0.5 \\ \cdots & \vdots & \cdots & \cdots \\ y & \vdots & 0.4 & 0.6 \end{bmatrix}$$

(2) Conditional distribution:

$$\begin{bmatrix} x & \vdots & x_1 & x_2 \\ \cdots\cdots & \vdots & \cdots\cdots & \cdots\cdots \\ y = y_1 & \vdots & \frac{0.3}{0.4} = 0.75 & \frac{0.1}{0.4} = 0.25 \\ \cdots\cdots & \vdots & \cdots\cdots & \cdots\cdots \\ y = y_2 & \vdots & \frac{0.2}{0.6} \approx 0.33 & \frac{0.4}{0.6} \approx 0.67 \end{bmatrix}$$

$$\begin{bmatrix} y & \vdots & y_1 & y_2 \\ \cdots\cdots & \vdots & \cdots\cdots & \cdots\cdots \\ x = x_1 & \vdots & \frac{0.3}{0.5} = 0.6 & \frac{0.2}{0.5} = 0.4 \\ \cdots\cdots & \vdots & \cdots\cdots & \cdots\cdots \\ x = x_2 & \vdots & \frac{0.1}{0.5} = 0.2 & \frac{0.4}{0.5} = 0.8 \end{bmatrix}$$

These population objects closely resemble the sample counterparts computed above.

Let's wrap some of the functions we have used in a Python class that will let us generate and sample from a discrete bivariate joint distribution.

```
class discrete_bijoint:

    def __init__(self, f, xs, ys):
        '''initialization
        -----------------
        parameters:
        f: the bivariate joint probability matrix
        xs: values of x vector
        ys: values of y vector
        '''
        self.f, self.xs, self.ys = f, xs, ys

    def joint_tb(self):
        '''print the joint distribution table'''
        xs = self.xs
        ys = self.ys
        f = self.f
        jtb = pt.PrettyTable()
        jtb.field_names = ['x_value/y_value', *ys, 'marginal sum for x']
        for i in range(len(xs)):
            jtb.add_row([xs[i], *f[i, :], np.sum(f[i, :])])
        jtb.add_row(['marginal_sum for y', *np.sum(f, 0), np.sum(f)])
        print("\nThe joint probability distribution for x and y\n", jtb)
        self.jtb = jtb

    def draw(self, n):
        '''draw random numbers
        ----------------------
        parameters:
        n: number of random numbers to draw
        '''
```

(continues on next page)

(continued from previous page)

```
        xs = self.xs
        ys = self.ys
        f_cum = np.cumsum(self.f)
        p = rng.random(n)
        x = np.empty([2, p.shape[0]])
        lf = len(f_cum)
        lx = len(xs)-1
        ly = len(ys)-1
        for i in range(lf):
            x[0, p < f_cum[lf-1-i]] = xs[lx]

            if i < len(ys):
                ymtb.add_row([ys[i], ymp[i]])
        xmtb.add_row(['sum', np.sum(xmp)])
        ymtb.add_row(['sum', np.sum(ymp)])
        print("\nmarginal distribution for x\n", xmtb)
        print("\nmarginal distribution for y\n", ymtb)

        self.xmp = xmp
        self.ymp = ymp

    def cond_dist(self):
        '''conditional distribution'''
        x = self.x
        xs = self.xs
        ys = self.ys
        n = self.n
        xcp = np.empty([len(ys), len(xs)])
        ycp = np.empty([len(xs), len(ys)])
        for i in range(max(len(ys), len(xs))):
            if i < len(ys):
                xi = x[0, x[1, :] == ys[i]]
```

(continues on next page)

(continued from previous page)

```
                idx = xi.reshape(len(xi), 1) == xs.reshape(1, len(xs))
                xcp[i, :] = np.sum(idx, 0)/len(xi)
            if i < len(xs):
                yi = x[1, x[0, :] == xs[i]]
                idy = yi.reshape(len(yi), 1) == ys.reshape(1, len(ys))
                ycp[i, :] = np.sum(idy, 0)/len(yi)

        # print output
        xctb = pt.PrettyTable()
        yctb = pt.PrettyTable()
        xctb.field_names = ['x_value', *xs, 'sum']
        yctb.field_names = ['y_value', *ys, 'sum']
        for i in range(max(len(xs), len(ys))):
            if i < len(ys):
                xctb.add_row([ys[i], *xcp[i], np.sum(xcp[i])])
            if i < len(xs):
                yctb.add_row([xs[i], *ycp[i], np.sum(ycp[i])])
        print("\nconditional distribution for x\n", xctb)
        print("\nconditional distribution for y\n", yctb)

        self.xcp = xcp
        self.xyp = ycp
```

Let's apply our code to some examples.

8.12.1 Numerical examples

Example 1

```
# joint
d = discrete_bijoint(f, xs, ys)
d.joint_tb()
```

```

8.13 A continuous bivariate random vector

A two-dimensional Gaussian distribution has joint density

$$f(x,y) = (2\pi\sigma_1\sigma_2\sqrt{1-\rho^2})^{-1} \exp\left[-\frac{1}{2(1-\rho^2)}\left(\frac{(x-\mu_1)^2}{\sigma_1^2} - \frac{2\rho(x-\mu_1)(y-\mu_2)}{\sigma_1\sigma_2} + \frac{(y-\mu_2)^2}{\sigma_2^2}\right)\right]$$

We start with a bivariate normal distribution pinned down by

$$\mu = \begin{bmatrix} 0 \\ 5 \end{bmatrix}, \quad \Sigma = \begin{bmatrix} 5 & .2 \\ .2 & 1 \end{bmatrix}$$

```
# define the joint probability density function
def func(x, y, μ1=0, μ2=5, σ1=np.sqrt(5), σ2=np.sqrt(1), ρ=.2/np.sqrt(5*1)):
    A = (2 * np.pi * σ1 * σ2 * np.sqrt(1 - ρ**2))**(-1)
    B = -1 / 2 / (1 - ρ**2)
    C1 = (x - μ1)**2 / σ1**2
```

(continues on next page)

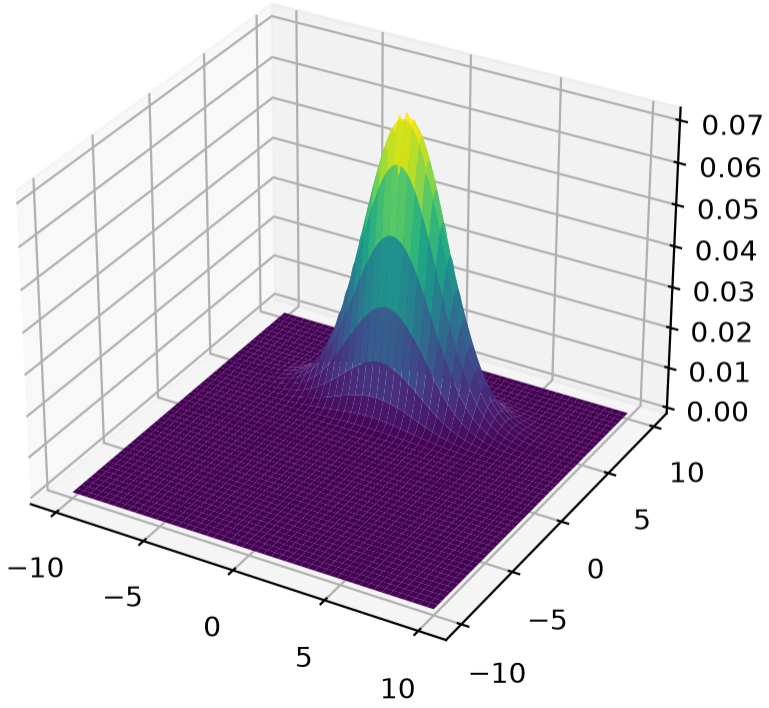
(continued from previous page)

```
    C2 = 2 * ρ * (x - μ1) * (y - μ2) / σ1 / σ2
    C3 = (y - μ2)**2 / σ2**2
    return A * np.exp(B * (C1 - C2 + C3))
```

```
μ1 = 0
μ2 = 5
σ1 = np.sqrt(5)
σ2 = np.sqrt(1)
ρ = .2 / np.sqrt(5 * 1)
```

```
x = np.linspace(-10, 10, 1_000)
y = np.linspace(-10, 10, 1_000)
x_mesh, y_mesh = np.meshgrid(x, y, indexing="ij")
```

8.13.1 Joint, marginal, and conditional distributions

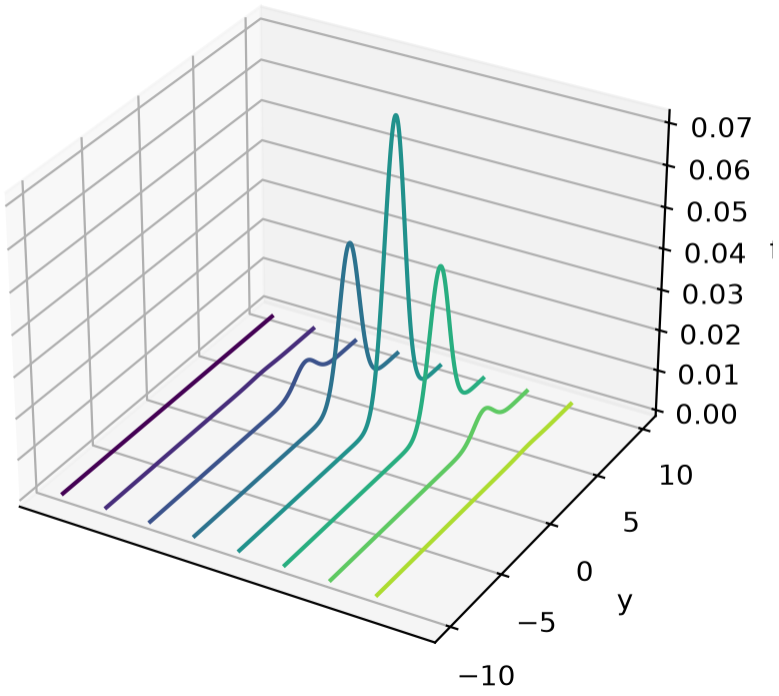


Joint distribution

Let's plot the **population** joint density.

```
# %matplotlib notebook

fig = plt.figure()
ax = plt.axes(projection='3d')

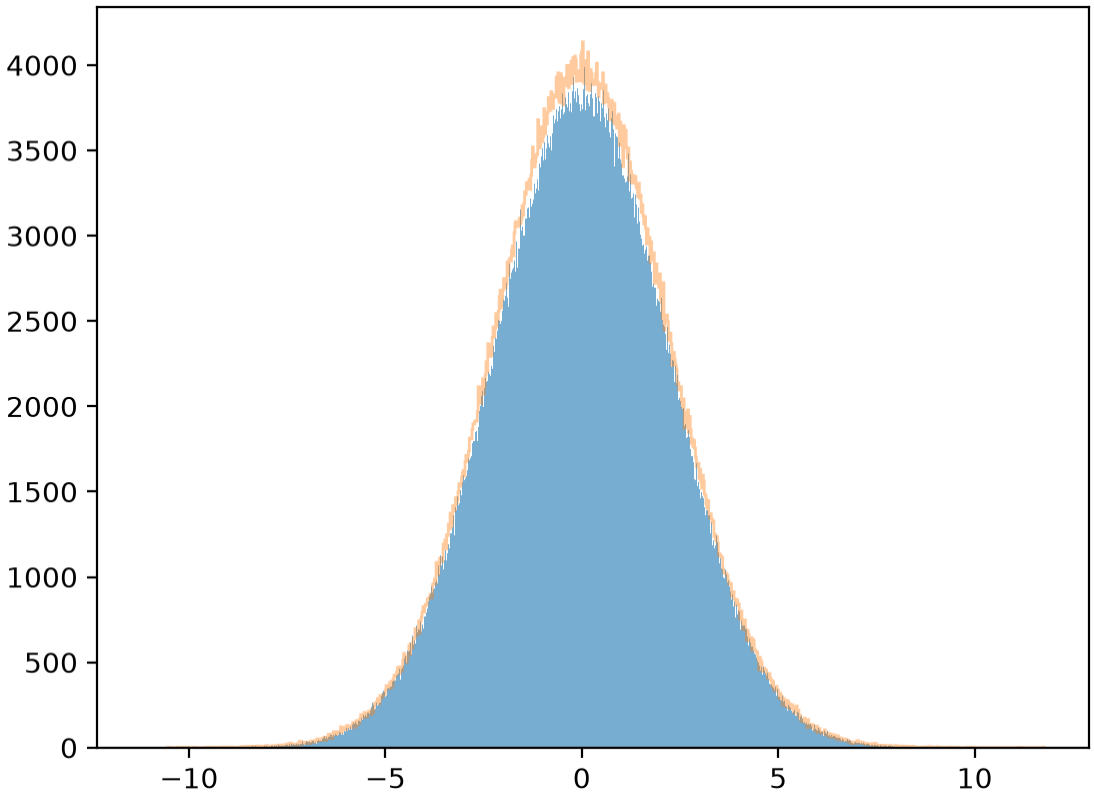


surf = ax.plot_surface(x_mesh, y_mesh, func(x_mesh, y_mesh), cmap='viridis')
plt.show()
```

```
# %matplotlib notebook

fig = plt.figure()
ax = plt.axes(projection='3d')

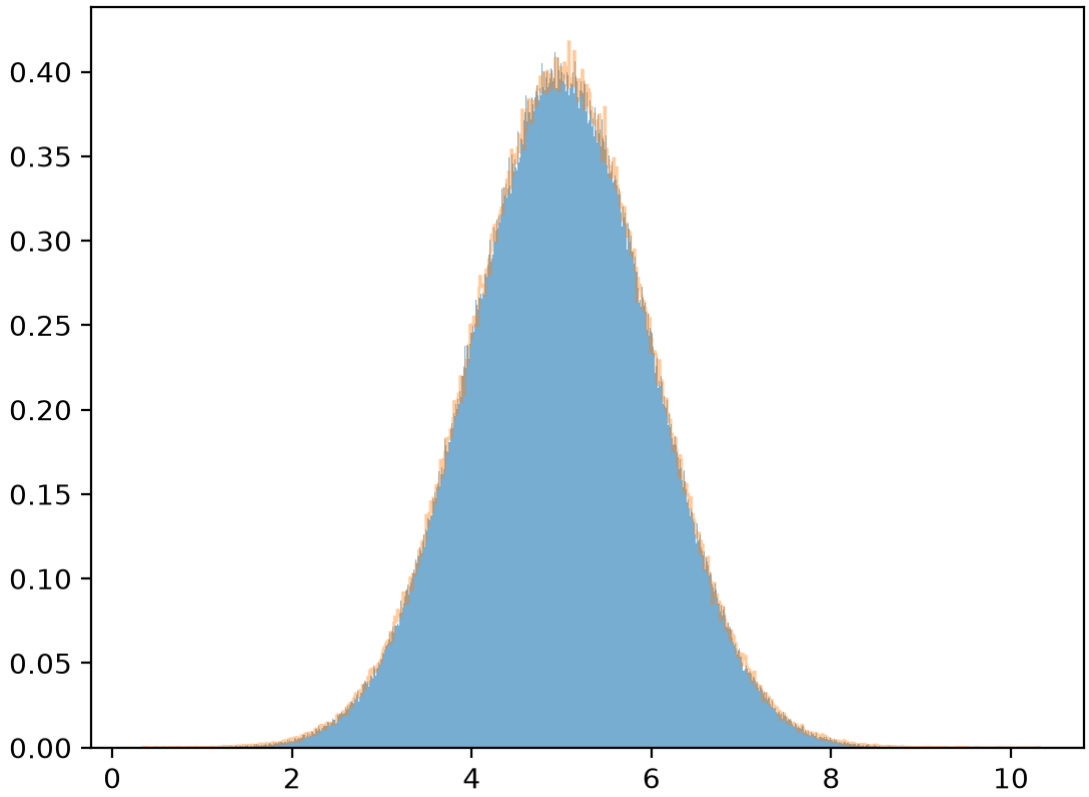
curve = ax.contour(x_mesh, y_mesh, func(x_mesh, y_mesh), zdir='x')
plt.ylabel('y')
ax.set_zlabel('f')
ax.set_xticks([])
plt.show()
```



Next we can use a built-in `numpy` function to draw random samples, then calculate a **sample** marginal distribution from the sample mean and variance.

```
μ= np.array([0, 5])
σ= np.array([[5, .2], [.2, 1]])
n = 1_000_000
data = rng.multivariate_normal(μ, σ, n)
x = data[:, 0]
y = data[:, 1]
```

Marginal distribution



```
plt.hist(x, bins=1_000, alpha=0.6)
μx_hat, σx_hat = np.mean(x), np.std(x)
print(μx_hat, σx_hat)
x_sim = rng.normal(μx_hat, σx_hat, 1_000_000)
plt.hist(x_sim, bins=1_000, alpha=0.4, histtype="step")
plt.show()
```

```
-0.002835018476282638 2.237281153907461
```

```
plt.hist(y, bins=1_000, density=True, alpha=0.6)
μy_hat, σy_hat = np.mean(y), np.std(y)
print(μy_hat, σy_hat)
y_sim = rng.normal(μy_hat, σy_hat, 1_000_000)
plt.hist(y_sim, bins=1_000, density=True, alpha=0.4, histtype="step")
plt.show()
```

```
4.998242637632656 0.9993565018250069
```

Conditional distribution

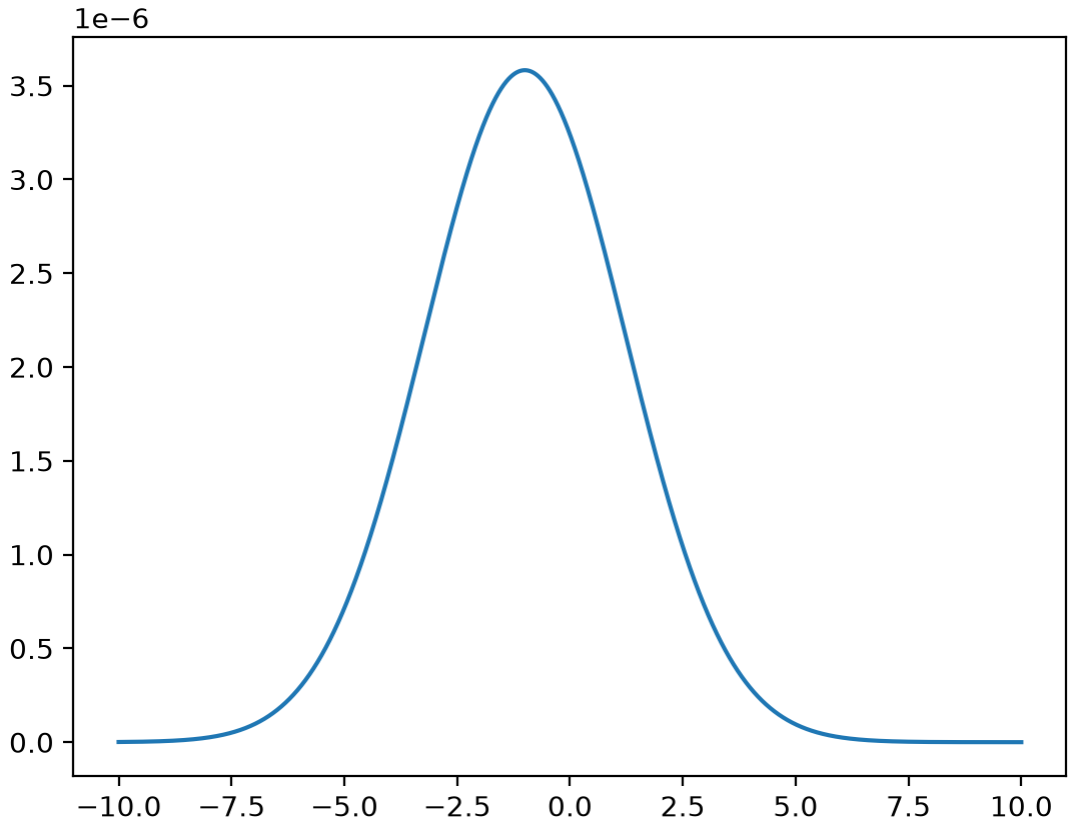
For a bivariate normal population distribution, the conditional distributions are also normal:

$$X \mid Y = y \sim \mathbb{N}\left[\mu_X + \rho\sigma_X \frac{y - \mu_Y}{\sigma_Y}, \sigma_X^2(1-\rho^2)\right]$$
$$Y \mid X = x \sim \mathbb{N}\left[\mu_Y + \rho\sigma_Y \frac{x - \mu_X}{\sigma_X}, \sigma_Y^2(1-\rho^2)\right]$$

Note

Please see this *quantecon lecture* for more details.

Let's approximate the joint density by discretizing and mapping the approximating joint density into a matrix.



On an evenly spaced grid, we can approximate the conditional distribution by assigning probability weights proportional to a slice of the joint density.

For fixed y, this means that

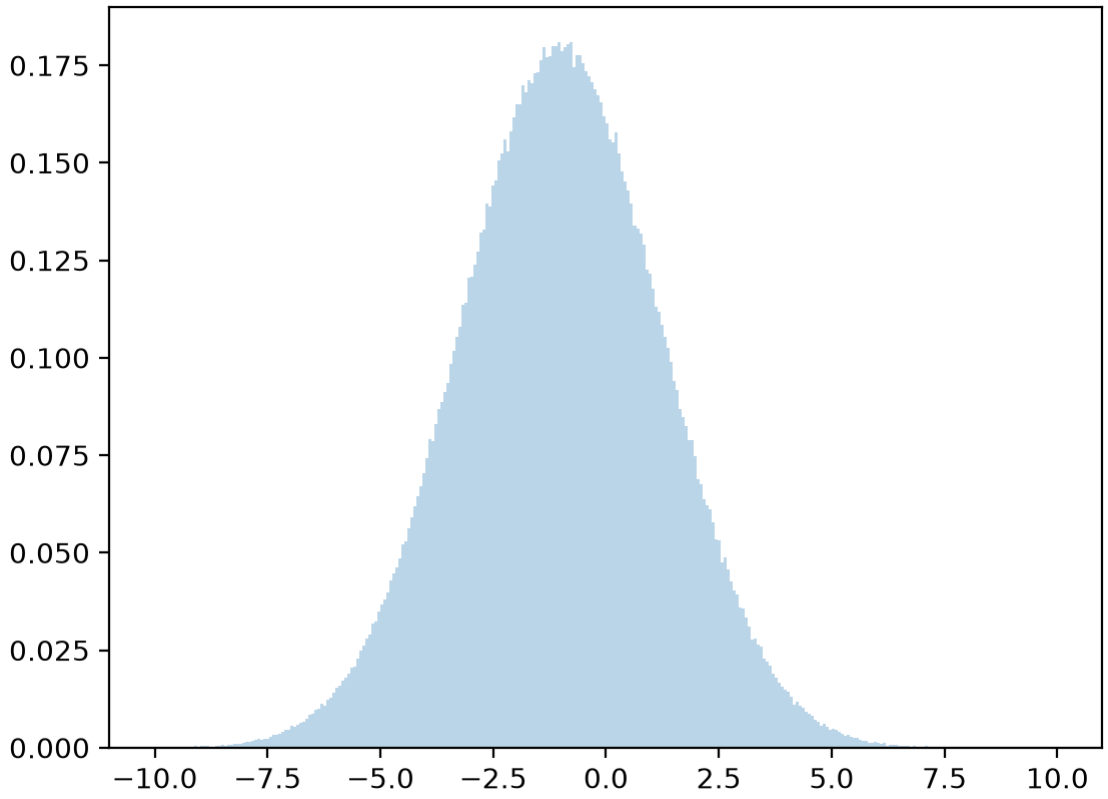
$$z_i \equiv \frac{f(x_i, y)}{\sum_k f(x_k, y)}$$

Fix $y = 0$.

```
# discretized conditional distribution of X given Y = 0
x = np.linspace(-10, 10, 1_000_000)
z = func(x, y=0) / np.sum(func(x, y=0))
plt.plot(x, z)
plt.show()
```

The conditional mean and variance are then approximated by

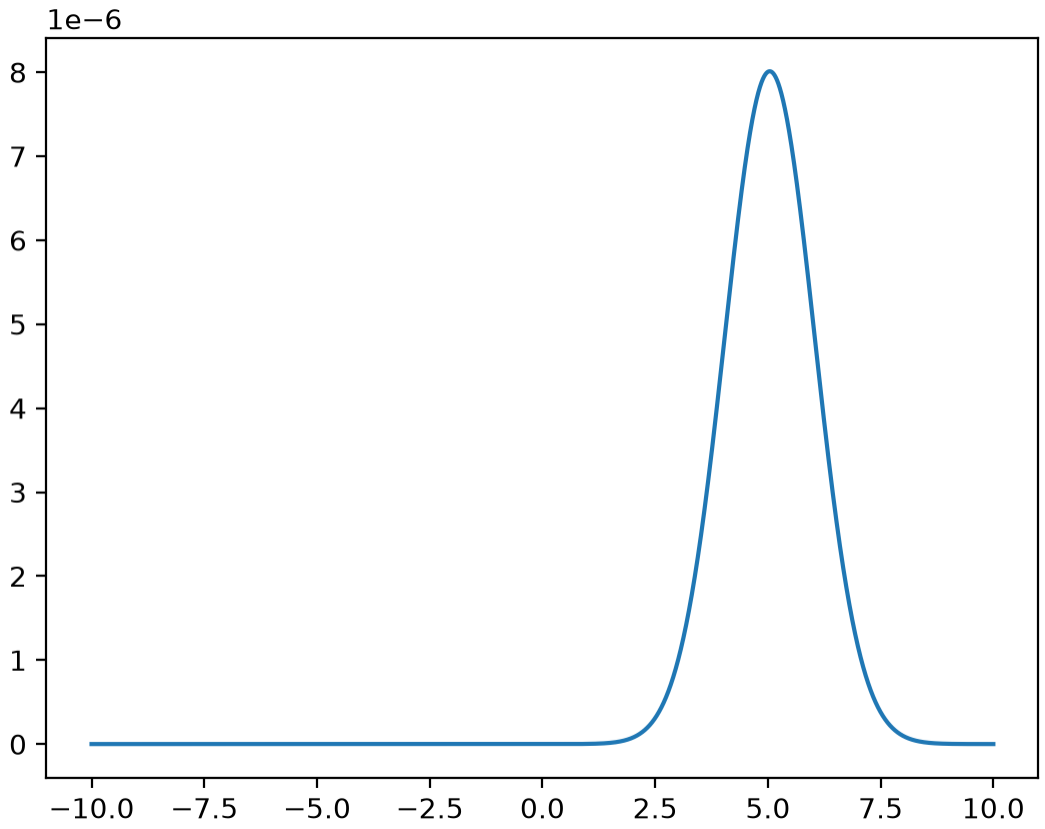
$$\mathbb{E}\left[X|Y=y\right] \approx \sum_i x_i z_i$$



$$\mathbb{D}\left[X|Y=y\right] \approx \sum_i \left(x_i - \mu_{X|Y=y}\right)^2 z_i$$

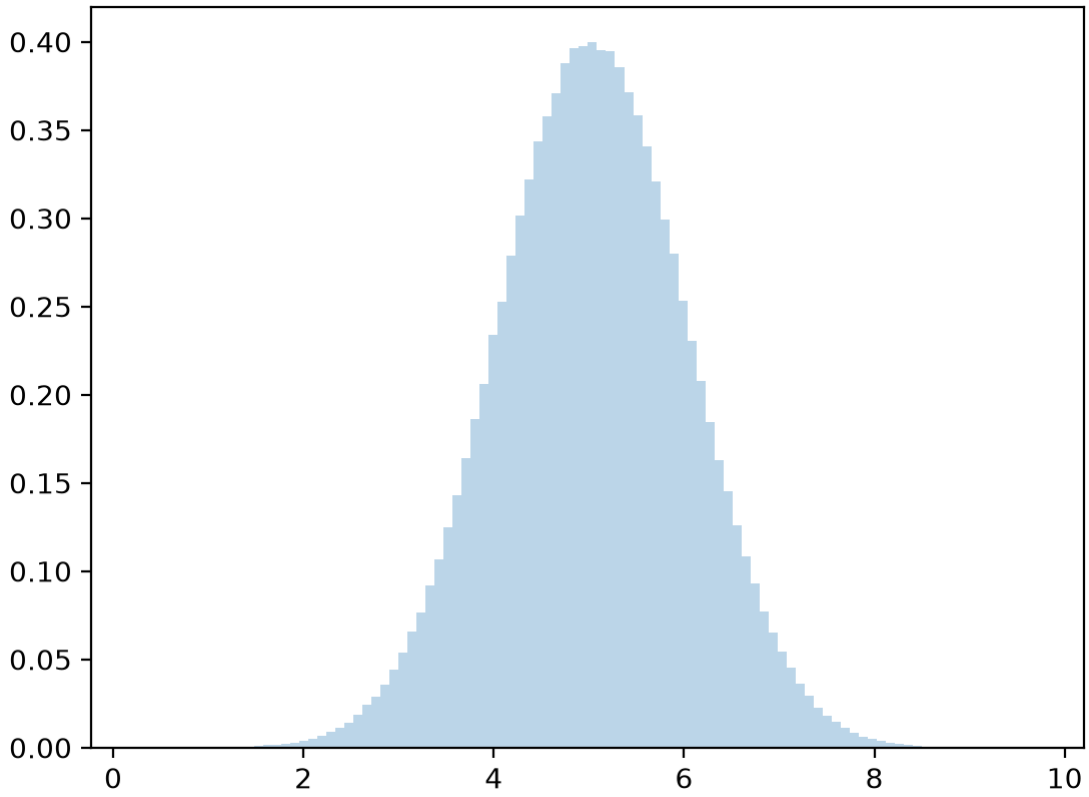
Let's draw from a normal distribution with above mean and variance and check how accurate our approximation is.

```
# discretized mean
μx = np.dot(x, z)



# discretized standard deviation
σx = np.sqrt(np.dot((x - μx)**2, z))

# sample
zz = rng.normal(μx, σx, 1_000_000)
plt.hist(zz, bins=300, density=True, alpha=0.3, range=[-10, 10])
plt.show()
```



Fix $x = 1$.

```
y = np.linspace(-10, 10, 1_000_000)
z = func(x=1, y=y) / np.sum(func(x=1, y=y))
plt.plot(y,z)
plt.show()
```

```
# discretized conditional mean and standard deviation
μy = np.dot(y,z)
σy = np.sqrt(np.dot((y - μy)**2, z))

# sample
zz = rng.normal(μy, σy, 1_000_000)
plt.hist(zz, bins=100, density=True, alpha=0.3)
plt.show()
```

We compare with the analytically computed parameters and note that they are close.

```
print(μx, σx)
print(μ1 + ρ * σ1 * (0 - μ2) / σ2, np.sqrt(σ1**2 * (1 - ρ**2)))

print(μy, σy)
print(μ2 + ρ * σ2 * (1 - μ1) / σ1, np.sqrt(σ2**2 * (1 - ρ**2)))
```

```
-0.9997518414498444 2.2265841331697698
-1.0 2.227105745132009
5.039998363587647 0.9959878931873033

```

8.14 Sum of two independently distributed random variables

Let X, Y be two independent discrete random variables that take values in $\bar{X}, \bar{Y}$, respectively.

Define a new random variable $Z = X + Y$.

Evidently, Z takes values from $\bar{Z}$ defined as follows:

$$\begin{aligned} \bar{X} &= \{0, 1, \ldots, I-1\}; \qquad & f_i &= \text{Prob}\{X = i\} \\ \bar{Y} &= \{0, 1, \ldots, J-1\}; \qquad & g_j &= \text{Prob}\{Y = j\} \\ \bar{Z} &= \{0, 1, \ldots, I+J-2\}; \qquad & h_k &= \text{Prob}\{X + Y = k\} \end{aligned}$$

Independence of X and Y implies that

$$h_k = \text{Prob}\{X = 0, Y = k\} + \text{Prob}\{X = 1, Y = k-1\} + ... + \text{Prob}\{X = k, Y = 0\}$$
$$h_k = f_0 g_k + f_1 g_{k-1} + ... + f_{k-1} g_1 + f_k g_0 \qquad \text{for} \quad k = 0, 1, ..., I + J - 2$$

Thus, we have:

$$h_k = \sum_{i=0}^{k} f_i g_{k-i} \equiv f * g$$

where $f * g$ denotes the **convolution** of the f and g sequences.

Similarly, for two random variables X, Y with densities f_X, g_Y, the density of $Z = X + Y$ is

$$f_Z(z) = \int_{-\infty}^{\infty} f_X(x) f_Y(z - x) dx \equiv f_X * g_Y$$

where $f_X * g_Y$ denotes the **convolution** of the f_X and g_Y functions.

8.15 Coupling

Start with a joint distribution

$$f_{ij} = \text{Prob}\{X = i, Y = j\}$$
$$i = 0, \cdots, I - 1$$
$$j = 0, \cdots, J - 1$$
$$\text{stacked to an } I \times J \text{ matrix}$$
$$e.g. \quad I = 2, J = 2$$

where

$$\begin{bmatrix} f_{00} & f_{01} \\ f_{10} & f_{11} \end{bmatrix}$$

From the joint distribution, we have shown above that we obtain **unique** marginal distributions.

Now we'll try to go in a reverse direction.

We'll find that from two marginal distributions we can usually construct more than one joint distribution that satisfies these marginals.

Each of these joint distributions is called a **coupling** of the two marginal distributions.

Let's start with marginal distributions

$$\text{Prob}\{X = i\} = \sum_j f_{ij} = \mu_i, i = 0, \cdots, I - 1$$
$$\text{Prob}\{Y = j\} = \sum_i f_{ij} = \nu_j, j = 0, \cdots, J - 1$$

Given two marginal distributions, μ for X and ν for Y, a joint distribution f_{ij} is said to be a **coupling** of μ and ν.

Consider the following bivariate example.

$$\text{Prob}\{X = 0\} = 1 - q = \mu_0$$
$$\text{Prob}\{X = 1\} = q = \mu_1$$
$$\text{Prob}\{Y = 0\} = 1 - r = \nu_0$$
$$\text{Prob}\{Y = 1\} = r = \nu_1$$
$$\text{where } 0 \leq q \leq r \leq 1$$

We construct two couplings.

The first coupling of our two marginal distributions is the joint distribution

$$f_{ij} = \begin{bmatrix} (1-q)(1-r) & (1-q)r \\ q(1-r) & qr \end{bmatrix}$$

To verify that it is a coupling, we check that

$$\begin{aligned} (1-q)(1-r) + (1-q)r + q(1-r) + qr &= 1 \\ \mu_0 = (1-q)(1-r) + (1-q)r &= 1-q \\ \mu_1 = q(1-r) + qr &= q \\ \nu_0 = (1-q)(1-r) + (1-r)q &= 1-r \\ \nu_1 = r(1-q) + qr &= r \end{aligned}$$

A second coupling of our two marginal distributions is the joint distribution

$$f_{ij} = \begin{bmatrix} (1-r) & r-q \\ 0 & q \end{bmatrix}$$

To verify that this is a coupling, note that

$$\begin{aligned} 1 - r + r - q + q &= 1 \\ \mu_0 &= 1-q \\ \mu_1 &= q \\ \nu_0 &= 1-r \\ \nu_1 &= r \end{aligned}$$

Thus, our two proposed joint distributions have the same marginal distributions.

But the joint distributions differ.

Thus, multiple joint distributions $[f_{ij}]$ can have the same marginals.

Couplings are important in optimal transport problems and in Markov processes. Please see this *lecture about optimal transport*.

8.16 Copula functions

Suppose that $X_1, X_2, \ldots, X_N$ are N random variables and that

- their marginal distributions are $F_1(x_1), F_2(x_2), \ldots, F_N(x_N)$, and
- their joint distribution is $H(x_1, x_2, \ldots, x_N)$

Then there exists a **copula function** $C(\cdot)$ that verifies

$$H(x_1, x_2, \ldots, x_N) = C(F_1(x_1), F_2(x_2), \ldots, F_N(x_N)).$$

If the marginal distributions are continuous, then the copula is unique.

In that case, we can recover it from the marginal inverses:

$$C(u_1, u_2, \ldots, u_N) = H(F_1^{-1}(u_1), F_2^{-1}(u_2), \ldots, F_N^{-1}(u_N))$$

When marginal distributions are not continuous, one uses generalized inverses, and the copula is uniquely determined only on $\text{Ran}(F_1) \times \cdots \times \text{Ran}(F_N)$.

In a reverse direction of logic, given univariate **marginal distributions** $F_1(x_1), F_2(x_2), \ldots, F_N(x_N)$ and a copula function $C(\cdot)$, the function $H(x_1, x_2, \ldots, x_N) = C(F_1(x_1), F_2(x_2), \ldots, F_N(x_N))$ is a **coupling** of $F_1(x_1), F_2(x_2), \ldots, F_N(x_N)$.

Thus, for given marginal distributions, we can use a copula function to determine a joint distribution when the associated univariate random variables are not independent.

Copula functions are often used to characterize **dependence** of random variables.

8.16.1 Bivariate examples with discrete and continuous distributions

Discrete marginal distribution

As mentioned above, for two given marginal distributions there can be more than one coupling.

For example, consider two random variables X, Y with distributions

$$\begin{aligned}\text{Prob}(X = 0) &= 0.6,\\ \text{Prob}(X = 1) &= 0.4,\\ \text{Prob}(Y = 0) &= 0.3,\\ \text{Prob}(Y = 1) &= 0.7,\end{aligned}$$

For these two random variables there can be more than one coupling.

Let's first generate X and Y.

```
μ = np.array([0.6, 0.4])
ν = np.array([0.3, 0.7])

# number of draws
draws = 1_000_000

# generate independent draws from uniform distribution for X and Y
p_x = rng.random(draws)
p_y = rng.random(draws)

# generate draws of X and Y via independent uniform draws
x = np.ones(draws)
y = np.ones(draws)
x[p_x <= μ[0]] = 0
x[p_x > μ[0]] = 1
y[p_y <= ν[0]] = 0
y[p_y > ν[0]] = 1
```

```
# calculate parameters from draws
q_hat = sum(x[x == 1])/draws
r_hat = sum(y[y == 1])/draws

# print output
print("distribution for x")
xmtb = pt.PrettyTable()
xmtb.field_names = ['x_value', 'x_prob']
xmtb.add_row([0, 1-q_hat])
xmtb.add_row([1, q_hat])
print(xmtb)
```

(continues on next page)

(continued from previous page)

```
print("distribution for y")
ymtb = pt.PrettyTable()
ymtb.field_names = ['y_value', 'y_prob']
ymtb.add_row([0, 1-r_hat])
ymtb.add_row([1, r_hat])
print(ymtb)
```

```
distribution for x
+---------+----------+
| x_value |  x_prob  |
+---------+----------+
|    0    | 0.599645 |
|    1    | 0.400355 |
+---------+----------+
distribution for y
+---------+---------------------+
| y_value |        y_prob       |
+---------+---------------------+
|    0    | 0.30042599999999997 |
|    1    |       0.699574      |
+---------+---------------------+
```

Let's now take our two marginal distributions, one for X, the other for Y, and construct two distinct couplings.

For the first joint distribution:

$$\text{Prob}(X = i, Y = j) = f_{ij}$$

where

$$[f_{ij}] = \begin{bmatrix} 0.18 & 0.42 \\ 0.12 & 0.28 \end{bmatrix}$$

Let's use Python to construct this joint distribution and then verify that its marginal distributions are what we want.

```
# define parameters
f1 = np.array([[0.18, 0.42], [0.12, 0.28]])
f1_cum = np.cumsum(f1)

# number of draws
draws1 = 1_000_000

# generate draws from uniform distribution
p = rng.random(draws1)

# generate draws of first coupling via uniform distribution
c1 = np.vstack([np.ones(draws1), np.ones(draws1)])
# X=0, Y=0
c1[0, p <= f1_cum[0]] = 0
c1[1, p <= f1_cum[0]] = 0
# X=0, Y=1
c1[0, (p > f1_cum[0])*(p <= f1_cum[1])] = 0
c1[1, (p > f1_cum[0])*(p <= f1_cum[1])] = 1
# X=1, Y=0
c1[0, (p > f1_cum[1])*(p <= f1_cum[2])] = 1
c1[1, (p > f1_cum[1])*(p <= f1_cum[2])] = 0
# X=1, Y=1
```

(continues on next page)

(continued from previous page)

```
c1[0, (p > f1_cum[2])*(p <= f1_cum[3])] = 1
c1[1, (p > f1_cum[2])*(p <= f1_cum[3])] = 1
```

```
# calculate parameters from draws
f1_00 = sum((c1[0, :] == 0)*(c1[1, :] == 0))/draws1
f1_01 = sum((c1[0, :] == 0)*(c1[1, :] == 1))/draws1
f1_10 = sum((c1[0, :] == 1)*(c1[1, :] == 0))/draws1
f1_11 = sum((c1[0, :] == 1)*(c1[1, :] == 1))/draws1

# print output of first joint distribution
print("first joint distribution for c1")
c1_mtb = pt.PrettyTable()
c1_mtb.field_names = ['c1_x_value', 'c1_y_value', 'c1_prob']
c1_mtb.add_row([0, 0, f1_00])
c1_mtb.add_row([0, 1, f1_01])
c1_mtb.add_row([1, 0, f1_10])
c1_mtb.add_row([1, 1, f1_11])
print(c1_mtb)
```

```
first joint distribution for c1
+------------+------------+----------+
| c1_x_value | c1_y_value | c1_prob  |

+------------+-----------+
|     0      |  0.599959 |
|     1      |  0.400041 |
+------------+-----------+
```

(continues on next page)

(continued from previous page)

```
marginal distribution for y
+------------+---------------------+
| c1_y_value |      c1_y_prob      |
+------------+---------------------+
|     0      | 0.30008900000000005 |
|     1      |       0.699911      |
+------------+---------------------+
```

Now, let's construct another joint distribution that is also a coupling of X and Y

$$[f_{ij}] = \begin{bmatrix} 0.3 & 0.3 \\ 0 & 0.4 \end{bmatrix}$$

```
# define parameters
f2 = np.array([[0.3, 0.3], [0, 0.4]])
f2_cum = np.cumsum(f2)

# number of draws
draws2 = 1_000_000

# generate draws from uniform distribution
p = rng.random(draws2)

# generate draws of second coupling via uniform distribution
c2 = np.vstack([np.ones(draws2), np.ones(draws2)])
# X=0, Y=0
c2[0, p <= f2_cum[0]] = 0
c2[1, p <= f2_cum[0]] = 0
# X=0, Y=1
c2[0, (p > f2_cum[0])*(p <= f2_cum[1])] = 0
c2[1, (p > f2_cum[0])*(p <= f2_cum[1])] = 1
# X=1, Y=0
c2[0, (p > f2_cum[1])*(p <= f2_cum[2])] = 1
c2[1, (p > f2_cum[1])*(p <= f2_cum[2])] = 0
# X=1, Y=1
c2[0, (p > f2_cum[2])*(p <= f2_cum[3])] = 1
c2[1, (p > f2_cum[2])*(p <= f2_cum[3])] = 1
```

```
# calculate parameters from draws
f2_00 = sum((c2[0, :] == 0)*(c2[1, :] == 0))/draws2
f2_01 = sum((c2[0, :] == 0)*(c2[1, :] == 1))/draws2
f2_10 = sum((c2[0, :] == 1)*(c2[1, :] == 0))/draws2
f2_11 = sum((c2[0, :] == 1)*(c2[1, :] == 1))/draws2

# print output of second joint distribution
print("second joint distribution for c2")
c2_mtb = pt.PrettyTable()
c2_mtb.field_names = ['c2_x_value', 'c2_y_value', 'c2_prob']
c2_mtb.add_row([0, 0, f2_00])
c2_mtb.add_row([0, 1, f2_01])
c2_mtb.add_row([1, 0, f2_10])
c2_mtb.add_row([1, 1, f2_11])
print(c2_mtb)
```

```
second joint distribution for c2
+------------+------------+----------+
```

(continues on next page)

(continued from previous page)

```
| c2_x_value | c2_y_value | c2_prob  |
+------------+------------+----------+
|     0      |     0      | 0.300568 |
|     0      |     1      | 0.299249 |
|     1      |     0      |   0.0    |
|     1      |     1      | 0.400183 |
+------------+------------+----------+
```

```
# calculate parameters from draws
c2_q_hat = sum(c2[0, :] == 1)/draws2
c2_r_hat = sum(c2[1, :] == 1)/draws2

# print output
print("marginal distribution for x")
c2_x_mtb = pt.PrettyTable()
c2_x_mtb.field_names = ['c2_x_value', 'c2_x_prob']
c2_x_mtb.add_row([0, 1-c2_q_hat])
c2_x_mtb.add_row([1, c2_q_hat])
print(c2_x_mtb)

print("marginal distribution for y")
c2_ymtb = pt.PrettyTable()
c2_ymtb.field_names = ['c2_y_value', 'c2_y_prob']
c2_ymtb.add_row([0, 1-c2_r_hat])
c2_ymtb.add_row([1, c2_r_hat])
print(c2_ymtb)
```

```
marginal distribution for x
+------------+-----------+
| c2_x_value | c2_x_prob |
+------------+-----------+
|     0      |  0.599817 |
|     1      |  0.400183 |
+------------+-----------+
marginal distribution for y
+------------+--------------------+
| c2_y_value |      c2_y_prob     |
+------------+--------------------+
|     0      | 0.30056799999999995 |
|     1      |       0.699432     |
+------------+--------------------+
```

We have verified that both joint distributions, c_1 and c_2, have identical marginal distributions of X and Y, respectively.

So they are both couplings of X and Y.

8.16.2 Gaussian copula example

A **Gaussian copula** uses the bivariate normal distribution to induce dependence between arbitrary marginal distributions.

The construction has three steps:

1. Draw (Z_1, Z_2) from a bivariate standard normal with correlation ρ.
2. Apply the standard normal CDF: $U_k = \Phi(Z_k)$.
    - The pair (U_1, U_2) has uniform marginals but retains the dependence structure of (Z_1, Z_2) — this is the copula.
3. Apply the inverse CDF of any desired marginal: $X_k = F_k^{-1}(U_k)$.

The following code illustrates this with exponential marginals.

```
# Gaussian copula parameters
ρ_cop = 0.8
n_cop = 100_000

# Draw from bivariate standard normal with correlation ρ_cop
z = rng.multivariate_normal(
    [0, 0], [[1, ρ_cop], [ρ_cop, 1]], n_cop
)

# Apply normal CDF -> uniform marginals (the copula itself)
u1 = stats.norm.cdf(z[:, 0])
u2 = stats.norm.cdf(z[:, 1])

# Apply inverse CDFs of desired marginals (here: Exponential)
x1 = stats.expon.ppf(u1, scale=1.0)    # Exp with mean 1
x2 = stats.expon.ppf(u2, scale=0.5)    # Exp with mean 0.5

fig, axes = plt.subplots(1, 2, figsize=(10, 4))
axes[0].scatter(u1[:3000], u2[:3000], alpha=0.2, s=2)
axes[0].set_xlabel('$u_1$')
axes[0].set_ylabel('$u_2$')
axes[1].scatter(x1[:3000], x2[:3000], alpha=0.2, s=2)
axes[1].set_xlabel('$x_1$ (Exp, mean=1)')
axes[1].set_ylabel('$x_2$ (Exp, mean=0.5)')
plt.show()

print(f"Sample correlation of (x1, x2): {np.corrcoef(x1, x2)[0, 1]:.3f}")
print(f"Sample correlation of (u1, u2): {np.corrcoef(u1, u2)[0, 1]:.3f}")
```

```
Sample correlation of (x1, x2): 0.768
Sample correlation of (u1, u2): 0.786
```

The left panel shows the copula itself – the dependence structure in uniform coordinates, drawn from a bivariate normal with correlation $\rho = 0.8$.

The right panel shows the same dependence translated to exponential marginals.

Changing ρ controls the strength of dependence while the marginals remain unchanged.

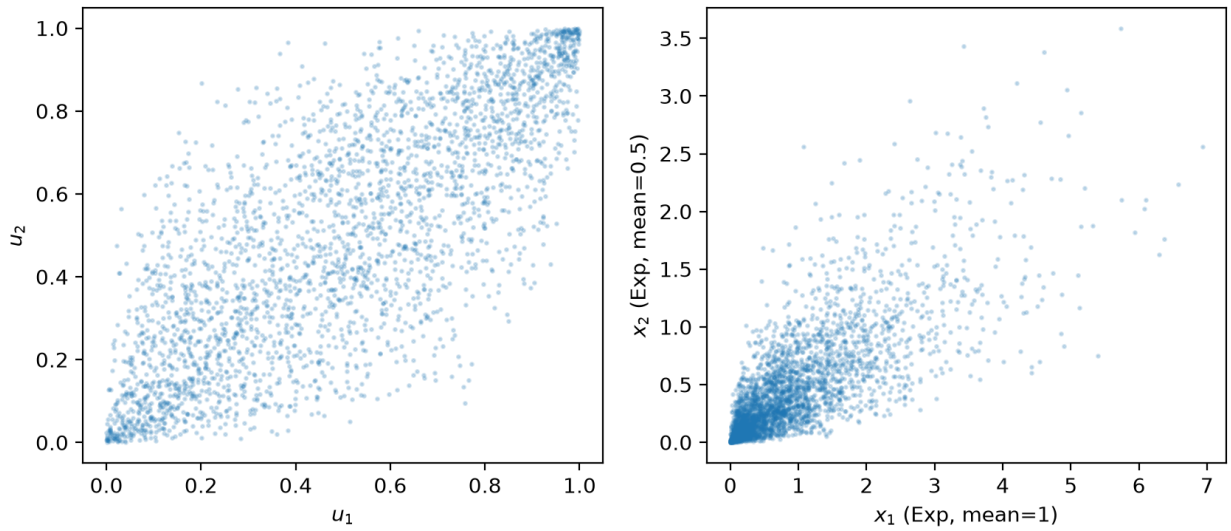

Fig. 8.1: gaussian copula with exponential marginals

8.17 Exercises

Exercise 8.17.1

Independence Test

Consider the joint distribution

$$F = \begin{bmatrix} 0.3 & 0.2 \\ 0.1 & 0.4 \end{bmatrix}$$

where $X \in \{0, 1\}$ and $Y \in \{10, 20\}$.

1. Compute the marginal distributions $\mu_i = \text{Prob}\{X = i\}$ and $\nu_j = \text{Prob}\{Y = j\}$.
2. Form the independence matrix $f_{ij}^{\perp} = \mu_i \nu_j$ (the outer product of the two marginal vectors).
3. Compare F with $f^{\perp}$ and determine whether X and Y are independent.
4. Verify your conclusion by computing $\text{Prob}\{X = 0 | Y = 10\}$ and checking whether it equals $\text{Prob}\{X = 0\}$.

Solution

Here is one solution:

```
F = np.array([[0.3, 0.2],
              [0.1, 0.4]])

μ = F.sum(axis=1)
ν = F.sum(axis=0)
print("μ (marginal of X):", μ)
print("ν (marginal of Y):", ν)

F_indep = np.outer(μ, ν)
```

```
print("\nIndependence matrix (outer product):\n", F_indep)
print("\nActual joint F:\n", F)

print("\nIndependent (F == μ times ν)?", np.allclose(F, F_indep))

prob_X0_given_Y10 = F[0, 0] / ν[0]
print(f"\nProb(X=0 | Y=10) = {prob_X0_given_Y10:.4f}")
print(f"Prob(X=0)          = {μ[0]:.4f}")
```

```
μ (marginal of X): [0.5 0.5]
ν (marginal of Y): [0.4 0.6]

Independence matrix (outer product):
 [[0.2 0.3]
 [0.2 0.3]]

Actual joint F:
 [[0.3 0.2]
 [0.1 0.4]]

Independent (F == μ times ν)? False

Prob(X=0 | Y=10) = 0.7500
Prob(X=0)          = 0.5000
```

Exercise 8.17.2

Covariance and Correlation

Using the same joint distribution F and values $X \in \{0, 1\}$, $Y \in \{10, 20\}$ as in Exercise 1:

1. Compute $\mathbb{E}[X]$, $\mathbb{E}[Y]$, and $\mathbb{E}[XY] = \sum_i \sum_j x_i y_j f_{ij}$.
2. Compute $\text{Cov}(X, Y) = \mathbb{E}[XY] - \mathbb{E}[X]\mathbb{E}[Y]$.
3. Compute $\text{Cor}(X, Y) = \text{Cov}(X, Y)/(\sigma_X \sigma_Y)$.
4. Show analytically that $X \perp Y$ implies $\text{Cov}(X, Y) = 0$.

Solution

Here is one solution:

```
xs = np.array([0, 1])
ys = np.array([10, 20])
F  = np.array([[0.3, 0.2],
               [0.1, 0.4]])

μ = F.sum(axis=1)
ν = F.sum(axis=0)

E_X  = xs @ μ
E_Y  = ys @ ν
E_XY = sum(xs[i] * ys[j] * F[i, j] for i in range(2) for j in range(2))
print(f"E[X] = {E_X}, E[Y] = {E_Y}, E[XY] = {E_XY}")

cov_XY = E_XY - E_X * E_Y
```

```
print(f"Cov(X,Y) = {cov_XY:.4f}")

var_X  = ((xs - E_X)**2) @ μ
var_Y  = ((ys - E_Y)**2) @ ν
cor_XY = cov_XY / np.sqrt(var_X * var_Y)
print(f"Cor(X,Y) = {cor_XY:.4f}")
```

```
E[X] = 0.5, E[Y] = 16.0, E[XY] = 9.0
Cov(X,Y) = 1.0000
Cor(X,Y) = 0.4082
```

For part 4: if $X \perp Y$ then $f_{ij} = \mu_i \nu_j$, so

$$\mathbb{E}[XY] = \sum_i \sum_j x_i y_j \mu_i \nu_j = \left(\sum_i x_i \mu_i\right)\left(\sum_j y_j \nu_j\right) = \mathbb{E}[X]\,\mathbb{E}[Y]$$

and therefore $\text{Cov}(X,Y) = \mathbb{E}[XY] - \mathbb{E}[X]\mathbb{E}[Y] = 0$.

Exercise 8.17.3

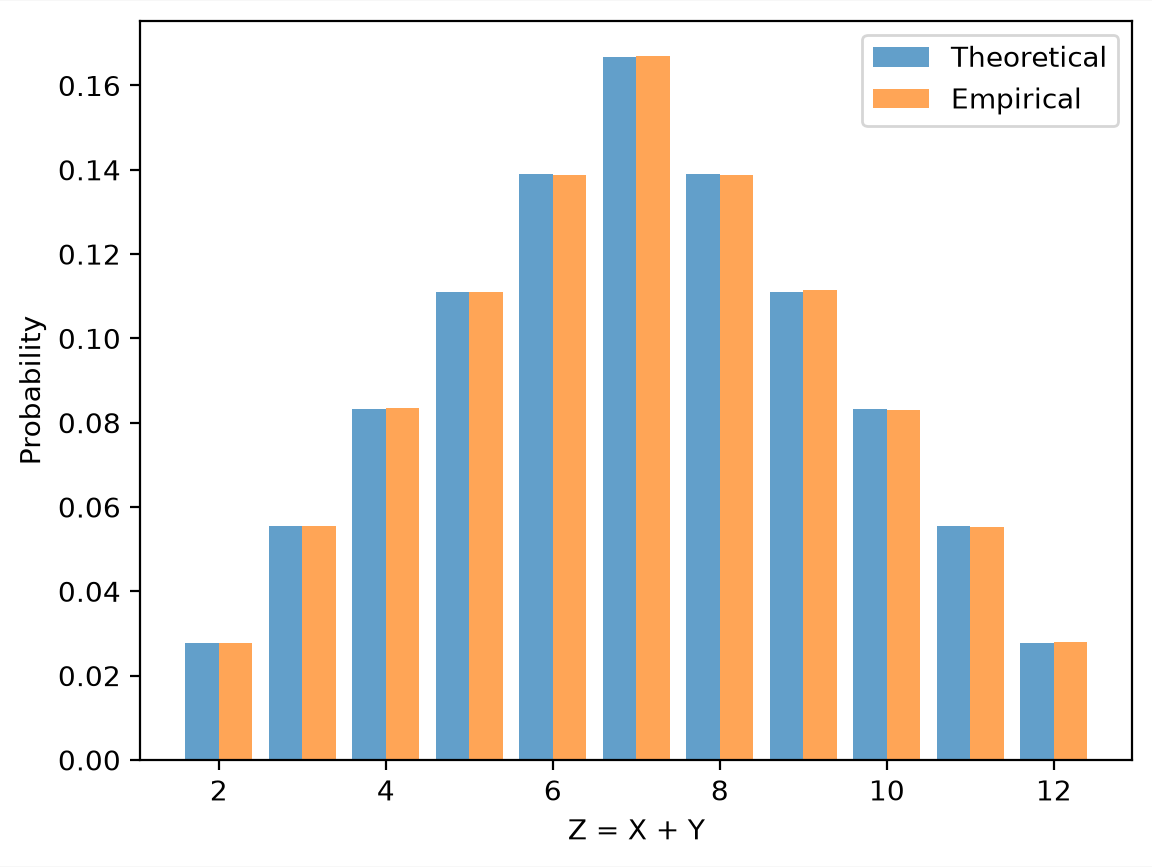
Sum of Two Dice

Let X and Y be **independent** random variables, each uniformly distributed on $\{1,2,3,4,5,6\}$, and let $Z = X + Y$.

1. Use the convolution formula $h_k = \sum_i f_i g_{k-i}$ to compute the distribution of Z.
2. Plot the result generated by the formula.
3. Simulate 10^6 rolls and overlay the empirical histogram on the plot.
4. Compute $\mathbb{E}[Z]$ and $\text{Var}(Z)$ from the two calculations

Solution

Here is one solution:



```
f = np.ones(6) / 6
g = np.ones(6) / 6
h = [
    sum(f[i]*g[k-i] for i in range(
        max(0, k-len(g)+1), # f_i exists
        min(len(f), k+1))   # g_{k-i} exists
        )
        for k in range(len(f) + len(g) - 1)]
z_vals = np.arange(2, 13)

n = 1_000_000
z_sim = rng.integers(1, 7, n) + rng.integers(1, 7, n)
counts = np.bincount(z_sim, minlength=13)[2:]

fig, ax = plt.subplots()
ax.bar(z_vals - 0.2, h,          0.4, alpha=0.7, label='Theoretical')
ax.bar(z_vals + 0.2, counts / n, 0.4, alpha=0.7, label='Empirical')
ax.set_xlabel('Z = X + Y')
ax.set_ylabel('Probability')
ax.legend()
```

```
plt.show()

E_Z   = z_vals @ h
Var_Z = ((z_vals - E_Z)**2) @ h
print(f"Theory:     E[Z] = {E_Z:.2f}, Var(Z) = {Var_Z:.4f}")
print(f"Simulation: E[Z] = {np.mean(z_sim):.2f}, Var(Z) = {np.var(z_sim):.4f}")
```

```
Theory:     E[Z] = 7.00, Var(Z) = 5.8333
Simulation: E[Z] = 7.00, Var(Z) = 5.8271
```

Exercise 8.17.4

Multi-Step Transition Probabilities

Consider a two-state Markov chain with transition matrix

$$P = \begin{bmatrix} 0.9 & 0.1 \\ 0.2 & 0.8 \end{bmatrix}$$

where $p_{ij} = \text{Prob}\{X(t+1) = j \mid X(t) = i\}$.

1. Starting from $\psi_0 = [1, 0]$, compute $\psi_n = \psi_0 P^n$ for $n = 1, 5, 20, 100$.
2. Find the stationary distribution ψ^* satisfying $\psi^* P = \psi^*$ and $\sum_i \psi_i^* = 1$.
3. Verify numerically that $\psi_n \to \psi^*$ as n grows.

Solution

Here is one solution:

```
P = np.array([[0.9, 0.1],
              [0.2, 0.8]])
ψ0 = np.array([1.0, 0.0])

for n in [1, 5, 20, 100]:
    print(f"ψ_{n:3d} = {ψ0 @ np.linalg.matrix_power(P, n)}")

A = np.vstack([P.T - np.eye(2), np.ones(2)])
b = np.array([0.0, 0.0, 1.0])
ψ_star, *_ = np.linalg.lstsq(A, b, rcond=None)
print(f"\nStationary distribution: {ψ_star}")

ψ_100 = ψ0 @ np.linalg.matrix_power(P, 100)
print(f"ψ_100 close to stationary? {np.allclose(ψ_100, ψ_star, atol=1e-6)}")
```

```
ψ_  1 = [0.9 0.1]
ψ_  5 = [0.72269 0.27731]
ψ_ 20 = [0.66693264 0.33306736]
ψ_100 = [0.66666667 0.33333333]

Stationary distribution: [0.66666667 0.33333333]
ψ_100 close to stationary? True
```

Exercise 8.17.5

Bayes' Law with a Discrete Prior

A coin has unknown bias $\theta \in \{0.2,\ 0.5,\ 0.8\}$ with prior $\pi = [0.25,\ 0.50,\ 0.25]$.

Assume that, conditional on θ, the coin flips are i.i.d. Bernoulli(θ).

1. After observing $k = 7$ heads in $n = 10$ flips, compute the likelihood

$$\mathcal{L}(\theta \mid \text{data}) = \binom{10}{7} \theta^7 (1-\theta)^3$$

   for each θ.

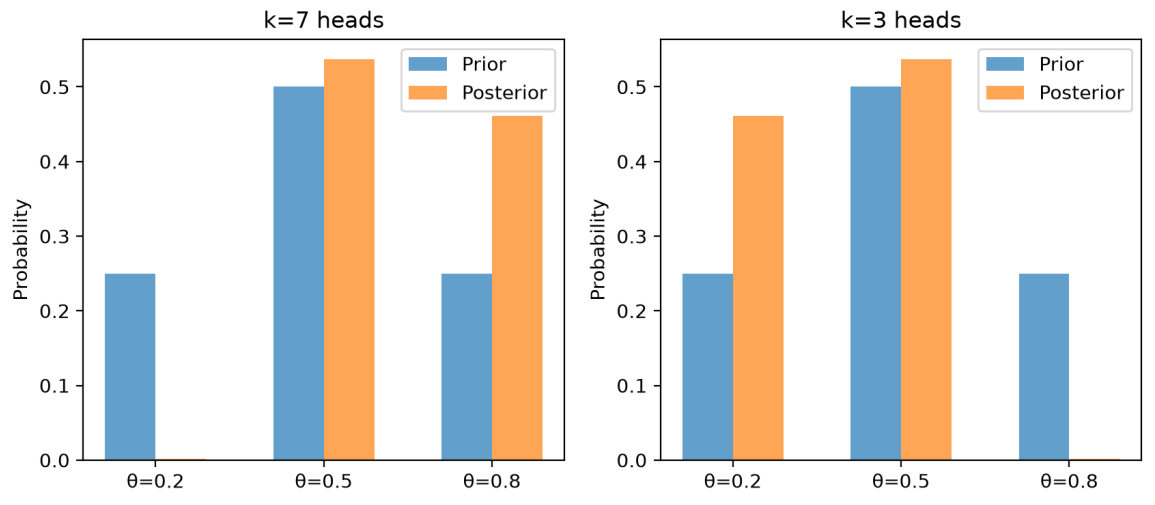
2. Apply equation (8.4) to compute the posterior $\pi(\theta \mid \text{data})$.
3. Plot the prior and posterior side by side.
4. Repeat for $k = 3$ heads and describe how the posterior shifts.

Solution

Here is one solution:

```
θ_vals = np.array([0.2, 0.5, 0.8])
π = np.array([0.25, 0.50, 0.25])

def compute_posterior(k, n, θ_vals, π):
    likelihood = comb(n, k) * θ_vals**k * (1 - θ_vals)**(n - k)
```



```
    unnorm = likelihood * π
    return unnorm / unnorm.sum(), likelihood

post7, lik7 = compute_posterior(7, 10, θ_vals, π)
post3, lik3 = compute_posterior(3, 10, θ_vals, π)

print("k=7:  likelihood =", lik7.round(4),
      " posterior =", post7.round(4))
print("k=3:  likelihood =", lik3.round(4),
      " posterior =", post3.round(4))

x = np.arange(len(θ_vals))
w = 0.3
fig, axes = plt.subplots(1, 2, figsize=(10, 4))
for ax, post, title in zip(
    axes, [post7, post3], ['k=7 heads', 'k=3 heads']):
    ax.bar(x - w/2, π, w, label='Prior',     alpha=0.7)
    ax.bar(x + w/2, post,  w, label='Posterior', alpha=0.7)
    ax.set_xticks(x)
    ax.set_xticklabels([f'θ={t}' for t in θ_vals])
    ax.set_ylabel('Probability')
    ax.set_title(title)
    ax.legend()
plt.show()
```

```
k=7:  likelihood = [0.0008 0.1172 0.2013]  posterior = [0.0018 0.537  0.4612]
k=3:  likelihood = [0.2013 0.1172 0.0008]  posterior = [0.4612 0.537  0.0018]
```

CHAPTER

NINE

SOME PROBABILITY DISTRIBUTIONS

This lecture is a supplement to *this lecture on statistics with matrices*.

It describes some popular distributions and uses Python to sample from them.

It also describes a way to sample from an arbitrary probability distribution that you make up by transforming a sample from a uniform probability distribution.

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install prettytable
```

As usual, we'll start with some imports

```
import numpy as np
import matplotlib.pyplot as plt
import prettytable as pt
from mpl_toolkits.mplot3d import Axes3D
from matplotlib_inline.backend_inline import set_matplotlib_formats
set_matplotlib_formats('retina')
```

9.1 Some Discrete Probability Distributions

Let's write some Python code to compute means and variances of some univariate random variables.

We'll use our code to

- compute population means and variances from the probability distribution
- generate a sample of N independently and identically distributed draws and compute sample means and variances
- compare population and sample means and variances

9.2 Geometric distribution

A discrete geometric distribution has probability mass function

$$\text{Prob}(X = k) = (1-p)^{k-1}p, k = 1, 2, \ldots, \quad p \in (0, 1)$$

where $k = 1, 2, \ldots$ is the number of trials before the first success.

The mean and variance of this one-parameter probability distribution are

$$\mathbb{E}(X) = \frac{1}{p}$$
$$\mathbb{V}\text{ar}(X) = \frac{1-p}{p^2}$$

Let's use Python draw observations from the distribution and compare the sample mean and variance with the theoretical results.

```
rng = np.random.default_rng()

# specify parameters
p, n = 0.3, 1_000_000

# draw observations from the distribution
x = rng.geometric(p, n)

# compute sample mean and variance
μ_hat = np.mean(x)
σ2_hat = np.var(x)

print("The sample mean is: ", μ_hat, "\nThe sample variance is: ", σ2_hat)

# compare with theoretical results
print("\nThe population mean is: ", 1/p)
print("The population variance is: ", (1-p)/(p**2))
```

```
The sample mean is:  3.335596
The sample variance is:  7.781979324784001

The population mean is:  3.3333333333333335
The population variance is:  7.777777777777778
```

9.3 Pascal (negative binomial) distribution

Consider a sequence of independent Bernoulli trials.

Let p be the probability of success.

Let X be a random variable that represents the number of failures before we get r successes.

Its distribution is

$$X \sim NB(r, p)$$
$$\text{Prob}(X = k; r, p) = \begin{bmatrix} k+r-1 \\ r-1 \end{bmatrix} p^r (1-p)^k$$

Here, we choose from among $k + r - 1$ possible outcomes because the last draw is by definition a success.

We compute the mean and variance to be

$$\mathbb{E}(X) = \frac{k(1-p)}{p}$$
$$\mathbb{V}(X) = \frac{k(1-p)}{p^2}$$

```
# specify parameters
r, p, n = 10, 0.3, 1_000_000

# draw observations from the distribution
x = rng.negative_binomial(r, p, n)

# compute sample mean and variance
μ_hat = np.mean(x)
σ2_hat = np.var(x)

print("The sample mean is: ", μ_hat, "\nThe sample variance is: ", σ2_hat)
print("\nThe population mean is: ", r*(1-p)/p)
print("The population variance is: ", r*(1-p)/p**2)
```

```
The sample mean is:  23.333584
The sample variance is:  77.88988771494401

The population mean is:  23.333333333333336
The population variance is:  77.77777777777779
```

9.4 Newcomb–Benford distribution

The **Newcomb–Benford law** fits many data sets, e.g., reports of incomes to tax authorities, in which the leading digit is more likely to be small than large.

See https://en.wikipedia.org/wiki/Benford's_law

A Benford probability distribution is

$$\text{Prob}\{X = d\} = \log_{10}(d+1) - \log_{10}(d) = \log_{10}\left(1 + \frac{1}{d}\right)$$

where $d \in \{1, 2, \cdots, 9\}$ can be thought of as a **first digit** in a sequence of digits.

This is a well defined discrete distribution since we can verify that probabilities are nonnegative and sum to 1.

$$\log_{10}\left(1 + \frac{1}{d}\right) \geq 0, \quad \sum_{d=1}^{9} \log_{10}\left(1 + \frac{1}{d}\right) = 1$$

The mean and variance of a Benford distribution are

$$\mathbb{E}[X] = \sum_{d=1}^{9} d \log_{10}\left(1 + \frac{1}{d}\right) \simeq 3.4402$$

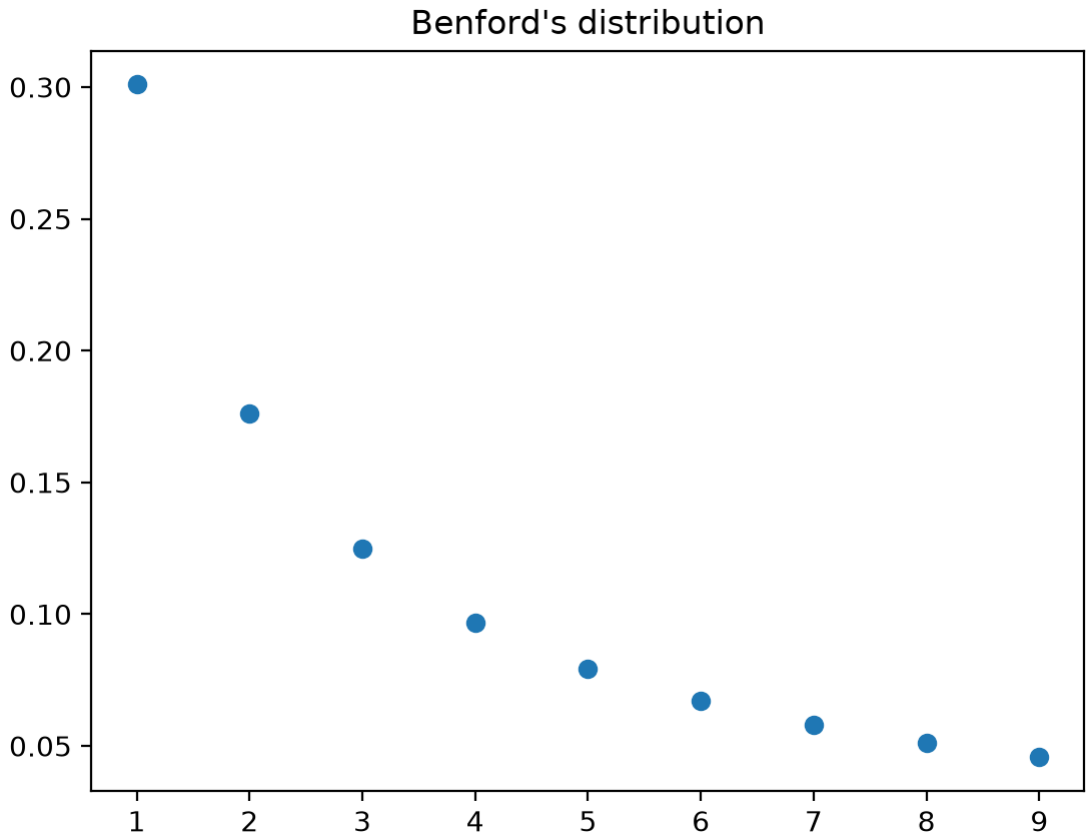
$$\mathbb{V}[X] = \sum_{d=1}^{9} (d - \mathbb{E}[X])^2 \log_{10}\left(1 + \frac{1}{d}\right) \simeq 6.0565$$

We verify the above and compute the mean and variance using `numpy`.

```
Benford_pmf = np.array([np.log10(1+1/d) for d in range(1,10)])
k = np.arange(1, 10)

# mean
mean = k @ Benford_pmf
```

(continues on next page)



(continued from previous page)

```
# variance
var = ((k - mean) ** 2) @ Benford_pmf

# verify sum to 1
print(np.sum(Benford_pmf))
print(mean)
print(var)
```

```
0.9999999999999999
3.4402369671232065
6.056512631375667
```

```
# plot distribution
plt.plot(range(1,10), Benford_pmf, 'o')
plt.title('Benford\'s distribution')
plt.show()
```

Now let's turn to some continuous random variables.

9.5 Univariate Gaussian distribution

We write

$$X \sim N(\mu, \sigma^2)$$

to indicate the probability distribution

$$f(x|u, \sigma^2) = \frac{1}{\sqrt{2\pi\sigma^2}} e^{[-\frac{1}{2\sigma^2}(x-u)^2]}$$

In the below example, we set $\mu = 0, \sigma = 0.1$.

```
# specify parameters
μ, σ = 0, 0.1

# specify number of draws
n = 1_000_000

# draw observations from the distribution
x = rng.normal(μ, σ, n)

# compute sample mean and variance
μ_hat = np.mean(x)
σ_hat = np.std(x)

print("The sample mean is: ", μ_hat)
print("The sample standard deviation is: ", σ_hat)
```

```
The sample mean is:  -8.602266003949955e-05
The sample standard deviation is:  0.09994046044105788
```

```
# compare
print(μ-μ_hat < 1e-3)
print(σ-σ_hat < 1e-3)
```

```
True
True
```

9.6 Uniform Distribution

$$X \sim U[a, b]$$

$$f(x) = \begin{cases} \frac{1}{b-a}, & a \leq x \leq b \\ 0, & \text{otherwise} \end{cases}$$

The population mean and variance are

$$\mathbb{E}(X) = \frac{a+b}{2}$$

$$\mathbb{V}(X) = \frac{(b-a)^2}{12}$$

```
# specify parameters
a, b = 10, 20

# specify number of draws
n = 1_000_000

# draw observations from the distribution
x = a + (b-a)*rng.random(n)

# compute sample mean and variance
μ_hat = np.mean(x)
σ2_hat = np.var(x)

print("The sample mean is: ", μ_hat, "\nThe sample variance is: ", σ2_hat)
print("\nThe population mean is: ", (a+b)/2)
print("The population variance is: ", (b-a)**2/12)
```

```
The sample mean is:  14.997286184872815
The sample variance is:  8.314142050156056

The population mean is:  15.0
The population variance is:  8.333333333333334
```

9.7 A Mixed Discrete-Continuous Distribution

We'll motivate this example with a little story.

Suppose that to apply for a job you take an interview and either pass or fail it.

You have 5% chance to pass an interview and you know your salary will uniformly distributed in the interval 300~400 a day only if you pass.

We can describe your daily salary as a discrete-continuous variable with the following probabilities:

$$P(X = 0) = 0.95$$

$$P(300 \leq X \leq 400) = \int_{300}^{400} f(x)\, dx = 0.05$$

$$f(x) = 0.0005$$

Let's start by generating a random sample and computing sample moments.

```
x = rng.random(1_000_000)
# x[x > 0.95] = 100*x[x > 0.95]+300
x[x > 0.95] = 100*rng.random(len(x[x > 0.95]))+300
x[x <= 0.95] = 0

μ_hat = np.mean(x)
σ2_hat = np.var(x)

print("The sample mean is: ", μ_hat, "\nThe sample variance is: ", σ2_hat)
```

```
The sample mean is:  17.348813182060855
The sample variance is:  5817.310047963084
```

The analytical mean and variance can be computed:

$$\begin{aligned}\mu &= \int_{300}^{400} xf(x)dx \\ &= 0.0005 \int_{300}^{400} xdx \\ &= 0.0005 \times \frac{1}{2}x^2\Big|_{300}^{400}\end{aligned}$$

$$\begin{aligned}\sigma^2 &= 0.95 \times (0-17.5)^2 + \int_{300}^{400} (x-17.5)^2 f(x)dx \\ &= 0.95 \times 17.5^2 + 0.0005 \int_{300}^{400} (x-17.5)^2 dx \\ &= 0.95 \times 17.5^2 + 0.0005 \times \frac{1}{3}(x-17.5)^3\Big|_{300}^{400}\end{aligned}$$

```
mean = 0.0005*0.5*(400**2 - 300**2)
var = 0.95*17.5**2+0.0005/3*((400-17.5)**3-(300-17.5)**3)
print("mean: ", mean)
print("variance: ", var)
```

```
mean:  17.5
variance:  5860.416666666666
```

9.8 Drawing a Random Number from a Particular Distribution

Suppose we have at our disposal a pseudo random number that draws a uniform random variable, i.e., one with probability distribution

$$\text{Prob}\{\tilde{X} = i\} = \frac{1}{I}, \quad i = 0, \dots, I-1$$

How can we transform $\tilde{X}$ to get a random variable X for which $\text{Prob}\{X = i\} = f_i, \quad i = 0, \dots, I-1$, where f_i is an arbitary discrete probability distribution on $i = 0, 1, \dots, I-1$?

The key tool is the inverse of a cumulative distribution function (CDF).

Observe that the CDF of a distribution is monotone and non-decreasing, taking values between 0 and 1.

We can draw a sample of a random variable X with a known CDF as follows:

- draw a random variable u from a uniform distribution on $[0, 1]$
- pass the sample value of u into the **"inverse"** target CDF for X
- X has the target CDF

Thus, knowing the **"inverse"** CDF of a distribution is enough to simulate from this distribution.

Note

The "inverse" CDF needs to exist for this method to work.

The inverse CDF is

$$F^{-1}(u) \equiv \inf\{x \in \mathbb{R} : F(x) \geq u\} \quad (0 < u < 1)$$

Here we use infimum because a CDF is a non-decreasing and right-continuous function.

Thus, suppose that

- U is a uniform random variable $U \in [0, 1]$
- We want to sample a random variable X whose CDF is F.

It turns out that if we use draw uniform random numbers U and then compute X from

$$X = F^{-1}(U),$$

then X is a random variable with CDF $F_X(x) = F(x) = \text{Prob}\{X \leq x\}$.

We'll verify this in the special case in which F is continuous and bijective so that its inverse function exists and can be denoted by F^{-1}.

Note that

$$\begin{aligned} F_X(x) &= \text{Prob}\{X \leq x\} \\ &= \text{Prob}\left\{F^{-1}(U) \leq x\right\} \\ &= \text{Prob}\{U \leq F(x)\} \\ &= F(x) \end{aligned}$$

where the last equality occurs because U is distributed uniformly on $[0, 1]$ while $F(x)$ is a constant given x that also lies on $[0, 1]$.

Let's use `numpy` to compute some examples.

Example: A continuous geometric (exponential) distribution

Let X follow a geometric distribution, with parameter $\lambda > 0$.

Its density function is

$$f(x) = \lambda e^{-\lambda x}$$

Its CDF is

$$F(x) = \int_0^\infty \lambda e^{-\lambda x} = 1 - e^{-\lambda x}$$

Let U follow a uniform distribution on $[0, 1]$.

X is a random variable such that $U = F(X)$.

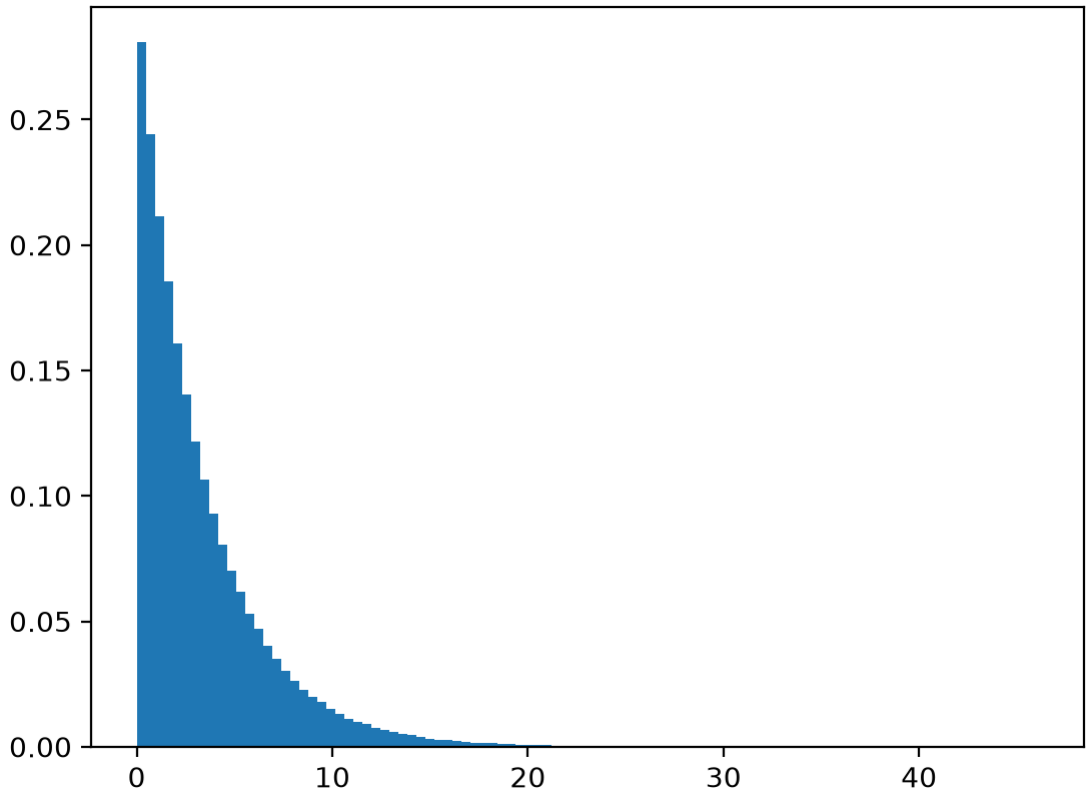
The distribution X can be deduced from

$$\begin{aligned} U = F(X) &= 1 - e^{-\lambda X} \\ \implies \quad -U &= e^{-\lambda X} \\ \implies \quad \log(1-U) &= -\lambda X \\ \implies \quad X &= \frac{(1-U)}{-\lambda} \end{aligned}$$

Let's draw u from $U[0, 1]$ and calculate $x = \frac{log(1-U)}{-\lambda}$.

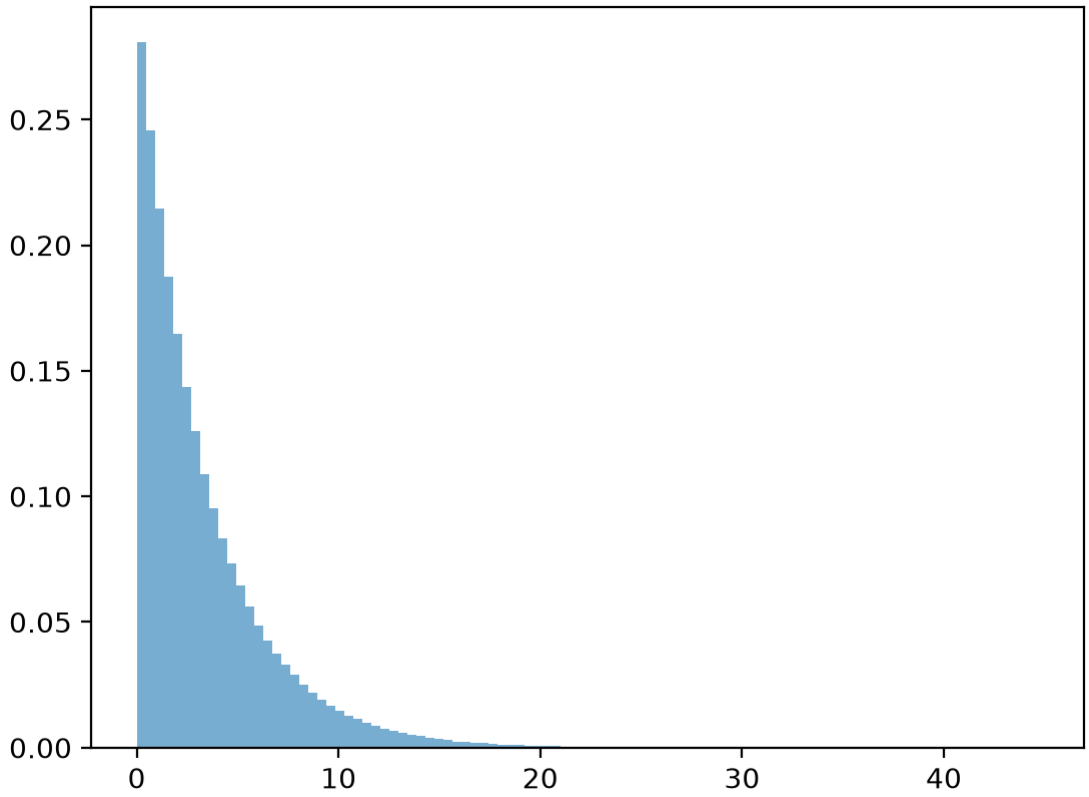
We'll check whether X seems to follow a **continuous geometric** (exponential) distribution.

Let's check with `numpy`.



```
n, λ = 1_000_000, 0.3

# draw uniform numbers
u = rng.random(n)



# transform
x = -np.log(1-u)/λ

# draw geometric distributions
x_g = rng.exponential(1 / λ, n)

# plot and compare
plt.hist(x, bins=100, density=True)
plt.show()
```

```
plt.hist(x_g, bins=100, density=True, alpha=0.6)
plt.show()
```

Geometric distribution

Let X distributed geometrically, that is

$$\text{Prob}(X = i) = (1-\lambda)\lambda^i, \quad \lambda \in (0,1), \quad i = 0, 1, ...$$

$$\sum_{i=0}^{\infty} \text{Prob}(X = i) = 1 \longleftrightarrow (1-\lambda)\sum_{i=0}^{\infty} \lambda^i = \frac{1-\lambda}{1-\lambda} = 1$$

Its CDF is given by

$$\begin{aligned} \text{Prob}(X \leq i) &= (1-\lambda)\sum_{j=0}^{i} \lambda^i \\ &= (1-\lambda)[\frac{1-\lambda^{i+1}}{1-\lambda}] \\ &= 1-\lambda^{i+1} \\ &= F(X) = F_i \end{aligned}$$

Again, let $\tilde{U}$ follow a uniform distribution and we want to find X such that $F(X) = \tilde{U}$.

Let's deduce the distribution of X from

$$\begin{aligned} \tilde{U} = F(X) &= 1-\lambda^{x+1} \\ 1-\tilde{U} &= \lambda^{x+1} \\ \log(1-\tilde{U}) &= (x+1)\log\lambda \\ \frac{\log(1-\tilde{U})}{\log\lambda} &= x+1 \\ \frac{\log(1-\tilde{U})}{\log\lambda} - 1 &= x \end{aligned}$$

However, $\tilde{U} = F^{-1}(X)$ may not be an integer for any $x \geq 0$.

So let

$$x = \lceil \frac{\log(1 - \tilde{U})}{\log \lambda} - 1 \rceil$$

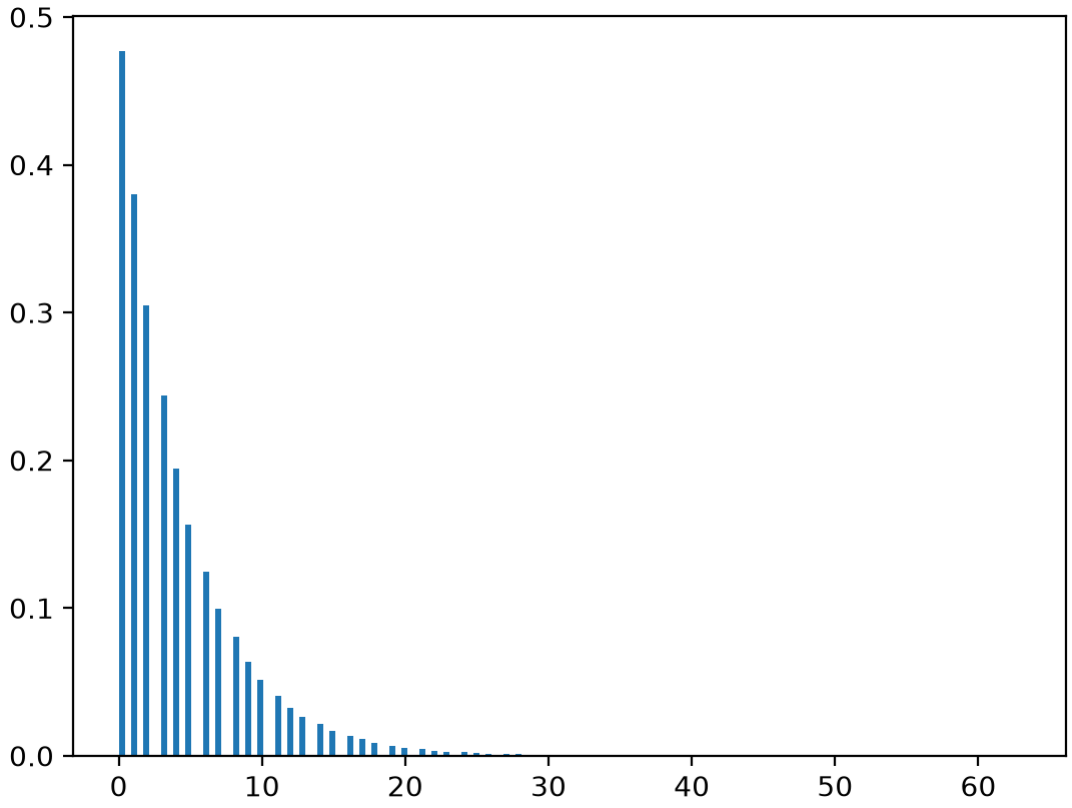
where $\lceil . \rceil$ is the ceiling function.

Thus x is the smallest integer such that the discrete geometric CDF is greater than or equal to $\tilde{U}$.

We can verify that x is indeed geometrically distributed by the following `numpy` program.

Note

The exponential distribution is the continuous analog of geometric distribution.



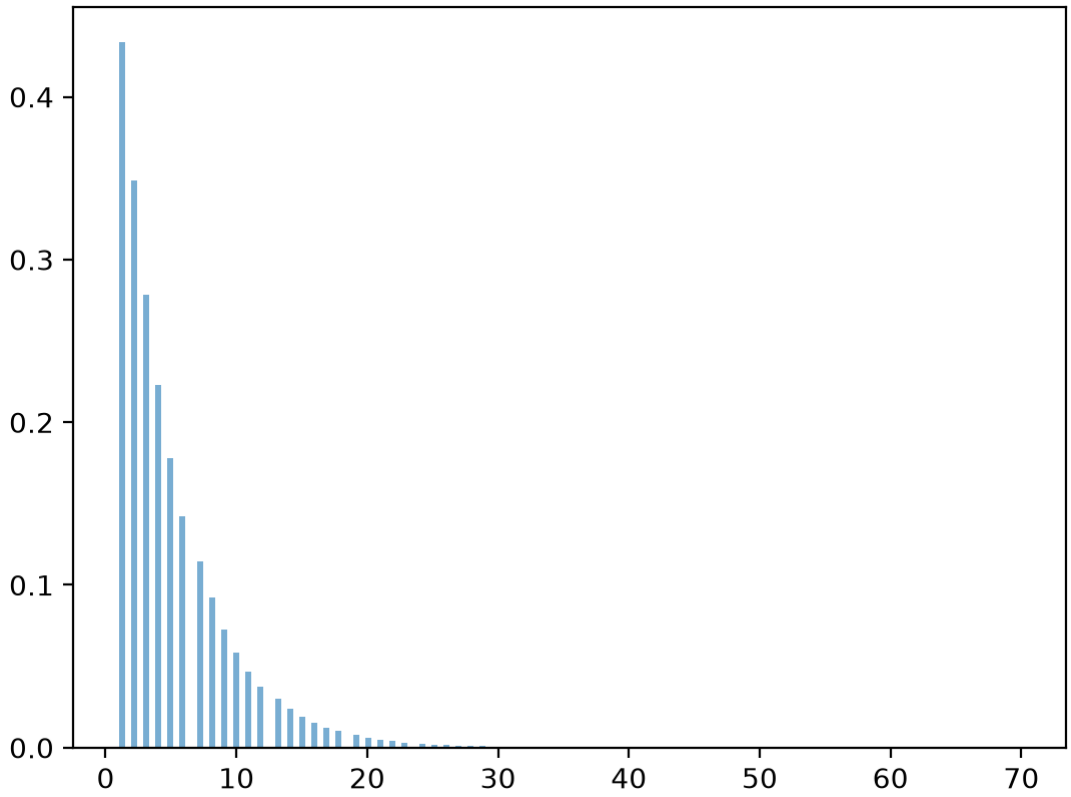
```
n, λ = 1_000_000, 0.8

# draw uniform numbers
u = rng.random(n)

# transform
x = np.ceil(np.log(1-u)/np.log(λ) - 1)

# draw geometric distributions
x_g = rng.geometric(1-λ, n)

# plot and compare
plt.hist(x, bins=150, density=True)
plt.show()
```



```
rng.geometric(1-λ, n).max()
```

```
np.int64(64)
```

```
np.log(0.4)/np.log(0.3)
```

```
np.float64(0.7610560044063083)
```

```
plt.hist(x_g, bins=150, density=True, alpha=0.6)
plt.show()

LLN AND CLT

Contents

- *LLN and CLT*
  - *Overview*
  - *Relationships*
  - *LLN*
  - *CLT*
  - *Exercises*

10.1 Overview

This lecture illustrates two of the most important theorems of probability and statistics: The law of large numbers (LLN) and the central limit theorem (CLT).

These beautiful theorems lie behind many of the most fundamental results in econometrics and quantitative economic modeling.

The lecture is based around simulations that show the LLN and CLT in action.

We also demonstrate how the LLN and CLT break down when the assumptions they are based on do not hold.

In addition, we examine several useful extensions of the classical theorems, such as

- The delta method, for smooth functions of random variables, and
- the multivariate case.

Some of these extensions are presented as exercises.

We'll need the following imports:

```
import matplotlib.pyplot as plt
import random
import numpy as np
from scipy.stats import t, beta, lognorm, expon, gamma, uniform
from scipy.stats import gaussian_kde, poisson, binom, norm, chi2
from mpl_toolkits.mplot3d import Axes3D
```

(continues on next page)

(continued from previous page)

```
from matplotlib.collections import PolyCollection
from scipy.linalg import inv, sqrtm
```

10.2 Relationships

The CLT refines the LLN.

The LLN gives conditions under which sample moments converge to population moments as sample size increases.

The CLT provides information about the rate at which sample moments converge to population moments as sample size increases.

10.3 LLN

We begin with the law of large numbers, which tells us when sample averages will converge to their population means.

10.3.1 The Classical LLN

The classical law of large numbers concerns independent and identically distributed (IID) random variables.

Here is the strongest version of the classical LLN, known as **Kolmogorov's strong law**.

Let $X_1, \ldots, X_n$ be independent and identically distributed scalar random variables, with common distribution F.

When it exists, let μ denote the common mean of this sample:

$$\mu := \mathbb{E}X = \int x F(dx)$$

In addition, let

$$\bar{X}_n := \frac{1}{n} \sum_{i=1}^{n} X_i$$

Kolmogorov's strong law states that, if $\mathbb{E}|X|$ is finite, then

$$\mathbb{P}\left\{\bar{X}_n \to \mu \text{ as } n \to \infty\right\} = 1 \tag{10.1}$$

What does this last expression mean?

Let's think about it from a simulation perspective, imagining for a moment that our computer can generate perfect random samples (which of course it can't).

Let's also imagine that we can generate infinite sequences so that the statement $\bar{X}_n \to \mu$ can be evaluated.

In this setting, (10.1) should be interpreted as meaning that the probability of the computer producing a sequence where $\bar{X}_n \to \mu$ fails to occur is zero.

10.3.2 Proof

The proof of Kolmogorov's strong law is nontrivial – see, for example, theorem 8.3.5 of [Dudley, 2002].

On the other hand, we can prove a weaker version of the LLN very easily and still get most of the intuition.

The version we prove is as follows: If $X_1, \ldots, X_n$ is IID with $\mathbb{E}X_i^2 < \infty$, then, for any $\epsilon > 0$, we have

$$\mathbb{P}\left\{|\bar{X}_n - \mu| \geq \epsilon\right\} \to 0 \quad \text{as} \quad n \to \infty \tag{10.2}$$

(This version is weaker because we claim only convergence in probability rather than almost sure convergence, and assume a finite second moment)

To see that this is so, fix $\epsilon > 0$, and let σ^2 be the variance of each X_i.

Recall the Chebyshev inequality, which tells us that

$$\mathbb{P}\left\{|\bar{X}_n - \mu| \geq \epsilon\right\} \leq \frac{\mathbb{E}[(\bar{X}_n - \mu)^2]}{\epsilon^2} \tag{10.3}$$

Now observe that

$$\begin{aligned}
\mathbb{E}[(\bar{X}_n - \mu)^2] &= \mathbb{E}\left\{\left[\frac{1}{n}\sum_{i=1}^{n}(X_i - \mu)\right]^2\right\} \\
&= \frac{1}{n^2}\sum_{i=1}^{n}\sum_{j=1}^{n}\mathbb{E}(X_i - \mu)(X_j - \mu) \\
&= \frac{1}{n^2}\sum_{i=1}^{n}\mathbb{E}(X_i - \mu)^2 \\
&= \frac{\sigma^2}{n}
\end{aligned}$$

Here the crucial step is at the third equality, which follows from independence.

Independence means that if $i \neq j$, then the covariance term $\mathbb{E}(X_i - \mu)(X_j - \mu)$ drops out.

As a result, $n^2 - n$ terms vanish, leading us to a final expression that goes to zero in n.

Combining our last result with (10.3), we come to the estimate

$$\mathbb{P}\left\{|\bar{X}_n - \mu| \geq \epsilon\right\} \leq \frac{\sigma^2}{n\epsilon^2} \tag{10.4}$$

The claim in (10.2) is now clear.

Of course, if the sequence $X_1, \ldots, X_n$ is correlated, then the cross-product terms $\mathbb{E}(X_i - \mu)(X_j - \mu)$ are not necessarily zero.

While this doesn't mean that the same line of argument is impossible, it does mean that if we want a similar result then the covariances should be "almost zero" for "most" of these terms.

In a long sequence, this would be true if, for example, $\mathbb{E}(X_i - \mu)(X_j - \mu)$ approached zero when the difference between i and j became large.

In other words, the LLN can still work if the sequence $X_1, \ldots, X_n$ has a kind of "asymptotic independence", in the sense that correlation falls to zero as variables become further apart in the sequence.

This idea is very important in time series analysis, and we'll come across it again soon enough.

10.3.3 Illustration

Let's now illustrate the classical IID law of large numbers using simulation.

In particular, we aim to generate some sequences of IID random variables and plot the evolution of $\bar{X}_n$ as n increases.

Below is a figure that does just this (as usual, you can click on it to expand it).

It shows IID observations from three different distributions and plots $\bar{X}_n$ against n in each case.

The dots represent the underlying observations X_i for $i = 1, \ldots, 100$.

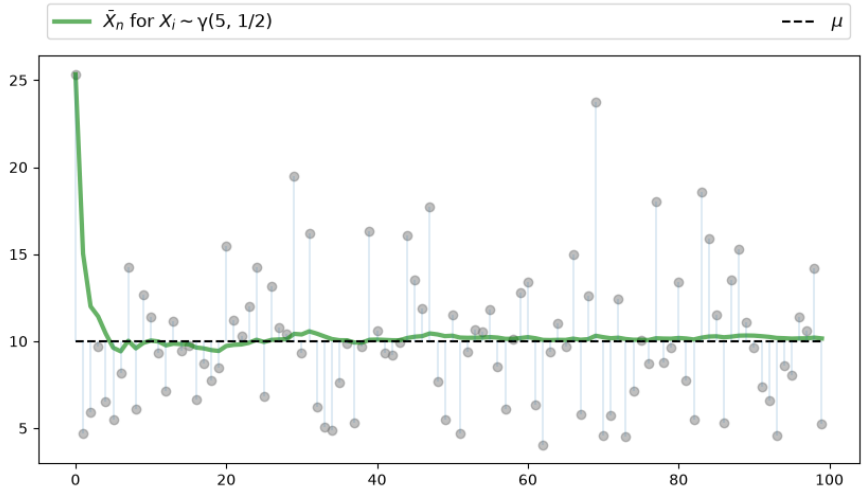
In each of the three cases, convergence of $\bar{X}_n$ to μ occurs as predicted

```
n = 100

# Arbitrary collection of distributions
distributions = {"student's t with 10 degrees of freedom": t(10),
                 "β(2, 2)": beta(2, 2),
                 "lognormal LN(0, 1/2)": lognorm(0.5),
                 "γ(5, 1/2)": gamma(5, scale=2),
                 "poisson(4)": poisson(4),
                 "exponential with λ = 1": expon(1)}

# Create a figure and some axes
num_plots = 3
fig, axes = plt.subplots(num_plots, 1, figsize=(10, 20))

# Set some plotting parameters to improve layout
bbox = (0., 1.02, 1., .102)
legend_args = {'ncol': 2,
               'bbox_to_anchor': bbox,
               'loc': 3,
               'mode': 'expand'}
plt.subplots_adjust(hspace=0.5)



for ax in axes:
    # Choose a randomly selected distribution
    name = random.choice(list(distributions.keys()))
    distribution = distributions.pop(name)

    # Generate n draws from the distribution
    data = distribution.rvs(n)

    # Compute sample mean at each n
    sample_mean = np.empty(n)
    for i in range(n):
        sample_mean[i] = np.mean(data[:i+1])

    # Plot
    ax.plot(list(range(n)), data, 'o', color='grey', alpha=0.5)
    axlabel = r'$\bar{X}_n$ for $X_i \sim$' + name
    ax.plot(list(range(n)), sample_mean, 'g-', lw=3, alpha=0.6, label=axlabel)
    m = distribution.mean()
    ax.plot(list(range(n)), [m] * n, 'k--', lw=1.5, label=r'$\mu$')
    ax.vlines(list(range(n)), m, data, lw=0.2)
    ax.legend(**legend_args, fontsize=12)

The three distributions are chosen at random from a selection stored in the dictionary `distributions`.

10.4 CLT

Next, we turn to the central limit theorem, which tells us about the distribution of the deviation between sample averages and population means.

10.4.1 Statement of the Theorem

The central limit theorem is one of the most remarkable results in all of mathematics.

In the classical IID setting, it tells us the following:

If the sequence $X_1, \ldots, X_n$ is IID, with common mean μ and common variance $\sigma^2 \in (0, \infty)$, then

$$\sqrt{n}(\bar{X}_n - \mu) \xrightarrow{d} N(0, \sigma^2) \quad \text{as} \quad n \to \infty \tag{10.5}$$

Here $\xrightarrow{d} N(0, \sigma^2)$ indicates convergence in distribution to a centered (i.e, zero mean) normal with standard deviation σ.

10.4.2 Intuition

The striking implication of the CLT is that for **any** distribution with finite second moment, the simple operation of adding independent copies **always** leads to a Gaussian curve.

A relatively simple proof of the central limit theorem can be obtained by working with characteristic functions (see, e.g., theorem 9.5.6 of [Dudley, 2002]).

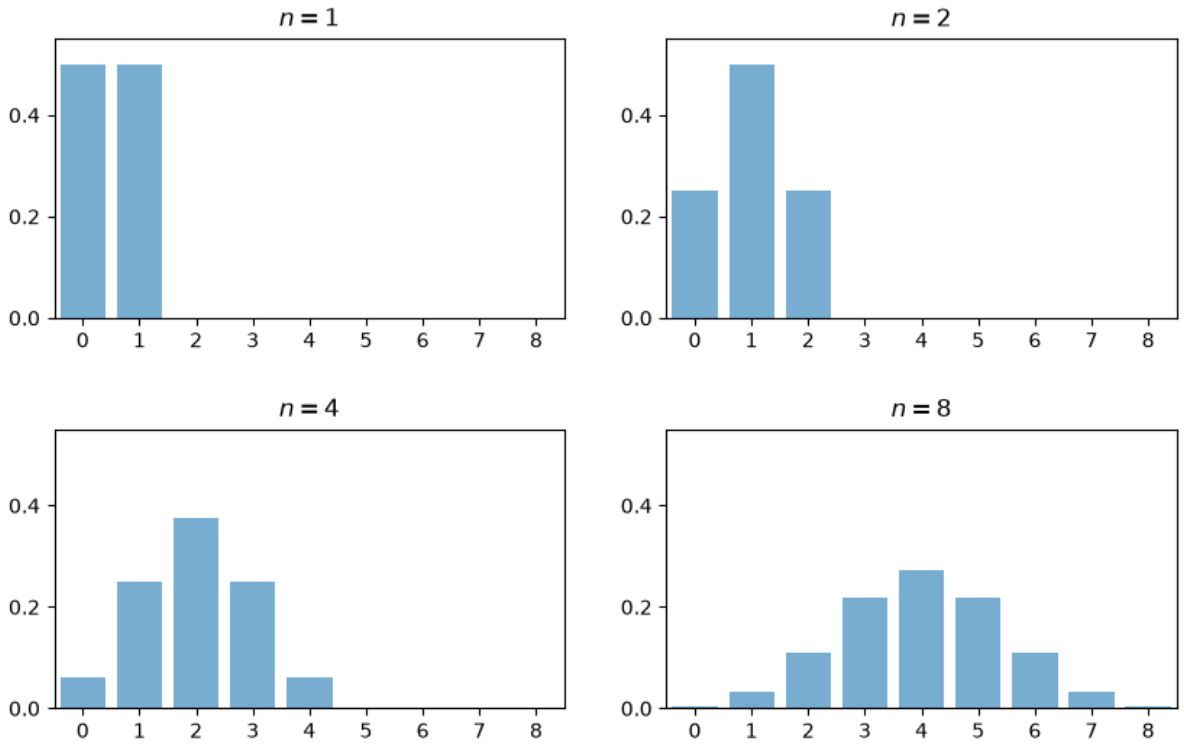
The proof is elegant but almost anticlimactic, and it provides surprisingly little intuition.

In fact, all of the proofs of the CLT that we know are similar in this respect.

Why does adding independent copies produce a bell-shaped distribution?

Part of the answer can be obtained by investigating the addition of independent Bernoulli random variables.

In particular, let X_i be binary, with $\mathbb{P}\{X_i = 0\} = \mathbb{P}\{X_i = 1\} = 0.5$, and let $X_1, \ldots, X_n$ be independent.



Think of $X_i = 1$ as a "success", so that $Y_n = \sum_{i=1}^n X_i$ is the number of successes in n trials.

The next figure plots the probability mass function of Y_n for $n = 1, 2, 4, 8$

```
fig, axes = plt.subplots(2, 2, figsize=(10, 6))
plt.subplots_adjust(hspace=0.4)
axes = axes.flatten()
ns = [1, 2, 4, 8]
dom = list(range(9))

for ax, n in zip(axes, ns):
    b = binom(n, 0.5)
    ax.bar(dom, b.pmf(dom), alpha=0.6, align='center')
    ax.set(xlim=(-0.5, 8.5), ylim=(0, 0.55),
           xticks=list(range(9)), yticks=(0, 0.2, 0.4),
           title=f'$n = {n}$')

plt.show()
```

When $n = 1$, the distribution is flat — one success or no successes have the same probability.

When $n = 2$ we can either have 0, 1 or 2 successes.

Notice the peak in probability mass at the mid-point $k = 1$.

The reason is that there are more ways to get 1 success ("fail then succeed" or "succeed then fail") than to get zero or two successes.

Moreover, the two trials are independent, so the outcomes "fail then succeed" and "succeed then fail" are just as likely as the outcomes "fail then fail" and "succeed then succeed".

(If there was positive correlation, say, then "succeed then fail" would be less likely than "succeed then succeed")

Here, already we have the essence of the CLT: addition under independence leads probability mass to pile up in the middle and thin out at the tails.

For $n = 4$ and $n = 8$ we again get a peak at the "middle" value (halfway between the minimum and the maximum possible value).

The intuition is the same — there are simply more ways to get these middle outcomes.

If we continue, the bell-shaped curve becomes even more pronounced.

We are witnessing the binomial approximation of the normal distribution.

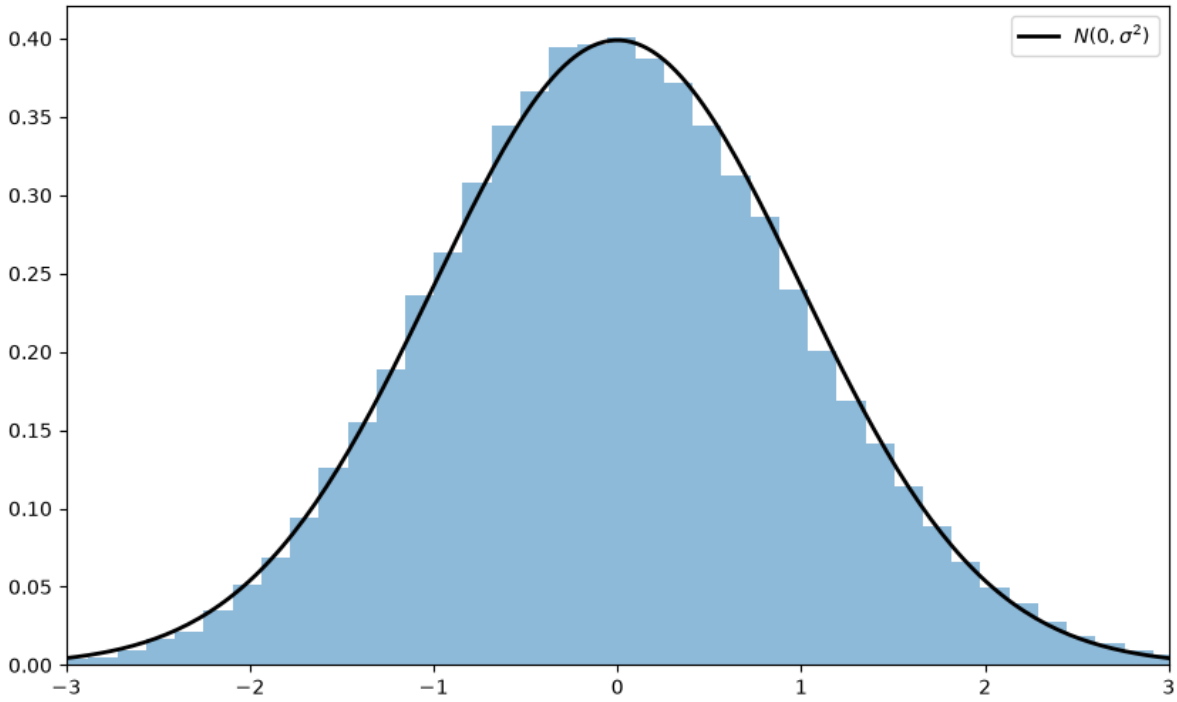
10.4.3 Simulation 1

Since the CLT seems almost magical, running simulations that verify its implications is one good way to build intuition.

To this end, we now perform the following simulation

1. Choose an arbitrary distribution F for the underlying observations X_i.
2. Generate independent draws of $Y_n := \sqrt{n}(\bar{X}_n - \mu)$.
3. Use these draws to compute some measure of their distribution — such as a histogram.
4. Compare the latter to $N(0, \sigma^2)$.

Here's some code that does exactly this for the exponential distribution $F(x) = 1 - e^{-\lambda x}$.



(Please experiment with other choices of F, but remember that, to conform with the conditions of the CLT, the distribution must have a finite second moment.)

```
# Set parameters
n = 250                  # Choice of n
k = 100000               # Number of draws of Y_n
distribution = expon(2)  # Exponential distribution, λ = 1/2
μ, s = distribution.mean(), distribution.std()

# Draw underlying RVs. Each row contains a draw of X_1,..,X_n
data = distribution.rvs((k, n))
# Compute mean of each row, producing k draws of \bar X_n
sample_means = data.mean(axis=1)
# Generate observations of Y_n
Y = np.sqrt(n) * (sample_means - μ)

# Plot
fig, ax = plt.subplots(figsize=(10, 6))
xmin, xmax = -3 * s, 3 * s
ax.set_xlim(xmin, xmax)
ax.hist(Y, bins=60, alpha=0.5, density=True)
xgrid = np.linspace(xmin, xmax, 200)
ax.plot(xgrid, norm.pdf(xgrid, scale=s), 'k-', lw=2, label=r'$N(0, \sigma^2)$')
ax.legend()

plt.show()
```

Notice the absence of for loops — every operation is vectorized, meaning that the major calculations are all shifted to highly optimized C code.

The fit to the normal density is already tight and can be further improved by increasing `n`.

You can also experiment with other specifications of F.

10.4.4 Simulation 2

Our next simulation is somewhat like the first, except that we aim to track the distribution of $Y_n := \sqrt{n}(\bar{X}_n - \mu)$ as n increases.

In the simulation, we'll be working with random variables having $\mu = 0$.

Thus, when $n = 1$, we have $Y_1 = X_1$, so the first distribution is just the distribution of the underlying random variable.

For $n = 2$, the distribution of Y_2 is that of $(X_1 + X_2)/\sqrt{2}$, and so on.

What we expect is that, regardless of the distribution of the underlying random variable, the distribution of Y_n will smooth out into a bell-shaped curve.

The next figure shows this process for $X_i \sim f$, where f was specified as the convex combination of three different beta densities.

(Taking a convex combination is an easy way to produce an irregular shape for f.)

In the figure, the closest density is that of Y_1, while the furthest is that of Y_5

```
beta_dist = beta(2, 2)

def gen_x_draws(k, rng):
    """
    Returns a flat array containing k independent draws from the
    distribution of X, the underlying random variable.  This distribution
```

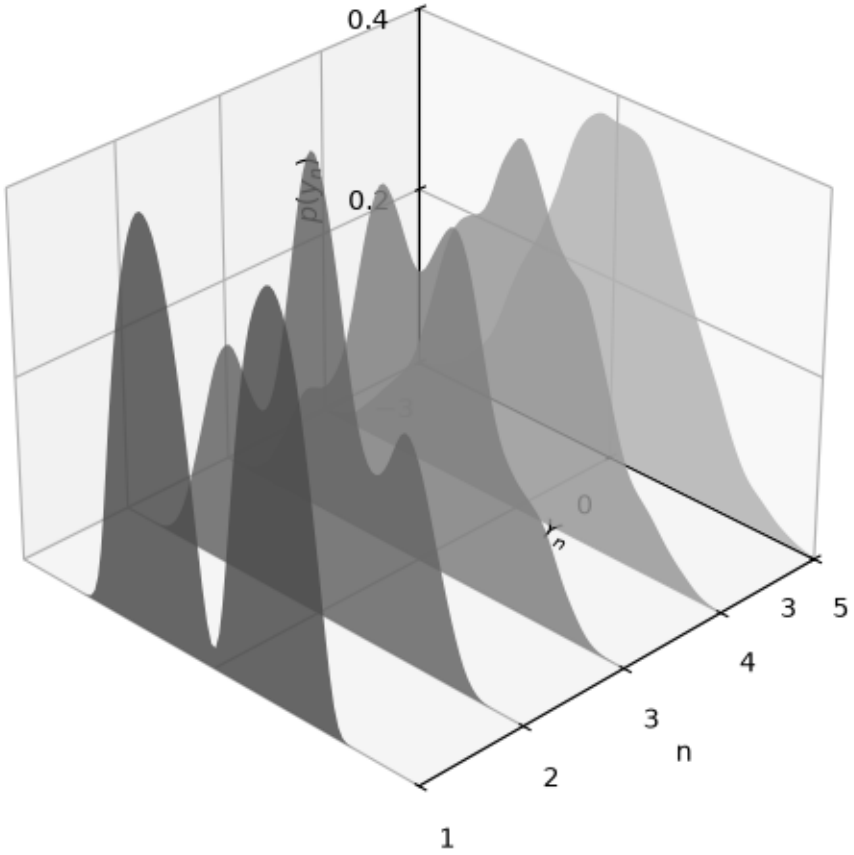
(continues on next page)

(continued from previous page)

```
    is itself a convex combination of three beta distributions.
    """
    bdraws = beta_dist.rvs((3, k))
    # Transform rows, so each represents a different distribution
    bdraws[0, :] -= 0.5
    bdraws[1, :] += 0.6
    bdraws[2, :] -= 1.1
    # Set X[i] = bdraws[j, i], where j is a random draw from {0, 1, 2}
    js = rng.integers(0, 2, size=k)
    X = bdraws[js, np.arange(k)]
    # Rescale, so that the random variable is zero mean
    m, sigma = X.mean(), X.std()
    return (X - m) / sigma

nmax = 5
reps = 100000
ns = list(range(1, nmax + 1))
rng = np.random.default_rng()

# Form a matrix Z such that each column is reps independent draws of X
Z = np.empty((reps, nmax))
for i in range(nmax):
    Z[:, i] = gen_x_draws(reps, rng)
# Take cumulative sum across columns
S = Z.cumsum(axis=1)
# Multiply j-th column by sqrt j
Y = (1 / np.sqrt(ns)) * S



# Plot
ax = plt.figure(figsize = (10, 6)).add_subplot(projection='3d')

a, b = -3, 3
gs = 100
xs = np.linspace(a, b, gs)

# Build verts
greys = np.linspace(0.3, 0.7, nmax)
verts = []
for n in ns:
    density = gaussian_kde(Y[:, n-1])
    ys = density(xs)
    verts.append(list(zip(xs, ys)))

poly = PolyCollection(verts, facecolors=[str(g) for g in greys])
poly.set_alpha(0.85)
ax.add_collection3d(poly, zs=ns, zdir='x')

ax.set(xlim3d=(1, nmax), xticks=(ns), ylabel='$Y_n$', zlabel='$p(y_n)$',
       xlabel=("n"), yticks=((-3, 0, 3)), ylim3d=(a, b),
       zlim3d=(0, 0.4), zticks=((0.2, 0.4)))
ax.invert_xaxis()
# Rotates the plot 30 deg on z axis and 45 deg on x axis
ax.view_init(30, 45)
plt.show()
```

As expected, the distribution smooths out into a bell curve as n increases.

We leave you to investigate its contents if you wish to know more.

If you run the file from the ordinary IPython shell, the figure should pop up in a window that you can rotate with your mouse, giving different views on the density sequence.

10.4.5 The Multivariate Case

The law of large numbers and central limit theorem work just as nicely in multidimensional settings.

To state the results, let's recall some elementary facts about random vectors.

A random vector $\mathbf{X}$ is just a sequence of k random variables $(X_1, \ldots, X_k)$.

Each realization of $\mathbf{X}$ is an element of $\mathbb{R}^k$.

A collection of random vectors $\mathbf{X}_1, \ldots, \mathbf{X}_n$ is called independent if, given any n vectors $\mathbf{x}_1, \ldots, \mathbf{x}_n$ in $\mathbb{R}^k$, we have

$$\mathbb{P}\{\mathbf{X}_1 \leq \mathbf{x}_1, \ldots, \mathbf{X}_n \leq \mathbf{x}_n\} = \mathbb{P}\{\mathbf{X}_1 \leq \mathbf{x}_1\} \times \cdots \times \mathbb{P}\{\mathbf{X}_n \leq \mathbf{x}_n\}$$

(The vector inequality $\mathbf{X} \leq \mathbf{x}$ means that $X_j \leq x_j$ for $j = 1, \ldots, k$)

Let $\mu_j := \mathbb{E}[X_j]$ for all $j = 1, \ldots, k$.

The expectation $\mathbb{E}[\mathbf{X}]$ of $\mathbf{X}$ is defined to be the vector of expectations:

$$\mathbb{E}[\mathbf{X}] := \begin{pmatrix} \mathbb{E}[X_1] \\ \mathbb{E}[X_2] \\ \vdots \\ \mathbb{E}[X_k] \end{pmatrix} = \begin{pmatrix} \mu_1 \\ \mu_2 \\ \vdots \\ \mu_k \end{pmatrix} =: \mu$$

The **variance-covariance matrix** of random vector $\mathbf{X}$ is defined as

$$\text{Var}[\mathbf{X}] := \mathbb{E}[(\mathbf{X} - \mu)(\mathbf{X} - \mu)']$$

Expanding this out, we get

$$\text{Var}[\mathbf{X}] = \begin{pmatrix} \mathbb{E}[(X_1 - \mu_1)(X_1 - \mu_1)] & \cdots & \mathbb{E}[(X_1 - \mu_1)(X_k - \mu_k)] \\ \mathbb{E}[(X_2 - \mu_2)(X_1 - \mu_1)] & \cdots & \mathbb{E}[(X_2 - \mu_2)(X_k - \mu_k)] \\ \vdots & \vdots & \vdots \\ \mathbb{E}[(X_k - \mu_k)(X_1 - \mu_1)] & \cdots & \mathbb{E}[(X_k - \mu_k)(X_k - \mu_k)] \end{pmatrix}$$

The j, k-th term is the scalar covariance between X_j and X_k.

With this notation, we can proceed to the multivariate LLN and CLT.

Let $\mathbf{X}_1, \ldots, \mathbf{X}_n$ be a sequence of independent and identically distributed random vectors, each one taking values in $\mathbb{R}^k$.

Let μ be the vector $\mathbb{E}[\mathbf{X}_i]$, and let Σ be the variance-covariance matrix of $\mathbf{X}_i$.

Interpreting vector addition and scalar multiplication in the usual way (i.e., pointwise), let

$$\bar{\mathbf{X}}_n := \frac{1}{n} \sum_{i=1}^{n} \mathbf{X}_i$$

In this setting, the LLN tells us that

$$\mathbb{P}\left\{\bar{\mathbf{X}}_n \to \mu \text{ as } n \to \infty\right\} = 1 \tag{10.6}$$

Here $\bar{\mathbf{X}}_n \to \mu$ means that $\|\bar{\mathbf{X}}_n - \mu\| \to 0$, where $\|\cdot\|$ is the standard Euclidean norm.

The CLT tells us that, provided Σ is finite,

$$\sqrt{n}(\bar{\mathbf{X}}_n - \mu) \xrightarrow{d} N(\mathbf{0}, \Sigma) \quad \text{as} \quad n \to \infty \tag{10.7}$$

10.5 Exercises

Exercise 10.5.1

One very useful consequence of the central limit theorem is as follows.

Assume the conditions of the CLT as *stated above*.

If $g\colon \mathbb{R} \to \mathbb{R}$ is differentiable at μ and $g'(\mu) \neq 0$, then

$$\sqrt{n}\{g(\bar{X}_n) - g(\mu)\} \xrightarrow{d} N(0, g'(\mu)^2 \sigma^2) \quad \text{as} \quad n \to \infty \tag{10.8}$$

This theorem is used frequently in statistics to obtain the asymptotic distribution of estimators — many of which can be expressed as functions of sample means.

(These kinds of results are often said to use the "delta method".)

The proof is based on a Taylor expansion of g around the point μ.

Taking the result as given, let the distribution F of each X_i be uniform on $[0, \pi/2]$ and let $g(x) = \sin(x)$.

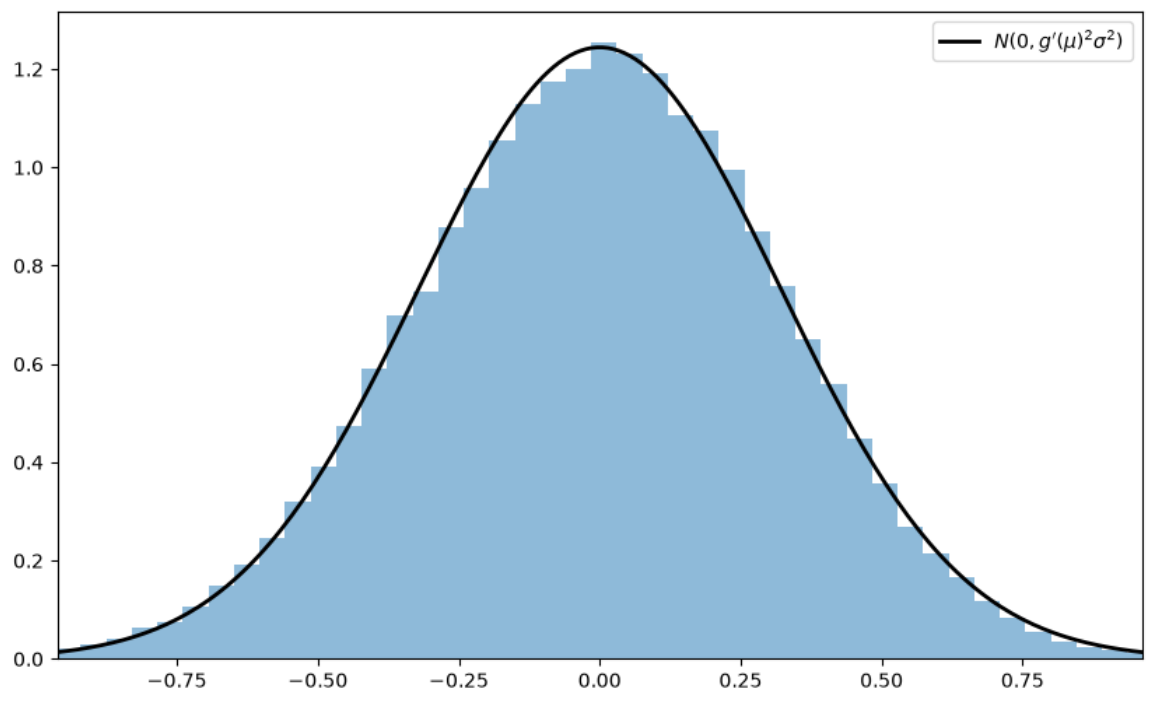
Derive the asymptotic distribution of $\sqrt{n}\{g(\bar{X}_n) - g(\mu)\}$ and illustrate convergence in the same spirit as the program discussed *above*.

What happens when you replace $[0, \pi/2]$ with $[0, \pi]$?

What is the source of the problem?

Solution

Here is one solution



```
"""
Illustrates the delta method, a consequence of the central limit theorem.
"""

# Set parameters
n = 250
replications = 100000
distribution = uniform(loc=0, scale=(np.pi / 2))
μ, s = distribution.mean(), distribution.std()

g = np.sin
g_prime = np.cos

# Generate obs of sqrt{n} (g(X_n) - g(μ))
data = distribution.rvs((replications, n))
sample_means = data.mean(axis=1)  # Compute mean of each row
error_obs = np.sqrt(n) * (g(sample_means) - g(μ))

# Plot
asymptotic_sd = g_prime(μ) * s
fig, ax = plt.subplots(figsize=(10, 6))
xmin = -3 * g_prime(μ) * s
xmax = -xmin
ax.set_xlim(xmin, xmax)
ax.hist(error_obs, bins=60, alpha=0.5, density=True)
xgrid = np.linspace(xmin, xmax, 200)
lb = r"$N(0, g'(\mu)^2  \sigma^2)$"
ax.plot(xgrid, norm.pdf(xgrid, scale=asymptotic_sd), 'k-', lw=2, label=lb)
ax.legend()
plt.show()
```

What happens when you replace $[0, \pi/2]$ with $[0, \pi]$?

In this case, the mean μ of this distribution is $\pi/2$, and since $g' = \cos$, we have $g'(\mu) = 0$.

Hence the conditions of the delta theorem are not satisfied.

Exercise 10.5.2

Here's a result that's often used in developing statistical tests, and is connected to the multivariate central limit theorem.

If you study econometric theory, you will see this result used again and again.

Assume the setting of the multivariate CLT *discussed above*, so that

1. $\mathbf{X}_1, \ldots, \mathbf{X}_n$ is a sequence of IID random vectors, each taking values in $\mathbb{R}^k$.
2. $\mu := \mathbb{E}[\mathbf{X}_i]$, and Σ is the variance-covariance matrix of $\mathbf{X}_i$.
3. The convergence

$$\sqrt{n}(\bar{\mathbf{X}}_n - \mu) \xrightarrow{d} N(\mathbf{0}, \Sigma) \tag{10.9}$$

is valid.

In a statistical setting, one often wants the right-hand side to be **standard** normal so that confidence intervals are easily computed.

This normalization can be achieved on the basis of three observations.

First, if $\mathbf{X}$ is a random vector in $\mathbb{R}^k$ and $\mathbf{A}$ is constant and $k \times k$, then

$$\operatorname{Var}[\mathbf{AX}] = \mathbf{A} \operatorname{Var}[\mathbf{X}] \mathbf{A}'$$

Second, by the continuous mapping theorem, if $\mathbf{Z}_n \xrightarrow{d} \mathbf{Z}$ in $\mathbb{R}^k$ and $\mathbf{A}$ is constant and $k \times k$, then

$$\mathbf{A}\mathbf{Z}_n \xrightarrow{d} \mathbf{A}\mathbf{Z}$$

Third, if $\mathbf{S}$ is a $k \times k$ symmetric positive definite matrix, then there exists a symmetric positive definite matrix $\mathbf{Q}$, called the inverse square root of $\mathbf{S}$, such that

$$\mathbf{Q}\mathbf{S}\mathbf{Q}' = \mathbf{I}$$

Here $\mathbf{I}$ is the $k \times k$ identity matrix.

Putting these things together, your first exercise is to show that if $\mathbf{Q}$ is the inverse square root of [?], then

$$\mathbf{Z}_n := \sqrt{n}\mathbf{Q}(\bar{\mathbf{X}}_n - \mu) \xrightarrow{d} \mathbf{Z} \sim N(\mathbf{0}, \mathbf{I})$$

Applying the continuous mapping theorem one more time tells us that

$$\|\mathbf{Z}_n\|^2 \xrightarrow{d} \|\mathbf{Z}\|^2$$

Given the distribution of $\mathbf{Z}$, we conclude that

$$n\|\mathbf{Q}(\bar{\mathbf{X}}_n - \mu)\|^2 \xrightarrow{d} \chi^2(k) \tag{10.10}$$

where $\chi^2(k)$ is the chi-squared distribution with k degrees of freedom.

(Recall that k is the dimension of $\mathbf{X}_i$, the underlying random vectors.)

Your second exercise is to illustrate the convergence in (10.10) with a simulation.

In doing so, let

$$\mathbf{X}_i := \begin{pmatrix} W_i \\ U_i + W_i \end{pmatrix}$$

where

- each W_i is an IID draw from the uniform distribution on $[-1, 1]$.
- each U_i is an IID draw from the uniform distribution on $[-2, 2]$.
- U_i and W_i are independent of each other.

Hint

1. `scipy.linalg.sqrtm(A)` computes the square root of `A`. You still need to invert it.
2. You should be able to work out Σ from the preceding information.

Solution

First we want to verify the claim that

$$\sqrt{n}\mathbf{Q}(\bar{\mathbf{X}}_n - \mu) \xrightarrow{d} N(\mathbf{0}, \mathbf{I})$$

This is straightforward given the facts presented in the exercise.

Let

$$\mathbf{Y}_n := \sqrt{n}(\bar{\mathbf{X}}_n - \mu) \quad \text{and} \quad \mathbf{Y} \sim N(\mathbf{0}, \Sigma)$$

By the multivariate CLT and the continuous mapping theorem, we have

$$\mathbf{QY}_n \xrightarrow{d} \mathbf{QY}$$

Since linear combinations of normal random variables are normal, the vector $\mathbf{QY}$ is also normal.

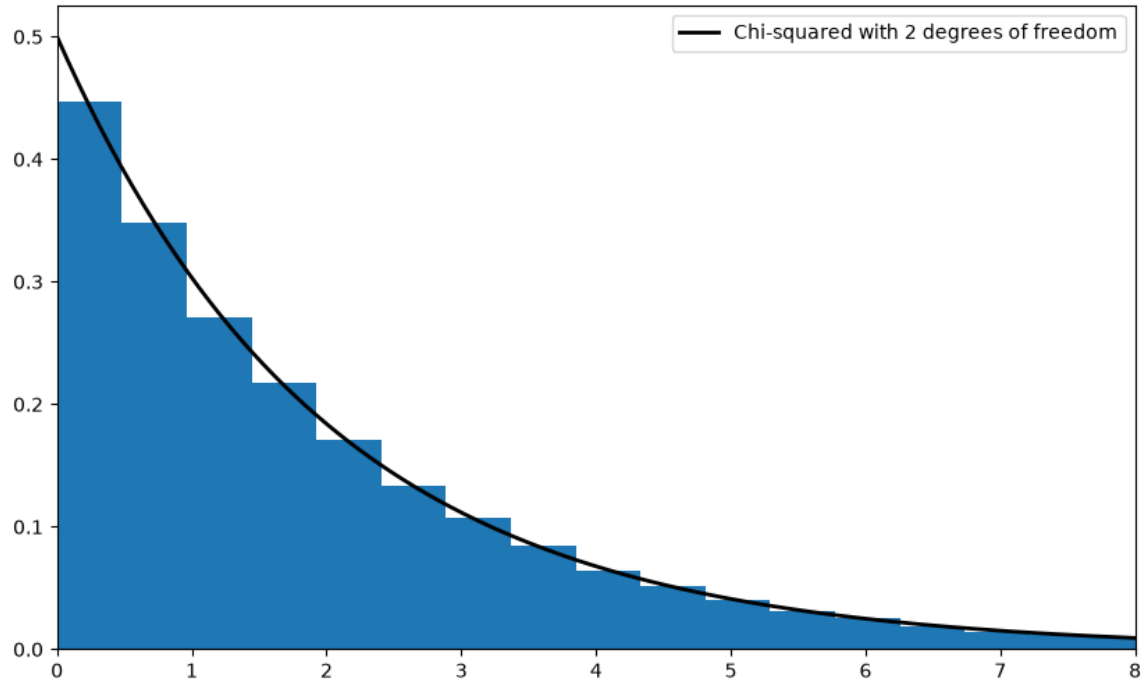
Its mean is clearly $\mathbf{0}$, and its variance-covariance matrix is

$$\text{Var}[\mathbf{QY}] = \mathbf{Q}\text{Var}[\mathbf{Y}]\mathbf{Q}' = \mathbf{Q}\Sigma\mathbf{Q}' = \mathbf{I}$$

In conclusion, $\mathbf{QY}_n \xrightarrow{d} \mathbf{QY} \sim N(\mathbf{0}, \mathbf{I})$, which is what we aimed to show.

Now we turn to the simulation exercise.

Our solution is as follows



```
# Set parameters
n = 250
replications = 50000
dw = uniform(loc=-1, scale=2)  # Uniform(-1, 1)
du = uniform(loc=-2, scale=4)  # Uniform(-2, 2)
sw, su = dw.std(), du.std()
vw, vu = sw**2, su**2
Σ = ((vw, vw), (vw, vw + vu))
Σ = np.array(Σ)

# Compute Σ^{-1/2}
Q = inv(sqrtm(Σ))

# Generate observations of the normalized sample mean
error_obs = np.empty((2, replications))
for i in range(replications):
    # Generate one sequence of bivariate shocks
    X = np.empty((2, n))
    W = dw.rvs(n)
    U = du.rvs(n)
    # Construct the n observations of the random vector
    X[0, :] = W
    X[1, :] = W + U
    # Construct the i-th observation of Y_n
    error_obs[:, i] = np.sqrt(n) * X.mean(axis=1)

# Premultiply by Q and then take the squared norm
temp = Q @ error_obs
chisq_obs = np.sum(temp**2, axis=0)

# Plot
fig, ax = plt.subplots(figsize=(10, 6))
xmax = 8
ax.set_xlim(0, xmax)
xgrid = np.linspace(0, xmax, 200)
lb = "Chi-squared with 2 degrees of freedom"
ax.plot(xgrid, chi2.pdf(xgrid, 2), 'k-', lw=2, label=lb)
ax.legend()
ax.hist(chisq_obs, bins=50, density=True)
plt.show()

CHAPTER

ELEVEN

TWO MEANINGS OF PROBABILITY

11.1 Overview

This lecture illustrates two distinct interpretations of a **probability distribution**

- A frequentist interpretation as **relative frequencies** anticipated to occur in a large IID sample
- A Bayesian interpretation as a **personal opinion** (about a parameter or list of parameters) after seeing a collection of observations

We recommend watching the following two videos before proceeding:

- Hypothesis testing within the frequentist approach
- The Bayesian approach to constructing coverage intervals

After you are familiar with the material in these videos, this lecture uses the Socratic method to help consolidate your understanding of these two meanings of probability.

Along the way we construct a **Bayesian coverage interval** and contrast the question it answers with the frequentist relative-frequency reasoning that opens the lecture.

We do this by inviting you to write some Python code.

It would be especially useful if you tried doing this after each question that we pose for you, before proceeding to read the rest of the lecture.

We provide our own answers as the lecture unfolds, but you'll learn more if you try writing your own code before reading and running ours.

11.1.1 Code for answering questions

To answer our coding questions, we'll start with some imports

```
import numpy as np
import pandas as pd
import matplotlib.pyplot as plt
from scipy.stats import binom
import scipy.stats as st
```

Empowered with these Python tools, we'll now explore the two meanings described above.

11.2 Frequentist Interpretation

Consider the following classic example.

The random variable X takes on possible values $k = 0, 1, 2, \ldots, n$ with probabilities

$$p(k \mid \theta) := \mathbb{P}\{X = k \mid \theta\} = \binom{n}{k} \theta^k (1-\theta)^{n-k}$$

where the fixed parameter $\theta \in (0, 1)$.

This is called the binomial distribution.

Here

- θ is the probability that one toss of a coin will be a head, an outcome that we encode as $Y = 1$.
- $1 - \theta$ is the probability that one toss of the coin will be a tail, an outcome that we denote $Y = 0$.
- X is the total number of heads that came up after flipping the coin n times.

Consider the following experiment:

Take I **independent** sequences of n **independent** flips of the coin

Notice the repeated use of the adjective **independent**:

- we use it once to describe that we are drawing n independent times from a **Bernoulli** distribution with parameter θ to arrive at one draw from a **Binomial** distribution with parameters θ, n.
- we use it again to describe that we are then drawing I sequences of n coin draws.

Let $y_h^i \in \{0, 1\}$ be the realized value of Y on the hth flip during the ith sequence of flips.

Let $\sum_{h=1}^n y_h^i$ denote the total number of times heads come up during the ith sequence of n independent coin flips.

Let f_k record the fraction of samples of length n for which $\sum_{h=1}^n y_h^i = k$:

$$f_k^I = \frac{1}{I} \sum_{i=1}^{I} \mathbb{1}\left\{ \sum_{h=1}^{n} y_h^i = k \right\}$$

The probability $p(k \mid \theta)$ answers the following question:

- As I becomes large, in what fraction of I independent draws of n coin flips should we anticipate k heads to occur?

As usual, a law of large numbers justifies this answer.

Exercise 11.2.1

1. Write Python code to compute f_k^I
2. Use your code to compute $f_k^I, k = 0, \ldots, n$ and compare them to $p(k \mid \theta)$ for various values of θ, n and I
3. With the Law of Large Numbers in mind, use your code to describe the relationship between f_k^I and $p(k \mid \theta)$ as I grows

Solution

Here is one solution.

We simulate the coin flips with one function and assemble the comparison table with another.

```
def simulate_head_counts(θ, n, I, seed=1234):
    "Simulate I sequences of n coin flips; return the heads count of each sequence.
 ↪"
    rng = np.random.default_rng(seed)
    Y = (rng.random((I, n)) <= θ).astype(int)
    return Y.sum(axis=1)
def compare_frequencies(θ, n, I, seed=1234):
    "Tabulate theoretical binomial probabilities against simulated frequencies."
    head_counts = simulate_head_counts(θ, n, I, seed)
    rows = [
        (k, binom.pmf(k, n, θ), np.mean(head_counts == k))
        for k in range(n + 1)
    ]
    return pd.DataFrame(
        rows, columns=['k', 'Theoretical', 'Frequentist']
    ).set_index('k')
θ, n, k, I = 0.7, 20, 10, 1_000_000

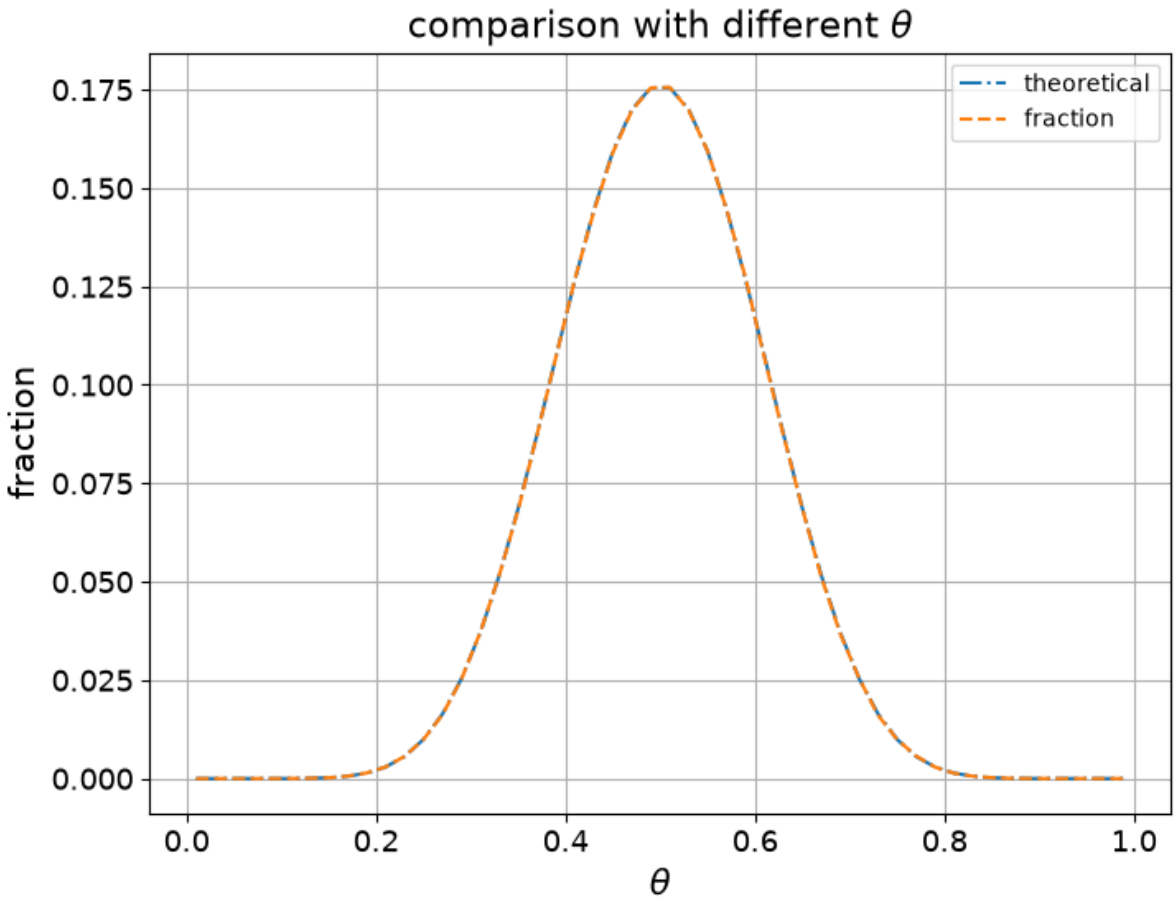
compare_frequencies(θ, n, I)
```

k	Theoretical	Frequentist
0	3.486784e-11	0.000000
1	1.627166e-09	0.000000
2	3.606885e-08	0.000000
3	5.049639e-07	0.000000
4	5.007558e-06	0.000002
5	3.738977e-05	0.000047
6	2.181070e-04	0.000247
7	1.017833e-03	0.001029
8	3.859282e-03	0.003721
9	1.200665e-02	0.011986
10	3.081708e-02	0.030698
11	6.536957e-02	0.065110
12	1.143967e-01	0.114892
13	1.642620e-01	0.164639
14	1.916390e-01	0.191724
15	1.788631e-01	0.178623
16	1.304210e-01	0.129870
17	7.160367e-02	0.072004
18	2.784587e-02	0.027818
19	6.839337e-03	0.006836
20	7.979227e-04	0.000754

From the table above, can you see the law of large numbers at work?

Let's do some more calculations.

11.2.1 Comparison with different θ



Now we fix

$$n = 20, k = 10, I = 1,000,000$$

We'll vary θ from 0.01 to 0.99 and plot outcomes against θ.

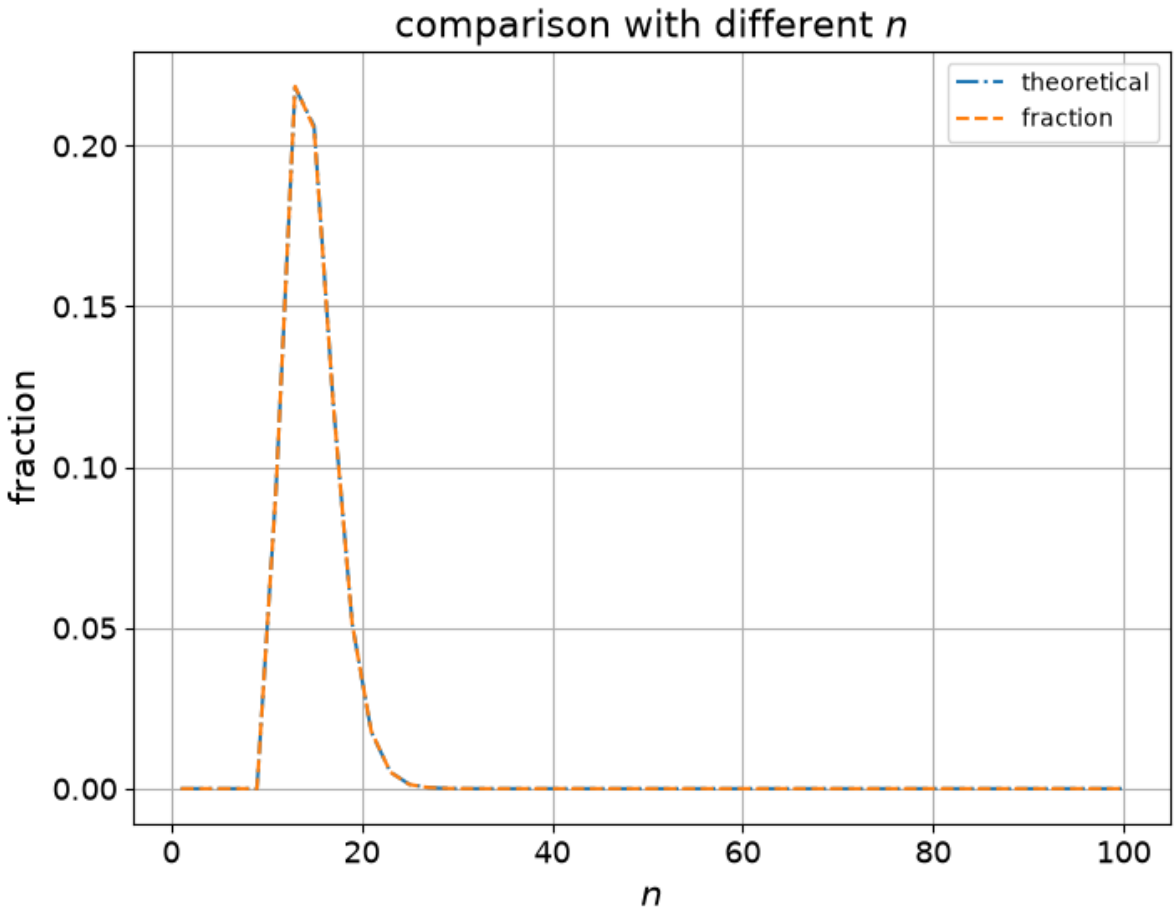
```
θ_low, θ_high, n_thetas = 0.01, 0.99, 50
thetas = np.linspace(θ_low, θ_high, n_thetas)
P = []
f_kI = []
for i in range(n_thetas):
    P.append(binom.pmf(k, n, thetas[i]))
    head_counts = simulate_head_counts(thetas[i], n, I, seed=i)
    f_kI.append(np.mean(head_counts == k))
```

```
fig, ax = plt.subplots(figsize=(8, 6))
ax.grid()
ax.plot(thetas, P, '-.', label='theoretical')
ax.plot(thetas, f_kI, '--', label='fraction')
ax.set_title(r'comparison with different $\theta$',
             fontsize=16)
ax.set_xlabel(r'$\theta$', fontsize=15)
ax.set_ylabel('fraction', fontsize=15)
ax.tick_params(labelsize=13)
ax.legend()
plt.show()
```

11.2.2 Comparison with different n

Now we fix $\theta = 0.7, k = 10, I = 1,000,000$ and vary n from 1 to 100.

Then we'll plot outcomes.



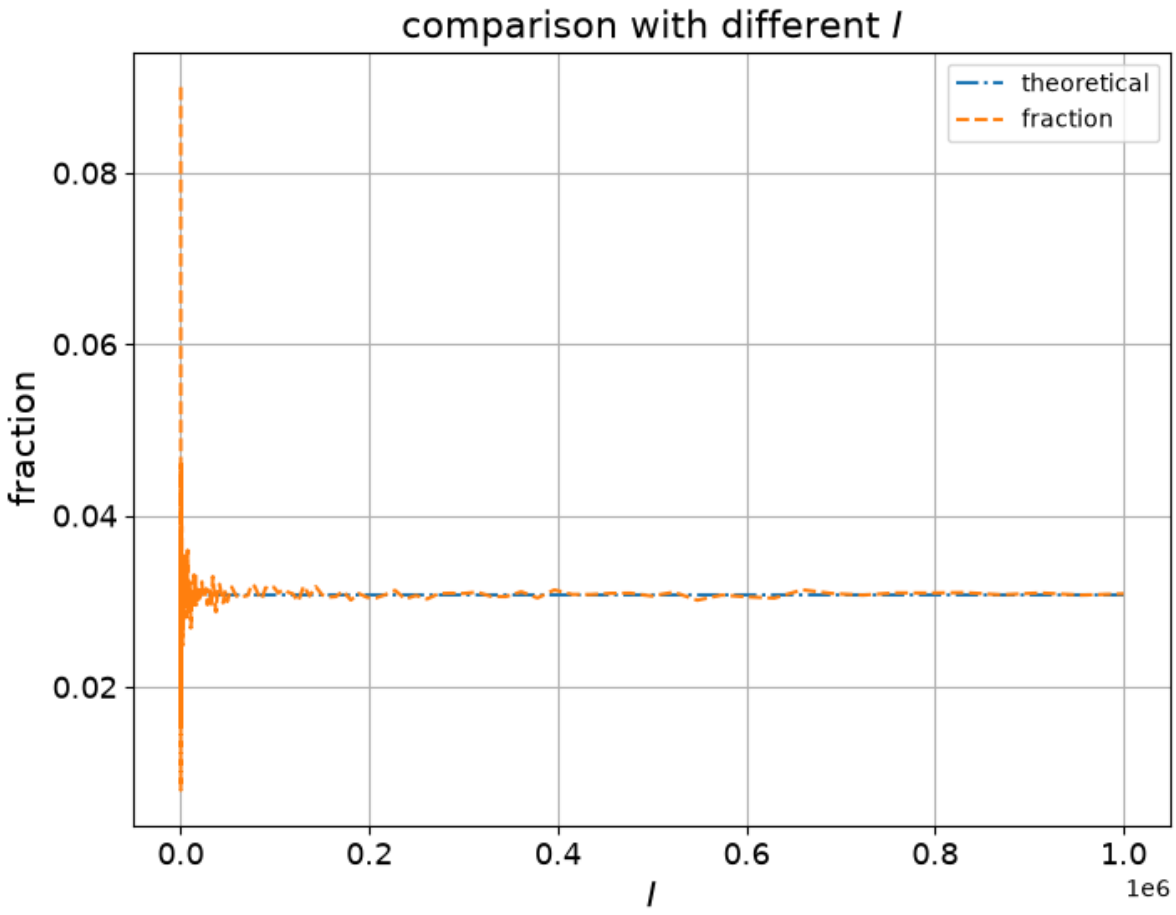
```
n_low, n_high, n_ns = 1, 100, 50
ns = np.linspace(n_low, n_high, n_ns, dtype='int')
P = []
f_kI = []
for i in range(n_ns):
    P.append(binom.pmf(k, ns[i], θ))
    head_counts = simulate_head_counts(θ, ns[i], I, seed=i)
    f_kI.append(np.mean(head_counts == k))
```

```
fig, ax = plt.subplots(figsize=(8, 6))
ax.grid()
ax.plot(ns, P, '-.', label='theoretical')
ax.plot(ns, f_kI, '--', label='fraction')
ax.set_title(r'comparison with different $n$',
             fontsize=16)
ax.set_xlabel(r'$n$', fontsize=15)
ax.set_ylabel('fraction', fontsize=15)
ax.tick_params(labelsize=13)
```

(continues on next page)

(continued from previous page)

```
ax.legend()
plt.show()
```



Because $k = 10$ is held fixed, $p(k \mid \theta)$ is zero whenever $n < 10$ — we cannot obtain 10 heads in fewer than 10 flips — and it is largest near $n \approx 14$, where the expected number of heads $n\theta$ is closest to k. The simulated fraction tracks this shape.

11.2.3 Comparison with different I

Now we fix $\theta = 0.7, n = 20, k = 10$ and vary $\log(I)$ from 2 to 6.

```
I_log_low, I_log_high, n_Is = 2, 6, 200
log_Is = np.linspace(I_log_low, I_log_high, n_Is)
Is = np.power(10, log_Is).astype(int)
P = []
f_kI = []
for i in range(n_Is):
    P.append(binom.pmf(k, n, θ))
    head_counts = simulate_head_counts(θ, n, Is[i], seed=i)
    f_kI.append(np.mean(head_counts == k))
```

```
fig, ax = plt.subplots(figsize=(8, 6))
ax.grid()
ax.plot(Is, P, '-.', label='theoretical')
ax.plot(Is, f_kI, '--', label='fraction')
ax.set_title(r'comparison with different $I$',
             fontsize=16)
ax.set_xlabel(r'$I$', fontsize=15)
ax.set_ylabel('fraction', fontsize=15)
ax.tick_params(labelsize=13)
ax.legend()
plt.show()
```

From the above graphs, we can see that I**, the number of independent sequences,** plays an important role.

When I becomes larger, the difference between theoretical probability and frequentist estimate becomes smaller.

Also, as long as I is large enough, changing θ or n does not substantially change the accuracy of the observed fraction as an approximation of $p(k \mid \theta)$.

The Law of Large Numbers is at work here.

For each independent sequence i, define the indicator $\rho_{k,i} = \mathbb{1}\{X_i = k\}$ — that is, $\rho_{k,i}$ equals 1 if the i-th sequence produces exactly k heads and 0 otherwise.

The $\rho_{k,i}$ are IID across i, each with mean $p(k \mid \theta)$ and variance

$$p(k \mid \theta) \cdot (1 - p(k \mid \theta)).$$

So, by the LLN, the average of $\rho_{k,i}$ converges to:

$$\mathbb{E}[\rho_{k,i}] = p(k \mid \theta) = \binom{n}{k} \theta^k (1-\theta)^{n-k}$$

as I goes to infinity.

11.3 Bayesian Interpretation

The likelihood remains binomial, but now we treat θ as a **random variable** rather than a fixed parameter.

So θ is described by a probability distribution.

But now this probability distribution means something different than a relative frequency that we can anticipate to occur in a large IID sample.

Instead, the probability distribution of θ is now a summary of our views about likely values of θ either

- **before** we have seen **any** data at all, or
- **before** we have seen **more** data, after we have seen **some** data

11.3.1 The beta prior and its posterior

Thus, suppose that, before seeing any data, you have a personal prior probability distribution with density

$$p(\theta) = \frac{\theta^{\alpha-1}(1-\theta)^{\beta-1}}{B(\alpha, \beta)}$$

where $B(\alpha, \beta)$ is a **beta function** , so that $p(\theta)$ is the density of a **beta distribution** with parameters α, β.

We can update this prior after observing data using Bayes' Law (see *Probability with Matrices* for an introduction).

For a sample of n coin flips that yields k heads, the **likelihood function** is the binomial PMF $p(k \mid \theta)$ introduced above.

Applying Bayes' Law with our beta prior, the **posterior density** is

$$p(\theta \mid k) = \frac{p(k \mid \theta) \cdot p(\theta)}{\int_0^1 p(k \mid \theta) \cdot p(\theta)\, d\theta}$$

Because the beta prior is conjugate to the binomial likelihood, this integral evaluates to (the kernel of) another beta density, so that

$$\theta \mid k \sim \text{Beta}(\alpha + k,\ \beta + n - k) \tag{11.1}$$

The first exercise below asks you to derive this closed form.

Exercise 11.3.1

a) Write down the **likelihood function** for a single coin flip with outcome $Y \in \{0, 1\}$.

b) Write down the **posterior** distribution for θ after observing that single flip.

c) Derive the closed-form posterior (11.1) for a sample of n flips that yields k heads.

Solution

a) The **likelihood function** for a single coin flip with outcome $Y \in \{0, 1\}$ is

$$p(Y \mid \theta) = \theta^Y (1-\theta)^{1-Y}$$

b) By Bayes' Law, the posterior density for θ after observing a single flip Y is

$$p(\theta \mid Y) = \frac{p(Y \mid \theta) \cdot p(\theta)}{\int_0^1 p(Y \mid \theta) \cdot p(\theta)\, d\theta}$$

Substituting the likelihood from (a) and the beta prior density, this becomes

$$p(\theta \mid Y) = \frac{\theta^Y (1-\theta)^{1-Y} \cdot \theta^{\alpha-1}(1-\theta)^{\beta-1}/B(\alpha,\beta)}{\int_0^1 \theta^Y (1-\theta)^{1-Y} \cdot \theta^{\alpha-1}(1-\theta)^{\beta-1}/B(\alpha,\beta)\, d\theta}$$

Collecting powers of θ and $(1-\theta)$, we recognize the kernel of a beta density:

$$p(\theta \mid Y) = \frac{\theta^{Y+\alpha-1}(1-\theta)^{1-Y+\beta-1}}{\int_0^1 \theta^{Y+\alpha-1}(1-\theta)^{1-Y+\beta-1}\, d\theta}$$

which means that

$$\theta \mid Y \sim \text{Beta}(\alpha + Y,\ \beta + (1-Y))$$

c) The same calculation, with the binomial likelihood in place of the Bernoulli likelihood, generalizes the result to a sample of n flips that yields k heads.

The beta prior contributes the factor $\theta^{\alpha-1}(1-\theta)^{\beta-1}$, and the binomial likelihood contributes $\theta^k(1-\theta)^{n-k}$, so the posterior is proportional to

$$\theta^{\alpha+k-1}(1-\theta)^{\beta+n-k-1},$$

which is the kernel of a beta density. Hence

$$\theta \mid k \sim \text{Beta}(\alpha + k,\ \beta + n - k),$$

as stated in (11.1).

11.3.2 Exploring the posterior numerically

The next exercise puts this posterior to work.

Exercise 11.3.2

a) Now pretend that the true value of $\theta = 0.4$ and that someone who doesn't know this has a beta prior distribution with parameters $\beta = \alpha = 0.5$. Write Python code to simulate this person's personal posterior distribution for θ for a *single* sequence of n draws.

b) Plot the posterior distribution for θ as a function of θ as n grows as $1, 2, \ldots$.

c) For various n's, describe and compute a Bayesian coverage interval for the interval $[0.45, 0.55]$.

d) Tell what question a Bayesian coverage interval answers.

e) Compute the posterior probability that $\theta \in [0.45, 0.55]$ for various values of sample size n.

f) Use your Python code to study what happens to the posterior distribution as $n \to +\infty$, again assuming that the true value of $\theta = 0.4$, though it is unknown to the person doing the updating via Bayes' Law.

Solution

a)

We use one function to simulate a sequence of coin flips and another to form the Beta posterior from the first `n_obs` of those flips.

```
def simulate_flips(θ=0.4, n=1_000_000, seed=1234):
    "Simulate n coin flips, each landing heads (1) with probability θ."
    rng = np.random.default_rng(seed)
    return (rng.random(n) < θ).astype(int)
```

```
def form_posterior(draws, n_obs, α=0.5, β=0.5):
    "Beta posterior for θ from the first n_obs flips, given a Beta(α, β) prior."
    heads = draws[:n_obs].sum()
    return st.beta(α + heads, β + n_obs - heads)
```

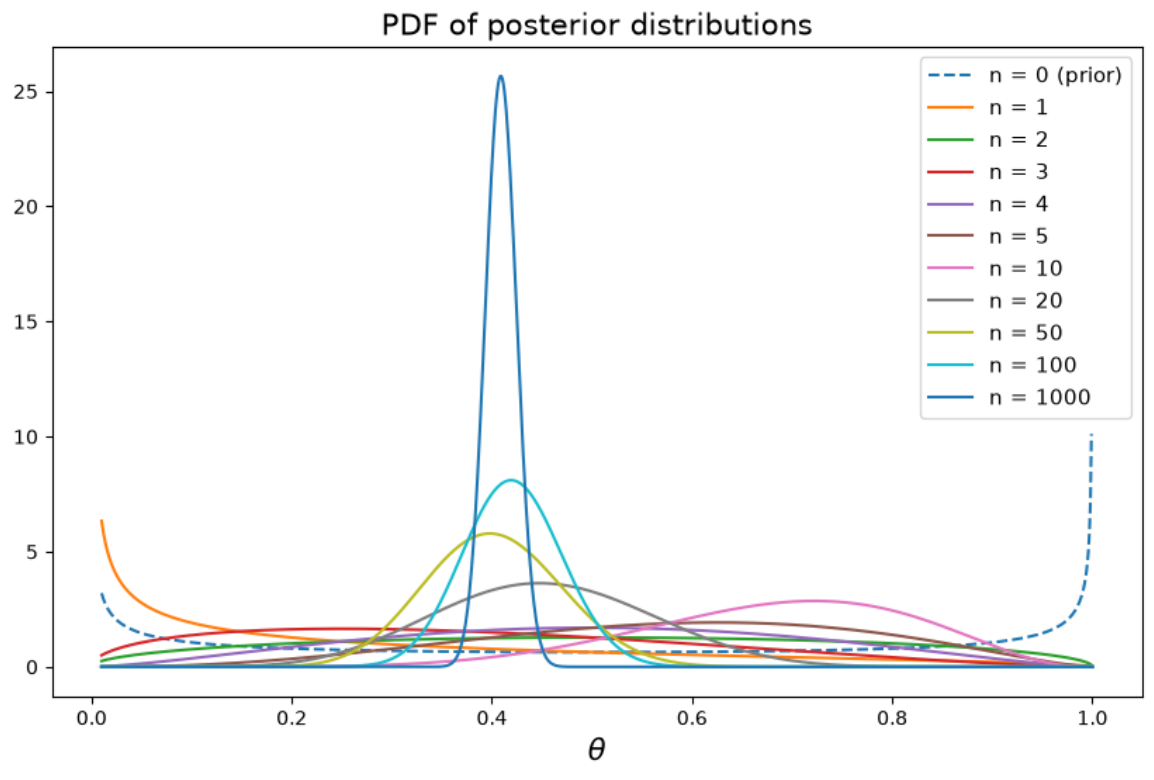
b)

```
draws = simulate_flips()

n_obs_list = [1, 2, 3, 4, 5, 10, 20, 50,
              100, 1000,
              5000, 10_000, 50_000, 100_000,
              200_000, 300_000]

posterior_list = [form_posterior(draws, n_obs) for n_obs in n_obs_list]

θ_values = np.linspace(0.01, 1, 1000)



fig, ax = plt.subplots(figsize=(10, 6))

prior = st.beta(0.5, 0.5)
ax.plot(θ_values, prior.pdf(θ_values),
        label='n = 0 (prior)', linestyle='--')

for i, n_obs in enumerate(n_obs_list[:10]):
    posterior = posterior_list[i]
    ax.plot(θ_values, posterior.pdf(θ_values),
            label=f'n = {n_obs}')

ax.set_title('PDF of posterior distributions',
             fontsize=15)
ax.set_xlabel(r"$\theta$", fontsize=15)

ax.legend(fontsize=11)
plt.show()
```

c)

```
lower_bound = [post.ppf(0.05) for post in posterior_list[:10]]
upper_bound = [post.ppf(0.95) for post in posterior_list[:10]]

interval_df = pd.DataFrame()
interval_df['upper'] = upper_bound
interval_df['lower'] = lower_bound
interval_df.index = n_obs_list[:10]
interval_df = interval_df.T
interval_df
```

```
            1         2         3        4         5         10        20    \
upper  0.771480  0.902692  0.764466  0.83472  0.872224  0.882671  0.629953
lower  0.001543  0.097308  0.062413  0.16528  0.260634  0.441873  0.280091

            50        100       1000
upper  0.516104  0.502138  0.434744
lower  0.292234  0.341239  0.383644
```

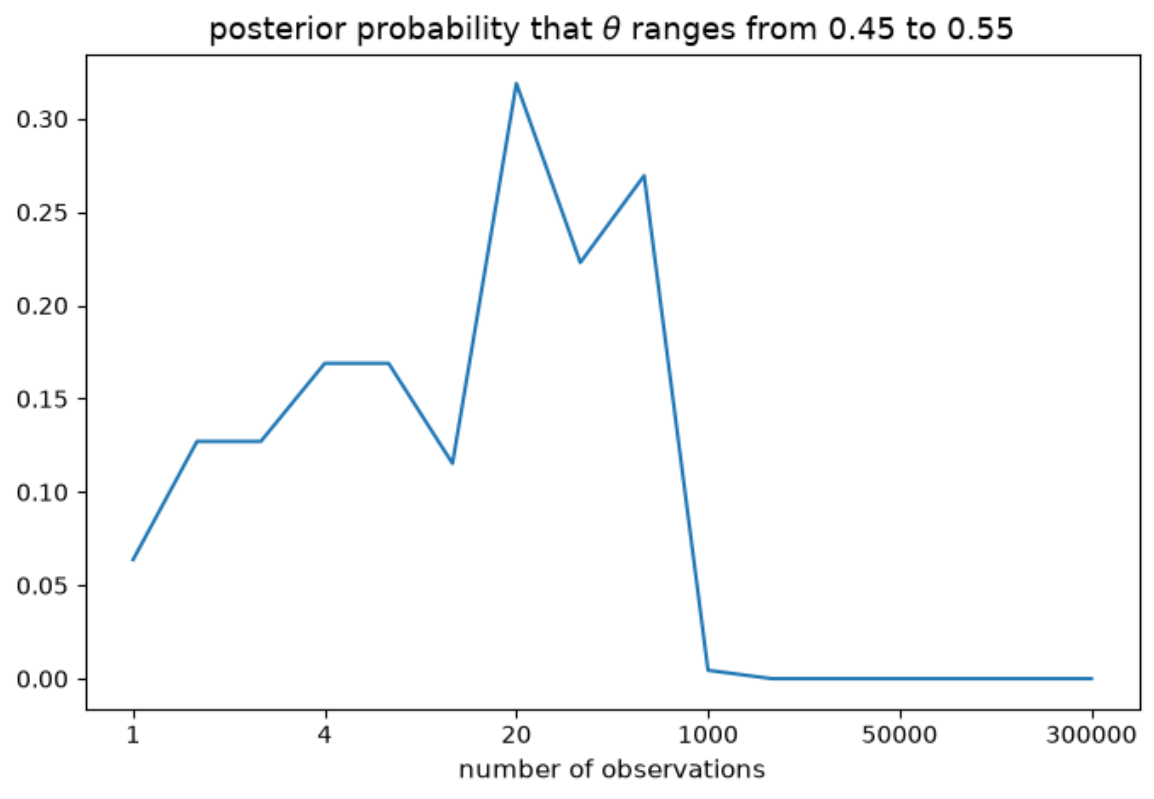
As n increases, we can see that Bayesian coverage intervals narrow and move toward 0.4.

d) The Bayesian coverage interval tells the range of θ that corresponds to the $[q_1, q_2]$ quantiles of the cumulative distribution function (CDF) of the posterior distribution.

To construct the coverage interval we first compute a posterior distribution of the unknown parameter θ.

If the CDF is $F(\theta)$, then the Bayesian coverage interval $[a, b]$ for the interval $[q_1, q_2]$ is described by

$$F(a) = q_1, F(b) = q_2$$



e)

```
left_value, right_value = 0.45, 0.55

posterior_prob_list = [
    post.cdf(right_value) - post.cdf(left_value)
    for post in posterior_list
]

fig, ax = plt.subplots(figsize=(8, 5))
ax.plot(posterior_prob_list)
ax.set_title(
    r'posterior probability that $\theta$'
    f' ranges from {left_value:.2f}'
    f' to {right_value:.2f}',
    fontsize=13)
ax.set_xticks(np.arange(0, len(posterior_prob_list), 3))
ax.set_xticklabels(n_obs_list[::3])
ax.set_xlabel('number of observations', fontsize=11)

plt.show()
```

Notice that in the graph above the posterior probability that $\theta \in [0.45, 0.55]$ exhibits a hump shape as n increases.

Two opposing forces are at work.

The first force is that the individual adjusts his belief as he observes new outcomes, so his posterior probability distribution becomes more and more realistic, which explains the rise of the posterior probability.

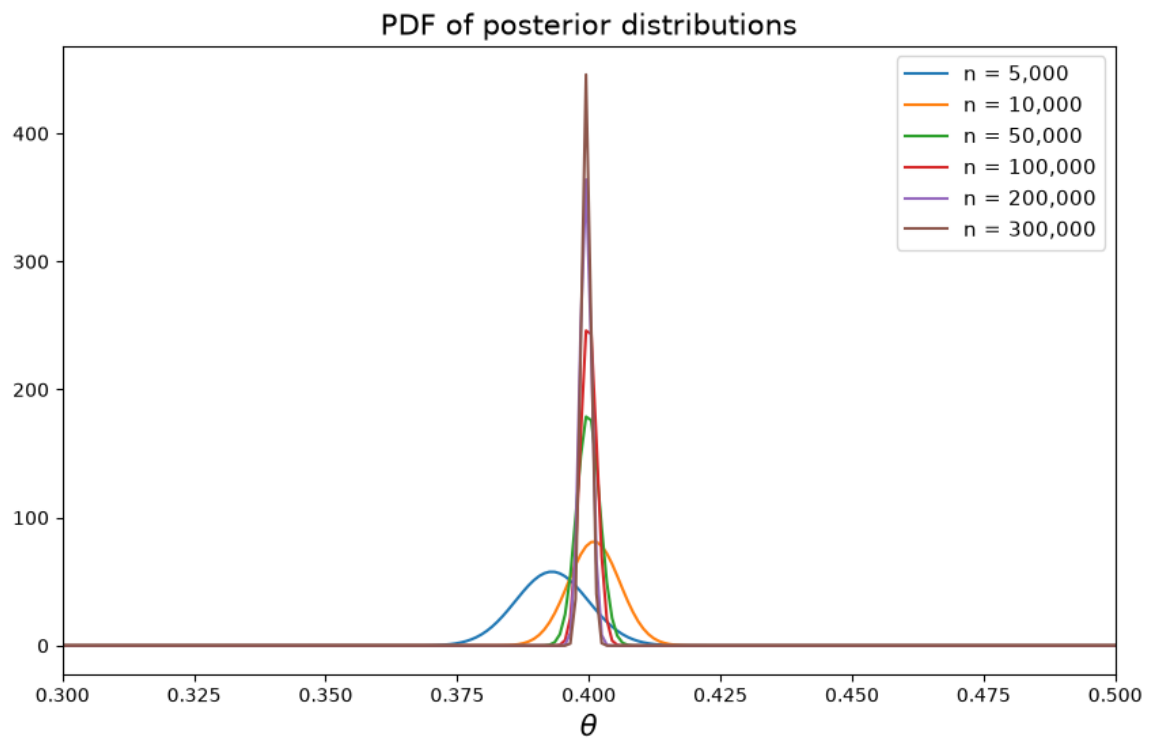
However, $[0.45, 0.55]$ actually excludes the true $\theta = 0.4$ that generates the data.

As a result, the posterior probability drops as larger and larger samples refine his posterior probability distribution of θ.

The descent seems precipitous only because of the scale of the graph that has the number of observations increasing disproportionately.

When the number of observations becomes large enough, our Bayesian becomes so confident about θ that he considers $\theta \in [0.45, 0.55]$ very unlikely.

That is why we see a nearly horizontal line when the number of observations exceeds 1000.



f) Using the functions we wrote above, we can see the evolution of posterior distributions as n approaches infinity.

```
fig, ax = plt.subplots(figsize=(10, 6))

for i, n_obs in enumerate(n_obs_list[10:]):
    posterior = posterior_list[i + 10]
    ax.plot(θ_values, posterior.pdf(θ_values),
            label=f'n = {n_obs:,}')

ax.set_title('PDF of posterior distributions', fontsize=15)
ax.set_xlabel(r"$\theta$", fontsize=15)
ax.set_xlim(0.3, 0.5)

ax.legend(fontsize=11)
plt.show()
```

As n increases, we can see that the probability density functions *concentrate* on 0.4, the true value of θ.

The next section explains *why* this concentration occurs and how fast it happens.

11.3.3 Why the posterior concentrates

In the solution to Exercise 11.3.2 we watched the posterior distribution concentrate ever more tightly around the true value $\theta = 0.4$ as the sample grew. Why does this happen?

The answer is encoded in the posterior we derived.

Recall that after observing k heads in n flips, the posterior is $\text{Beta}(\alpha + k,\ \beta + n - k)$.

A beta distribution with parameters a and b has

- mean $\dfrac{a}{a+b}$,
- variance $\dfrac{a\,b}{(a+b)^2\,(a+b+1)}$.

Substituting the *posterior* parameters $a = \alpha + k$ and $b = \beta + n - k$, so that $a + b = \alpha + \beta + n$, gives

$$\mathbb{E}[\theta \mid k] = \frac{\alpha + k}{\alpha + \beta + n}, \qquad \text{Var}[\theta \mid k] = \frac{(\alpha + k)(\beta + n - k)}{(\alpha + \beta + n)^2\,(\alpha + \beta + n + 1)}.$$

As n grows, the fixed prior counts α and β become negligible beside the data.

Since the data are generated with $\theta = 0.4$, the Law of Large Numbers gives $k/n \to 0.4$ (see Exercise 11.2.1), so the posterior mean

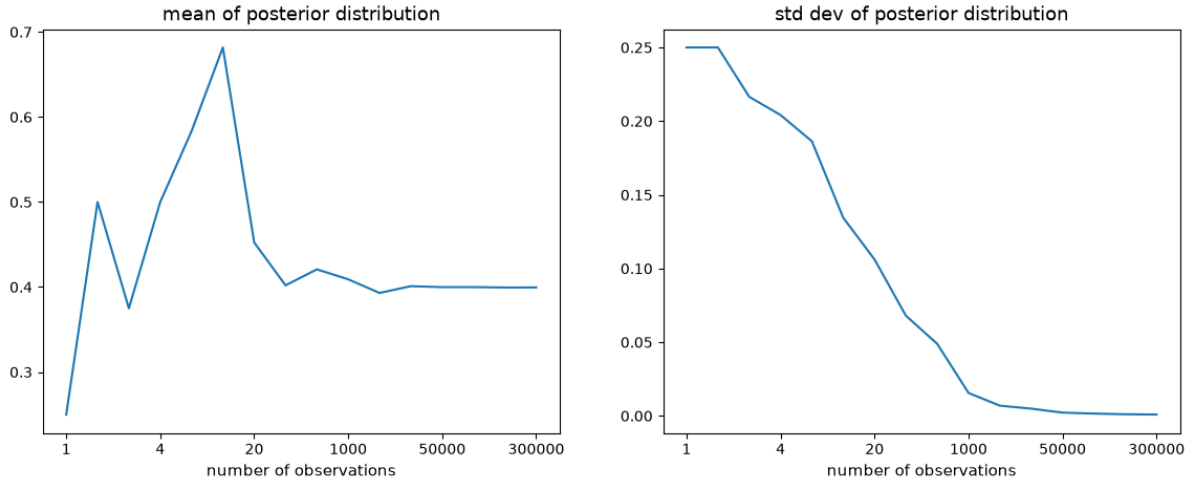
$$\frac{\alpha + k}{\alpha + \beta + n} \;\approx\; \frac{k}{n} \;\to\; 0.4.$$

In the variance, the numerator grows like n^2 while the denominator grows like n^3, so

$$\text{Var}[\theta \mid k] \;\approx\; \frac{\theta(1-\theta)}{n} \;\longrightarrow\; 0.$$

The posterior mean therefore homes in on the truth while its spread vanishes at rate $1/n$.

The next figure confirms both claims: the posterior mean settles on 0.4 and the standard deviation decays toward zero.



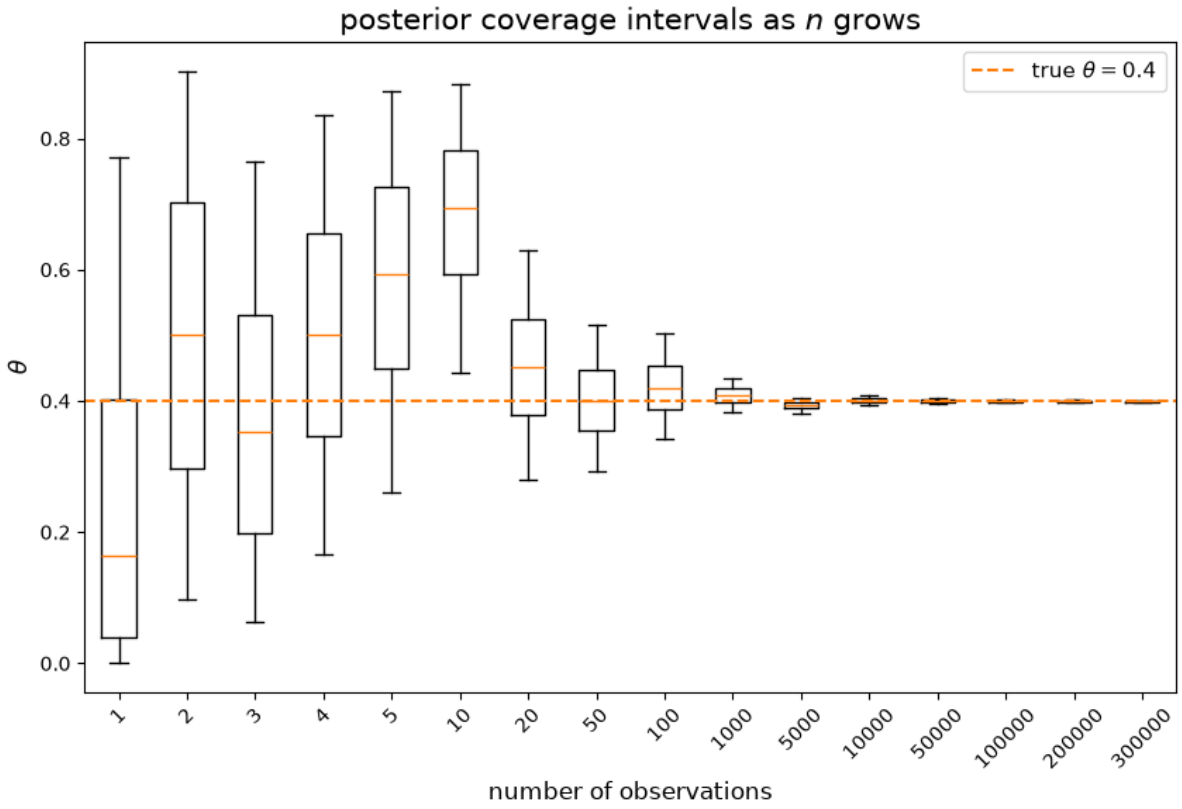
```
mean_list = [post.mean() for post in posterior_list]
std_list = [post.std() for post in posterior_list]

fig, ax = plt.subplots(1, 2, figsize=(14, 5))

ax[0].plot(mean_list)
ax[0].set_title('mean of posterior distribution',
                fontsize=13)
ax[0].set_xticks(np.arange(0, len(mean_list), 3))
ax[0].set_xticklabels(n_obs_list[::3])
ax[0].set_xlabel('number of observations', fontsize=11)

ax[1].plot(std_list)
ax[1].set_title('std dev of posterior distribution',
                fontsize=13)
ax[1].set_xticks(np.arange(0, len(std_list), 3))
ax[1].set_xticklabels(n_obs_list[::3])
ax[1].set_xlabel('number of observations', fontsize=11)

plt.show()
```



We can also display the Bayesian coverage intervals directly.

The box-and-whisker plot below summarizes each posterior by its median (central line), interquartile range (box), and 5th–95th percentile range (whiskers), with the true value $\theta = 0.4$ marked.

```
quantiles = [0.05, 0.25, 0.5, 0.75, 0.95]
box_stats = []
for post in posterior_list:
    lo, q1, med, q3, hi = post.ppf(quantiles)
    box_stats.append({'med': med, 'q1': q1, 'q3': q3,
                      'whislo': lo, 'whishi': hi, 'fliers': []})

fig, ax = plt.subplots(figsize=(10, 6))
ax.bxp(box_stats, positions=np.arange(len(box_stats)), showfliers=False)
ax.axhline(0.4, color='C1', linestyle='--', label=r'true $\theta = 0.4$')
ax.set_xticks(np.arange(len(box_stats)))
ax.set_xticklabels(n_obs_list, rotation=45)
ax.set_xlabel('number of observations', fontsize=12)
ax.set_ylabel(r'$\theta$', fontsize=12)
ax.set_title('posterior coverage intervals as $n$ grows', fontsize=15)
ax.legend(fontsize=11)
plt.show()
```

After observing a large number of outcomes, the posterior distribution collapses around 0.4.

Thus, the Bayesian statistician comes to believe that θ is near 0.4.

As shown in the figure above, as the number of observations grows, the Bayesian coverage intervals (BCIs) become narrower and narrower around 0.4.

However, if you take a closer look, you will find that the centers of the BCIs are not exactly 0.4, due to the persistent influence of the prior distribution and the randomness of the simulation path.

11.4 Comparing the two interpretations

We can now place the two meanings of probability side by side.

In the frequentist calculations, θ was a *fixed* number and a probability was a *relative frequency*: $p(k \mid \theta)$ is the fraction of a large number of independent length-n sequences in which exactly k heads occur, and we confirmed by simulation that $f_k^I \to p(k \mid \theta)$ as $I \to \infty$.

In the Bayesian calculations, θ was itself a *random variable* describing our beliefs, and a probability was a *degree of belief*. The Bayesian coverage interval summarizes the posterior $p(\theta \mid k)$: it reports the range of θ lying between two posterior quantiles, and so answers the question "given the data I have seen and my prior, where do I now believe θ lies?"

These are genuinely different questions, even though both rest on the same binomial likelihood. The frequentist statement describes the data-generating mechanism for a fixed θ; the Bayesian statement describes our uncertainty about θ given the particular data we happened to observe.

11.5 Role of a Conjugate Prior

We have made assumptions that link functional forms of our likelihood function and our prior in a way that has eased our calculations considerably.

In particular, our assumptions that the likelihood function is **binomial** and that the prior distribution is a **beta distribution** have the consequence that the posterior distribution implied by Bayes' Law is also a **beta distribution**.

So posterior and prior are both beta distributions, albeit ones with different parameters.

When a likelihood function and prior fit together like hand and glove in this way, we can say that the prior and posterior are **conjugate distributions**.

In this situation, we also sometimes say that we have **conjugate prior** for the likelihood function $p(k \mid \theta)$.

Typically, the functional form of the likelihood function determines the functional form of a **conjugate prior**.

A natural question to ask is why should a person's personal prior about a parameter θ be restricted to be described by a conjugate prior?

Why not some other functional form that more sincerely describes the person's beliefs?

To be argumentative, one could ask, why should the form of the likelihood function have *anything* to say about my personal beliefs about θ?

A dignified response to that question is, well, it shouldn't, but if you want to compute a posterior easily you'll just be happier if your prior is conjugate to your likelihood.

Otherwise, your posterior won't have a convenient analytical form and you'll be in the situation of wanting to apply the Markov chain Monte Carlo techniques deployed in *Non-Conjugate Priors*.

We also apply these powerful methods to approximating Bayesian posteriors for non-conjugate priors in *Posterior Distributions for AR(1) Parameters* and *Forecasting an AR(1) Process*.

CHAPTER

TWELVE

MULTIVARIATE HYPERGEOMETRIC DISTRIBUTION

Contents

- *Multivariate Hypergeometric Distribution*
  - *Overview*
  - *The administrator's problem*
  - *Usage*

12.1 Overview

This lecture describes how an administrator deployed a **multivariate hypergeometric distribution** in order to access the fairness of a procedure for awarding research grants.

In the lecture we'll learn about

- properties of the multivariate hypergeometric distribution
- first and second moments of a multivariate hypergeometric distribution
- using a Monte Carlo simulation of a multivariate normal distribution to evaluate the quality of a normal approximation
- the administrator's problem and why the multivariate hypergeometric distribution is the right tool

12.2 The administrator's problem

An administrator in charge of allocating research grants is in the following situation.

To help us forget details that are none of our business here and to protect the anonymity of the administrator and the subjects, we call research proposals **balls** and continents of residence of authors of a proposal a **color**.

There are K_i balls (proposals) of color i.

There are c distinct colors (continents of residence).

Thus, $i = 1, 2, \ldots, c$

So there is a total of $N = \sum_{i=1}^{c} K_i$ balls.

All N of these balls are placed in an urn.

Then n balls are drawn randomly.

The selection procedure is supposed to be **color blind** meaning that **ball quality**, a random variable that is supposed to be independent of **ball color**, governs whether a ball is drawn.

Thus, the selection procedure is supposed randomly to draw n balls from the urn.

The n balls drawn represent successful proposals and are awarded research funds.

The remaining $N - n$ balls receive no research funds.

12.2.1 Details of the awards procedure under study

Let k_i be the number of balls of color i that are drawn.

Things have to add up so $\sum_{i=1}^{c} k_i = n$.

Under the hypothesis that the selection process judges proposals on their quality and that quality is independent of continent of the author's continent of residence, the administrator views the outcome of the selection procedure as a random vector

$$X = \begin{bmatrix} k_1 \\ k_2 \\ \vdots \\ k_c \end{bmatrix}.$$

To evaluate whether the selection procedure is **color blind** the administrator wants to study whether the particular realization of X drawn can plausibly be said to be a random draw from the probability distribution that is implied by the **color blind** hypothesis.

The appropriate probability distribution is the one described here.

Let's now instantiate the administrator's problem, while continuing to use the colored balls metaphor.

The administrator has an urn with $N = 238$ balls.

157 balls are blue, 11 balls are green, 46 balls are yellow, and 24 balls are black.

So $(K_1, K_2, K_3, K_4) = (157, 11, 46, 24)$ and $c = 4$.

15 balls are drawn without replacement.

So $n = 15$.

The administrator wants to know the probability distribution of outcomes

$$X = \begin{bmatrix} k_1 \\ k_2 \\ \vdots \\ k_4 \end{bmatrix}.$$

In particular, he wants to know whether a particular outcome - in the form of a 4×1 vector of integers recording the numbers of blue, green, yellow, and black balls, respectively, - contains evidence against the hypothesis that the selection process is *fair*, which here means *color blind* and truly are random draws without replacement from the population of N balls.

The right tool for the administrator's job is the **multivariate hypergeometric distribution**.

12.2.2 Multivariate hypergeometric distribution

Let's start with some imports.

```
import matplotlib.pyplot as plt
import numpy as np
from scipy.special import comb
from scipy.stats import normaltest
from numba import jit, prange
```

To recapitulate, we assume there are in total c types of objects in an urn.

If there are K_i type i object in the urn and we take n draws at random without replacement, then the numbers of type i objects in the sample $(k_1, k_2, \ldots, k_c)$ has the multivariate hypergeometric distribution.

Note again that $N = \sum_{i=1}^{c} K_i$ is the total number of objects in the urn and $n = \sum_{i=1}^{c} k_i$.

Notation

We use the following notation for **binomial coefficients**: $\binom{m}{q} = \frac{m!}{(m-q)!}$.

The multivariate hypergeometric distribution has the following properties:

Probability mass function:

$$\Pr\{X_i = k_i \ \forall i\} = \frac{\prod_{i=1}^{c} \binom{K_i}{k_i}}{\binom{N}{n}}$$

Mean:

$$\mathrm{E}(X_i) = n\frac{K_i}{N}$$

Variances and covariances:

$$\mathrm{Var}(X_i) = n\frac{N-n}{N-1}\ \frac{K_i}{N}\left(1-\frac{K_i}{N}\right)$$

$$\mathrm{Cov}(X_i, X_j) = -n\frac{N-n}{N-1}\ \frac{K_i}{N}\frac{K_j}{N}$$

To do our work for us, we'll write an `Urn` class.

```
class Urn:

    def __init__(self, K_arr):
        """
        Initialization given the number of each type i object in the urn.

        Parameters
        ----------
        K_arr: ndarray(int)
            number of each type i object.
        """

        self.K_arr = np.array(K_arr)
        self.N = np.sum(K_arr)
        self.c = len(K_arr)

    def pmf(self, k_arr):
        """
```

(continues on next page)

(continued from previous page)

```
        Probability mass function.

        Parameters
        ----------
        k_arr: ndarray(int)
            number of observed successes of each object.
        """

        K_arr, N = self.K_arr, self.N

        k_arr = np.atleast_2d(k_arr)
        n = np.sum(k_arr, 1)

        num = np.prod(comb(K_arr, k_arr), 1)
        denom = comb(N, n)

        pr = num / denom

        return pr

    def moments(self, n):
        """
        Compute the mean and variance-covariance matrix for
        multivariate hypergeometric distribution.

        Parameters
        ----------
        n: int
            number of draws.
        """

        K_arr, N = self.K_arr, self.N

        # mean
        μ = n * K_arr / N

        # variance-covariance matrix
        p = K_arr / N
        Σ = n * (N - n) / (N - 1) * (np.diag(p) - np.outer(p, p))

        return μ, Σ

    def simulate(self, n, size=1, seed=None):
        """
        Simulate a sample from multivariate hypergeometric
        distribution where at each draw we take n objects
        from the urn without replacement.

        Parameters
        ----------
        n: int
            number of objects for each draw.
        size: int(optional)
            sample size.
        seed: int(optional)
            random seed.
        """
```

(continues on next page)

(continued from previous page)

```
        K_arr = self.K_arr

        gen = np.random.Generator(np.random.PCG64(seed))
        sample = gen.multivariate_hypergeometric(K_arr, n, size=size)

        return sample
```

12.3 Usage

12.3.1 First example

Apply this to an example from wiki:

Suppose there are 5 black, 10 white, and 15 red marbles in an urn. If six marbles are chosen without replacement, the probability that exactly two of each color are chosen is

$$P(2 \text{ black}, 2 \text{ white}, 2 \text{ red}) = \frac{\binom{5}{2}\binom{10}{2}\binom{15}{2}}{\binom{30}{6}} = 0.079575596816976$$

```
# construct the urn
K_arr = [5, 10, 15]
urn = Urn(K_arr)
```

Now use the Urn Class method `pmf` to compute the probability of the outcome $X = \begin{bmatrix} 2 & 2 & 2 \end{bmatrix}$

```
k_arr = [2, 2, 2] # array of number of observed successes
urn.pmf(k_arr)
```

```
array([0.0795756])
```

We can use the code to compute probabilities of a list of possible outcomes by constructing a 2-dimensional array `k_arr` and `pmf` will return an array of probabilities for observing each case.

```
k_arr = [[2, 2, 2], [1, 3, 2]]
urn.pmf(k_arr)
```

```
array([0.0795756, 0.1061008])
```

Now let's compute the mean vector and variance-covariance matrix.

```
n = 6
μ, Σ = urn.moments(n)
```

```
μ
```

```
array([1., 2., 3.])
```

```
Σ
```

```
array([[ 0.68965517, -0.27586207, -0.4137931 ],
       [-0.27586207,  1.10344828, -0.82758621],
       [-0.4137931 , -0.82758621,  1.24137931]])
```

12.3.2 Back to the administrator's problem

Now let's turn to the grant administrator's problem.

Here the array of numbers of i objects in the urn is $(157, 11, 46, 24)$.

```
K_arr = [157, 11, 46, 24]
urn = Urn(K_arr)
```

Let's compute the probability of the outcome $(10, 1, 4, 0)$.

```
k_arr = [10, 1, 4, 0]
urn.pmf(k_arr)
```

```
array([0.01547738])
```

We can compute probabilities of three possible outcomes by constructing a 3-dimensional arrays `k_arr` and utilizing the method `pmf` of the `Urn` class.

```
k_arr = [[5, 5, 4 ,1], [10, 1, 2, 2], [13, 0, 2, 0]]
urn.pmf(k_arr)
```

```
array([6.21412534e-06, 2.70935969e-02, 1.61839976e-02])
```

Now let's compute the mean and variance-covariance matrix of X when $n = 6$.

```
n = 6 # number of draws
μ, Σ = urn.moments(n)
```

```
# mean
μ
```

```
array([3.95798319, 0.27731092, 1.15966387, 0.60504202])
```

```
# variance-covariance matrix
Σ
```

```
array([[ 1.31862604, -0.17907267, -0.74884935, -0.39070401],
       [-0.17907267,  0.25891399, -0.05246715, -0.02737417],
       [-0.74884935, -0.05246715,  0.91579029, -0.11447379],
       [-0.39070401, -0.02737417, -0.11447379,  0.53255196]])
```

We can simulate a large sample and verify that sample means and covariances closely approximate the population means and covariances.

```
size = 10_000_000
sample = urn.simulate(n, size=size)
```

```
# mean
np.mean(sample, 0)
```

```
array([3.9582878, 0.2773269, 1.1592989, 0.6050864])
```

```
# variance covariance matrix
np.cov(sample.T)
```

```
array([[ 1.31942622, -0.1790873 , -0.74896487, -0.39137405],
       [-0.1790873 ,  0.25897412, -0.05246658, -0.02742024],
       [-0.74896487, -0.05246658,  0.91533025, -0.11389881],
       [-0.39137405, -0.02742024, -0.11389881,  0.5326931 ]])
```

Evidently, the sample means and covariances approximate their population counterparts well.

12.3.3 Quality of normal approximation

To judge the quality of a multivariate normal approximation to the multivariate hypergeometric distribution, we draw a large sample from a multivariate normal distribution with the mean vector and covariance matrix for the corresponding multivariate hypergeometric distribution and compare the simulated distribution with the population multivariate hypergeometric distribution.

```
sample_normal = np.random.multivariate_normal(μ, Σ, size=size)
```

```
def bivariate_normal(x, y, μ, Σ, i, j):

    μ_x, μ_y = μ[i], μ[j]
    σ_x, σ_y = np.sqrt(Σ[i, i]), np.sqrt(Σ[j, j])
    σ_xy = Σ[i, j]

    x_μ = x - μ_x
    y_μ = y - μ_y

    ρ = σ_xy / (σ_x * σ_y)
    z = x_μ**2 / σ_x**2 + y_μ**2 / σ_y**2 - 2 * ρ * x_μ * y_μ / (σ_x * σ_y)
    denom = 2 * np.pi * σ_x * σ_y * np.sqrt(1 - ρ**2)

    return np.exp(-z / (2 * (1 - ρ**2))) / denom
```

```
@jit
def count(vec1, vec2, n):
    size = sample.shape[0]

    count_mat = np.zeros((n+1, n+1))
    for i in prange(size):
        count_mat[vec1[i], vec2[i]] += 1

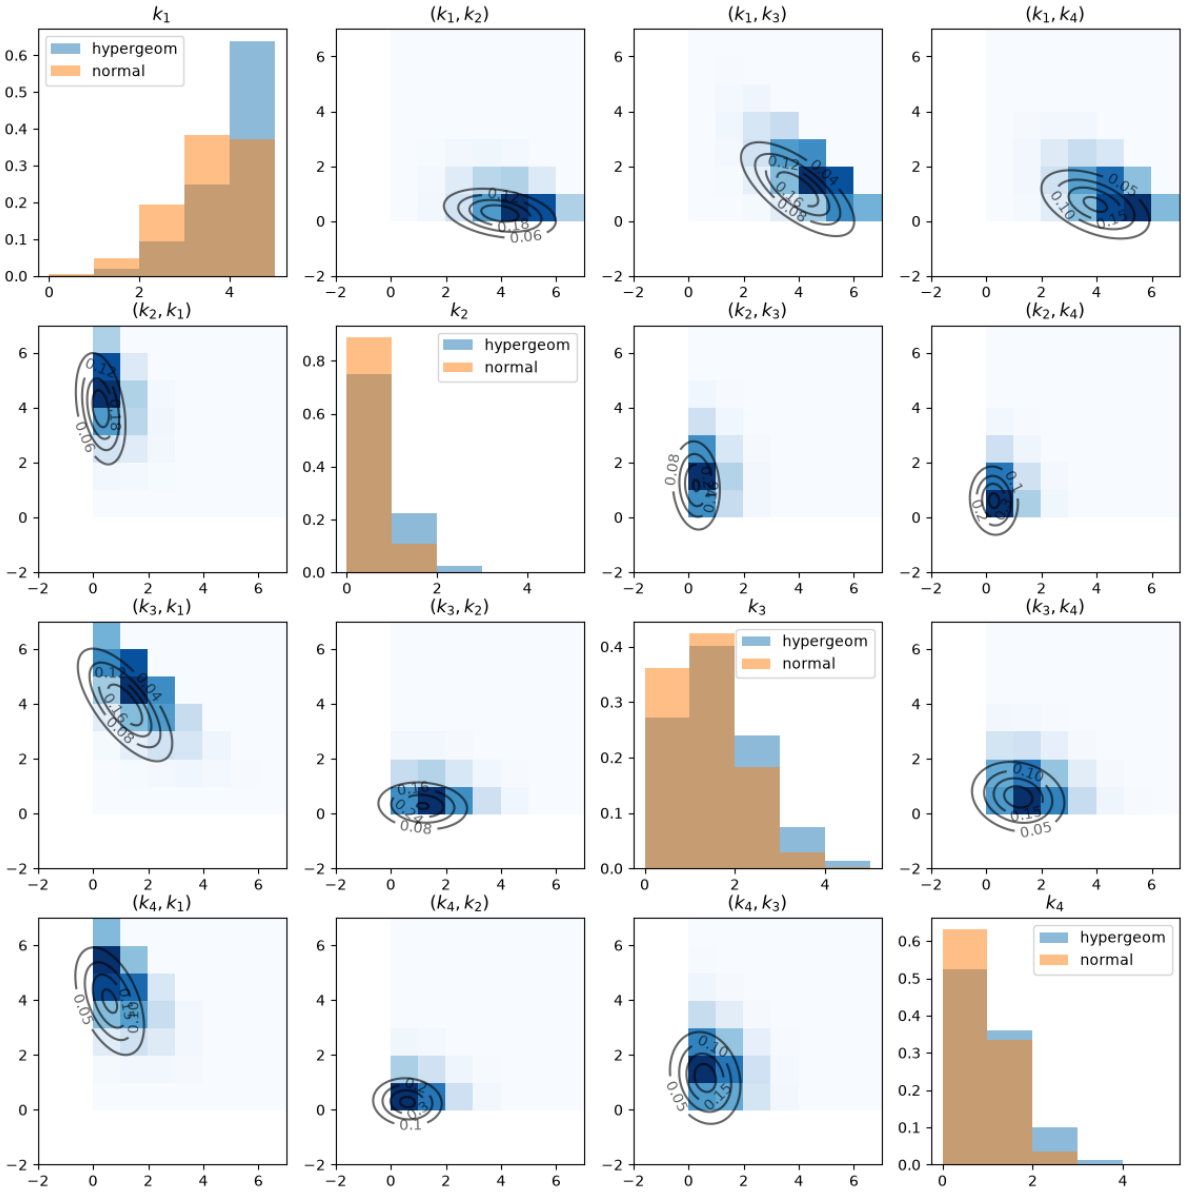
    return count_mat
```

```
c = urn.c
fig, axs = plt.subplots(c, c, figsize=(14, 14))

# grids for ploting the bivariate Gaussian
```

(continues on next page)

(continued from previous page)



```
x_grid = np.linspace(-2, n+1, 100)
y_grid = np.linspace(-2, n+1, 100)
X, Y = np.meshgrid(x_grid, y_grid)

for i in range(c):
    axs[i, i].hist(sample[:, i], bins=np.arange(0, n, 1), alpha=0.5, density=True,␣
↪label='hypergeom')
    axs[i, i].hist(sample_normal[:, i], bins=np.arange(0, n, 1), alpha=0.5,␣
↪density=True, label='normal')
    axs[i, i].legend()
    axs[i, i].set_title('$k_{' +str(i+1) +'}$')
    for j in range(c):
        if i == j:
            continue

        # bivariate Gaussian density function
        Z = bivariate_normal(X, Y, μ, Σ, i, j)
        cs = axs[i, j].contour(X, Y, Z, 4, colors="black", alpha=0.6)
        axs[i, j].clabel(cs, inline=1, fontsize=10)

        # empirical multivariate hypergeometric distrbution
        count_mat = count(sample[:, i], sample[:, j], n)
        axs[i, j].pcolor(count_mat.T/size, cmap='Blues')
        axs[i, j].set_title('$(k_{' +str(i+1) +'}, k_{' + str(j+1) + '})$')

plt.show()
```

The diagonal graphs plot the marginal distributions of k_i for each i using histograms.

Note the substantial differences between hypergeometric distribution and the approximating normal distribution.

The off-diagonal graphs plot the empirical joint distribution of k_i and k_j for each pair (i, j).

The darker the blue, the more data points are contained in the corresponding cell. (Note that k_i is on the x-axis and k_j is on the y-axis).

The contour maps plot the bivariate Gaussian density function of $\left(k_i, k_j\right)$ with the population mean and covariance given by slices of μ and Σ that we computed above.

Let's also test the normality for each k_i using `scipy.stats.normaltest` that implements D'Agostino and Pearson's test that combines skew and kurtosis to form an omnibus test of normality.

The null hypothesis is that the sample follows normal distribution.

> `normaltest` returns an array of p-values associated with tests for each k_i sample.

```
test_multihyper = normaltest(sample)
test_multihyper.pvalue
```

```
array([0., 0., 0., 0.])
```

As we can see, all the p-values are almost 0 and the null hypothesis is soundly rejected.

By contrast, the sample from normal distribution does not reject the null hypothesis.

```
test_normal = normaltest(sample_normal)
test_normal.pvalue
```

```
array([0.17068467, 0.429687  , 0.539212  , 0.85347899])
```

The lesson to take away from this is that the normal approximation is imperfect.

13.1 Overview

This lecture describes a workhorse in probability theory, statistics, and economics, namely, the **multivariate normal distribution**.

In this lecture, you will learn formulas for

- the joint distribution of a random vector x of length N
- marginal distributions for all subvectors of x
- conditional distributions for subvectors of x conditional on other subvectors of x

We will use the multivariate normal distribution to formulate some useful models:

- a factor analytic model of an intelligence quotient, i.e., IQ
- a factor analytic model of two independent inherent abilities, say, mathematical and verbal.
- a more general factor analytic model
- Principal Components Analysis (PCA) as an approximation to a factor analytic model
- time series generated by linear stochastic difference equations
- optimal linear filtering theory

13.2 The multivariate normal distribution

This lecture defines a Python class `MultivariateNormal` to be used to generate **marginal** and **conditional** distributions associated with a multivariate normal distribution.

For a multivariate normal distribution it is very convenient that

- conditional expectations equal linear least squares projections
- conditional distributions are characterized by multivariate linear regressions

We apply our Python class to some examples.

We use the following imports:

```
import matplotlib.pyplot as plt
import numpy as np
from numba import jit
import statsmodels.api as sm

rng = np.random.default_rng(0)
```

Assume that an $N \times 1$ random vector z has a multivariate normal probability density.

This means that the probability density takes the form

$$f\left(z;\mu,\Sigma\right)=\left(2\pi\right)^{-\left(\frac{N}{2}\right)}\det\left(\Sigma\right)^{-\frac{1}{2}}\exp\left(-.5\left(z-\mu\right)^{\top}\Sigma^{-1}\left(z-\mu\right)\right)$$

where $\mu=Ez$ is the mean of the random vector z and $\Sigma=E\left(z-\mu\right)\left(z-\mu\right)^{\top}$ is the covariance matrix of z.

The covariance matrix Σ is symmetric and positive definite.

```
@jit
def f(z, μ, Σ):
    """
    The density function of multivariate normal distribution.

    Parameters
    ---------------
    z: ndarray(float, dim=2)
        random vector, N by 1
    μ: ndarray(float, dim=1 or 2)
        the mean of z, N by 1
    Σ: ndarray(float, dim=2)
        the covariance matrix of z, N by N
    """
```

(continues on next page)

(continued from previous page)

```
    z = np.atleast_2d(z)
    μ = np.atleast_2d(μ)
    Σ = np.atleast_2d(Σ)

    N = z.size

    temp1 = np.linalg.det(Σ) ** (-1/2)
    temp2 = np.exp(-.5 * (z - μ).T @ np.linalg.inv(Σ) @ (z - μ))

    return (2 * np.pi) ** (-N/2) * temp1 * temp2
```

For some integer $k \in \{1, \ldots, N-1\}$, partition z as

$$z = \begin{bmatrix} z_1 \\ z_2 \end{bmatrix},$$

where z_1 is an $(N-k) \times 1$ vector and z_2 is a $k \times 1$ vector.

Let

$$\mu = \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix}, \quad \Sigma = \begin{bmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{bmatrix}$$

be corresponding partitions of μ and Σ.

The **marginal** distribution of z_1 is

- multivariate normal with mean μ_1 and covariance matrix Σ_{11}.

The **marginal** distribution of z_2 is

- multivariate normal with mean μ_2 and covariance matrix Σ_{22}.

The distribution of z_1 **conditional** on z_2 is

- multivariate normal with mean

$$\hat{\mu}_1 = \mu_1 + \beta (z_2 - \mu_2)$$

and covariance matrix

$$\hat{\Sigma}_{11} = \Sigma_{11} - \Sigma_{12}\Sigma_{22}^{-1}\Sigma_{21} = \Sigma_{11} - \beta\Sigma_{22}\beta^\top$$

where

$$\beta = \Sigma_{12}\Sigma_{22}^{-1}$$

is an $(N-k) \times k$ matrix of **population regression coefficients** of the $(N-k) \times 1$ random vector $z_1 - \mu_1$ on the $k \times 1$ random vector $z_2 - \mu_2$.

The following class constructs a multivariate normal distribution instance with two methods.

- a method `partition` computes β, taking k as an input
- a method `cond_dist` computes either the distribution of z_1 conditional on z_2 or the distribution of z_2 conditional on z_1

```
class MultivariateNormal:
    """
    Class of multivariate normal distribution.

    Parameters
    ----------
    μ: ndarray(float, dim=1)
        the mean of z, N by 1
    Σ: ndarray(float, dim=2)
        the covariance matrix of z, N by N

    Arguments
    ---------
    μ, Σ:
        see parameters
    μs: list(ndarray(float, dim=1))
        list of mean vectors μ1 and μ2 in order
    Σs: list(list(ndarray(float, dim=2)))
        2 dimensional list of covariance matrices
        Σ11, Σ12, Σ21, Σ22 in order
    βs: list(ndarray(float, dim=1))
        list of regression coefficients β1 and β2 in order
    """

    def __init__(self, μ, Σ):
        "initialization"
        self.μ = np.array(μ)
        self.Σ = np.atleast_2d(Σ)

    def partition(self, k):
        """
        Given k, partition the random vector z into a size k vector z1
        and a size N-k vector z2. Partition the mean vector μ into
        μ1 and μ2, and the covariance matrix Σ into Σ11, Σ12, Σ21, Σ22
        correspondingly. Compute the regression coefficients β1 and β2
        using the partitioned arrays.
        """
        μ = self.μ
        Σ = self.Σ

        self.μs = [μ[:k], μ[k:]]
        self.Σs = [[Σ[:k, :k], Σ[:k, k:]],
                   [Σ[k:, :k], Σ[k:, k:]]]

        self.βs = [self.Σs[0][1] @ np.linalg.inv(self.Σs[1][1]),
                   self.Σs[1][0] @ np.linalg.inv(self.Σs[0][0])]

    def cond_dist(self, ind, z):
        """
        Compute the conditional distribution of z1 given z2, or reversely.
        Argument ind determines whether we compute the conditional
        distribution of z1 (ind=0) or z2 (ind=1).

        Returns
        ---------
        μ_hat: ndarray(float, ndim=1)
            The conditional mean of z1 or z2.
```

(continues on next page)

(continued from previous page)

```
        Σ_hat: ndarray(float, ndim=2)
            The conditional covariance matrix of z1 or z2.
        """
        β = self.βs[ind]
        μs = self.μs
        Σs = self.Σs

        μ_hat = μs[ind] + β @ (z - μs[1-ind])
        Σ_hat = Σs[ind][ind] - β @ Σs[1-ind][1-ind] @ β.T

        return μ_hat, Σ_hat
```

Let's put this code to work on a suite of examples.

We begin with a simple bivariate example; after that we'll turn to a trivariate example.

We'll compute population moments of some conditional distributions using our `MultivariateNormal` class.

For fun we'll also compute sample analogs of the associated population regressions by generating simulations and then computing linear least squares regressions.

We'll compare those linear least squares regressions for the simulated data to their population counterparts.

13.3 Bivariate example

We start with a bivariate normal distribution pinned down by

$$\mu = \begin{bmatrix} .5 \\ 1.0 \end{bmatrix}, \quad \Sigma = \begin{bmatrix} 1 & .5 \\ .5 & 1 \end{bmatrix}$$

```
μ = np.array([.5, 1.])
Σ = np.array([[1., .5], [.5 ,1.]])

# construction of the multivariate normal instance
multi_normal = MultivariateNormal(μ, Σ)
```

```
k = 1 # choose partition

# partition and compute regression coefficients
multi_normal.partition(k)
multi_normal.βs[0],multi_normal.βs[1]
```

```
(array([[0.5]]), array([[0.5]]))
```

Let's illustrate the fact that you *can regress anything on anything else*.

We have computed everything we need to compute two regression lines, one of z_2 on z_1, the other of z_1 on z_2.

We'll represent these regressions as

$$z_1 = a_1 + b_1 z_2 + \epsilon_1$$

and

$$z_2 = a_2 + b_2 z_1 + \epsilon_2$$

where we have the population least squares orthogonality conditions

$$E\epsilon_1 z_2 = 0$$

and

$$E\epsilon_2 z_1 = 0$$

Let's compute a_1, a_2, b_1, b_2.

```
β = multi_normal.βs

a1 = μ[0] - β[0]*μ[1]
b1 = β[0]

a2 = μ[1] - β[1]*μ[0]
b2 = β[1]
```

Let's print out the intercepts and slopes.

For the regression of z_1 on z_2 we have

```
print ("a1 = ", a1)
print ("b1 = ", b1)
```

```
a1 =  [[0.]]
b1 =  [[0.5]]
```

For the regression of z_2 on z_1 we have

```
print ("a2 = ", a2)
print ("b2 = ", b2)
```

```
a2 =  [[0.75]]
b2 =  [[0.5]]
```

Now let's plot the two regression lines and stare at them.

```
z2 = np.linspace(-4,4,100)

a1 = np.squeeze(a1)
b1 = np.squeeze(b1)

a2 = np.squeeze(a2)
b2 = np.squeeze(b2)

z1  = b1*z2 + a1

z1h = z2/b2 - a2/b2

fig = plt.figure(figsize=(12,12))
ax = fig.add_subplot(1, 1, 1)
ax.set(xlim=(-4, 4), ylim=(-4, 4))
ax.spines['left'].set_position('center')
```

(continues on next page)

(continued from previous page)

```
ax.spines['bottom'].set_position('zero')
ax.spines['right'].set_color('none')
ax.spines['top'].set_color('none')
ax.xaxis.set_ticks_position('bottom')
ax.yaxis.set_ticks_position('left')
plt.ylabel('$z_1$', loc = 'top')
plt.xlabel('$z_2$,', loc = 'right')
plt.plot(z2,z1, 'r', label = "$z_1$ on $z_2$")
plt.plot(z2,z1h, 'b', label = "$z_2$ on $z_1$")
plt.legend()
plt.show()
```

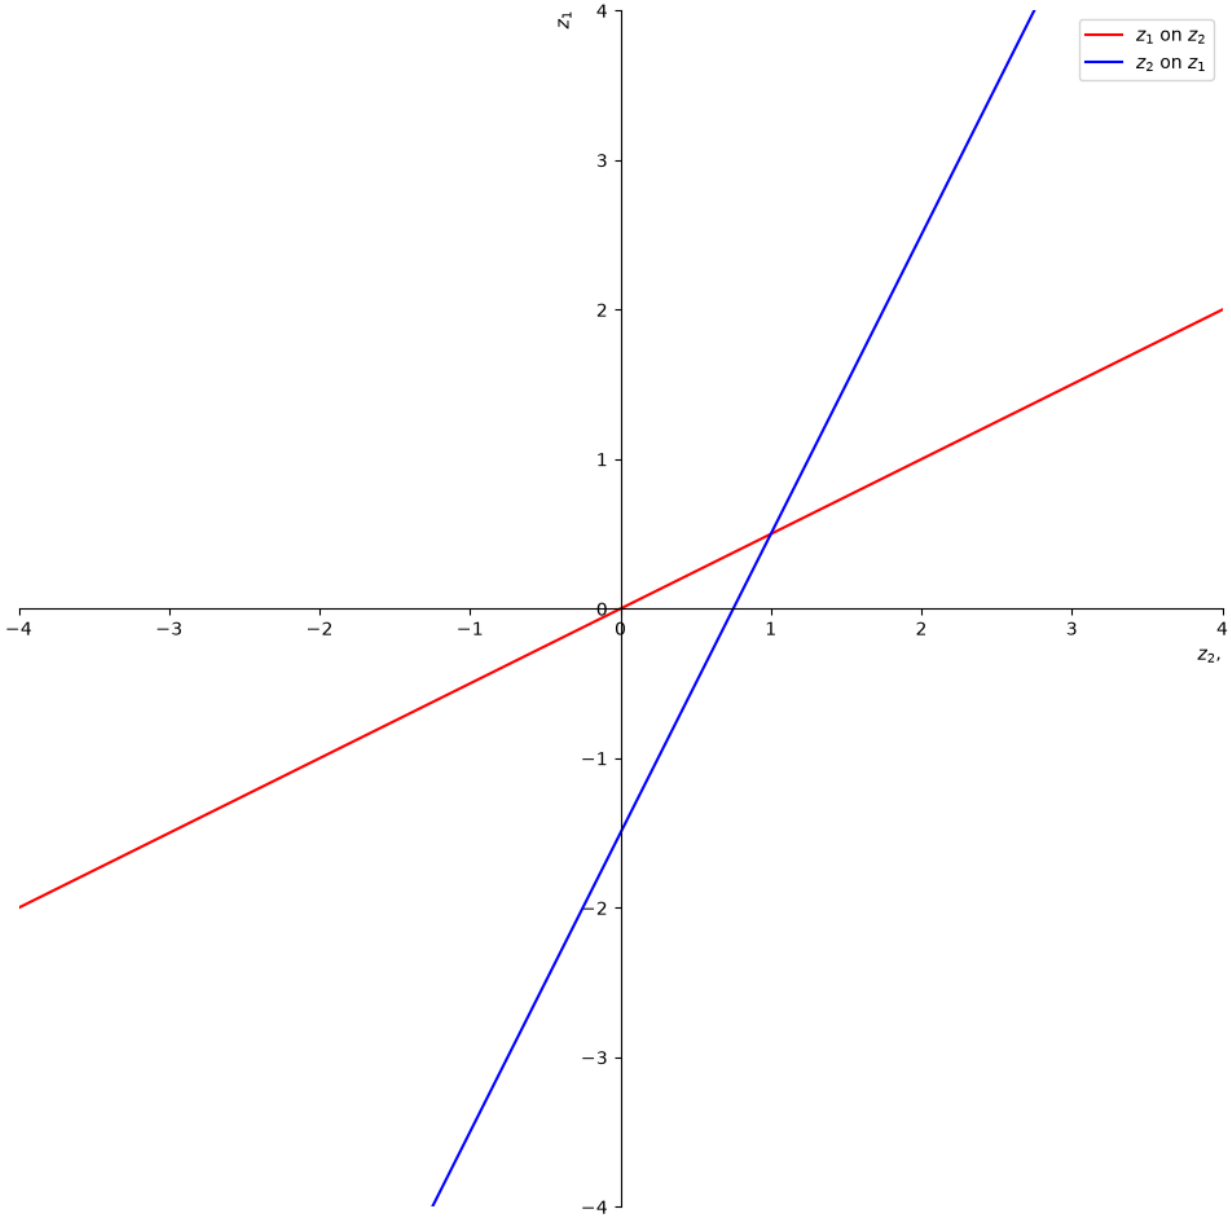

Fig. 13.1: two regressions

The red line is the expectation of z_1 conditional on z_2.

The intercept and slope of the red line are

```
print("a1 = ", a1)
print("b1 = ", b1)
```

```
a1 =  0.0
b1 =  0.5
```

The blue line is the expectation of z_2 conditional on z_1.

The intercept and slope of the blue line are

```
print("-a2/b2 = ", - a2/b2)
print("1/b2 = ", 1/b2)
```

```
-a2/b2 =  -1.5
1/b2 =  2.0
```

We can use these regression lines or our code to compute conditional expectations.

Let's compute the mean and variance of the distribution of z_2 conditional on $z_1 = 5$.

After that we'll reverse what are on the left and right sides of the regression.

```
# compute the cond. dist. of z1
ind = 1
z1 = np.array([5.]) # given z1

μ2_hat, Σ2_hat = multi_normal.cond_dist(ind, z1)
print('μ2_hat, Σ2_hat = ', μ2_hat, Σ2_hat)
```

```
μ2_hat, Σ2_hat =  [3.25] [[0.75]]
```

Now let's compute the mean and variance of the distribution of z_1 conditional on $z_2 = 5$.

```
# compute the cond. dist. of z1
ind = 0
z2 = np.array([5.]) # given z2

μ1_hat, Σ1_hat = multi_normal.cond_dist(ind, z2)
print('μ1_hat, Σ1_hat = ', μ1_hat, Σ1_hat)
```

```
μ1_hat, Σ1_hat =  [2.5] [[0.75]]
```

Let's compare the preceding population mean and variance with outcomes from drawing a large sample and then regressing $z_1 - \mu_1$ on $z_2 - \mu_2$.

We know that

$$Ez_1|z_2 = (\mu_1 - \beta\mu_2) + \beta z_2$$

which can be arranged to

$$z_1 - \mu_1 = \beta\left(z_2 - \mu_2\right) + \epsilon,$$

We anticipate that for larger and larger sample sizes, estimated OLS coefficients will converge to β and the estimated variance of ϵ will converge to $\hat{\Sigma}_1$.

```
n = 1_000_000 # sample size

# simulate multivariate normal random vectors
data = rng.multivariate_normal(μ, Σ, size=n)
z1_data = data[:, 0]
z2_data = data[:, 1]

# OLS regression
μ1, μ2 = multi_normal.μs
results = sm.OLS(z1_data - μ1, z2_data - μ2).fit()
```

Let's compare the preceding population β with the OLS sample estimate on $z_2 - \mu_2$

```
multi_normal.βs[0], results.params
```

```
(array([[0.5]]), array([0.49918333]))
```

Let's compare our population $\hat{\Sigma}_1$ with the degrees-of-freedom adjusted estimate of the variance of ϵ

```
Σ1_hat, results.resid @ results.resid.T / (n - 1)
```

```
(array([[0.75]]), np.float64(0.7489203195072748))
```

Lastly, let's compute the estimate of $\hat{Ez_1|z_2}$ and compare it with $\hat{\mu}_1$

```
μ1_hat, results.predict(z2 - μ2) + μ1
```

```
(array([2.5]), array([2.49673331]))
```

Thus, in each case, for our very large sample size, the sample analogues closely approximate their population counterparts.

A Law of Large Numbers explains why sample analogues approximate population objects.

13.4 Trivariate example

Let's apply our code to a trivariate example.

We'll specify the mean vector and the covariance matrix as follows.

```
μ = rng.random(3)
C = rng.random((3, 3))
Σ = C @ C.T # positive semi-definite

multi_normal = MultivariateNormal(μ, Σ)
```

```
μ, Σ
```

```
(array([0.4201905 , 0.04279279, 0.32149359]),
 array([[0.95070417, 0.48194854, 0.38025012],
        [0.48194854, 1.34029754, 0.43476327],
        [0.38025012, 0.43476327, 0.20864566]]))
```

```
k = 1
multi_normal.partition(k)
```

Let's compute the distribution of z_1 conditional on $z_2 = \begin{bmatrix} 2 \\ 5 \end{bmatrix}$.

```
ind = 0
z2 = np.array([2., 5.])

μ1_hat, Σ1_hat = multi_normal.cond_dist(ind, z2)
```

```
n = 1_000_000
data = rng.multivariate_normal(μ, Σ, size=n)
z1_data = data[:, :k]
z2_data = data[:, k:]
```

```
μ1, μ2 = multi_normal.μs
results = sm.OLS(z1_data - μ1, z2_data - μ2).fit()
```

As above, we compare population and sample regression coefficients, the conditional covariance matrix, and the conditional mean vector in that order.

```
multi_normal.βs[0], results.params
```

```
(array([[-0.71459379,  3.311496  ]]), array([-0.71383888,  3.31026328]))
```

```
Σ1_hat, results.resid @ results.resid.T / (n - 1)
```

```
(array([[0.03590485]]), np.float64(0.035947932906627136))
```

```
μ1_hat, results.predict(z2 - μ2) + μ1
```

```
(array([14.5144376]), array([14.51014783]))
```

Once again, sample analogues do a good job of approximating their populations counterparts.

13.5 One dimensional intelligence (IQ)

Let's move closer to a real-life example, namely, inferring a one-dimensional measure of intelligence called IQ from a list of test scores.

The ith test score y_i equals the sum of an unknown scalar IQ θ and a random variable w_i.

$$y_i = \theta + \sigma_y w_i, \quad i = 1, \ldots, n$$

The distribution of IQ's for a cross-section of people is a normal random variable described by

$$\theta = \mu_\theta + \sigma_\theta w_{n+1}.$$

We assume that the noises $\{w_i\}_{i=1}^N$ in the test scores are IID and not correlated with IQ.

We also assume that $\{w_i\}_{i=1}^{n+1}$ are i.i.d. standard normal:

$$w = \begin{bmatrix} w_1 \\ w_2 \\ \vdots \\ w_n \\ w_{n+1} \end{bmatrix} \sim N\left(0, I_{n+1}\right)$$

The following system describes the $(n+1) \times 1$ random vector X that interests us:

$$X = \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_n \\ \theta \end{bmatrix} = \begin{bmatrix} \mu_\theta \\ \mu_\theta \\ \vdots \\ \mu_\theta \\ \mu_\theta \end{bmatrix} + \begin{bmatrix} \sigma_y & 0 & \cdots & 0 & \sigma_\theta \\ 0 & \sigma_y & \cdots & 0 & \sigma_\theta \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & \sigma_y & \sigma_\theta \\ 0 & 0 & \cdots & 0 & \sigma_\theta \end{bmatrix} \begin{bmatrix} w_1 \\ w_2 \\ \vdots \\ w_n \\ w_{n+1} \end{bmatrix},$$

or equivalently,

$$X = \mu_\theta 1_{n+1} + Dw$$

where $X = \begin{bmatrix} y \\ \theta \end{bmatrix}$, 1_{n+1} is a vector of 1s of size $n+1$, and D is an $n+1$ by $n+1$ matrix.

Let's define a Python function that constructs the mean μ and covariance matrix Σ of the random vector X that we know is governed by a multivariate normal distribution.

As arguments, the function takes the number of tests n, the mean μ_θ and the standard deviation σ_θ of the IQ distribution, and the standard deviation of the randomness in test scores σ_y.

```
def construct_moments_IQ(n, μθ, σθ, σy):

    μ_IQ = np.full(n+1, μθ)

    D_IQ = np.zeros((n+1, n+1))
    D_IQ[range(n), range(n)] = σy
    D_IQ[:, n] = σθ

    Σ_IQ = D_IQ @ D_IQ.T

    return μ_IQ, Σ_IQ, D_IQ
```

Now let's consider a specific instance of this model.

Assume we have recorded 50 test scores and we know that $\mu_\theta = 100$, $\sigma_\theta = 10$, and $\sigma_y = 10$.

We can compute the mean vector and covariance matrix of X easily with our `construct_moments_IQ` function as follows.

```
n = 50
μθ, σθ, σy = 100., 10., 10.

μ_IQ, Σ_IQ, D_IQ = construct_moments_IQ(n, μθ, σθ, σy)
μ_IQ, Σ_IQ, D_IQ
```

```
(array([100., 100., 100., 100., 100., 100., 100., 100., 100., 100., 100.,
        100., 100., 100., 100., 100., 100., 100., 100., 100., 100., 100.,
        100., 100., 100., 100., 100., 100., 100., 100., 100., 100., 100.,
        100., 100., 100., 100., 100., 100., 100., 100., 100., 100., 100.,
```

(continues on next page)

(continued from previous page)

```
       100., 100., 100., 100., 100., 100., 100.]),
array([[200., 100., 100., ..., 100., 100., 100.],
       [100., 200., 100., ..., 100., 100., 100.],
       [100., 100., 200., ..., 100., 100., 100.],
       ...,
       [100., 100., 100., ..., 200., 100., 100.],
       [100., 100., 100., ..., 100., 200., 100.],
       [100., 100., 100., ..., 100., 100., 100.]], shape=(51, 51)),
array([[10.,  0.,  0., ...,  0.,  0., 10.],
       [ 0., 10.,  0., ...,  0.,  0., 10.],
       [ 0.,  0., 10., ...,  0.,  0., 10.],
       ...,
       [ 0.,  0.,  0., ..., 10.,  0., 10.],
       [ 0.,  0.,  0., ...,  0., 10., 10.],
       [ 0.,  0.,  0., ...,  0.,  0., 10.]], shape=(51, 51)))
```

We can now use our `MultivariateNormal` class to construct an instance, then partition the mean vector and covariance matrix as we wish.

We want to regress IQ, the random variable θ (*what we don't know*), on the vector y of test scores (*what we do know*).

We choose `k=n` so that $z_1 = y$ and $z_2 = \theta$.

```
multi_normal_IQ = MultivariateNormal(μ_IQ, Σ_IQ)

k = n
multi_normal_IQ.partition(k)
```

Using the generator `multivariate_normal`, we can make one draw of the random vector from our distribution and then compute the distribution of θ conditional on our test scores.

Let's do that and then print out some pertinent quantities.

```
x = rng.multivariate_normal(μ_IQ, Σ_IQ)
y = x[:-1] # test scores
θ = x[-1]  # IQ
```

```
# the true value
θ
```

```
np.float64(98.2495327983163)
```

The method `cond_dist` takes test scores y as input and returns the conditional normal distribution of the IQ θ.

In the following code, `ind` sets the variables on the right side of the regression.

Given the way we have defined the vector X, we want to set `ind=1` in order to make θ the left side variable in the population regression.

```
ind = 1
multi_normal_IQ.cond_dist(ind, y)
```

```
(array([97.20269774]), array([[1.96078431]]))
```

The first number is the conditional mean $\hat{\mu}_\theta$ and the second is the conditional variance $\hat{\Sigma}_\theta$.

How do additional test scores affect our inferences?

To shed light on this, we compute a sequence of conditional distributions of θ by varying the number of test scores in the conditioning set from 1 to n.

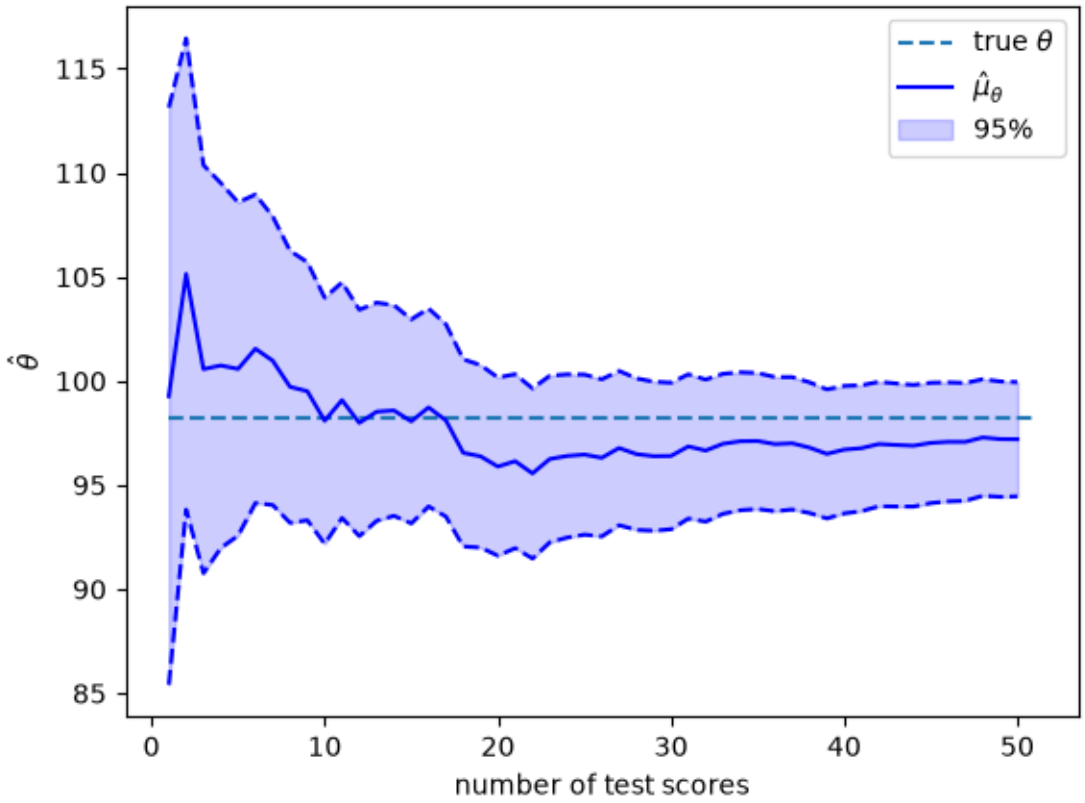
We'll make a pretty graph showing how our judgment of the person's IQ change as more test results come in.

```
# array for containing moments
μθ_hat_arr = np.empty(n)
Σθ_hat_arr = np.empty(n)

# loop over number of test scores
for i in range(1, n+1):
    # construction of multivariate normal distribution instance
    μ_IQ_i, Σ_IQ_i, D_IQ_i = construct_moments_IQ(i, μθ, σθ, σy)
    multi_normal_IQ_i = MultivariateNormal(μ_IQ_i, Σ_IQ_i)

    # partition and compute conditional distribution
    multi_normal_IQ_i.partition(i)
    scores_i = y[:i]
    μθ_hat_i, Σθ_hat_i = multi_normal_IQ_i.cond_dist(1, scores_i)

    # store the results
    μθ_hat_arr[i-1] = μθ_hat_i[0]
    Σθ_hat_arr[i-1] = Σθ_hat_i[0, 0]



# transform variance to standard deviation
σθ_hat_arr = np.sqrt(Σθ_hat_arr)
```

```
μθ_hat_lower = μθ_hat_arr - 1.96 * σθ_hat_arr
μθ_hat_higher = μθ_hat_arr + 1.96 * σθ_hat_arr

plt.hlines(θ, 1, n+1, ls='--', label='true $θ$')
plt.plot(range(1, n+1), μθ_hat_arr, color='b', label=r'$\hat{μ}_{θ}$')
plt.plot(range(1, n+1), μθ_hat_lower, color='b', ls='--')
plt.plot(range(1, n+1), μθ_hat_higher, color='b', ls='--')
plt.fill_between(range(1, n+1), μθ_hat_lower, μθ_hat_higher,
                 color='b', alpha=0.2, label='95%')

plt.xlabel('number of test scores')
plt.ylabel(r'$\hat{θ}$')
plt.legend()

plt.show()
```

The solid blue line in the plot above shows $\hat{\mu}_\theta$ as a function of the number of test scores that we have recorded and conditioned on.

The blue area shows the span that comes from adding or subtracting $1.96\hat{\sigma}_\theta$ from $\hat{\mu}_\theta$.

Therefore, 95% of the probability mass of the conditional distribution falls in this range.

The value of the random θ that we drew is shown by the black dotted line.

As more and more test scores come in, our estimate of the person's θ become more and more reliable.

By staring at the changes in the conditional distributions, we see that adding more test scores makes $\hat{\theta}$ settle down and approach θ.

Thus, each y_i adds information about θ.

If we were to drive the number of tests $n \to +\infty$, the conditional standard deviation $\hat{\sigma}_\theta$ would converge to 0 at rate $\frac{1}{n^{.5}}$.

13.6 Information as surprise

By using a different representation, let's look at things from a different perspective.

We can represent the random vector X defined above as

$$X = \mu_\theta 1_{n+1} + C\epsilon, \quad \epsilon \sim N(0, I)$$

where C is a lower triangular **Cholesky factor** of Σ so that

$$\Sigma \equiv DD^\top = CC^\top$$

and

$$E\epsilon\epsilon^\top = I.$$

It follows that

$$\epsilon \sim N(0, I).$$

Let $G = C^{-1}$

G is also lower triangular.

We can compute ϵ from the formula

$$\epsilon = G\left(X - \mu_\theta 1_{n+1}\right)$$

This formula confirms that the orthonormal vector ϵ contains the same information as the non-orthogonal vector $(X - \mu_\theta 1_{n+1})$.

We can say that ϵ is an orthogonal basis for $(X - \mu_\theta 1_{n+1})$.

Let c_i be the ith element in the last row of C.

Then we can write

$$\theta = \mu_\theta + c_1\epsilon_1 + c_2\epsilon_2 + \cdots + c_n\epsilon_n + c_{n+1}\epsilon_{n+1} \tag{13.1}$$

The mutual orthogonality of the ϵ_i's provides us with an informative way to interpret them in light of equation (13.1).

Thus, relative to what is known from tests $i = 1, \ldots, n-1$, $c_i\epsilon_i$ is the amount of **new information** about θ brought by the test number i.

Here **new information** means **surprise** or what could not be predicted from earlier information.

Formula (13.1) also provides us with an enlightening way to express conditional means and conditional variances that we computed earlier.

In particular,

$$E\left[\theta \mid y_1, \ldots, y_k\right] = \mu_\theta + c_1\epsilon_1 + \cdots + c_k\epsilon_k$$

and

$$Var\left(\theta \mid y_1, \ldots, y_k\right) = c_{k+1}^2 + c_{k+2}^2 + \cdots + c_{n+1}^2.$$

```
C = np.linalg.cholesky(Σ_IQ)
G = np.linalg.inv(C)

ε = G @ (x - μθ)
```

```
cε = C[n, :] * ε

# compute the sequence of μθ and Σθ conditional on y1, y2, ..., yk
μθ_hat_arr_C = np.array([np.sum(cε[:k+1]) for k in range(n)]) + μθ
Σθ_hat_arr_C = np.array([C[n, i+1:n+1] @ C[n, i+1:n+1] for i in range(n)])
```

To confirm that these formulas give the same answers that we computed earlier, we can compare the means and variances of θ conditional on $\{y_i\}_{i=1}^k$ with what we obtained above using the formulas implemented in the class `MultivariateNormal` built on our original representation of conditional distributions for multivariate normal distributions.

```
# conditional mean
np.max(np.abs(μθ_hat_arr - μθ_hat_arr_C)) < 1e-10
```

```
np.True_
```

```
# conditional variance
np.max(np.abs(Σθ_hat_arr - Σθ_hat_arr_C)) < 1e-10
```

```
np.True_
```

13.7 Cholesky factor magic

Evidently, the Cholesky factorizations automatically computes the population **regression coefficients** and associated statistics that are produced by our `MultivariateNormal` class.

The Cholesky factorization computes these things **recursively**.

Indeed, in formula (13.1),

- the random variable $c_i \epsilon_i$ is information about θ that is not contained by the information in $\epsilon_1, \epsilon_2, \ldots, \epsilon_{i-1}$
- the coefficient c_i is the simple population regression coefficient of $\theta - \mu_\theta$ on ϵ_i

13.8 Math and verbal intelligence

We can alter the preceding example to be more realistic.

There is ample evidence that IQ is not a scalar.

Some people are good in math skills but poor in language skills.

Other people are good in language skills but poor in math skills.

So now we shall assume that there are two dimensions of IQ, θ and η.

These determine average performances in math and language tests, respectively.

We observe math scores $\{y_i\}_{i=1}^n$ and language scores $\{y_i\}_{i=n+1}^{2n}$.

When $n = 2$, we assume that outcomes are draws from a multivariate normal distribution with representation

$$X = \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \\ \theta \\ \eta \end{bmatrix} = \begin{bmatrix} \mu_\theta \\ \mu_\theta \\ \mu_\eta \\ \mu_\eta \\ \mu_\theta \\ \mu_\eta \end{bmatrix} + \begin{bmatrix} \sigma_y & 0 & 0 & 0 & \sigma_\theta & 0 \\ 0 & \sigma_y & 0 & 0 & \sigma_\theta & 0 \\ 0 & 0 & \sigma_y & 0 & 0 & \sigma_\eta \\ 0 & 0 & 0 & \sigma_y & 0 & \sigma_\eta \\ 0 & 0 & 0 & 0 & \sigma_\theta & 0 \\ 0 & 0 & 0 & 0 & 0 & \sigma_\eta \end{bmatrix} \begin{bmatrix} w_1 \\ w_2 \\ w_3 \\ w_4 \\ w_5 \\ w_6 \end{bmatrix}$$

where $w = \begin{bmatrix} w_1 \\ w_2 \\ \vdots \\ w_6 \end{bmatrix}$ is a standard normal random vector.

We construct a Python function `construct_moments_IQ2d` to construct the mean vector and covariance matrix of the joint normal distribution.

```
def construct_moments_IQ2d(n, μθ, σθ, μη, ση, σy):

    μ_IQ2d = np.empty(2*(n+1))
    μ_IQ2d[:n] = μθ
    μ_IQ2d[2*n] = μθ
    μ_IQ2d[n:2*n] = μη
    μ_IQ2d[2*n+1] = μη

    D_IQ2d = np.zeros((2*(n+1), 2*(n+1)))
    D_IQ2d[range(2*n), range(2*n)] = σy
    D_IQ2d[:n, 2*n] = σθ
    D_IQ2d[2*n, 2*n] = σθ
    D_IQ2d[n:2*n, 2*n+1] = ση
    D_IQ2d[2*n+1, 2*n+1] = ση

    Σ_IQ2d = D_IQ2d @ D_IQ2d.T

    return μ_IQ2d, Σ_IQ2d, D_IQ2d
```

Let's put the function to work.

```
n = 2
# mean and variance of θ, η, and y
μθ, σθ, μη, ση, σy = 100., 10., 100., 10, 10

μ_IQ2d, Σ_IQ2d, D_IQ2d = construct_moments_IQ2d(n, μθ, σθ, μη, ση, σy)
μ_IQ2d, Σ_IQ2d, D_IQ2d
```

```
(array([100., 100., 100., 100., 100., 100.]),
 array([[200., 100.,   0.,   0., 100.,   0.],
        [100., 200.,   0.,   0., 100.,   0.],
        [  0.,   0., 200., 100.,   0., 100.],
        [  0.,   0., 100., 200.,   0., 100.],
        [100., 100.,   0.,   0., 100.,   0.],
        [  0.,   0., 100., 100.,   0., 100.]]),
 array([[10.,  0.,  0.,  0., 10.,  0.],
        [ 0., 10.,  0.,  0., 10.,  0.],
        [ 0.,  0., 10.,  0.,  0., 10.],
        [ 0.,  0.,  0., 10.,  0., 10.],
        [ 0.,  0.,  0.,  0., 10.,  0.],
        [ 0.,  0.,  0.,  0.,  0., 10.]]))
```

```
# take one draw
x = rng.multivariate_normal(μ_IQ2d, Σ_IQ2d)
y1 = x[:n]
y2 = x[n:2*n]
θ = x[2*n]
η = x[2*n+1]

# the true values
θ, η
```

```
(np.float64(86.84580129140488), np.float64(98.5057398320253))
```

We first compute the joint normal distribution of (θ, η).

```
multi_normal_IQ2d = MultivariateNormal(μ_IQ2d, Σ_IQ2d)

k = 2*n # the length of data vector
multi_normal_IQ2d.partition(k)

multi_normal_IQ2d.cond_dist(1, [*y1, *y2])
```

```
(array([ 87.15090791, 104.56448792]),
 array([[33.33333333,  0.        ],
        [ 0.        , 33.33333333]]))
```

Now let's compute distributions of θ and η separately conditional on various subsets of test scores.

It will be fun to compare outcomes with the help of an auxiliary function `cond_dist_IQ2d` that we now construct.

```
def cond_dist_IQ2d(μ, Σ, data):

    n = len(μ)

    multi_normal = MultivariateNormal(μ, Σ)
    multi_normal.partition(n-1)
    μ_hat, Σ_hat = multi_normal.cond_dist(1, data)

    return μ_hat, Σ_hat
```

Let's see how things work for an example.

```
for indices, IQ, conditions in [([*range(2*n), 2*n], 'θ', 'y1, y2, y3, y4'),
                                ([*range(n), 2*n], 'θ', 'y1, y2'),
                                ([*range(n, 2*n), 2*n], 'θ', 'y3, y4'),
                                ([*range(2*n), 2*n+1], 'η', 'y1, y2, y3, y4'),
                                ([*range(n), 2*n+1], 'η', 'y1, y2'),
                                ([*range(n, 2*n), 2*n+1], 'η', 'y3, y4')]:

    μ_hat, Σ_hat = cond_dist_IQ2d(μ_IQ2d[indices], Σ_IQ2d[indices][:, indices],␣
↪x[indices[:-1]])
    print(f'The mean and variance of {IQ} conditional on {conditions: <15} are ' +
          f'{μ_hat[0]:1.2f} and {Σ_hat[0, 0]:1.2f} respectively')
```

```
The mean and variance of θ conditional on y1, y2, y3, y4  are 87.15 and 33.33␣
↪respectively
The mean and variance of θ conditional on y1, y2          are 87.15 and 33.33␣
↪respectively
The mean and variance of θ conditional on y3, y4          are 100.00 and 100.00␣
↪respectively
The mean and variance of η conditional on y1, y2, y3, y4  are 104.56 and 33.33␣
↪respectively
The mean and variance of η conditional on y1, y2          are 100.00 and 100.00␣
↪respectively
The mean and variance of η conditional on y3, y4          are 104.56 and 33.33␣
↪respectively
```

Evidently, math tests provide no information about η and language tests provide no information about θ.

13.9 Univariate time series analysis

We can use the multivariate normal distribution and a little matrix algebra to present foundations of univariate linear time series analysis.

Let x_t, y_t, v_t, w_{t+1} each be scalars for $t \geq 0$.

Consider the following model:

$$\begin{aligned} x_0 &\sim N\left(0, \sigma_0^2\right) \\ x_{t+1} &= ax_t + bw_{t+1}, \quad w_{t+1} \sim N\left(0,1\right), t \geq 0 \\ y_t &= cx_t + dv_t, \quad v_t \sim N\left(0,1\right), t \geq 0 \end{aligned}$$

We can compute the moments of x_t

1. $Ex_{t+1}^2 = a^2 Ex_t^2 + b^2, t \geq 0$, where $Ex_0^2 = \sigma_0^2$
2. $Ex_{t+j}x_t = a^j Ex_t^2, \forall t \; \forall j$

Given some T, we can formulate the sequence $\{x_t\}_{t=0}^T$ as a random vector

$$X = \begin{bmatrix} x_0 \\ x_1 \\ \vdots \\ x_T \end{bmatrix}$$

and the covariance matrix Σ_x can be constructed using the moments we have computed above.

Similarly, we can define

$$Y = \begin{bmatrix} y_0 \\ y_1 \\ \vdots \\ y_T \end{bmatrix}, \quad v = \begin{bmatrix} v_0 \\ v_1 \\ \vdots \\ v_T \end{bmatrix}$$

and therefore

$$Y = CX + DV$$

where C and D are both diagonal matrices with constant c and d as diagonal respectively.

Consequently, the covariance matrix of Y is

$$\Sigma_y = EYY^\top = C\Sigma_x C^\top + DD^\top$$

By stacking X and Y, we can write

$$Z = \begin{bmatrix} X \\ Y \end{bmatrix}$$

and

$$\Sigma_z = EZZ^\top = \begin{bmatrix} \Sigma_x & \Sigma_x C^\top \\ C\Sigma_x & \Sigma_y \end{bmatrix}$$

Thus, the stacked sequences $\{x_t\}_{t=0}^T$ and $\{y_t\}_{t=0}^T$ jointly follow the multivariate normal distribution $N\left(0, \Sigma_z\right)$.

```

```
# construct the mean vector of Z
μz = np.zeros(2*(T+1))
```

The following Python code lets us sample random vectors X and Y.

This is going to be very useful for doing the conditioning to be used in the fun exercises below.

```
z = rng.multivariate_normal(μz, Σz)

x = z[:T+1]
y = z[T+1:]
```

13.9.1 Smoothing example

This is an instance of a classic `smoothing` calculation whose purpose is to compute $EX \mid Y$.

An interpretation of this example is

- X is a random sequence of hidden Markov state variables x_t
- Y is a sequence of observed signals y_t bearing information about the hidden state

```
# construct a MultivariateNormal instance
multi_normal_ex1 = MultivariateNormal(μz, Σz)
x = z[:T+1]
y = z[T+1:]
```

```
# partition Z into X and Y
multi_normal_ex1.partition(T+1)
```

```
# compute the conditional mean and covariance matrix of X given Y=y

print("X = ", x)
print("Y = ", y)
print(" E [ X | Y] = ", )

multi_normal_ex1.cond_dist(0, y)
```

```
X =  [ 0.241748   -0.48167052 -0.2751467   0.62696378]
Y =  [ 0.2465054  -0.55890629 -0.28918582  0.57124943]
 E [ X | Y] =
```

```
(array([ 0.24414853, -0.55648653, -0.28785472,  0.56917881]),
 array([[2.48875094e-03, 5.57449314e-06, 1.24861727e-08, 2.80242496e-11],
        [5.57449314e-06, 2.48876343e-03, 5.57452116e-06, 1.25113948e-08],
        [1.24861727e-08, 5.57452116e-06, 2.48876346e-03, 5.58575339e-06],
        [2.80242496e-11, 1.25113948e-08, 5.58575339e-06, 2.49377812e-03]]))
```

13.9.2 Filtering exercise

Compute $E\left[x_t \mid y_{t-1}, y_{t-2}, \dots, y_0\right]$.

To do so, we need to first construct the mean vector and the covariance matrix of the subvector $\left[x_t, y_0, \dots, y_{t-2}, y_{t-1}\right]$.

For example, let's say that we want the conditional distribution of x_3.

```
t = 3
```

```
# mean of the subvector
sub_μz = np.zeros(t+1)

# covariance matrix of the subvector
sub_Σz = np.empty((t+1, t+1))

sub_Σz[0, 0] = Σz[t, t] # x_t
sub_Σz[0, 1:] = Σz[t, T+1:T+t+1]
sub_Σz[1:, 0] = Σz[T+1:T+t+1, t]
sub_Σz[1:, 1:] = Σz[T+1:T+t+1, T+1:T+t+1]
```

```
sub_Σz
```

```
array([[2.997541, 0.729   , 1.4661  , 2.21949 ],
       [0.729   , 1.0025  , 0.9     , 0.81    ],
       [1.4661  , 0.9     , 1.8125  , 1.629   ],
       [2.21949 , 0.81    , 1.629   , 2.4686  ]])
```

```
multi_normal_ex2 = MultivariateNormal(sub_μz, sub_Σz)
multi_normal_ex2.partition(1)
```

```
sub_y = y[:t]

multi_normal_ex2.cond_dist(0, sub_y)
```

```
(array([-0.26074227]), array([[1.00201996]]))
```

13.9.3 Prediction exercise

Compute $E\left[y_t \mid y_{t-j}, \dots, y_0\right]$.

As what we did in exercise 2, we will construct the mean vector and covariance matrix of the subvector $\left[y_t, y_0, \dots, y_{t-j-1}, y_{t-j}\right]$.

For example, we take a case in which $t = 3$ and $j = 2$.

```
t = 3
j = 2
```

```
sub_μz = np.zeros(t-j+2)
sub_Σz = np.empty((t-j+2, t-j+2))

sub_Σz[0, 0] = Σz[T+t+1, T+t+1]
sub_Σz[0, 1:] = Σz[T+t+1, T+1:T+t-j+2]
```

(continues on next page)

(continued from previous page)

```
sub_Σz[1:, 0] = Σz[T+1:T+t-j+2, T+t+1]
sub_Σz[1:, 1:] = Σz[T+1:T+t-j+2, T+1:T+t-j+2]
```

```
sub_Σz
```

```
array([[3.000041, 0.729   , 1.4661  ],
       [0.729   , 1.0025  , 0.9     ],
       [1.4661  , 0.9     , 1.8125  ]])
```

```
multi_normal_ex3 = MultivariateNormal(sub_μz, sub_Σz)
multi_normal_ex3.partition(1)
```

```
sub_y = y[:t-j+1]

multi_normal_ex3.cond_dist(0, sub_y)
```

```
(array([-0.45114129]), array([[1.81413617]]))
```

13.9.4 Constructing a Wold representation

Now we'll apply Cholesky decomposition to decompose $\Sigma_y = HH^\top$ and form

$$\epsilon = H^{-1}Y.$$

Then we can represent y_t as

$$y_t = h_{t,t}\epsilon_t + h_{t,t-1}\epsilon_{t-1} + \cdots + h_{t,0}\epsilon_0.$$

```
H = np.linalg.cholesky(Σy)

H
```

```
array([[1.00124922, 0.        , 0.        , 0.        ],
       [0.8988771 , 1.00225743, 0.        , 0.        ],
       [0.80898939, 0.89978675, 1.00225743, 0.        ],
       [0.72809046, 0.80980808, 0.89978676, 1.00225743]])
```

```
ε = np.linalg.inv(H) @ y

ε
```

```
array([ 0.24619784, -0.7784506 ,  0.2116046 ,  0.83011777])
```

```
y
```

```
array([ 0.2465054 , -0.55890629, -0.28918582,  0.57124943])
```

This example is an instance of what is known as a **Wold representation** in time series analysis.

13.10 Stochastic difference equation

Consider the stochastic second-order linear difference equation

$$y_t = \alpha_0 + \alpha_1 y_{t-1} + \alpha_2 y_{t-2} + u_t$$

where $u_t \sim N\left(0, \sigma_u^2\right)$ and

$$\begin{bmatrix} y_{-1} \\ y_0 \end{bmatrix} \sim N\left(\mu_{\tilde{y}}, \Sigma_{\tilde{y}}\right)$$

It can be written as a stacked system

$$\underbrace{\begin{bmatrix} 1 & 0 & 0 & 0 & \cdots & 0 & 0 & 0 \\ -\alpha_1 & 1 & 0 & 0 & \cdots & 0 & 0 & 0 \\ -\alpha_2 & -\alpha_1 & 1 & 0 & \cdots & 0 & 0 & 0 \\ 0 & -\alpha_2 & -\alpha_1 & 1 & \cdots & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \cdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \cdots & -\alpha_2 & -\alpha_1 & 1 \end{bmatrix}}_{\equiv A} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \\ \vdots \\ y_T \end{bmatrix} = \underbrace{\begin{bmatrix} \alpha_0 + \alpha_1 y_0 + \alpha_2 y_{-1} \\ \alpha_0 + \alpha_2 y_0 \\ \alpha_0 \\ \alpha_0 \\ \vdots \\ \alpha_0 \end{bmatrix}}_{\equiv b} + \underbrace{\begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \\ \vdots \\ u_T \end{bmatrix}}_{\equiv u}$$

We can compute y by solving the system

$$y = A^{-1}\left(b + u\right)$$

We have

$$\begin{aligned} \mu_y &= A^{-1}\mu_b \\ \Sigma_y &= A^{-1}E\left[\left(b - \mu_b + u\right)\left(b - \mu_b + u\right)^\top\right]\left(A^{-1}\right)^\top \\ &= A^{-1}\left(\Sigma_b + \Sigma_u\right)\left(A^{-1}\right)^\top \end{aligned}$$

where

$$\mu_b = \begin{bmatrix} \alpha_0 + \alpha_1 \mu_{y_0} + \alpha_2 \mu_{y_{-1}} \\ \alpha_0 + \alpha_2 \mu_{y_0} \\ \alpha_0 \\ \vdots \\ \alpha_0 \end{bmatrix}$$

$$\Sigma_b = \begin{bmatrix} C\Sigma_{\tilde{y}} C^\top & 0_{N-2\times N-2} \\ 0_{N-2\times 2} & 0_{N-2\times N-2} \end{bmatrix}, \quad C = \begin{bmatrix} \alpha_2 & \alpha_1 \\ 0 & \alpha_2 \end{bmatrix}$$

$$\Sigma_u = \begin{bmatrix} \sigma_u^2 & 0 & \cdots & 0 \\ 0 & \sigma_u^2 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & \sigma_u^2 \end{bmatrix}$$

```
# set parameters
T = 160
# coefficients of the second order difference equation
a0 = 10
a1 = 1.53
a2 = -.9

# variance of u
σu = 10.

# distribution of y_{-1} and y_{0}
μy_tilde = np.array([1., 0.5])
Σy_tilde = np.array([[2., 1.], [1., 0.5]])
```

```
# construct A and A^\top
A = np.zeros((T, T))

for i in range(T):
    A[i, i] = 1

    if i-1 >= 0:
        A[i, i-1] = -α1

    if i-2 >= 0:
        A[i, i-2] = -α2

A_inv = np.linalg.inv(A)
```

```
# compute the mean vectors of b and y
μb = np.full(T, α0)
μb[0] += α1 * μy_tilde[1] + α2 * μy_tilde[0]
μb[1] += α2 * μy_tilde[1]

μy = A_inv @ μb
```

```
# compute the covariance matrices of b and y
Σu = np.eye(T) * σu ** 2

Σb = np.zeros((T, T))

C = np.array([[α2, α1], [0, α2]])
Σb[:2, :2] = C @ Σy_tilde @ C.T

Σy = A_inv @ (Σb + Σu) @ A_inv.T
```

13.11 Application to stock price model

Let

$$p_t = \sum_{j=0}^{T-t} \beta^j y_{t+j}$$

Form

$$\underbrace{\begin{bmatrix} p_1 \\ p_2 \\ p_3 \\ \vdots \\ p_T \end{bmatrix}}_{\equiv p} = \underbrace{\begin{bmatrix} 1 & \beta & \beta^2 & \cdots & \beta^{T-1} \\ 0 & 1 & \beta & \cdots & \beta^{T-2} \\ 0 & 0 & 1 & \cdots & \beta^{T-3} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \end{bmatrix}}_{\equiv B} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ \vdots \\ y_T \end{bmatrix}$$

we have

$$\mu_p = B\mu_y$$
$$\Sigma_p = B\Sigma_y B^\top$$

```
β = .96
```

```
# construct B
B = np.zeros((T, T))

for i in range(T):
    B[i, i:] = β ** np.arange(0, T-i)
```

Denote

$$z = \begin{bmatrix} y \\ p \end{bmatrix} = \underbrace{\begin{bmatrix} I \\ B \end{bmatrix}}_{\equiv D} y$$

Thus, $\{y_t\}_{t=1}^T$ and $\{p_t\}_{t=1}^T$ jointly follow the multivariate normal distribution $N(\mu_z, \Sigma_z)$, where

$$\mu_z = D\mu_y$$

$$\Sigma_z = D\Sigma_y D^\top$$

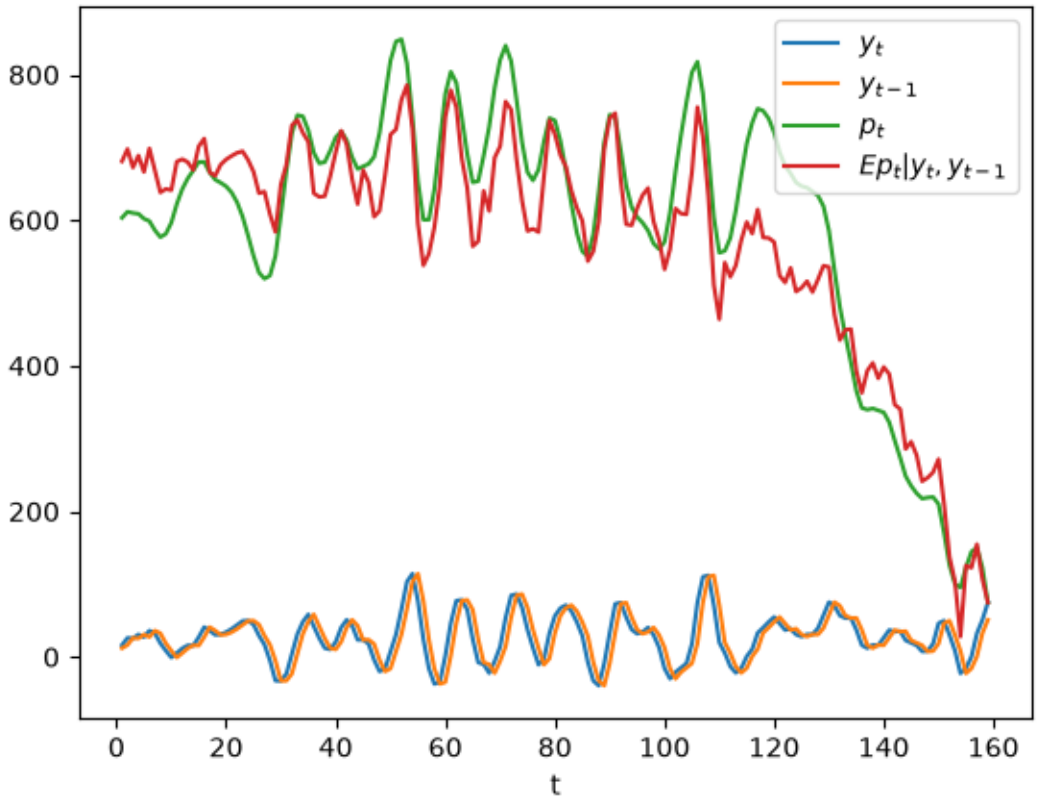
```
D = np.vstack([np.eye(T), B])
```

```
μz = D @ μy
Σz = D @ Σy @ D.T
```

We can simulate paths of y_t and p_t and compute the conditional mean $E[p_t \mid y_{t-1}, y_t]$ using the `MultivariateNormal` class.

```
z = rng.multivariate_normal(μz, Σz)
y, p = z[:T], z[T:]
```

```
cond_Ep = np.empty(T-1)



sub_μ = np.empty(3)
sub_Σ = np.empty((3, 3))
for t in range(2, T+1):
    sub_μ[:] = μz[[t-2, t-1, T-1+t]]
    sub_Σ[:, :] = Σz[[t-2, t-1, T-1+t], :][:, [t-2, t-1, T-1+t]]

    multi_normal = MultivariateNormal(sub_μ, sub_Σ)
    multi_normal.partition(2)

    cond_Ep[t-2] = multi_normal.cond_dist(1, y[t-2:t])[0][0]
```

```
plt.plot(range(1, T), y[1:], label='$y_{t}$')
plt.plot(range(1, T), y[:-1], label='$y_{t-1}$')
plt.plot(range(1, T), p[1:], label='$p_{t}$')
plt.plot(range(1, T), cond_Ep, label='$Ep_{t}|y_{t}, y_{t-1}$')

plt.xlabel('t')
plt.legend(loc=1)
plt.show()
```

In the above graph, the green line is what the price of the stock would be if people had perfect foresight about the path of dividends while the red line is the conditional expectation $Ep_t|y_t, y_{t-1}$, which is what the price would be if people did not have perfect foresight but were optimally predicting future dividends on the basis of the information y_t, y_{t-1} at time t.

13.12 Filtering foundations

Assume that x_0 is an $n \times 1$ random vector and that y_0 is a $p \times 1$ random vector determined by the *observation equation*

$$y_0 = Gx_0 + v_0, \quad x_0 \sim \mathcal{N}(\hat{x}_0, \Sigma_0), \quad v_0 \sim \mathcal{N}(0, R)$$

where v_0 is orthogonal to x_0, G is a $p \times n$ matrix, and R is a $p \times p$ positive definite matrix.

We consider the problem of someone who

- *observes* y_0
- does not observe x_0,
- knows $\hat{x}_0, \Sigma_0, G, R$ and therefore the joint probability distribution of the vector $\begin{bmatrix} x_0 \\ y_0 \end{bmatrix}$
- wants to infer x_0 from y_0 in light of what he knows about that joint probability distribution.

Therefore, the person wants to construct the probability distribution of x_0 conditional on the random vector y_0.

The joint distribution of $\begin{bmatrix} x_0 \\ y_0 \end{bmatrix}$ is multivariate normal $\mathcal{N}(\mu, \Sigma)$ with

$$\mu = \begin{bmatrix} \hat{x}_0 \\ G\hat{x}_0 \end{bmatrix}, \quad \Sigma = \begin{bmatrix} \Sigma_0 & \Sigma_0 G' \\ G\Sigma_0 & G\Sigma_0 G' + R \end{bmatrix}$$

By applying an appropriate instance of the above formulas for the mean vector $\hat{\mu}_1$ and covariance matrix $\hat{\Sigma}_{11}$ of z_1 conditional on z_2, we find that the probability distribution of x_0 conditional on y_0 is $\mathcal{N}(\tilde{x}_0, \tilde{\Sigma}_0)$ where

$$\begin{aligned}\beta_0 &= \Sigma_0 G'(G\Sigma_0 G' + R)^{-1} \\ \tilde{x}_0 &= \hat{x}_0 + \beta_0(y_0 - G\hat{x}_0) \\ \tilde{\Sigma}_0 &= \Sigma_0 - \Sigma_0 G'(G\Sigma_0 G' + R)^{-1} G\Sigma_0\end{aligned}$$

We can express our finding that the probability distribution of x_0 conditional on y_0 is $\mathcal{N}(\tilde{x}_0, \tilde{\Sigma}_0)$ by representing x_0 as

$$x_0 = \tilde{x}_0 + \zeta_0 \tag{13.2}$$

where ζ_0 is a Gaussian random vector that is orthogonal to $\tilde{x}_0$ and y_0 and that has mean vector 0 and conditional covariance matrix $E[\zeta_0 \zeta_0' | y_0] = \tilde{\Sigma}_0$.

13.12.1 Step toward dynamics

Now suppose that we are in a time series setting and that we have the one-step state transition equation

$$x_1 = Ax_0 + Cw_1, \quad w_1 \sim \mathcal{N}(0, I)$$

where A is an $n \times n$ matrix and C is an $n \times m$ matrix.

Using equation (13.2), we can also represent x_1 as

$$x_1 = A(\tilde{x}_0 + \zeta_0) + Cw_1$$

It follows that

$$Ex_1 | y_0 = A\tilde{x}_0$$

and that the corresponding conditional covariance matrix $E(x_1 - Ex_1|y_0)(x_1 - Ex_1|y_0)' \equiv \Sigma_1$ is

$$\Sigma_1 = A\tilde{\Sigma}_0 A' + CC'$$

or

$$\Sigma_1 = A\Sigma_0 A' - A\Sigma_0 G'(G\Sigma_0 G' + R)^{-1} G\Sigma_0 A'$$

We can write the mean of x_1 conditional on y_0 as

$$\hat{x}_1 = A\hat{x}_0 + A\Sigma_0 G'(G\Sigma_0 G' + R)^{-1}(y_0 - G\hat{x}_0)$$

or

$$\hat{x}_1 = A\hat{x}_0 + K_0(y_0 - G\hat{x}_0)$$

where

$$K_0 = A\Sigma_0 G'(G\Sigma_0 G' + R)^{-1}$$

13.12.2 Dynamic version

Suppose now that for $t \geq 0$, $\{x_{t+1}, y_t\}_{t=0}^{\infty}$ are governed by the equations

$$\begin{aligned} x_{t+1} &= Ax_t + Cw_{t+1} \\ y_t &= Gx_t + v_t \end{aligned}$$

where as before $x_0 \sim \mathcal{N}(\hat{x}_0, \Sigma_0)$, w_{t+1} is the $t+1$th component of an i.i.d. stochastic process distributed as $w_{t+1} \sim \mathcal{N}(0, I)$, and v_t is the tth component of an i.i.d. process distributed as $v_t \sim \mathcal{N}(0, R)$ and the $\{w_{t+1}\}_{t=0}^{\infty}$ and $\{v_t\}_{t=0}^{\infty}$ processes are orthogonal at all pairs of dates.

The logic and formulas that we applied above imply that the probability distribution of x_t conditional on $y_0, y_1, \ldots, y_{t-1} = y^{t-1}$ is

$$x_t | y^{t-1} \sim \mathcal{N}(A\tilde{x}_{t-1}, A\tilde{\Sigma}_{t-1}A' + CC')$$

where $\{\tilde{x}_t, \tilde{\Sigma}_t\}_{t=1}^{\infty}$ can be computed by iterating on the following equations starting from $t = 1$ and initial conditions for $\tilde{x}_0, \tilde{\Sigma}_0$ computed as we have above:

$$\begin{aligned} \Sigma_t &= A\tilde{\Sigma}_{t-1}A' + CC' \\ \hat{x}_t &= A\tilde{x}_{t-1} \\ \beta_t &= \Sigma_t G'(G\Sigma_t G' + R)^{-1} \\ \tilde{x}_t &= \hat{x}_t + \beta_t(y_t - G\hat{x}_t) \\ \tilde{\Sigma}_t &= \Sigma_t - \Sigma_t G'(G\Sigma_t G' + R)^{-1} G\Sigma_t \end{aligned}$$

If we shift the first equation forward one period and then substitute the expression for $\tilde{\Sigma}_t$ on the right side of the fifth equation into it we obtain

$$\Sigma_{t+1} = CC' + A\Sigma_t A' - A\Sigma_t G'(G\Sigma_t G' + R)^{-1} G\Sigma_t A'.$$

This is a matrix Riccati difference equation that is closely related to another matrix Riccati difference equation that appears in a quantecon lecture on the basics of linear quadratic control theory.

That equation has the form

$$P_{t-1} = R + A'P_t A - A'P_t B(B'P_t B + Q)^{-1} B'P_t A.$$

Stare at the two preceding equations for a moment or two, the first being a matrix difference equation for a conditional covariance matrix, the second being a matrix difference equation in the matrix appearing in a quadratic form for an intertemporal cost of value function.

Although the two equations are not identical, they display striking family resemblances.

- the first equation tells dynamics that work **forward** in time
- the second equation tells dynamics that work **backward** in time
- while many of the terms are similar, one equation seems to apply matrix transformations to some matrices that play similar roles in the other equation

The family resemblences of these two equations reflects a transcendent **duality** that prevails between control theory and filtering theory.

13.12.3 An example

We can use the Python class *MultivariateNormal* to construct examples.

Here is an example for a single period problem at time 0

```
G = np.array([[1., 3.]])
R = np.array([[1.]])

x0_hat = np.array([0., 1.])
Σ0 = np.array([[1., .5], [.5, 2.]])

μ = np.hstack([x0_hat, G @ x0_hat])
Σ = np.block([[Σ0, Σ0 @ G.T], [G @ Σ0, G @ Σ0 @ G.T + R]])
```

```
# construction of the multivariate normal instance
multi_normal = MultivariateNormal(μ, Σ)
```

```
multi_normal.partition(2)
```

```
# the observation of y
y0 = 2.3

# conditional distribution of x0
μ1_hat, Σ11 = multi_normal.cond_dist(0, y0)
μ1_hat, Σ11
```

```
(array([-0.07608696,  0.80217391]),
 array([[ 0.72826087, -0.20652174],
        [-0.20652174,  0.16304348]]))
```

```
A = np.array([[0.5, 0.2], [-0.1, 0.3]])
C = np.array([[2.], [1.]])

# conditional distribution of x1
x1_cond = A @ μ1_hat
Σ1_cond = C @ C.T + A @ Σ11 @ A.T
x1_cond, Σ1_cond
```

```
(array([0.1223913 , 0.24826087]),
 array([[4.14728261, 1.94652174],
        [1.94652174, 1.03434783]]))
```

13.12.4 Code for iterating

Here is code for solving a dynamic filtering problem by iterating on our equations, followed by an example.

```
def iterate(x0_hat, Σ0, A, C, G, R, y_seq):

    p, n = G.shape

    T = len(y_seq)
    x_hat_seq = np.empty((T+1, n))
    Σ_hat_seq = np.empty((T+1, n, n))
```

(continues on next page)

(continued from previous page)

```
    x_hat_seq[0] = x0_hat
    Σ_hat_seq[0] = Σ0

    for t in range(T):
        xt_hat = x_hat_seq[t]
        Σt = Σ_hat_seq[t]
        μ = np.hstack([xt_hat, G @ xt_hat])
        Σ = np.block([[Σt, Σt @ G.T], [G @ Σt, G @ Σt @ G.T + R]])

        # filtering
        multi_normal = MultivariateNormal(μ, Σ)
        multi_normal.partition(n)
        x_tilde, Σ_tilde = multi_normal.cond_dist(0, y_seq[t])

        # forecasting
        x_hat_seq[t+1] = A @ x_tilde
        Σ_hat_seq[t+1] = C @ C.T + A @ Σ_tilde @ A.T

    return x_hat_seq, Σ_hat_seq
```

```
iterate(x0_hat, Σ0, A, C, G, R, [2.3, 1.2, 3.2])
```

```
(array([[0.        , 1.        ],
        [0.1223913 , 0.24826087],
        [0.18729801, 0.06881254],
        [0.75600369, 0.05547207]]),
 array([[[1.        , 0.5       ],
         [0.5       , 2.        ]],

        [[4.14728261, 1.94652174],
         [1.94652174, 1.03434783]],

        [[4.08853181, 1.98917687],
         [1.98917687, 1.00757802]],

        [[4.06650435, 1.99952946],
         [1.99952946, 1.00271293]]]))
```

The iterative algorithm just described is a version of the celebrated **Kalman filter**.

We describe the Kalman filter and some applications of it in *A First Look at the Kalman Filter*

13.13 Classic factor analysis model

The factor analysis model can be represented as

$$Y = \Lambda f + U$$

where

1. Y is $n \times 1$ random vector, $EUU^\top = D$ is a diagonal matrix,
2. Λ is $n \times k$ coefficient matrix,
3. f is $k \times 1$ random vector, $Eff^\top = I$,

4. U is $n \times 1$ random vector, and $U \perp f$ (i.e., $EUf^\top = 0$)
5. It is presumed that k is small relative to n; often k is only 1 or 2, as in our IQ examples.

This implies that

$$\begin{aligned} \Sigma_y = EYY^\top &= \Lambda\Lambda^\top + D \\ EYf^\top &= \Lambda \\ EfY^\top &= \Lambda^\top \end{aligned}$$

Thus, the covariance matrix Σ_Y is the sum of a diagonal matrix D and a positive semi-definite matrix $\Lambda\Lambda^\top$ of rank k.

This means that all covariances among the n components of the Y vector are intermediated by their common dependencies on the k factors.

Form

$$Z = \begin{pmatrix} f \\ Y \end{pmatrix}$$

the covariance matrix of the expanded random vector Z can be computed as

$$\Sigma_z = EZZ^\top = \begin{pmatrix} I & \Lambda^\top \\ \Lambda & \Lambda\Lambda^\top + D \end{pmatrix}$$

In the following, we first construct the mean vector and the covariance matrix for the case where $N = 10$ and $k = 2$.

```
N = 10
k = 2
```

We set the coefficient matrix Λ and the covariance matrix of U to be

$$\Lambda = \begin{pmatrix} 1 & 0 \\ \vdots & \vdots \\ 1 & 0 \\ 0 & 1 \\ \vdots & \vdots \\ 0 & 1 \end{pmatrix}, \quad D = \begin{pmatrix} \sigma_u^2 & 0 & \cdots & 0 \\ 0 & \sigma_u^2 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & \sigma_u^2 \end{pmatrix}$$

where the first half of the first column of Λ is filled with 1s and 0s for the rest half, and symmetrically for the second column.

D is a diagonal matrix with parameter σ_u^2 on the diagonal.

```
Λ = np.zeros((N, k))
Λ[:N//2, 0] = 1
Λ[N//2:, 1] = 1

σu = .5
D = np.eye(N) * σu ** 2
```

```
# compute Σy
Σy = Λ @ Λ.T + D
```

We can now construct the mean vector and the covariance matrix for Z.

```
μz = np.zeros(k+N)

Σz = np.empty((k+N, k+N))
```

(continues on next page)

(continued from previous page)

```
Σz[:k, :k] = np.eye(k)
Σz[:k, k:] = Λ.T
Σz[k:, :k] = Λ
Σz[k:, k:] = Σy
```

```
z = rng.multivariate_normal(μz, Σz)

f = z[:k]
y = z[k:]
```

```
multi_normal_factor = MultivariateNormal(μz, Σz)
multi_normal_factor.partition(k)
```

Let's compute the conditional distribution of the hidden factor f on the observations Y, namely, $f \mid Y = y$.

```
multi_normal_factor.cond_dist(0, y)
```

```
(array([0.14356426, 1.84615504]),
 array([[0.04761905, 0.        ],
        [0.        , 0.04761905]]))
```

We can verify that the conditional mean $E[f \mid Y = y] = BY$ where $B = \Lambda^\top \Sigma_y^{-1}$.

```
B = Λ.T @ np.linalg.inv(Σy)

B @ y
```

```
array([0.14356426, 1.84615504])
```

Similarly, we can compute the conditional distribution $Y \mid f$.

```
multi_normal_factor.cond_dist(1, f)
```

```
(array([0.41858317, 0.41858317, 0.41858317, 0.41858317, 0.41858317,
        2.04367341, 2.04367341, 2.04367341, 2.04367341, 2.04367341]),
 array([[0.25, 0.  , 0.  , 0.  , 0.  , 0.  , 0.  , 0.  , 0.  , 0.  ],
        [0.  , 0.25, 0.  , 0.  , 0.  , 0.  , 0.  , 0.  , 0.  , 0.  ],
        [0.  , 0.  , 0.25, 0.  , 0.  , 0.  , 0.  , 0.  , 0.  , 0.  ],
        [0.  , 0.  , 0.  , 0.25, 0.  , 0.  , 0.  , 0.  , 0.  , 0.  ],
        [0.  , 0.  , 0.  , 0.  , 0.25, 0.  , 0.  , 0.  , 0.  , 0.  ],
        [0.  , 0.  , 0.  , 0.  , 0.  , 0.25, 0.  , 0.  , 0.  , 0.  ],
        [0.  , 0.  , 0.  , 0.  , 0.  , 0.  , 0.25, 0.  , 0.  , 0.  ],
        [0.  , 0.  , 0.  , 0.  , 0.  , 0.  , 0.  , 0.25, 0.  , 0.  ],
        [0.  , 0.  , 0.  , 0.  , 0.  , 0.  , 0.  , 0.  , 0.25, 0.  ],
        [0.  , 0.  , 0.  , 0.  , 0.  , 0.  , 0.  , 0.  , 0.  , 0.25]]))
```

It can be verified that the mean is $\Lambda I^{-1} f = \Lambda f$.

```
Λ @ f
```

```
array([0.41858317, 0.41858317, 0.41858317, 0.41858317, 0.41858317,
       2.04367341, 2.04367341, 2.04367341, 2.04367341, 2.04367341])
```

13.14 PCA and factor analysis

To learn about Principal Components Analysis (PCA), please see this lecture *Singular Value Decompositions*.

For fun, let's apply a PCA decomposition to a covariance matrix Σ_y that in fact is governed by our factor-analytic model.

Technically, this means that the PCA model is misspecified.

(Can you explain why?)

Nevertheless, this exercise will let us study how well the first two principal components from a PCA can approximate the conditional expectations $Ef_i|Y$ for our two factors $f_i, i = 1, 2$ for the factor analytic model that we have assumed truly governs the data on Y we have generated.

So we compute the PCA decomposition

$$\Sigma_y = P\tilde{\Lambda}P^\top$$

where $\tilde{\Lambda}$ is a diagonal matrix.

We have

$$Y = P\epsilon$$

and

$$\epsilon = P^\top Y$$

Note that we will arrange the eigenvectors in P in the *descending* order of eigenvalues.

```
λ_tilde, P = np.linalg.eigh(Σy)

# arrange the eigenvectors by eigenvalues
ind = sorted(range(N), key=lambda x: λ_tilde[x], reverse=True)

P = P[:, ind]
λ_tilde = λ_tilde[ind]
Λ_tilde = np.diag(λ_tilde)

print('λ_tilde =', λ_tilde)
```

```
λ_tilde = [5.25 5.25 0.25 0.25 0.25 0.25 0.25 0.25 0.25 0.25]
```

```
# verify the orthogonality of eigenvectors
np.abs(P @ P.T - np.eye(N)).max()
```

```
np.float64(4.440892098500626e-16)
```

```
# verify the eigenvalue decomposition is correct
P @ Λ_tilde @ P.T
```

```
array([[1.25, 1.  , 1.  , 1.  , 1.  , 0.  , 0.  , 0.  , 0.  , 0.  ],
       [1.  , 1.25, 1.  , 1.  , 1.  , 0.  , 0.  , 0.  , 0.  , 0.  ],
       [1.  , 1.  , 1.25, 1.  , 1.  , 0.  , 0.  , 0.  , 0.  , 0.  ],
       [1.  , 1.  , 1.  , 1.25, 1.  , 0.  , 0.  , 0.  , 0.  , 0.  ],
       [1.  , 1.  , 1.  , 1.  , 1.25, 0.  , 0.  , 0.  , 0.  , 0.  ],
```

(continues on next page)

(continued from previous page)

```
       [0.  , 0.  , 0.  , 0.  , 0.  , 1.25, 1.  , 1.  , 1.  , 1.  ],
       [0.  , 0.  , 0.  , 0.  , 0.  , 1.  , 1.25, 1.  , 1.  , 1.  ],
       [0.  , 0.  , 0.  , 0.  , 0.  , 1.  , 1.  , 1.25, 1.  , 1.  ],
       [0.  , 0.  , 0.  , 0.  , 0.  , 1.  , 1.  , 1.  , 1.25, 1.  ],
       [0.  , 0.  , 0.  , 0.  , 0.  , 1.  , 1.  , 1.  , 1.  , 1.25]])
```

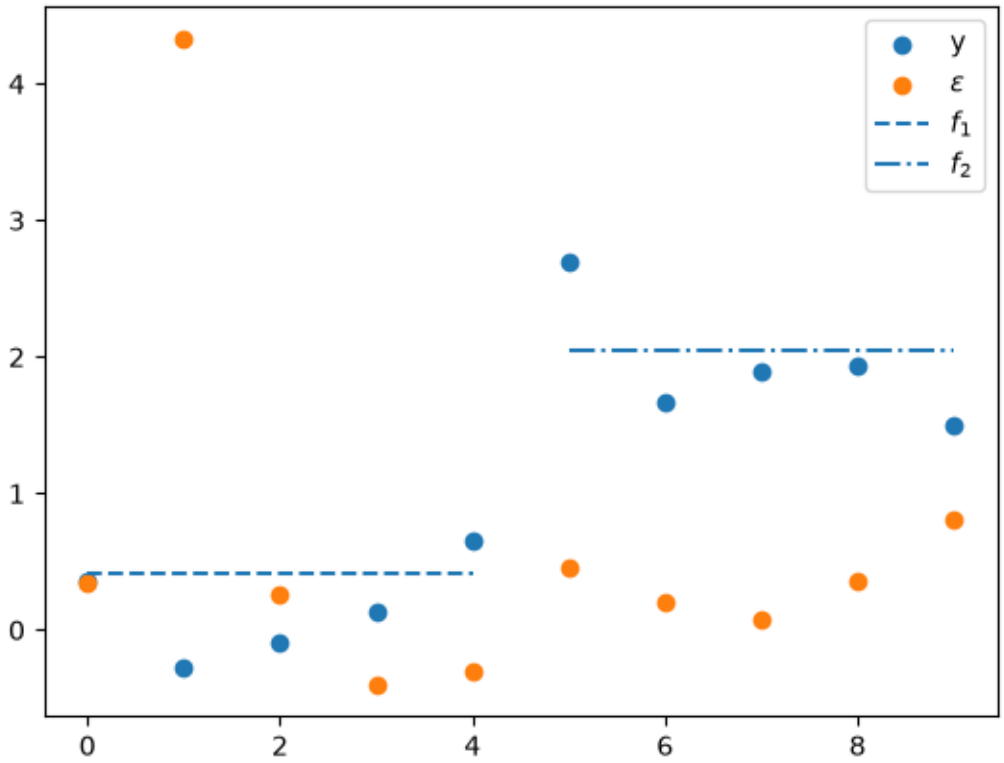
```
ε = P.T @ y

print("ε = ", ε)
```

```
ε =  [ 0.33707041  4.33453458  0.26386722 -0.39706296 -0.30020843  0.45473871
  0.19640695  0.07004059  0.35348891  0.81330557]
```

```
# print the values of the two factors

print('f = ', f)
```



```
f =  [0.41858317 2.04367341]
```

Below we'll plot several things

- the N values of y
- the N values of the principal components ϵ
- the value of the first factor f_1 plotted only for the first $N/2$ observations of y for which it receives a non-zero loading in Λ
- the value of the second factor f_2 plotted only for the final $N/2$ observations for which it receives a non-zero loading in Λ

```
plt.scatter(range(N), y, label='y')
plt.scatter(range(N), ε, label=r'$\epsilon$')
plt.hlines(f[0], 0, N//2-1, ls='--', label='$f_{1}$')
plt.hlines(f[1], N//2, N-1, ls='-.', label='$f_{2}$')
plt.legend()

plt.show()
```

Consequently, the first two ϵ_j correspond to the largest two eigenvalues.

Let's look at them, after which we'll look at $Ef|y = By$

```
ε[:2]
```

```
array([0.33707041, 4.33453458])
```

```
# compare with Ef|y
B @ y
```

```
array([0.14356426, 1.84615504])
```

Note

The two largest eigenvalues are both 5.25 in this example.

When an eigenvalue is repeated, the associated principal components are not individually pinned down: any orthonormal basis for the same two-dimensional eigenspace is valid.

For that reason, it is not meaningful to compare ϵ_1 and ϵ_2 component-by-component with $E[f \mid Y]$.

The PC scores live in a PCA coordinate system, while $E[f \mid Y]$ lives in factor space.

Even within the common two-dimensional subspace, the PCA basis can be rotated or sign-flipped, and its coordinates need not use the same scaling as the factor coordinates.

What is uniquely determined is the two-dimensional subspace spanned by the first two columns of P.

In this symmetric example, that subspace is exactly the column space of Λ.

The fraction of variance in y_t explained by the first two principal components is

```
λ_tilde[:2].sum() / λ_tilde.sum()
```

```
np.float64(0.84)
```

To compare PCA with the factor model in observation space, compute

$$\hat{Y} = P_j \epsilon_j + P_k \epsilon_k$$

where P_j and P_k are the eigenvectors associated with the two largest eigenvalues.

```
y_hat = P[:, :2] @ ε[:2]
```

$\hat{Y}$ is the rank-2 PCA approximation to Y in observation space, so it is a 10-vector rather than a 2-vector.

The natural observation-space counterpart from the factor model is $\Lambda E[f \mid Y]$, which is also a 10-vector.

In this symmetric example, both vectors lie in the same two-dimensional subspace, namely the column space of Λ.

They are therefore close, but not identical.

The PCA reconstruction uses the block means directly, while $\Lambda E[f \mid Y]$ shrinks those block means toward zero by the factor $5/(5 + \sigma_u^2) \approx 0.952$.

The next plot makes this comparison concrete.

The two scatter plots, $E[Y \mid f] = \Lambda f$ and $\hat{Y}$, are both 10-vectors in observation space, so they can be compared directly.

The horizontal lines show the factor values f_1 and f_2, together with their posterior means $E[f_i \mid Y]$.

These are 2-dimensional factor-space quantities, drawn over the relevant half of the index set to match the block structure of Λ.

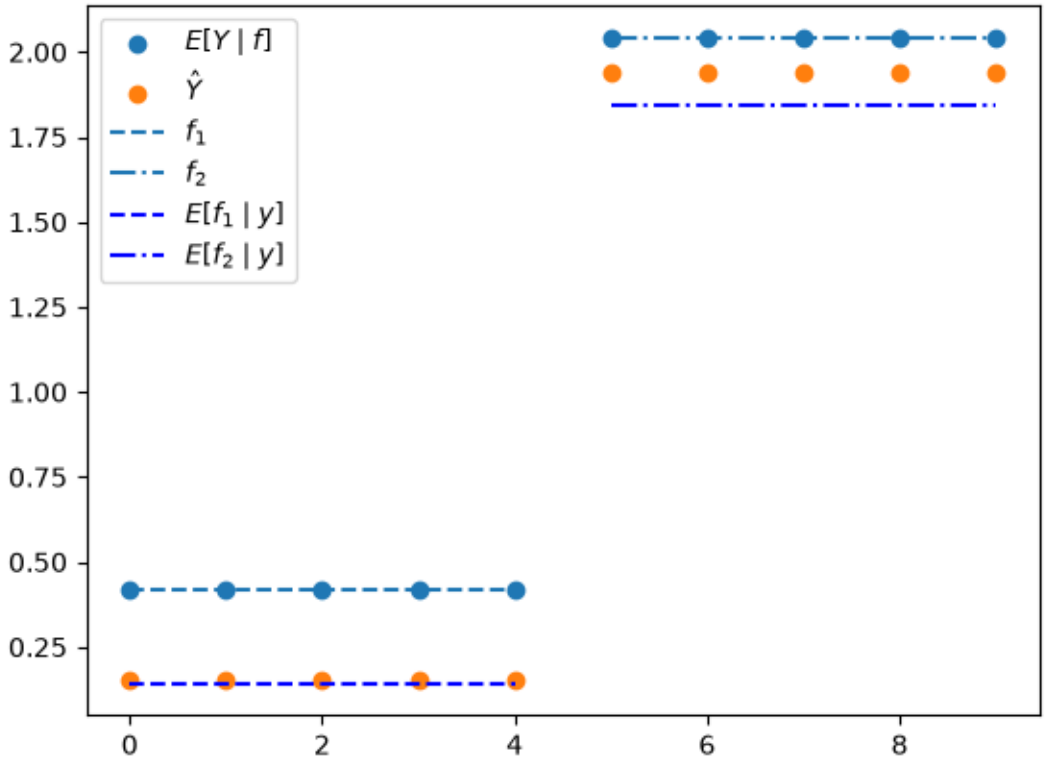
This uses the same idea as the earlier formula $E[Y \mid f] = \Lambda f$: the matrix Λ maps a 2-vector in factor space into a 10-vector in observation space.

In our example,

$$\Lambda a = \begin{bmatrix} a_1 \\ \vdots \\ a_1 \\ a_2 \\ \vdots \\ a_2 \end{bmatrix} \quad \text{for any } a = \begin{bmatrix} a_1 \\ a_2 \end{bmatrix},$$

because the first five rows of Λ are $(1, 0)$ and the last five rows are $(0, 1)$.

Therefore, once we observe $Y = y$, the posterior mean $E[f \mid Y = y] = \begin{bmatrix} E[f_1 \mid y] \\ E[f_2 \mid y] \end{bmatrix}$ is converted into the observation-space vector



$$\Lambda E[f \mid Y = y] = \begin{bmatrix} E[f_1 \mid y] \\ \vdots \\ E[f_1 \mid y] \\ E[f_2 \mid y] \\ \vdots \\ E[f_2 \mid y] \end{bmatrix}.$$

So the horizontal line at height $E[f_1 \mid y]$ over the first five indices, together with the horizontal line at height $E[f_2 \mid y]$ over the last five indices, is exactly a picture of $\Lambda E[f \mid Y = y]$.

```
plt.scatter(range(N), Λ @ f, label=r'$E[Y \mid f]$')
plt.scatter(range(N), y_hat, label=r'$\hat{Y}$')
plt.hlines(f[0], 0, N//2-1, ls='--', label='$f_{1}$')
plt.hlines(f[1], N//2, N-1, ls='-.', label='$f_{2}$')

Efy = B @ y
plt.hlines(Efy[0], 0, N//2-1, ls='--', color='b', label=r'$E[f_1 \mid y]$')
plt.hlines(Efy[1], N//2, N-1, ls='-.', color='b', label=r'$E[f_2 \mid y]$')
plt.legend()

plt.show()
```

To compute the covariance matrix of $\hat{Y}$, first form the covariance matrix of ϵ and then extract the upper-left block corresponding to ϵ_1 and ϵ_2.

```
Σεjk = (P.T @ Σy @ P)[:2, :2]

Pjk = P[:, :2]

Σy_hat = Pjk @ Σεjk @ Pjk.T
print('Σy_hat = \n', Σy_hat)
```

```
Σy_hat =
 [[1.05 1.05 1.05 1.05 1.05 0.   0.   0.   0.   0.  ]

```

13.15 Exercises

Exercise 13.15.1

Verify conditional mean and variance by simulation

For the bivariate normal with

$$\mu = \begin{bmatrix} 0.5 \\ 1.0 \end{bmatrix}, \quad \Sigma = \begin{bmatrix} 1 & 0.5 \\ 0.5 & 1 \end{bmatrix}$$

fix $z_2 = 2$.

1. Use `MultivariateNormal` to compute the analytical conditional mean $\hat{\mu}_1$ and variance $\hat{\Sigma}_{11}$ of $z_1 \mid z_2 = 2$.
2. Draw 10^6 samples from the joint distribution.

   Retain only those for which $|z_2 - 2| < 0.05$.

   Compute the sample mean and variance of the retained z_1 values.
3. Confirm that the sample estimates are close to the analytical values.

Solution

Here is one solution:

```
μ = np.array([.5, 1.])
Σ = np.array([[1., .5], [.5, 1.]])

mn = MultivariateNormal(μ, Σ)
mn.partition(1)
μ1_hat, Σ11_hat = mn.cond_dist(0, np.array([2.]))
print(f"Analytical  μ1_hat = {μ1_hat[0]:.4f},  Σ11_hat = {Σ11_hat[0,0]:.4f}")

n = 1_000_000
data = rng.multivariate_normal(μ, Σ, size=n)
z1_all, z2_all = data[:, 0], data[:, 1]

mask = np.abs(z2_all - 2.) < 0.05
z1_cond = z1_all[mask]
print(f"Sample size in band: {mask.sum()}")
print(f"Sample      μ1_hat = {np.mean(z1_cond):.4f},  Σ11_hat = {np.var(z1_cond,␣
↪ddof=1):.4f}")
```

```
Analytical  μ1_hat = 1.0000,  Σ11_hat = 0.7500
Sample size in band: 24314
Sample      μ1_hat = 1.0050,  Σ11_hat = 0.7458
```

Exercise 13.15.2

Product of regression slopes equals squared correlation

For a bivariate normal with standard deviations $\sigma_1 = \sigma_2 = 1$ and correlation ρ, show analytically that $b_1 b_2 = \rho^2$, where b_1 is the slope of z_1 on z_2 and b_2 is the slope of z_2 on z_1.

Then verify numerically for $\rho \in \{0.2, 0.5, 0.9\}$ that `βs[0] * βs[1]` $= \rho^2$ by constructing the appropriate `MultivariateNormal` instances.

Solution

The regression slopes are

$$b_1 = \frac{\Sigma_{12}}{\Sigma_{22}} = \frac{\rho \sigma_1 \sigma_2}{\sigma_2^2} = \rho \frac{\sigma_1}{\sigma_2}, \qquad b_2 = \frac{\Sigma_{21}}{\Sigma_{11}} = \rho \frac{\sigma_2}{\sigma_1}$$

so $b_1 b_2 = \rho^2$.

```
for ρ in [0.2, 0.5, 0.9]:
    Σ = np.array([[1., ρ], [ρ, 1.]])
    mn = MultivariateNormal(np.zeros(2), Σ)
    mn.partition(1)
    product = mn.βs[0].item() * mn.βs[1].item()
    print(f"ρ={ρ:.1f}:  b1*b2 = {product:.4f}")
    print(f"ρ^2 = {ρ**2:.4f},  match: {np.isclose(product, ρ**2)}")
```

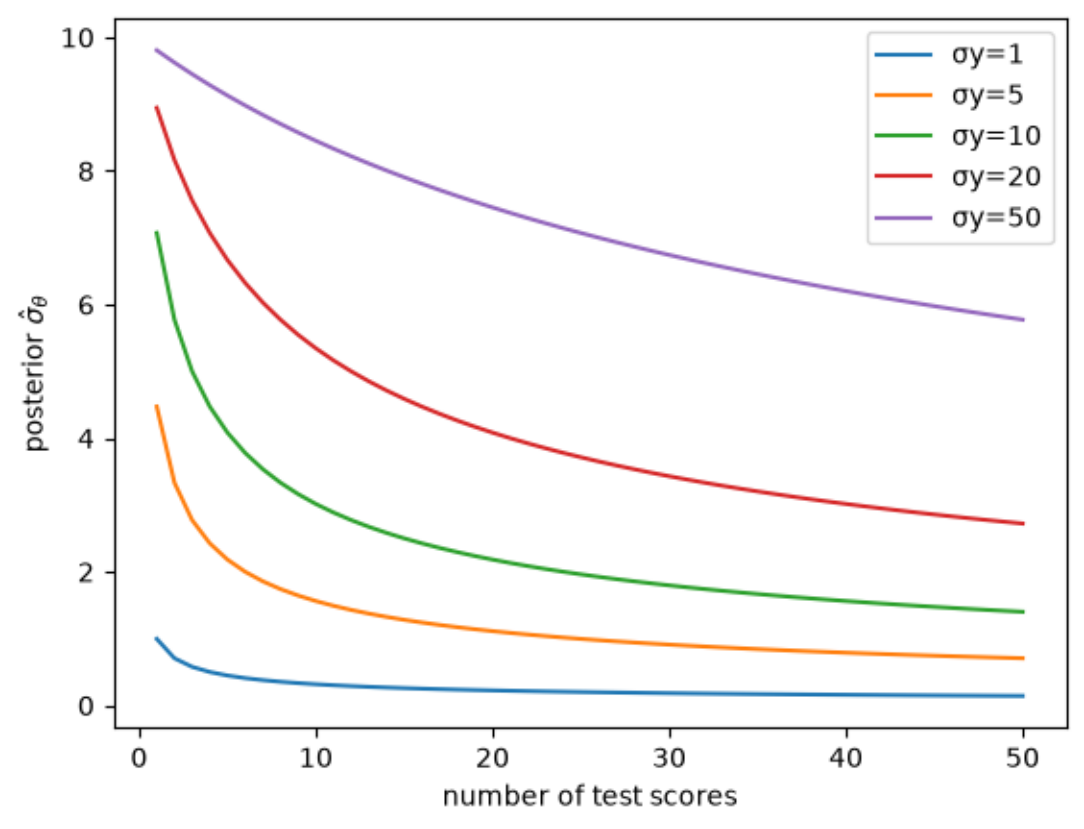
```
ρ=0.2:  b1*b2 = 0.0400
ρ^2 = 0.0400,  match: True
ρ=0.5:  b1*b2 = 0.2500
ρ^2 = 0.2500,  match: True
ρ=0.9:  b1*b2 = 0.8100
ρ^2 = 0.8100,  match: True
```

Exercise 13.15.3

IQ inference: effect of the signal-to-noise ratio

Using the one-dimensional IQ model with $n = 50$ test scores and $\mu_\theta = 100$, $\sigma_\theta = 10$:

1. Vary the test-score noise $\sigma_y \in \{1, 5, 10, 20, 50\}$.
   - For each value, plot the posterior standard deviation $\hat{\sigma}_\theta$ as a function of the number of test scores included (from 1 to 50), with all curves on the same axes.
2. Explain intuitively why a larger σ_y leads to a slower decline of posterior uncertainty.



Solution

Here is one solution:

```
n_max = 50
μθ_val, σθ_val = 100., 10.

fig, ax = plt.subplots()
for σy_val in [1., 5., 10., 20., 50.]:
    σθ_hat_arr = np.empty(n_max)
    for i in range(1, n_max + 1):
        μ_i, Σ_i, _ = construct_moments_IQ(i, μθ_val, σθ_val, σy_val)
        mn_i = MultivariateNormal(μ_i, Σ_i)
        mn_i.partition(i)
        _, Σθ_i = mn_i.cond_dist(1, np.zeros(i))
        σθ_hat_arr[i - 1] = np.sqrt(Σθ_i[0, 0])
    ax.plot(range(1, n_max + 1), σθ_hat_arr, label=f'σy={σy_val:.0f}')

ax.set_xlabel('number of test scores')
ax.set_ylabel(r'posterior $\hat{\sigma}_\theta$')
ax.legend()
plt.show()
```

When σ_y is large each test score is a noisy signal about θ, so many more observations are required before the posterior variance falls appreciably.

In the limit $\sigma_y \to 0$ a single observation pins down θ exactly.

Exercise 13.15.4

Prior vs. likelihood in IQ inference

Using the one-dimensional IQ model with $n = 20$ test scores and $\mu_\theta = 100$, $\sigma_y = 10$:

1. Fix $\sigma_y = 10$ and vary the prior spread $\sigma_\theta \in \{1, 5, 10, 50, 500\}$.
   - For each value compute the posterior mean $\hat{\mu}_\theta$ given the same set of $n = 20$ test scores and plot $\hat{\mu}_\theta$ against σ_θ.
2. Show analytically (or verify numerically) that
   - as $\sigma_\theta \to \infty$ the posterior mean converges to the sample mean $\bar{y}$ (the data dominate the prior), and
   - as $\sigma_\theta \to 0$ the posterior mean converges to the prior mean μ_θ (the prior dominates the data).

Hint

The posterior mean formula is $\hat{\mu}_\theta = (\mu_\theta/\sigma_\theta^2 + n\bar{y}/\sigma_y^2)\big/(1/\sigma_\theta^2 + n/\sigma_y^2)$.

Examine each limit by letting σ_θ go to ∞ or 0.

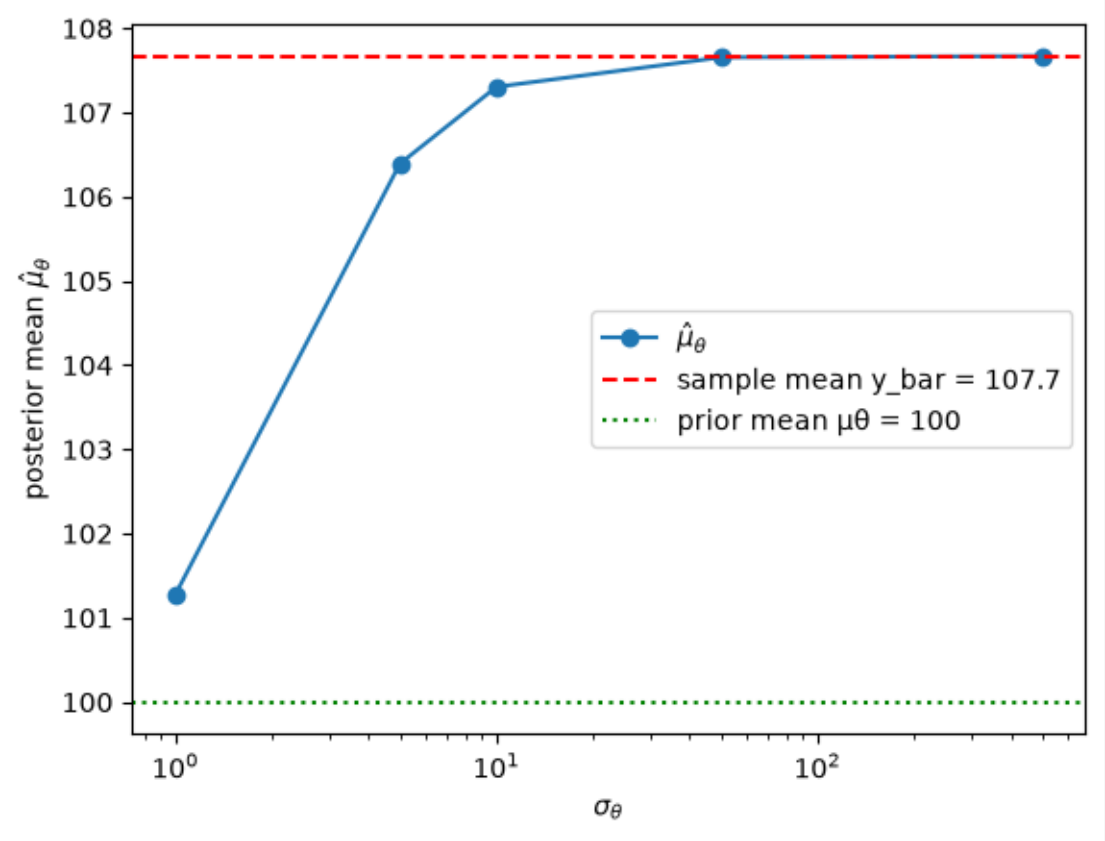
Solution

Here is one solution:

```
n_scores = 20
μθ_val, σy_val = 100., 10.

rng = np.random.default_rng(42)
true_θ = 108.
y_obs = true_θ + σy_val * rng.standard_normal(n_scores)
y_bar = np.mean(y_obs)

σθ_vals = [1., 5., 10., 50., 500.]
μθ_hat_vals = []



for σθ_val in σθ_vals:
    μ_i, Σ_i, _ = construct_moments_IQ(n_scores, μθ_val, σθ_val, σy_val)
    mn_i = MultivariateNormal(μ_i, Σ_i)
    mn_i.partition(n_scores)
    μθ_hat, _ = mn_i.cond_dist(1, y_obs)
    μθ_hat_vals.append(μθ_hat.item())

def posterior_mean(σθ_val):
    μ_i, Σ_i, _ = construct_moments_IQ(n_scores, μθ_val, σθ_val, σy_val)
    mn_i = MultivariateNormal(μ_i, Σ_i)
    mn_i.partition(n_scores)
    μθ_hat, _ = mn_i.cond_dist(1, y_obs)
    return μθ_hat.item()

fig, ax = plt.subplots()
ax.semilogx(σθ_vals, μθ_hat_vals, 'o-',
            label=r'$\hat{\mu}_\theta$')
ax.axhline(y_bar,  ls='--', color='r',
            label=f'sample mean y_bar = {y_bar:.1f}')
ax.axhline(μθ_val, ls=':',  color='g',
            label=f'prior mean μθ = {μθ_val:.0f}')
ax.set_xlabel(r'$\sigma_\theta$')
ax.set_ylabel(r'posterior mean $\hat{\mu}_\theta$')
ax.legend()
plt.show()

σθ_small = 1e-2
σθ_large = 1e4

print(f"y_bar = {y_bar:.4f}")
print(f"Posterior mean with σθ={σθ_large:.0e}: {posterior_mean(σθ_large):.4f}")
print(f"Posterior mean with σθ={σθ_small:.0e}: {posterior_mean(σθ_small):.4f}")
print(f"Prior mean μθ = {μθ_val:.4f}")
```

```
y_bar = 107.6707
Posterior mean with σθ=1e+04: 107.6707
Posterior mean with σθ=1e-02: 100.0002
Prior mean μθ = 100.0000
```

Exercise 13.15.5

Kalman filter convergence

Using the `iterate` function from the Filtering Foundations section with

$$A = \begin{bmatrix} 0.9 & 0 \\ 0 & 0.5 \end{bmatrix}, \quad C = \begin{bmatrix} 1 \\ 1 \end{bmatrix}, \quad G = \begin{bmatrix} 1 & 0 \end{bmatrix}, \quad R = [1]$$

and initial conditions $\hat{x}_0 = [0, 0]'$, $\Sigma_0 = I_2$:

1. Simulate $T = 60$ periods of $\{x_t, y_t\}$ and run the filter.
2. Plot the sequences of conditional variances $\Sigma_t[0, 0]$ and $\Sigma_t[1, 1]$ over time.

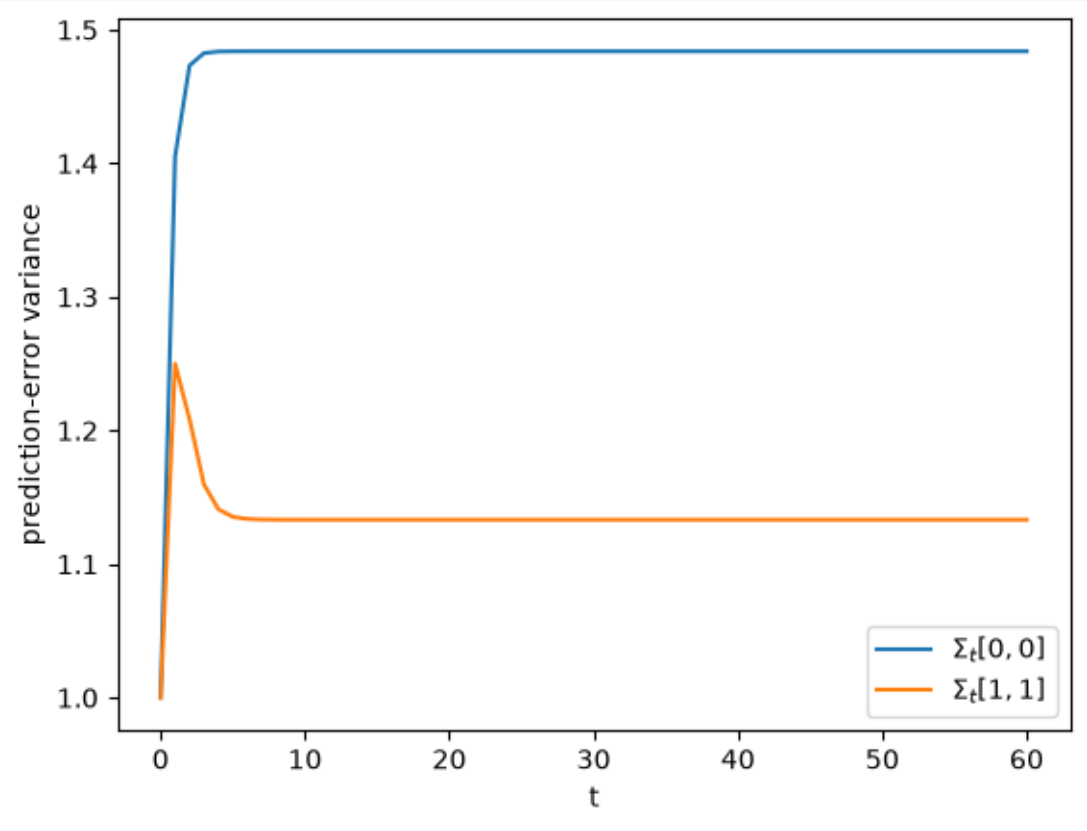
   Verify that they converge to a steady state.
3. Plot the filtered state estimates $\tilde{x}_t[0]$ together with the true $x_t[0]$ and the raw observations y_t on a single figure.

Solution

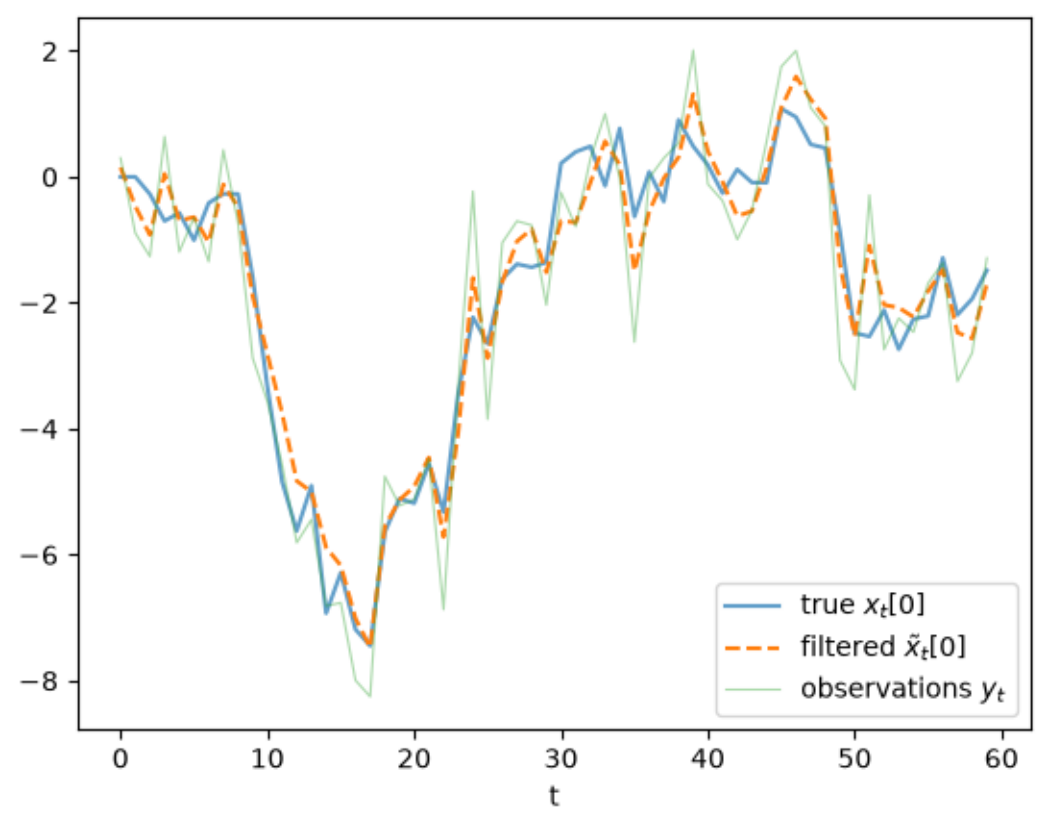
Here is one solution:

```
A_ex = np.array([[0.9, 0.], [0., 0.5]])
C_ex = np.array([[1.], [1.]])
G_ex = np.array([[1., 0.]])
R_ex = np.array([[1.]])

T_ex = 60
x0_hat_ex = np.zeros(2)
Σ0_ex = np.eye(2)



rng = np.random.default_rng(7)
x_true = np.zeros((T_ex + 1, 2))
y_seq_ex = np.zeros(T_ex)
for t in range(T_ex):
    x_true[t + 1] = A_ex @ x_true[t] + C_ex[:, 0] * rng.standard_normal()
    y_seq_ex[t] = (G_ex @ x_true[t]).item() + rng.standard_normal()



x_hat_seq, Σ_hat_seq = iterate(
    x0_hat_ex, Σ0_ex, A_ex, C_ex, G_ex, R_ex, y_seq_ex)

# x_hat_seq[t] = E[x_t | y^{t-1}] (one-step-ahead prediction)
# Σ_hat_seq[t] = corresponding prediction-error covariance
fig, ax = plt.subplots()
ax.plot(Σ_hat_seq[:, 0, 0], label=r'$\Sigma_t[0,0]$')
ax.plot(Σ_hat_seq[:, 1, 1], label=r'$\Sigma_t[1,1]$')
ax.set_xlabel('t')
ax.set_ylabel('prediction-error variance')
ax.legend()
plt.show()

# The `iterate` function stores one-step-ahead predictions.
# We recover the filtered estimates E[x_t | y^t] by re-applying
# the measurement-update step at each t.
n_state = 2
x_filt_seq = np.empty((T_ex, n_state))
for t in range(T_ex):
    xt_hat = x_hat_seq[t]
    Σt     = Σ_hat_seq[t]
    μ_k = np.hstack([xt_hat, G_ex @ xt_hat])
    Σ_k = np.block([[Σt,          Σt  @ G_ex.T          ],
                    [G_ex @ Σt,   G_ex @ Σt @ G_ex.T + R_ex]])
    mn_k = MultivariateNormal(μ_k, Σ_k)
    mn_k.partition(n_state)
    x_filt_seq[t], _ = mn_k.cond_dist(0, y_seq_ex[t:t+1])

fig, ax = plt.subplots()
ax.plot(x_true[:-1, 0], label='true $x_t[0]$', alpha=0.7)
ax.plot(x_filt_seq[:, 0], label=r'filtered $\tilde{x}_t[0]$', ls='--')
ax.plot(y_seq_ex, label='observations $y_t$', alpha=0.4, lw=0.8)
ax.set_xlabel('t')

Exercise 13.15.6

PCA vs. factor analysis

In the classic factor analysis model at the end of the lecture the true covariance is $\Sigma_y = \Lambda\Lambda' + D$.

1. Set $\sigma_u = 2$ (instead of 0.5).
   - Recompute the fraction of variance explained by the first two principal components and compare it with the $\sigma_u = 0.5$ result.
   - Explain the change.
2. Show that the observation-space factor-analytic posterior $\Lambda E[f \mid Y] = \Lambda BY$ (an N-vector) is **not** equal to the two-component PCA reconstruction $\hat{Y} = P_{:,1:2}\,\epsilon_{1:2}$ (also an N-vector).
   - Plot both on the same axes.

   Note: $E[f \mid Y] = BY$ is a k-vector and $\hat{Y}$ is an N-vector, so they cannot be compared directly; the comparison must be made in observation space via $\Lambda E[f \mid Y]$.
3. In one or two sentences, explain why PCA is misspecified for factor-analytic data.

Solution

Here is one solution:

```
rng = np.random.default_rng(42)

N_fa = 10
k_fa = 2

Λ_fa = np.zeros((N_fa, k_fa))
Λ_fa[:N_fa//2, 0] = 1
Λ_fa[N_fa//2:, 1] = 1

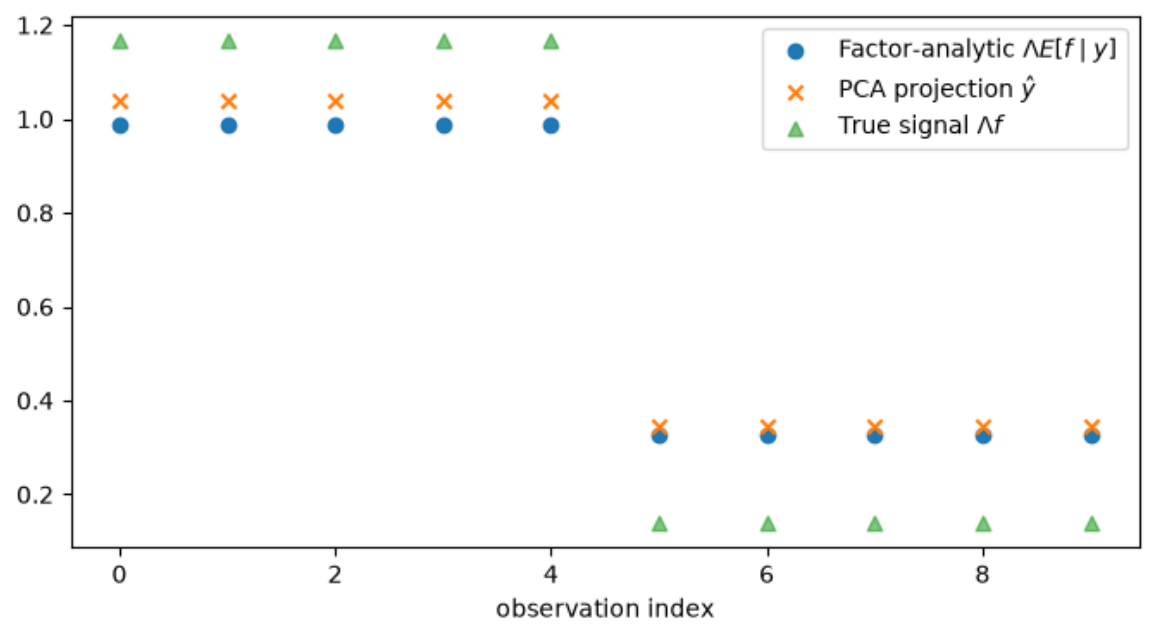
for σu_val in [0.5, 2.0]:
    D_fa = np.eye(N_fa) * σu_val ** 2
    Σy_fa = Λ_fa @ Λ_fa.T + D_fa

    λ_fa, P_fa = np.linalg.eigh(Σy_fa)
    ind_fa = sorted(range(N_fa), key=lambda x: λ_fa[x], reverse=True)
    P_fa   = P_fa[:, ind_fa]
    λ_fa   = λ_fa[ind_fa]

    frac = λ_fa[:2].sum() / λ_fa.sum()
    print(f"σu={σu_val}: fraction explained by first 2 PCs = {frac:.4f}")

σu_b = 0.5
D_b = np.eye(N_fa) * σu_b ** 2
Σy_b = Λ_fa @ Λ_fa.T + D_b

μz_b = np.zeros(k_fa + N_fa)
Σz_b = np.block([[np.eye(k_fa), Λ_fa.T], [Λ_fa, Σy_b]])
z_b = rng.multivariate_normal(μz_b, Σz_b)
f_b = z_b[:k_fa]
y_b = z_b[k_fa:]



B_b = Λ_fa.T @ np.linalg.inv(Σy_b)
```

```
Efy_b  = B_b @ y_b

λ_b, P_b = np.linalg.eigh(Σy_b)
ind_b = sorted(range(N_fa), key=lambda x: λ_b[x], reverse=True)
P_b = P_b[:, ind_b]
ε_b = P_b.T @ y_b
y_hat_b = P_b[:, :2] @ ε_b[:2]

fig, ax = plt.subplots(figsize=(8, 4))
ax.scatter(range(N_fa),
        Λ_fa @ Efy_b, label=r'Factor-analytic $\Lambda E[f\mid y]$')
ax.scatter(range(N_fa),
        y_hat_b, marker='x', label=r'PCA projection $\hat{y}$')
ax.scatter(range(N_fa),
        Λ_fa @ f_b, marker='^', alpha=0.6, label=r'True signal $\Lambda f$')
ax.set_xlabel('observation index')
ax.legend()
plt.show()
```

```
σu=0.5: fraction explained by first 2 PCs = 0.8400
σu=2.0: fraction explained by first 2 PCs = 0.3600
```

In this symmetric example, PCA does recover the same two-dimensional observation-space subspace as the factor model, namely the column space of Λ. But PCA is still misspecified for factor-analytic data, because it treats the covariance matrix as an arbitrary matrix to be approximated and does not use the special decomposition $\Sigma_y = \Lambda\Lambda^\top + D$ into a common part and an idiosyncratic noise part.

So the two methods are solving different problems. PCA forms $\hat{Y}$ as the best rank-2 approximation to the observed data vector Y, which in this example amounts to using the block means. The factor model instead computes $\Lambda E[f \mid Y]$, the conditional mean of the latent common component Λf given the data, and because it accounts for noise it shrinks those block means toward zero.

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon tabulate
```

14.1 Overview

This lecture puts elementary tools to work to approximate probability distributions of the annual failure rates of a system consisting of a number of critical parts.

We'll use log normal distributions to approximate probability distributions of critical component parts.

To approximate the probability distribution of the *sum* of n lognormal random variables (representing the system's total failure rate), we compute the convolution of these distributions.

We'll use the following concepts and tools:

- lognormal distributions
- the convolution theorem that describes the probability distribution of the sum of independent random variables
- fault tree analysis for approximating a failure rate of a multi-component system

- a hierarchical probability model for describing uncertain probabilities
- Fourier transforms and inverse Fourier transforms as efficient ways of computing convolutions of sequences

See also

For more on Fourier transforms, see *Circulant Matrices* as well as Covariance Stationary Processes and Estimation of Spectra.

El-Shanawany *et al.* [2018] and Greenfield and Sargent [1993] applied these methods to approximate failure probabilities of safety systems in nuclear facilities.

These techniques respond to recommendations by Apostolakis [1990] for quantifying uncertainty in safety system reliability.

We will use the following imports and settings throughout this lecture:

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.signal import fftconvolve
from tabulate import tabulate
import quantecon as qe
```

14.2 The lognormal distribution

If random variable x follows a normal distribution with mean μ and variance σ^2, then $y = \exp(x)$ follows a **lognormal distribution** with parameters μ, σ^2.

Note

We refer to μ and σ^2 as *parameters* rather than mean and variance because:

- μ and σ^2 are the mean and variance of $x = \log(y)$
- They are *not* the mean and variance of y
- The mean of y is $\exp(\mu + \frac{1}{2}\sigma^2)$ and the variance is $(e^{\sigma^2} - 1)e^{2\mu+\sigma^2}$

A lognormal random variable y is always nonnegative.

The probability density function for y is

$$f(y) = \frac{1}{y\sigma\sqrt{2\pi}} \exp\left(\frac{-(\log y - \mu)^2}{2\sigma^2}\right), \quad y \geq 0 \tag{14.1}$$

Important properties of a lognormal random variable are:

$$\begin{aligned}
\text{Mean:} &\quad e^{\mu+\frac{1}{2}\sigma^2} \\
\text{Variance:} &\quad (e^{\sigma^2} - 1)e^{2\mu+\sigma^2} \\
\text{Median:} &\quad e^{\mu} \\
\text{Mode:} &\quad e^{\mu-\sigma^2} \\
\text{0.95 quantile:} &\quad e^{\mu+1.645\sigma} \\
\text{0.95/0.05 quantile ratio:} &\quad e^{3.29\sigma}
\end{aligned} \tag{14.2}$$

14.2.1 Stability properties

Recall that independent normally distributed random variables have the following stability property:

If $x_1 \sim N(\mu_1, \sigma_1^2)$ and $x_2 \sim N(\mu_2, \sigma_2^2)$ are independent, then $x_1 + x_2 \sim N(\mu_1 + \mu_2, \sigma_1^2 + \sigma_2^2)$.

Independent lognormal distributions have a different stability property: the *product* of independent lognormal random variables is also lognormal.

Specifically, if y_1 is lognormal with parameters (μ_1, σ_1^2) and y_2 is lognormal with parameters (μ_2, σ_2^2), then $y_1 y_2$ is lognormal with parameters $(\mu_1 + \mu_2, \sigma_1^2 + \sigma_2^2)$.

Warning

While the product of two lognormal distributions is lognormal, the *sum* of two lognormal distributions is *not* lognormal.

This observation motivates the central challenge of this lecture: approximating the probability distribution of *sums* of independent lognormal random variables.

14.3 The convolution theorem

Let x and y be independent random variables with probability densities $f(x)$ and $g(y)$, where $x, y \in \mathbb{R}$.

Let $z = x + y$.

Then the probability density of z is

$$h(z) = (f * g)(z) \equiv \int_{-\infty}^{\infty} f(\tau) g(z - \tau) d\tau \tag{14.3}$$

where $(f * g)$ denotes the **convolution** of f and g.

For nonnegative random variables, this specializes to

$$h(z) = (f * g)(z) \equiv \int_{0}^{z} f(\tau) g(z - \tau) d\tau \tag{14.4}$$

14.3.1 Discrete convolution

We will use a discretized version of the convolution formula.

We replace both f and g with discretized counterparts, normalized to sum to 1.

The discrete convolution formula is

$$h_n = (f * g)_n = \sum_{m=0}^{n} f_m g_{n-m}, \quad n \geq 0 \tag{14.5}$$

This computes the probability mass function of the sum of two discrete random variables.

14.3.2 Example: discrete distributions

Consider two probability mass functions:

$$f_j = \mathbb{P}\{X = j\}, \quad j = 0, 1$$

and

$$g_j = \mathbb{P}\{Y = j\}, \quad j = 0, 1, 2, 3$$

The distribution of $Z = X + Y$ is given by the convolution $h = f * g$.

```
# Define probability mass functions
f = [0.75, 0.25]
g = [0.0, 0.6, 0.0, 0.4]

# Compute convolution using two methods
h = np.convolve(f, g)
hf = fftconvolve(f, g)

print(f"f = {f}, sum = {np.sum(f):.3f}")
print(f"g = {g}, sum = {np.sum(g):.3f}")
print(f"h = {h}, sum = {np.sum(h):.3f}")
print(f"hf = {hf}, sum = {np.sum(hf):.3f}")
```

```
f = [0.75, 0.25], sum = 1.000
g = [0.0, 0.6, 0.0, 0.4], sum = 1.000
h = [0.   0.45 0.15 0.3  0.1 ], sum = 1.000
hf = [0.   0.45 0.15 0.3  0.1 ], sum = 1.000
```

Both `numpy.convolve` and `scipy.signal.fftconvolve` produce the same result, but `fftconvolve` is much faster for long sequences.

We will use `fftconvolve` throughout this lecture for efficiency.

14.4 Approximating continuous distributions

We now verify that discretized distributions can accurately approximate samples from underlying continuous distributions.

We generate samples of size 25,000 from three independent lognormal random variables and compute their pairwise and triple-wise sums.

We then compare histograms of the samples with histograms of the discretized distributions.

```
# Set parameters for lognormal distributions
μ, σ = 5.0, 1.0
n_samples = 25000

# Generate samples
rng = np.random.default_rng(1234)
s1 = rng.lognormal(μ, σ, n_samples)
s2 = rng.lognormal(μ, σ, n_samples)
s3 = rng.lognormal(μ, σ, n_samples)

# Compute sums
ssum2 = s1 + s2
```

(continues on next page)

(continued from previous page)

```
ssum3 = s1 + s2 + s3

# Plot histogram of s1
fig, ax = plt.subplots()
ax.hist(s1, 1000, density=True, alpha=0.6)
ax.set_xlabel('value')
ax.set_ylabel('density')
plt.show()
```

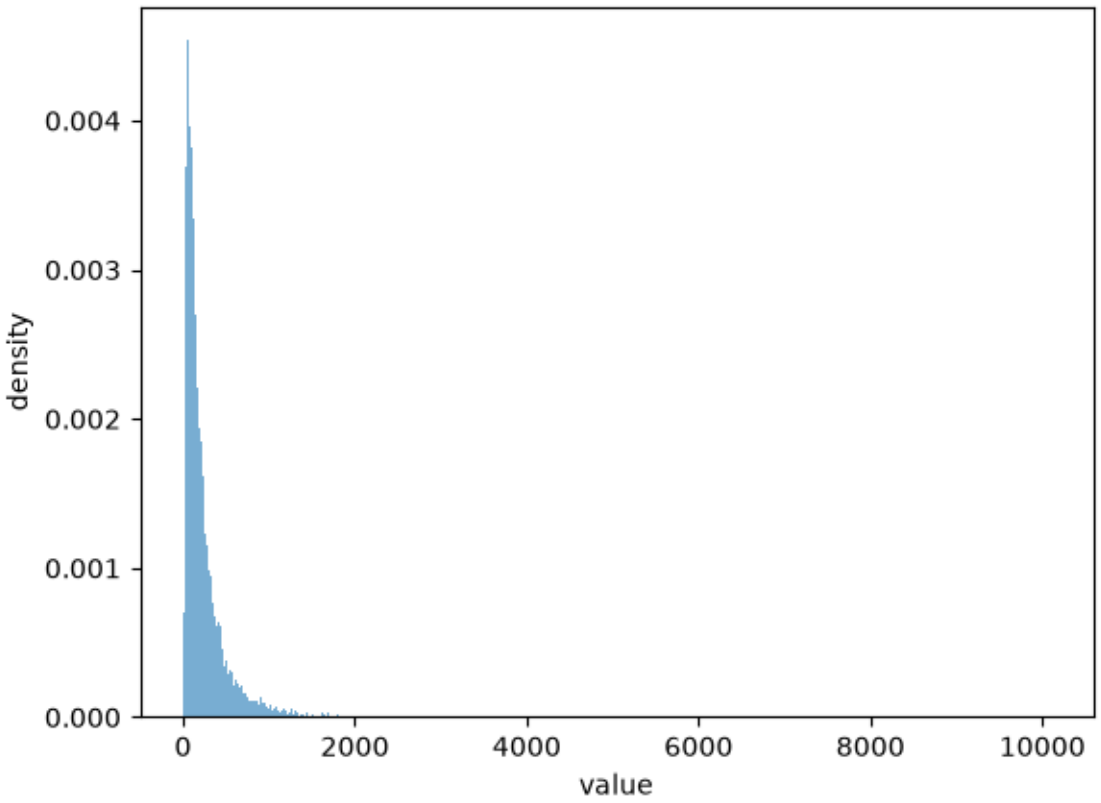

Fig. 14.1: Sample histogram of one lognormal

```
# Plot histogram of sum of two lognormal distributions
fig, ax = plt.subplots()
ax.hist(ssum2, 1000, density=True, alpha=0.6)
ax.set_xlabel('value')
ax.set_ylabel('density')
plt.show()
```

```
# Plot histogram of sum of three lognormal distributions
fig, ax = plt.subplots()
ax.hist(ssum3, 1000, density=True, alpha=0.6)
ax.set_xlabel('value')
```

(continues on next page)

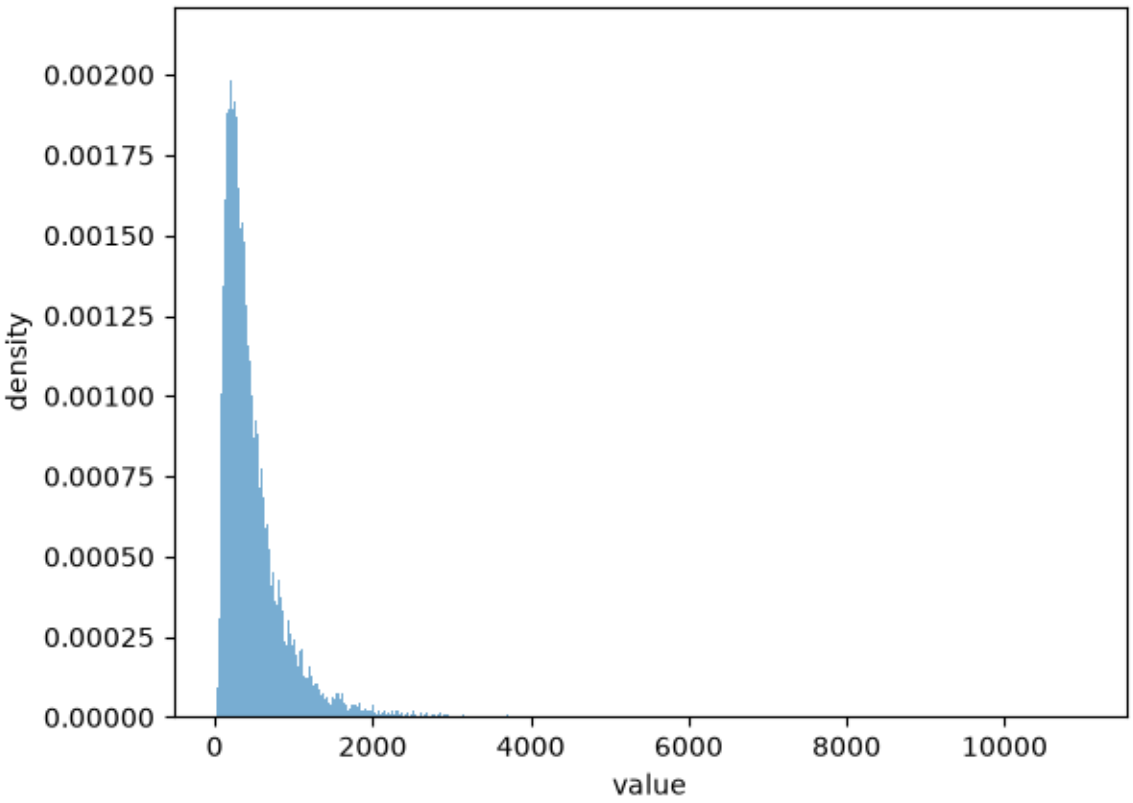

Fig. 14.2: Histogram of a sum of two lognormals

(continued from previous page)

```
ax.set_ylabel('density')
plt.show()
```

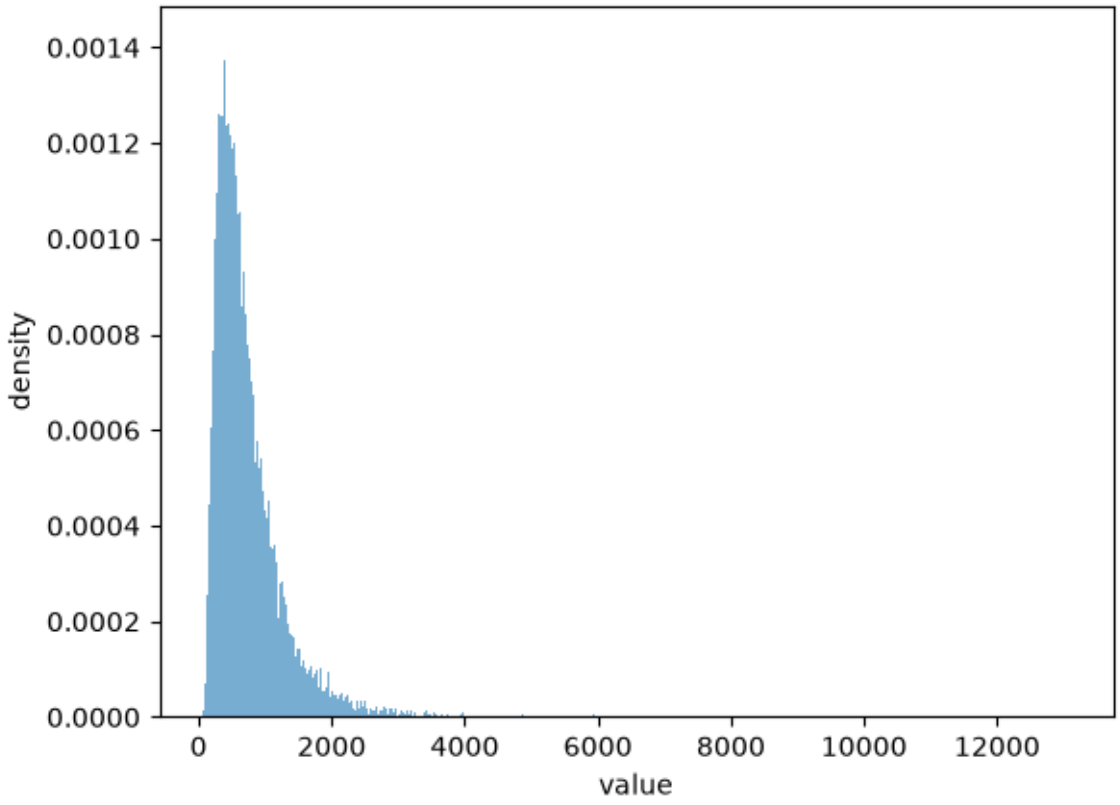

Fig. 14.3: Histogram of a sum of three lognormals

Let's verify that the sample mean matches the theoretical mean:

```
samp_mean = np.mean(s2)
theoretical_mean = np.exp(μ + σ**2 / 2)

print(f"Theoretical mean: {theoretical_mean:.3f}")
print(f"Sample mean: {samp_mean:.3f}")
```

```
Theoretical mean: 244.692
Sample mean: 243.197
```

14.5 Discretizing the lognormal distribution

We define helper functions to create discretized versions of lognormal probability density functions.

We write out the density by hand to keep the formula (14.1) in view; `scipy.stats.lognorm(s=σ, scale=np.exp(μ)).pdf(x)` computes the same thing.

```
def lognormal_pdf(x, μ, σ):
    """
    Compute lognormal probability density function.
    """
    p = 1 / (σ * x * np.sqrt(2 * np.pi)) \
            * np.exp(-0.5 * ((np.log(x) - μ) / σ)**2)
    return p

def discretize_lognormal(μ, σ, I, m):
    """
    Discretize a lognormal distribution on the grid 0, m, 2m, ..., up to I.

    Parameters
    ----------
    μ, σ : parameters of the lognormal distribution
    I    : upper end of the grid, which truncates the right tail
    m    : spacing between grid points, which sets the resolution

    Returns
    -------
    p_array      : the density evaluated on the grid
    p_array_norm : the implied probability mass function, summing to one
    x            : the grid itself, with I / m points
    """
    x = np.arange(1e-7, I, m)
    p_array = lognormal_pdf(x, μ, σ)
    p_array_norm = p_array / np.sum(p_array)
    return p_array, p_array_norm, x
```

Two separate choices govern the quality of this approximation, and it pays to keep them straight.

- I fixes where the grid *stops*, so it controls how much of the right tail we throw away
- m fixes the *spacing* between grid points, so it controls resolution

The grid has I/m points, so raising I at fixed m buys range, while lowering m at fixed I buys accuracy.

Once I is large enough that almost no probability mass lies beyond it, further increases change nothing, and only m matters.

Exercise 14.10.1 asks you to verify this.

Note

`scipy.signal.fftconvolve` pads its inputs to a convenient length internally, so there is no need to choose I/m to be a power of two.

```
# Set grid parameters
p = 15
```

(continues on next page)

(continued from previous page)

```
I = 2**p  # where the grid stops: truncates the right tail
m = 0.1   # spacing between grid points: sets the resolution
```

Let's visualize how well the discretized distribution approximates the continuous lognormal distribution:

```
# Compute discretized PDF
pdf, pdf_norm, x = discretize_lognormal(μ, σ, I, m)

# Plot discretized PDF against histogram
fig, ax = plt.subplots(figsize=(10, 6))
ax.plot(x, pdf, 'r-', lw=2, label='discretized PDF')
ax.hist(s1, 1000, density=True, alpha=0.6, label='sample histogram')
ax.set_xlim(0, 2500)
ax.set_xlabel('value')
ax.set_ylabel('density')
ax.legend()
plt.show()
```

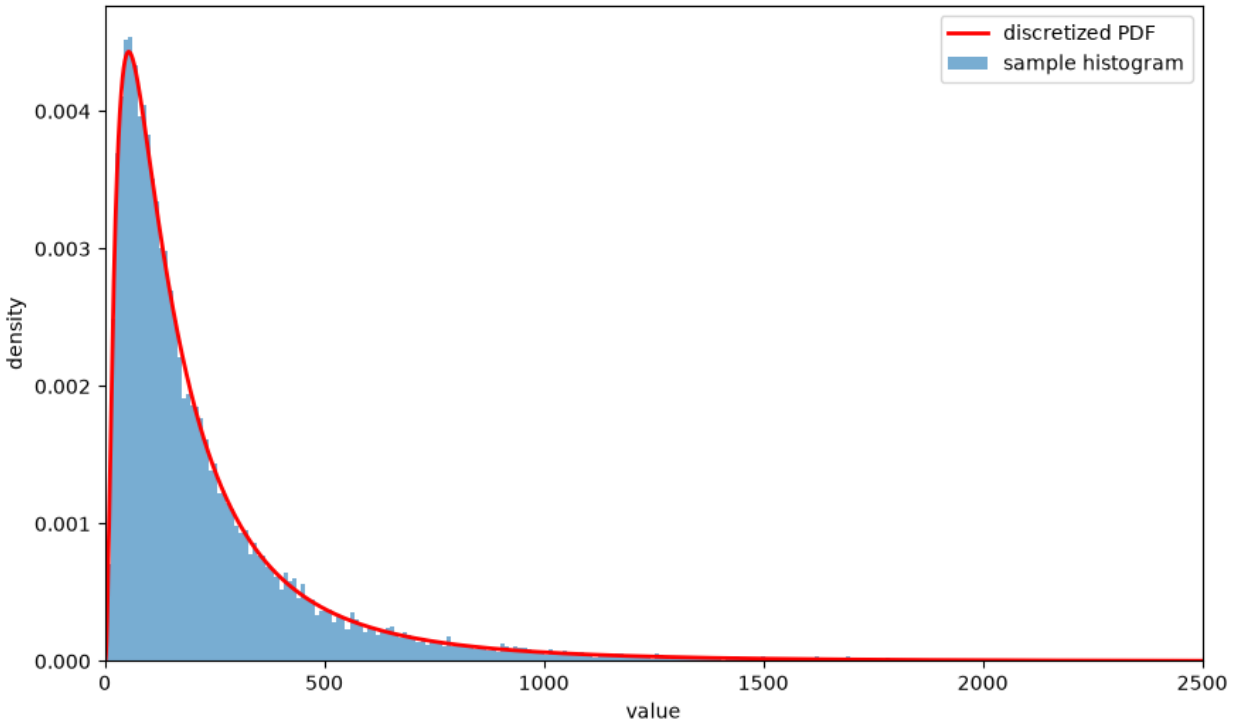

Fig. 14.4: Discretized density against sample

Now let's verify that the discretized distribution has the correct mean:

```
# Compute mean from discretized PDF
mean_discrete = np.sum(x * pdf_norm)
mean_theory = np.exp(μ + 0.5 * σ**2)

print(f"Theoretical mean: {mean_theory:.3f}")
print(f"Discretized mean: {mean_discrete:.3f}")
```

```
Theoretical mean: 244.692
Discretized mean: 244.691
```

14.6 Convolving probability mass functions

Now let's use the convolution theorem to compute the probability distribution of a sum of the two lognormal random variables we have parameterized above.

We'll also compute the probability distribution of a sum of three log normal distributions constructed above.

For long sequences, `scipy.signal.fftconvolve` is much faster than `numpy.convolve` because it uses fast Fourier transforms.

Let's define the Fourier transform and the inverse Fourier transform first

14.6.1 The fast Fourier transform

The **Fourier transform** of a sequence $\{x_t\}_{t=0}^{T-1}$ is

$$x(\omega_j) = \sum_{t=0}^{T-1} x_t \exp(-i\omega_j t) \tag{14.6}$$

where $\omega_j = \frac{2\pi j}{T}$ for $j = 0, 1, \ldots, T-1$.

The **inverse Fourier transform** of the sequence $\{x(\omega_j)\}_{j=0}^{T-1}$ is

$$x_t = T^{-1} \sum_{j=0}^{T-1} x(\omega_j) \exp(i\omega_j t) \tag{14.7}$$

The sequences $\{x_t\}_{t=0}^{T-1}$ and $\{x(\omega_j)\}_{j=0}^{T-1}$ contain the same information.

The pair of equations (14.6) and (14.7) tell how to recover one series from its Fourier partner.

The program `scipy.signal.fftconvolve` deploys the theorem that a convolution of two sequences $\{f_k\}, \{g_k\}$ can be computed in the following way:

- Compute Fourier transforms $F(\omega), G(\omega)$ of the $\{f_k\}$ and $\{g_k\}$ sequences, respectively
- Form the product $H(\omega) = F(\omega)G(\omega)$
- The convolution of $f * g$ is the inverse Fourier transform of $H(\omega)$

The **fast Fourier transform** and the associated **inverse fast Fourier transform** execute these calculations very quickly.

This is the algorithm used by `fftconvolve`.

Let's do a warmup calculation that compares the times taken by `numpy.convolve` and `scipy.signal.fftconvolve`

Our three components are identically distributed, so a single discretization serves for all of them.

```
# Discretize the lognormal distribution; the three components are IID
_, pmf1, x = discretize_lognormal(μ, σ, I, m)
pmf2 = pmf3 = pmf1

# Direct convolution costs O(N²), so we time it on a short prefix
```

(continues on next page)

(continued from previous page)

```
short = pmf1[:20_000]

with qe.Timer() as timer_numpy:
    np.convolve(short, short)
time_numpy = timer_numpy.elapsed

with qe.Timer() as timer_fft:
    fftconvolve(short, short)
time_fft = timer_fft.elapsed

print(f"On {len(short):,} points:")
print(f"  np.convolve: {time_numpy:.4f} seconds")
print(f"  fftconvolve: {time_fft:.4f} seconds")
print(f"  speedup:     {time_numpy / time_fft:.0f}x")
```

```
0.0668 seconds elapsed
0.0025 seconds elapsed
On 20,000 points:
  np.convolve: 0.0668 seconds
  fftconvolve: 0.0025 seconds
  speedup:     26x
```

The gap widens rapidly with the length of the sequences, because direct convolution costs $O(N^2)$ operations while the FFT approach costs $O(N \log N)$.

On the full grid used below, the direct method would be far slower still.

```
# The full calculation, done the fast way
conv_fft = fftconvolve(fftconvolve(pmf1, pmf2), pmf3)
print(f"grid points per component: {len(pmf1):,}")
```

```
grid points per component: 327,680
```

Now let's plot our computed probability mass function approximation for the sum of two log normal random variables against the histogram of the sample that we formed above

```
# Compute convolution of two distributions for comparison
conv2 = fftconvolve(pmf1, pmf2)

fig, ax = plt.subplots(figsize=(10, 6))
ax.plot(x, conv2[:len(x)] / m, 'r-', lw=2, label='convolution (FFT)')
ax.hist(ssum2, 1000, density=True, alpha=0.6, label='sample histogram')
ax.set_xlim(0, 5000)
ax.set_xlabel('value')
ax.set_ylabel('density')
ax.legend()
plt.show()
```

Now we present the plot for the sum of three lognormal random variables:

```
fig, ax = plt.subplots(figsize=(10, 6))
ax.plot(x, conv_fft[:len(x)] / m, 'r-', lw=2, label='convolution (FFT)')
ax.hist(ssum3, 1000, density=True, alpha=0.6, label='sample histogram')
ax.set_xlim(0, 5000)
```

(continues on next page)

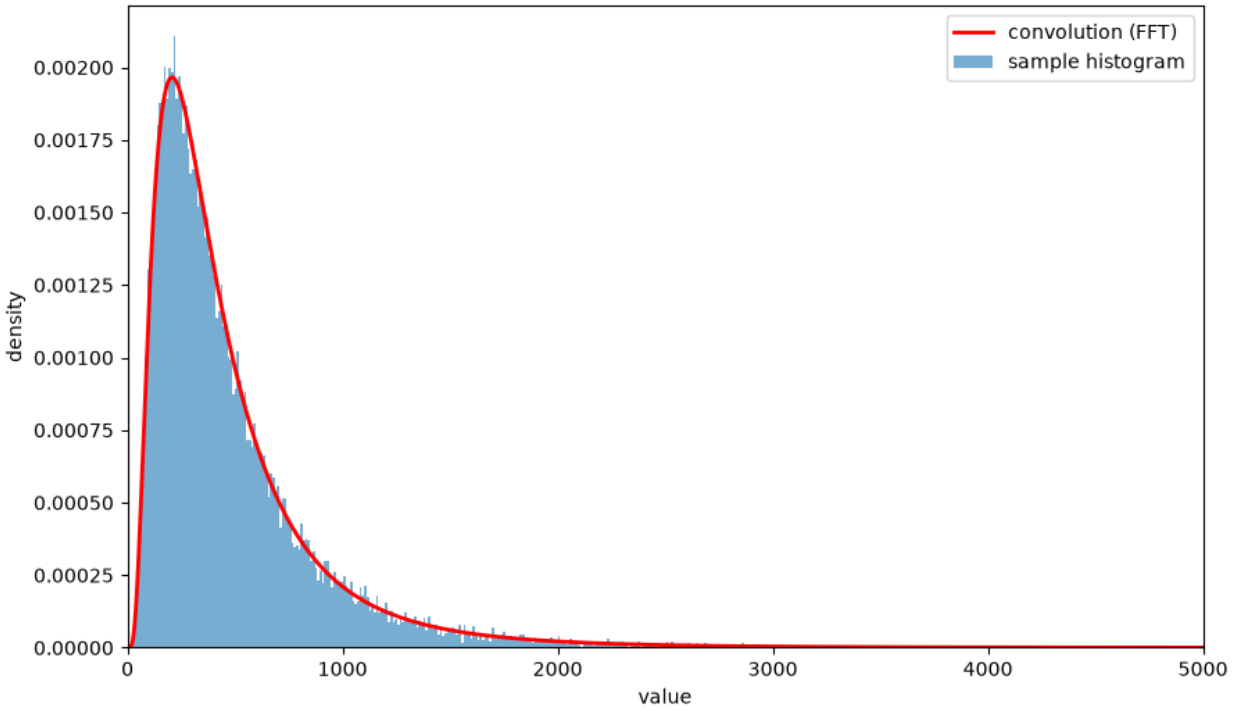

Fig. 14.5: Convolution against sample, two components

(continued from previous page)

```
ax.set_xlabel('value')
ax.set_ylabel('density')
ax.legend()
plt.show()
```

Let's verify that the means are correct

```
# Mean of sum of two distributions
mean_conv2 = np.sum(x * conv2[:len(x)])
mean_theory2 = 2 * np.exp(μ + 0.5 * σ**2)

print(f"Sum of two distributions:")
print(f"  Theoretical mean: {mean_theory2:.3f}")
print(f"  Computed mean: {mean_conv2:.3f}")
```

```
Sum of two distributions:
  Theoretical mean: 489.384
  Computed mean: 489.381
```

```
# Mean of sum of three distributions
mean_conv3 = np.sum(x * conv_fft[:len(x)])
mean_theory3 = 3 * np.exp(μ + 0.5 * σ**2)

print(f"Sum of three distributions:")
print(f"  Theoretical mean: {mean_theory3:.3f}")
print(f"  Computed mean: {mean_conv3:.3f}")
```

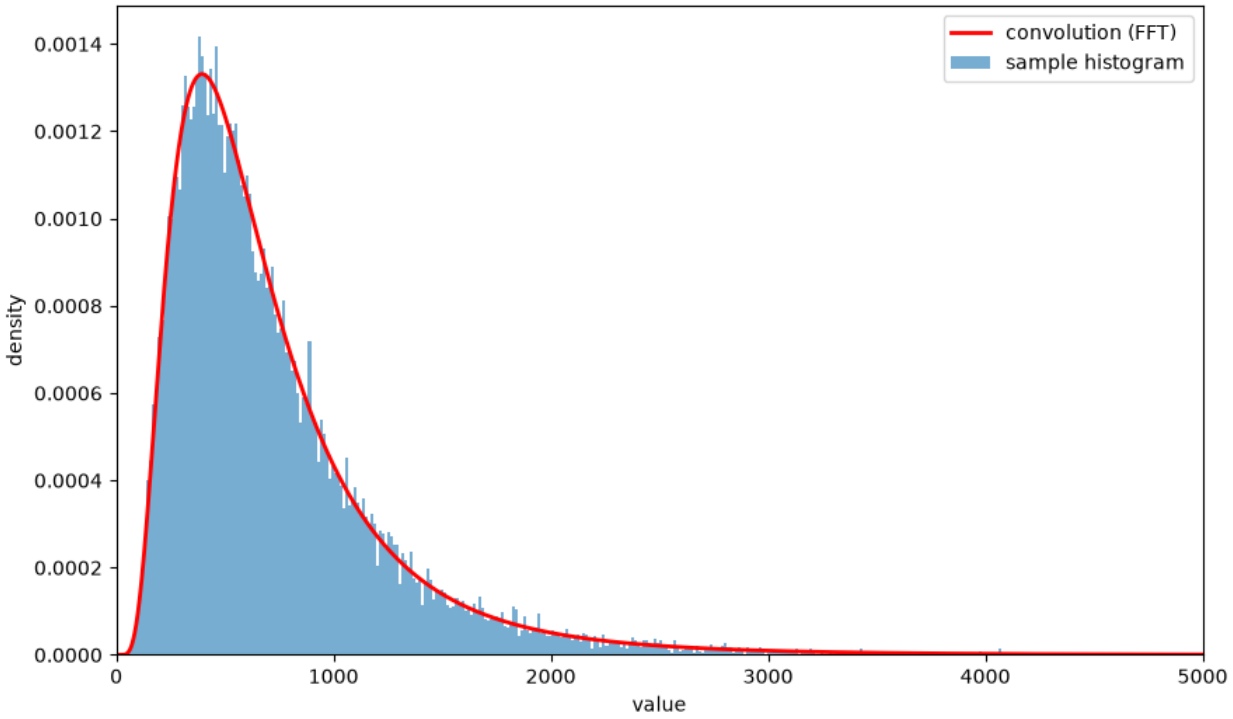

Fig. 14.6: Convolution against sample, three components

```
Sum of three distributions:
  Theoretical mean: 734.076
  Computed mean: 734.071
```

14.7 Fault tree analysis

We shall soon apply the convolution theorem to compute the probability of a **top event** in a failure tree analysis.

Before applying the convolution theorem, we first describe the model that connects constituent events to the *top event* whose failure rate we seek to quantify.

Fault tree analysis is a widely used technique for assessing system reliability, as described by El-Shanawany *et al.* [2018].

To construct the statistical model, we repeatedly use what is called the **rare event approximation**.

14.7.1 The rare event approximation

We want to compute the probability of an event $A \cup B$.

For events A and B, the probability of the union is

$$P(A \cup B) = P(A) + P(B) - P(A \cap B)$$

where $A \cup B$ is the event that A **or** B occurs, and $A \cap B$ is the event that A **and** B both occur.

If A and B are independent, then $P(A \cap B) = P(A)P(B)$.

When $P(A)$ and $P(B)$ are both small, $P(A)P(B)$ is even smaller.

The **rare event approximation** is

$$P(A \cup B) \approx P(A) + P(B)$$

This approximation is widely used in system failure analysis.

14.7.2 System failure probability

Consider a system with n critical components where system failure occurs when *any* component fails.

We assume:

- The failure probability $P(A_i)$ of each component A_i is small
- Component failures are statistically independent

We repeatedly apply a **rare event approximation** to obtain the following formula for the probability of a system failure:

$$P(F) \approx P(A_1) + P(A_2) + \cdots + P(A_n)$$

or

$$P(F) \approx \sum_{i=1}^{n} P(A_i) \tag{14.8}$$

where $P(F)$ is the system failure probability.

Probabilities for each event are recorded as failure rates per year.

> **Note**
>
> Strictly speaking, a failure *rate* per year and a failure *probability* within a year are different objects.
>
> For rare events they nearly coincide, because $1 - e^{-\lambda} \approx \lambda$ when λ is small.
>
> The same approximation that lets us add probabilities across components also lets us move between rates and probabilities, so we follow the reliability literature in using the two words interchangeably here.

14.8 Failure rates unknown

Now we come to the problem that really interests us, following El-Shanawany *et al.* [2018] and Greenfield and Sargent [1993] in the spirit of Apostolakis [1990].

The component failure rates $P(A_i)$ are not known precisely and must be estimated.

We address this problem by specifying **probabilities of probabilities** that capture one notion of not knowing the constituent probabilities that are inputs into a failure tree analysis.

Thus, we assume that a system analyst is uncertain about the failure rates $P(A_i), i = 1, \ldots, n$ for components of a system.

The analyst copes with this situation by regarding the system's failure probability $P(F)$ and each of the component probabilities $P(A_i)$ as random variables.

- dispersions of the probability distribution of $P(A_i)$ characterizes the analyst's uncertainty about the failure probability $P(A_i)$

- the dispersion of the implied probability distribution of $P(F)$ characterizes his uncertainty about the probability of a system's failure.

This leads to what is sometimes called a **hierarchical** model in which the analyst has probabilities about the probabilities $P(A_i)$.

Note

Two distinct kinds of randomness appear in this model, and it is worth keeping them apart.

Aleatory uncertainty is the randomness in whether a component fails during a given year; it is described by the failure rate $P(A_i)$.

Epistemic uncertainty is the analyst's ignorance about the value of that rate; it is described by the lognormal distribution that he places over $P(A_i)$.

The distribution that we compute below is an epistemic object: it describes what the analyst knows about a failure rate, not how often the system fails.

Separating the two is the central recommendation of Apostolakis [1990].

The analyst formalizes his uncertainty by assuming that

- the failure probability $P(A_i)$ is itself a log normal random variable with parameters (μ_i, σ_i).
- failure rates $P(A_i)$ and $P(A_j)$ are statistically independent for all pairs with $i \neq j$.

The analyst calibrates the parameters (μ_i, σ_i) for the failure events $i = 1, \ldots, n$ by reading reliability studies in engineering papers that have studied historical failure rates of components that are as similar as possible to the components being used in the system under study.

The analyst assumes that such information about the observed dispersion of annual failure rates, or times to failure, can inform him of what to expect about parts' performances in his system.

The analyst assumes that the random variables $P(A_i)$ are statistically mutually independent.

Warning

Independence is a strong assumption and it is the one that reliability analysts worry about most.

A design flaw, a shared power supply, a common maintenance crew, or a single environmental shock can push many components toward failure at once.

Such **common-cause** failures make the upper tail of the distribution of $P(F)$ much fatter than the independent calculation suggests, which is precisely the region that a safety regulator cares about.

Exercise 14.10.5 quantifies how much difference this makes.

The analyst wants to approximate a probability mass function and cumulative distribution function of the system's failure probability $P(F)$.

- We say probability mass function because of how we discretize each random variable, as described earlier.

The analyst calculates the probability mass function for the *top event* F, i.e., a *system failure*, by repeatedly applying the convolution theorem to compute the probability distribution of a sum of independent log normal random variables, as described in equation (14.8).

14.9 Application: waste hoist failure rate

We now analyze a real-world example with $n = 14$ components.

The application estimates the annual failure rate of a critical hoist at a nuclear waste facility.

A regulatory agency requires the system to be designed so that the top event failure rate is small with high probability.

14.9.1 Model specification

This example is Design Option B-2 (Case I) described in Table 10 on page 27 of Greenfield and Sargent [1993].

The table describes parameters μ_i, σ_i for fourteen log normal random variables that consist of **seven pairs** of random variables that are identically and independently distributed.

- Within a pair, parameters μ_i, σ_i are the same
- As described in table 10 of Greenfield and Sargent [1993] p. 27, parameters of log normal distributions for the seven unique probabilities $P(A_i)$ have been calibrated to be the values in the following Python code:

```
# Component failure rate parameters
# (see Table 10 of Greenfield & Sargent 1993)
params = [
    (4.28, 1.1947),    # Component type 1
    (3.39, 1.1947),    # Component type 2
    (2.795, 1.1947),   # Component type 3
    (2.717, 1.1947),   # Component type 4
    (2.717, 1.1947),   # Component type 5
    (1.444, 1.4632),   # Component type 6
    (-0.040, 1.4632), # Component type 7 (appears 8 times)
]
```

Note

Since failure rates are very small, these lognormal distributions actually describe $P(A_i) \times 10^{-9}$.

So the probabilities that we'll put on the x axis of the probability mass function and associated cumulative distribution function should be multiplied by 10^{-09}

We define a helper function to find array indices:

```
def find_nearest(array, value):
    """
    Index of the array element nearest to the given value.

    Applied to a cumulative distribution function, this returns the grid point
    whose cumulative probability is closest to a target, which for a finely
    discretized distribution is indistinguishable from the usual definition of
    a quantile as the smallest x with CDF(x) >= q.
    """
    array = np.asarray(array)
    idx = (np.abs(array - value)).argmin()
    return idx
```

We compute the required thirteen convolutions in the following code.

(Please feel free to try different values of the power parameter p that we use to set the number of points in our grid for constructing the probability mass functions that discretize the continuous log normal distributions.)

```
# Set grid parameters
p = 15
I = 2**p
m = 0.05

# Discretize all component failure rate distributions
# First 6 components use unique parameters, last 8 share the same parameters
component_pmfs = []
for μ, σ in params[:6]:
    _, pmf, x = discretize_lognormal(μ, σ, I, m)
    component_pmfs.append(pmf)

# Add 8 copies of component type 7
μ7, σ7 = params[6]
_, pmf7, x = discretize_lognormal(μ7, σ7, I, m)
component_pmfs.extend([pmf7] * 8)

# Compute system failure distribution via sequential convolution
with qe.Timer() as timer:
    system_pmf = component_pmfs[0]
    for pmf in component_pmfs[1:]:
        system_pmf = fftconvolve(system_pmf, pmf)

print(f"Time for 13 convolutions: {timer.elapsed:.4f} seconds")

# the convolution lives on the same grid spacing, but extends much further
system_grid = np.arange(len(system_pmf)) * m
print(f"grid points in the answer: {len(system_pmf):,}")
```

```
7.6475 seconds elapsed
Time for 13 convolutions: 7.6475 seconds
grid points in the answer: 9,175,027
```

Before plotting the cumulative distribution function, let's look at the density itself.

```
fig, ax = plt.subplots(figsize=(10, 6))
upper = 2000
ax.plot(system_grid[:int(upper/m)], system_pmf[:int(upper/m)] / m, 'b-', lw=2)
ax.set_xlabel(r'failure rate ($\times 10^{-9}$ per year)')
ax.set_ylabel('density')
plt.show()
```

The density is strongly skewed to the right: a long upper tail stretches far beyond the bulk of the distribution.

This asymmetry is what makes a single point estimate of a failure rate a poor summary, and it is why the analyst reports quantiles instead.

We now plot a counterpart to the cumulative distribution function (CDF) in figure 5 on page 29 of Greenfield and Sargent [1993]

```
# Compute cumulative distribution function
cdf = np.cumsum(system_pmf)
```

(continues on next page)

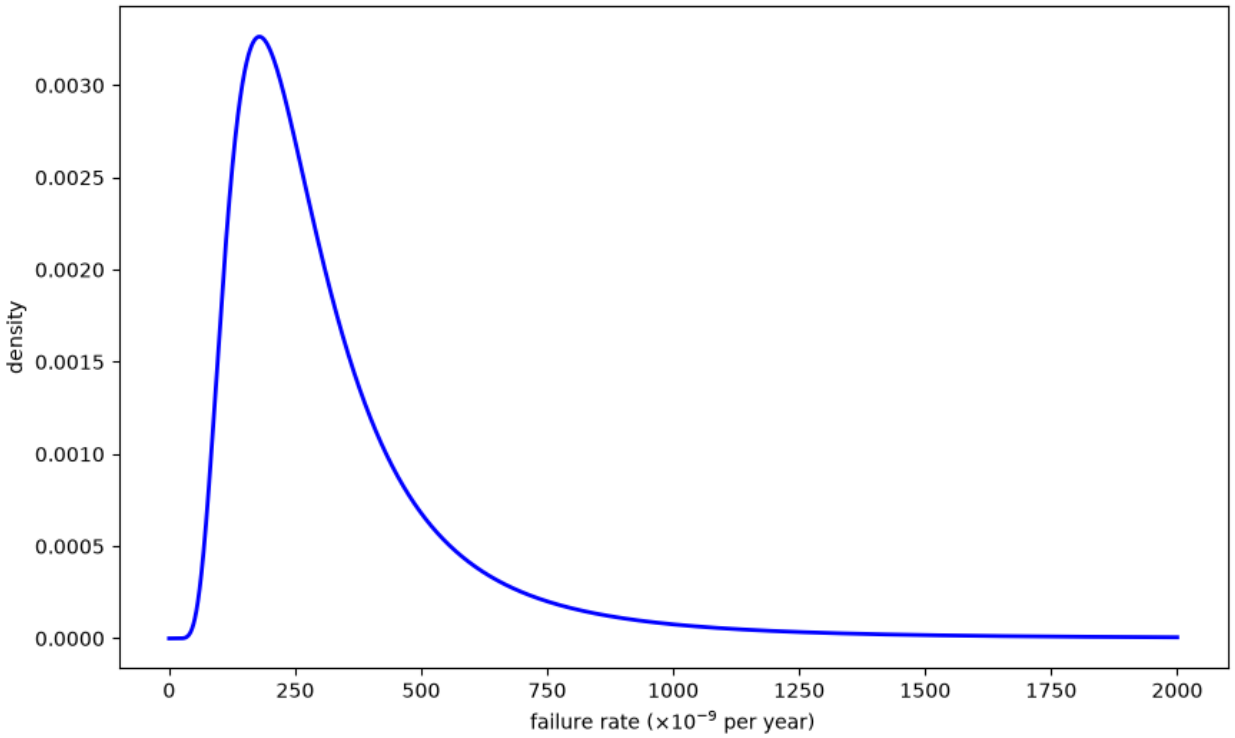

Fig. 14.7: Density of the system failure rate

(continued from previous page)

```
# Plot CDF
Nx = 1400
fig, ax = plt.subplots(figsize=(10, 6))
ax.plot(x[:int(Nx / m)], cdf[:int(Nx / m)], 'b-', lw=2)

# Add reference lines for key quantiles
quantile_levels = [0.05, 0.10, 0.50, 0.90, 0.95]
for q in quantile_levels:
    ax.axhline(q, color='gray', linestyle='--', alpha=0.5)

ax.set_xlim(0, Nx)
ax.set_ylim(0, 1)
ax.set_xlabel(r'failure rate ($\times 10^{-9}$ per year)')
ax.set_ylabel('cumulative probability')
plt.show()
```

We also present a counterpart to their Table 11 on page 28 of Greenfield and Sargent [1993], which lists key quantiles of the system failure rate distribution

```
# Percentiles reported in Table 11 of Greenfield and Sargent (1993),
# together with their published values, in units of 10^-9 per year
reference = {1.0: 77, 10.0: 130, 50.0: 263, 66.5: 341,
             85.0: 513, 95.0: 811, 99.0: 1480, 99.78: 2490}

table_data = []
```

(continues on next page)

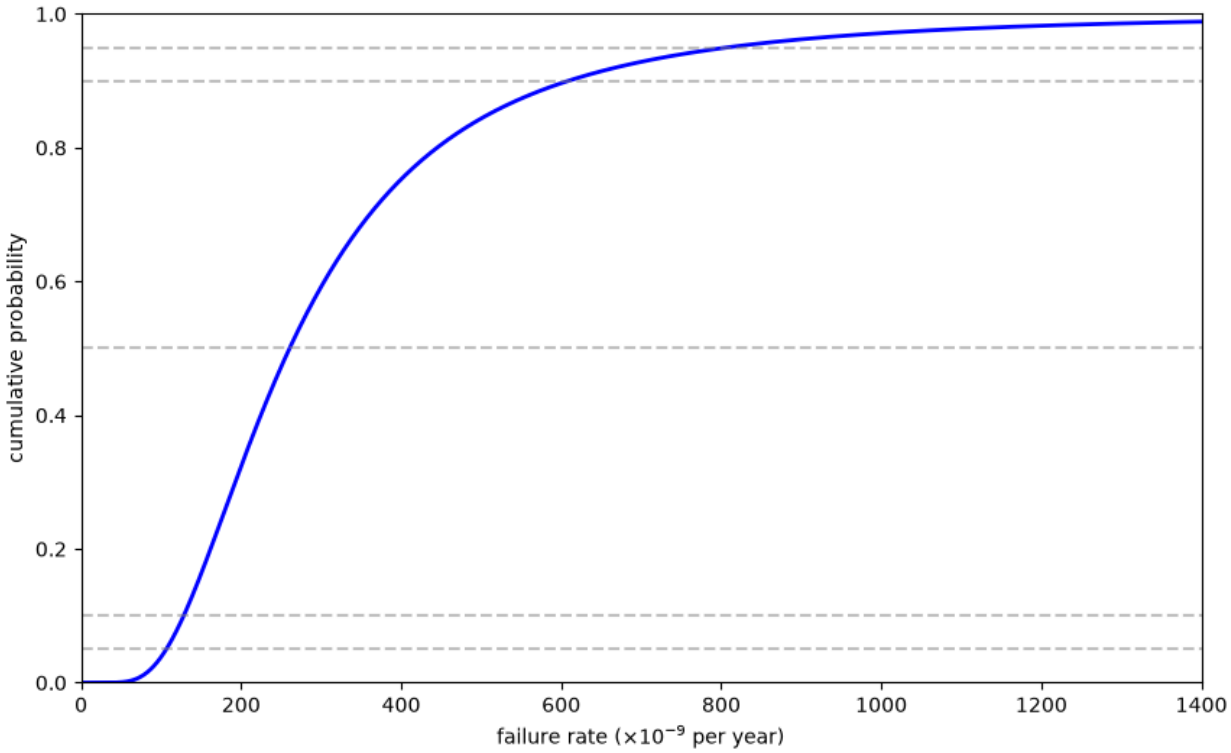

Fig. 14.8: CDF of the system failure rate

(continued from previous page)

```
for pc, published in reference.items():
    ours = system_grid[find_nearest(cdf, pc/100)]
    table_data.append([f"{pc}%", f"{ours:.1f}", published,
                       f"{100*(ours - published)/published:+.1f}%"])

print("\nSystem failure rate quantiles (×10^-9 per year):")
print(tabulate(table_data,
      headers=['Percentile', 'Computed here', 'Greenfield-Sargent', 'Difference'],
      tablefmt='grid'))
```

```
System failure rate quantiles (×10^-9 per year):
+--------------+-----------------+----------------------+--------------+
| Percentile   |   Computed here |   Greenfield-Sargent | Difference   |
+==============+=================+======================+==============+
| 1.0%         |            76.2 |                   77 | -1.1%        |
+--------------+-----------------+----------------------+--------------+
| 10.0%        |           128.2 |                  130 | -1.4%        |
+--------------+-----------------+----------------------+--------------+
| 50.0%        |           260.6 |                  263 | -0.9%        |
+--------------+-----------------+----------------------+--------------+
| 66.5%        |           338.6 |                  341 | -0.7%        |
+--------------+-----------------+----------------------+--------------+
| 85.0%        |           509.4 |                  513 | -0.7%        |
+--------------+-----------------+----------------------+--------------+
| 95.0%        |           807.6 |                  811 | -0.4%        |
+--------------+-----------------+----------------------+--------------+
```

(continues on next page)

(continued from previous page)

```
| 99.0%        |          1470.2 |                  1480 | -0.7%        |
+--------------+-----------------+-----------------------+--------------+
| 99.78%       |          2474.9 |                  2490 | -0.6%        |
+--------------+-----------------+-----------------------+--------------+
```

Our quantiles reproduce the published ones to within one and a half per cent, and slightly understate each of them.

The small discrepancies reflect the precision of the reported parameters μ_i, σ_i, the grid spacing m, and the point at which the grid is truncated.

14.9.2 Reading the answer

The numbers in this table, rather than any single one of them, are the output of the analysis.

The median failure rate is about 261×10^{-9} per year, while the 95th percentile is about 808×10^{-9}, three times larger.

That spread is not a statement about how often the hoist fails; it is a statement about how little the analyst knows about how often the hoist fails.

Notice also where the *mean* of the distribution falls.

```
mean_rate = np.sum(system_grid * system_pmf)
mean_percentile = 100 * cdf[find_nearest(system_grid, mean_rate)]

print(f"mean failure rate: {mean_rate:.1f} × 10⁻⁹ per year")
print(f"the mean sits at the {mean_percentile:.1f}th percentile")
```

```
mean failure rate: 338.1 × 10⁻⁹ per year
the mean sits at the 66.4th percentile
```

Because the distribution is skewed, the mean lies well above the median, at about the 66th percentile.

This is why Table 11 of Greenfield and Sargent [1993] records the mean alongside the 66.5th percentile.

The practical implication is the one that motivated the original study.

```
# The point estimate used in the U.S. Department of Energy's 1990 risk
# assessment, expressed in the same units
doe_estimate = 220    # 2.2 × 10^-7 per year

pct = 100 * cdf[find_nearest(system_grid, doe_estimate)]
print(f"the DOE point estimate of {doe_estimate} × 10⁻⁹ lies at "
      f"the {pct:.0f}th percentile")
print(f"so the analyst assigns probability {100-pct:.0f}% to the "
      f"true rate exceeding it")
```

```
the DOE point estimate of 220 × 10⁻⁹ lies at the 39th percentile
so the analyst assigns probability 61% to the true rate exceeding it
```

An analysis that reports a single number in place of a distribution conveys none of this.

Greenfield and Sargent [1993] made exactly this point: reading their figure, they put the Department of Energy's point estimate at the 36th percentile and concluded that there was roughly a 64 per cent chance that the true failure rate was higher.

14.10 Exercises

Exercise 14.10.1

Our discretization involves two separate choices: where the grid stops, $I = 2^p$, and how finely it is spaced, m.

Investigate what each one controls.

1. Holding $m = 0.05$ fixed, compute the median, the 95th percentile and the 99.78th percentile of the system failure rate for $p = 10, 11, \ldots, 15$. For each p, also compute how much probability mass the truncation discards, using $\sum_i \mathbb{P}\{P(A_i) > I\}$.
2. Holding $p = 14$ fixed, repeat for $m = 0.4, 0.2, 0.1, 0.05, 0.025$.
3. Which statistic is sensitive to which choice, and why? Are the values $p = 15$, $m = 0.05$ used in the lecture well chosen?

Solution

```
from scipy.stats import norm

def system_distribution(p_grid, m_grid):
    "Failure rate distribution of the whole system on a given grid."
    I_grid = 2**p_grid
    pmfs = []
    for μ_i, σ_i in params[:6]:
        _, pmf_i, _ = discretize_lognormal(μ_i, σ_i, I_grid, m_grid)
        pmfs.append(pmf_i)
    μ7, σ7 = params[6]
    _, pmf7, _ = discretize_lognormal(μ7, σ7, I_grid, m_grid)
    pmfs.extend([pmf7] * 8)

    total = pmfs[0]
    for pmf_i in pmfs[1:]:
        total = fftconvolve(total, pmf_i)
    return total, np.arange(len(total)) * m_grid

def quantiles_of(pmf, grid, levels=(0.5, 0.95, 0.9978)):
    cdf_local = np.cumsum(pmf)
    return [grid[find_nearest(cdf_local, q)] for q in levels]

def discarded_mass(I_grid):
    "Probability that a component's rate exceeds the end of the grid."
    lost = sum(norm.sf((np.log(I_grid) - μ_i)/σ_i) for μ_i, σ_i in params[:6])
    μ7, σ7 = params[6]
    return lost + 8 * norm.sf((np.log(I_grid) - μ7)/σ7)

rows = []
for p_test in range(10, 16):
    pmf_t, grid_t = system_distribution(p_test, 0.05)
    med, q95, q9978 = quantiles_of(pmf_t, grid_t)
    rows.append([p_test, 2**p_test, f"{discarded_mass(2**p_test):.1e}",
                 f"{med:.2f}", f"{q95:.2f}", f"{q9978:.2f}"])
```

```
print(tabulate(rows, headers=['p', 'I', 'mass discarded',
                              'median', '95th', '99.78th'], tablefmt='grid'))
```

```
+-----+-------+------------------+----------+--------+------------+
|   p |     I |   mass discarded |   median |   95th |   99.78th |
+=====+=======+==================+==========+========+============+

```

The two choices do quite different jobs.

Truncation governs the *far tail*.

At $p = 10$ the 99.78th percentile is badly understated, and it keeps rising until about $p = 14$, by which point the discarded mass has fallen to roughly 10^{-6}.

The median, by contrast, has settled by $p = 12$: throwing away the extreme right tail of each component hardly moves the middle of the distribution of their sum.

Resolution governs *overall precision*.

Halving m shifts every quantile slightly and uniformly, and the shifts are small: going from $m = 0.4$ to $m = 0.025$ moves the median by about 1.5 per cent.

The lecture's choices are sensible.

With $p = 15$ the discarded mass is around 10^{-7}, so even the 99.78th percentile is accurate, and $m = 0.05$ is fine enough that further refinement changes little.

The moral is that a grid that looks adequate for the median can be badly inadequate for the upper tail, which is exactly the region a safety regulator cares about.

Exercise 14.10.2

The rare event approximation replaces $P(A \cup B)$ by $P(A) + P(B)$, discarding $P(A \cap B)$.

Assess how good it is here.

1. Using the *mean* failure rate of each of the fourteen components as a representative value, compare $\sum_i p_i$ with the exact probability that at least one component fails, $1 - \prod_i (1 - p_i)$.
2. Repeat with all the rates multiplied by 10^3, 10^6 and 10^7, and report the relative error in each case.
3. At what order of magnitude does the approximation start to matter?

Solution

```
# representative rate for each of the 14 components
component_means = [np.exp(μ_i + 0.5*σ_i**2) for μ_i, σ_i in params[:6]]
μ7, σ7 = params[6]
component_means.extend([np.exp(μ7 + 0.5*σ7**2)] * 8)
component_means = np.array(component_means)

rows = []
for factor, label in ((1e-9, 'as calibrated'), (1e-6, '× 10³'),
                      (1e-3, '× 10⁶'), (1e-2, '× 10⁷')):
    probs = component_means * factor
    approx = probs.sum()
    exact = 1 - np.prod(1 - probs)
    rows.append([label, f"{approx:.6e}", f"{exact:.6e}",
                 f"{100*(approx - exact)/exact:.4f}%"])

print(tabulate(rows, headers=['failure rates', 'Σ pᵢ', '1 - Π(1-pᵢ)',
                              'relative error'], tablefmt='grid'))
```

```
+-----------------+-------------+---------------+------------------+
| failure rates   |        Σ pᵢ |   1 - Π(1-pᵢ) | relative error   |
+=================+=============+===============+==================+
| as calibrated   | 3.38012e-07 |   3.38012e-07 | 0.0000%          |
+-----------------+-------------+---------------+------------------+
| × 10³           | 0.000338012 |   0.000337969 | 0.0127%          |
+-----------------+-------------+---------------+------------------+
| × 10⁶           | 0.338012    |   0.297883    | 13.4715%         |
+-----------------+-------------+---------------+------------------+
| × 10⁷           | 3.38012     |   1.04157     | 224.5216%        |
+-----------------+-------------+---------------+------------------+
```

At the calibrated magnitudes, around 3×10^{-7} per year in total, the approximation is exact to the precision shown: the neglected term is of order $p_i p_j \approx 10^{-14}$.

Multiplying every rate by a thousand still leaves an error of about one part in ten thousand.

The approximation only becomes consequential once individual failure probabilities reach the order of a per cent, where it overstates the system failure probability by more than ten per cent, and it fails completely when $\sum_i p_i$ approaches or exceeds one, where it can return a "probability" greater than one.

Note that a naive check of this approximation – comparing the mean of the computed distribution of $\sum_i P(A_i)$ with the sum of the component means – reveals nothing, because those two quantities are equal by linearity of expectation whatever the quality of the approximation.

Exercise 14.10.3

A regulator who learns that the 95th percentile of the failure rate is too high will ask which components to improve.

Answer that question by computing, for each of the seven component types, the 95th percentile of the system failure rate when that type is removed from the system entirely.

Rank the component types by how much they contribute to the upper tail, and compare the ranking with the components' mean failure rates.

Solution

```
def system_without(drop):
    "System failure rate distribution with component type `drop` removed."
    pmfs = []
    for k, (μ_i, σ_i) in enumerate(params[:6]):
        if k == drop:
            continue
        _, pmf_i, _ = discretize_lognormal(μ_i, σ_i, I, m)
        pmfs.append(pmf_i)
    if drop != 6:
        μ7, σ7 = params[6]
        _, pmf7, _ = discretize_lognormal(μ7, σ7, I, m)
        pmfs.extend([pmf7] * 8)

    total = pmfs[0]
    for pmf_i in pmfs[1:]:
        total = fftconvolve(total, pmf_i)
    return total, np.arange(len(total)) * m

base_q95 = system_grid[find_nearest(cdf, 0.95)]

rows = []
for k in range(7):
    pmf_k, grid_k = system_without(k)
    q95 = grid_k[find_nearest(np.cumsum(pmf_k), 0.95)]
    μ_k, σ_k = params[k]
    n_units = 8 if k == 6 else 1
    rows.append([f"type {k+1}", n_units, f"{np.exp(μ_k + 0.5*σ_k**2):.1f}",
                 f"{q95:.1f}", f"{100*(base_q95 - q95)/base_q95:.1f}%"])

rows.sort(key=lambda r: -float(r[4].rstrip('%')))
print(f"95th percentile with all components: {base_q95:.1f}\n")
print(tabulate(rows, headers=['removed', 'units', 'mean rate each',
                              '95th pct without it', 'reduction'],
               tablefmt='grid'))
```

```
95th percentile with all components: 807.6

+-----------+---------+------------------+-----------------------+-------------+
| removed   |   units |   mean rate each |   95th pct without it | reduction   |
+===========+=========+==================+=======================+=============+
| type 1    |       1 |            147.5 |                 439.3 | 45.6%       |
+-----------+---------+------------------+-----------------------+-------------+
| type 2    |       1 |             60.6 |                 699.4 | 13.4%       |
+-----------+---------+------------------+-----------------------+-------------+
| type 3    |       1 |             33.4 |                 760.1 | 5.9%        |
+-----------+---------+------------------+-----------------------+-------------+
| type 4    |       1 |             30.9 |                 764.7 | 5.3%        |
+-----------+---------+------------------+-----------------------+-------------+
| type 5    |       1 |             30.9 |                 764.7 | 5.3%        |
+-----------+---------+------------------+-----------------------+-------------+
| type 7    |       8 |              2.8 |                 783.7 | 3.0%        |
+-----------+---------+------------------+-----------------------+-------------+
| type 6    |       1 |             12.4 |                 791.1 | 2.0%        |
+-----------+---------+------------------+-----------------------+-------------+
```

Component type 1 dominates: removing that single unit cuts the 95th percentile by almost half, far more than any other change available to the designer.

The ranking follows the components' mean rates closely here, because all seven types have similar dispersions.

It need not do so in general: a component with a modest mean but a large σ contributes disproportionately to the upper tail, which is why the analyst works with the whole distribution rather than with means.

Note also that type 7, which appears eight times, matters less than type 1, which appears once.

Counting components is no guide to where the risk lies.

Exercise 14.10.4

We could have computed the distribution of the system failure rate by simulation instead of by convolution.

Draw samples of all fourteen component rates, sum them, and compare the resulting quantiles with those from the convolution, for sample sizes 10^4, 10^5 and 10^6.

Compare the median, the 95th percentile and the 99.78th percentile.

Which method would you prefer, and why?

Solution

```
all_params = list(params[:6]) + [params[6]] * 8
rng_mc = np.random.default_rng(0)
levels = (50, 95, 99.78)

rows = []
for N in (10_000, 100_000, 1_000_000):
    draws = sum(rng_mc.lognormal(μ_i, σ_i, N) for μ_i, σ_i in all_params)
    rows.append([f"{N:,}"] + [f"{np.percentile(draws, pc):.1f}" for pc in levels])

rows.append(['convolution'] +
            [f"{system_grid[find_nearest(cdf, pc/100)]:.1f}" for pc in levels])
```

```
print(tabulate(rows, headers=['method', 'median', '95th', '99.78th'],
               tablefmt='grid'))
```

```
+-------------+----------+--------+-----------+
| method      |   median |   95th |   99.78th |
+=============+==========+========+===========+
| 10,000      |    262.7 |  811.8 |    2240.6 |
+-------------+----------+--------+-----------+
| 100,000     |    261.1 |  807.1 |    2458.4 |
+-------------+----------+--------+-----------+
| 1,000,000   |    260.4 |  807.5 |    2447   |
+-------------+----------+--------+-----------+
| convolution |    260.6 |  807.6 |    2474.9 |
+-------------+----------+--------+-----------+
```

Simulation converges to the same answer, which is a useful check on both calculations.

The two methods differ in where their errors lie.

Monte Carlo error is largest exactly where the analysis matters most: the 99.78th percentile is pinned down by roughly one draw in five hundred, so with 10^4 draws only about twenty observations inform it, and the estimate is visibly off.

The convolution, by contrast, computes the whole distribution at once and its error comes from the grid rather than from sampling noise, so it is equally accurate in the tail as in the middle.

It is also deterministic: the answer does not change when you rerun it with a different seed.

Exercise 14.10.5

The entire calculation assumes that the fourteen component failure rates are statistically independent.

Investigate what happens when they are not.

Suppose that

$$\log P(A_i) = \mu_i + \sigma_i \left(\sqrt{\rho}\, z_0 + \sqrt{1-\rho}\, z_i \right),$$

where z_0 is a shock common to all components and $z_1, \ldots, z_{14}$ are idiosyncratic, all standard normal.

Each component still has exactly its original marginal distribution, but any two of them now have correlation ρ in logs.

Simulate the system failure rate for $\rho = 0, 0.2, 0.5, 0.8$ and report the median, the 95th, the 99th and the 99.9th percentiles.

Explain what happens and why it matters for a safety analysis.

Solution

```
μ_vec = np.array([q[0] for q in all_params])
σ_vec = np.array([q[1] for q in all_params])

N_sim = 400_000
rng_cc = np.random.default_rng(1)

rows = []
for ρ in (0.0, 0.2, 0.5, 0.8):
```

```
    z0 = rng_cc.normal(size=(N_sim, 1))
    zi = rng_cc.normal(size=(N_sim, len(all_params)))
    logs = μ_vec + σ_vec * (np.sqrt(ρ)*z0 + np.sqrt(1-ρ)*zi)
    totals = np.exp(logs).sum(axis=1)
    rows.append([ρ] + [f"{np.percentile(totals, pc):.0f}"
                       for pc in (50, 95, 99, 99.9)])

print(tabulate(rows, headers=['ρ', 'median', '95th', '99th', '99.9th'],
               tablefmt='grid'))
```

```
+-----+----------+--------+--------+----------+
|   ρ |   median |   95th |   99th |   99.9th |
+=====+==========+========+========+==========+
| 0   |      261 |    811 |   1481 |     3235 |
+-----+----------+--------+--------+----------+
| 0.2 |      242 |    910 |   1650 |     3416 |
+-----+----------+--------+--------+----------+
| 0.5 |      209 |   1043 |   2074 |     4396 |
+-----+----------+--------+--------+----------+
| 0.8 |      179 |   1136 |   2444 |     5763 |
+-----+----------+--------+--------+----------+
```

Correlation leaves each component's marginal distribution untouched, and it leaves the mean of the sum untouched as well.

What it changes is the shape of the distribution of the sum.

With independent components, a high draw for one is typically offset by ordinary draws for the others, and the fourteen-fold averaging produces a relatively concentrated total.

A common shock removes that diversification: when z_0 is large every component is bad at once.

The result is a distribution with a *lower* median and a much *heavier* upper tail.

At $\rho = 0.8$ the median falls by about a third while the 99.9th percentile rises by roughly three quarters.

For a safety analysis this is the dangerous direction of error.

Assuming independence when a common cause is present makes the system look both typically safer and much less likely to suffer a very bad year than it really is.

This is why reliability studies devote so much attention to identifying shared power supplies, shared maintenance procedures, common design faults, and other mechanisms that defeat the independence assumption.

CHAPTER

FIFTEEN

INTRODUCTION TO ARTIFICIAL NEURAL NETWORKS

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

In addition to what's included in base Anaconda, we need to install the following packages

```
!pip install -U kaleido plotly
!conda install -y -c plotly plotly-orca

# kaleido needs chrome to build images
import kaleido
kaleido.get_chrome_sync()
```

Note

If you are running this on Google Colab the above cell will present an error. This is because Google Colab doesn't use Anaconda to manage the Python packages. However this lecture will still execute as Google Colab has `plotly` installed.

We also need to install JAX to run this lecture

```
!pip install --upgrade jax
```

```
import jax
print(f"JAX backend: {jax.devices()[0].platform}") # to check that gpu is activated␣
↪in environment
```

```
JAX backend: gpu
```

15.1 Overview

Substantial parts of **machine learning** and **artificial intelligence** are about

- approximating an unknown function with a known function
- estimating the known function from a set of data on the left- and right-hand variables

This lecture describes the structure of a plain vanilla **artificial neural network** (ANN) of a type that is widely used to approximate a function f that maps x in a space X into y in a space Y.

To introduce elementary concepts, we study an example in which x and y are scalars.

We'll describe the following concepts that are brick and mortar for neural networks:

- a neuron
- an activation function
- a network of neurons
- A neural network as a composition of functions
- back-propagation and its relationship to the chain rule of differential calculus

15.2 A Deep (but not Wide) Artificial Neural Network

We describe a "deep" neural network of "width" one.

Deep means that the network composes a large number of functions organized into nodes of a graph.

Width refers to the number of right hand side variables on the right hand side of the function being approximated.

Setting "width" to one means that the network composes just univariate functions.

Let $x \in \mathbb{R}$ be a scalar and $y \in \mathbb{R}$ be another scalar.

We assume that y is a nonlinear function of x:

$$y = f(x)$$

We want to approximate $f(x)$ with another function that we define recursively.

For a network of depth $N \geq 1$, each **layer** $i = 1, \ldots N$ consists of

- an input x_i
- an **affine function** $w_i x_i + bI$, where w_i is a scalar **weight** placed on the input x_i and b_i is a scalar **bias**
- an **activation function** h_i that takes $(w_i x_i + b_i)$ as an argument and produces an output x_{i+1}

An example of an activation function h is the **sigmoid** function

$$h(z) = \frac{1}{1 + e^{-z}}$$

Another popular activation function is the **rectified linear unit** (ReLU) function

$$h(z) = \max(0, z)$$

Yet another activation function is the identity function

$$h(z) = z$$

As activation functions below, we'll use the sigmoid function for layers 1 to $N-1$ and the identity function for layer N.

To approximate a function $f(x)$ we construct $\hat{f}(x)$ by proceeding as follows.

Let

$$l_i(x) = w_i x + b_i.$$

We construct $\hat{f}$ by iterating on compositions of functions $h_i \circ l_i$:

$$f(x) \approx \hat{f}(x) = h_N \circ l_N \circ h_{N-1} \circ l_1 \circ \cdots \circ h_1 \circ l_1(x)$$

If $N > 1$, we call the right side a "deep" neural net.

The larger is the integer N, the "deeper" is the neural net.

Evidently, if we know the parameters $\{w_i, b_i\}_{i=1}^N$, then we can compute $\hat{f}(x)$ for a given $x = \tilde{x}$ by iterating on the recursion

$$x_{i+1} = h_i \circ l_i(x_i), \quad , i = 1, \ldots N \tag{15.1}$$

starting from $x_1 = \tilde{x}$.

The value of x_{N+1} that emerges from this iterative scheme equals $\hat{f}(\tilde{x})$.

15.3 Calibrating Parameters

We now consider a neural network like the one describe above with width 1, depth N, and activation functions h_i for $1 \leqslant i \leqslant N$ that map $\mathbb{R}$ into itself.

Let $\{(w_i, b_i)\}_{i=1}^N$ denote a sequence of weights and biases.

As mentioned above, for a given input x_1, our approximating function $\hat{f}$ evaluated at x_1 equals the "output" x_{N+1} from our network that can be computed by iterating on $x_{i+1} = h_i(w_i x_i + b_i)$.

For a given **prediction** $\hat{y}(x)$ and **target** $y = f(x)$, consider the loss function

$$\mathcal{L}(\hat{y}, y)(x) = \frac{1}{2}(\hat{y} - y)^2(x).$$

This criterion is a function of the parameters $\{(w_i, b_i)\}_{i=1}^N$ and the point x.

We're interested in solving the following problem:

$$\min_{\{(w_i, b_i)\}_{i=1}^N} \int \mathcal{L}(x_{N+1}, y)(x) d\mu(x)$$

where $\mu(x)$ is some measure of points $x \in \mathbb{R}$ over which we want a good approximation $\hat{f}(x)$ to $f(x)$.

Stack weights and biases into a vector of parameters p:

$$p = \begin{bmatrix} w_1 \\ b_1 \\ w_2 \\ b_2 \\ \vdots \\ w_N \\ b_N \end{bmatrix}$$

Applying a "poor man's version" of a **stochastic gradient descent** algorithm for finding a zero of a function leads to the following update rule for parameters:

$$p_{k+1} = p_k - \alpha \frac{d\mathcal{L}}{dx_{N+1}} \frac{dx_{N+1}}{dp_k} \tag{15.2}$$

where $\frac{d\mathcal{L}}{dx_{N+1}} = -\left(x_{N+1} - y\right)$ and $\alpha > 0$ is a step size.

(See this and this to gather insights about how stochastic gradient descent relates to Newton's method.)

To implement one step of this parameter update rule, we want the vector of derivatives $\frac{dx_{N+1}}{dp_k}$.

In the neural network literature, this step is accomplished by what is known as **back propagation**.

15.4 Back Propagation and the Chain Rule

Thanks to properties of

- the chain and product rules for differentiation from differential calculus, and
- lower triangular matrices

back propagation can actually be accomplished in one step by

- inverting a lower triangular matrix, and
- matrix multiplication

(This idea is from the last 7 minutes of this great youtube video by MIT's Alan Edelman)

https://youtu.be/rZS2LGiurKY

Here goes.

Define the derivative of $h(z)$ with respect to z evaluated at $z = z_i$ as δ_i:

$$\delta_i = \frac{d}{dz} h(z)|_{z=z_i}$$

or

$$\delta_i = h'\left(w_i x_i + b_i\right).$$

Repeated application of the chain rule and product rule to our recursion (15.1) allows us to obtain:

$$dx_{i+1} = \delta_i \left(dw_i x_i + w_i dx_i + b_i\right)$$

After imposing $dx_1 = 0$, we get the following system of equations:

$$\begin{pmatrix} dx_2 \\ \vdots \\ dx_{N+1} \end{pmatrix} = \underbrace{\begin{pmatrix} \delta_1 w_1 & \delta_1 & 0 & 0 & 0 \\ 0 & 0 & \ddots & 0 & 0 \\ 0 & 0 & 0 & \delta_N w_N & \delta_N \end{pmatrix}}_{D} \begin{pmatrix} dw_1 \\ db_1 \\ \vdots \\ dw_N \\ db_N \end{pmatrix} + \underbrace{\begin{pmatrix} 0 & 0 & 0 & 0 \\ w_2 & 0 & 0 & 0 \\ 0 & \ddots & 0 & 0 \\ 0 & 0 & w_N & 0 \end{pmatrix}}_{L} \begin{pmatrix} dx_2 \\ \vdots \\ dx_{N+1} \end{pmatrix}$$

or

$$dx = Ddp + Ldx$$

which implies that

$$dx = (I - L)^{-1} D dp$$

which in turn implies

$$\begin{pmatrix} dx_{N+1}/dw_1 \\ dx_{N+1}/db_1 \\ \vdots \\ dx_{N+1}/dw_N \\ dx_{N+1}/db_N \end{pmatrix} = e_N (I - L)^{-1} D.$$

We can then solve the above problem by applying our update for p multiple times for a collection of input-output pairs $\{(x_1^i, y^i)\}_{i=1}^M$ that we'll call our "training set".

15.5 Training Set

Choosing a training set amounts to a choice of measure μ in the above formulation of our function approximation problem as a minimization problem.

In this spirit, we shall use a uniform grid of, say, 50 or 200 points.

There are many possible approaches to the minimization problem posed above:

- batch gradient descent in which you use an average gradient over the training set
- stochastic gradient descent in which you sample points randomly and use individual gradients
- something in-between (so-called "mini-batch gradient descent")

The update rule (15.2) described above amounts to a stochastic gradient descent algorithm.

15.6 Example 1

Consider the function

$$f(x) = -3x + 2$$

on $[0.5, 3]$.

We use a uniform grid of 200 points and update the parameters for each point on the grid 300 times.

h_i is the sigmoid activation function for all layers except the final one for which we use the identity function and $N = 3$.

Weights are initialized randomly.

```
def f(x):
    return -3 * x + 2

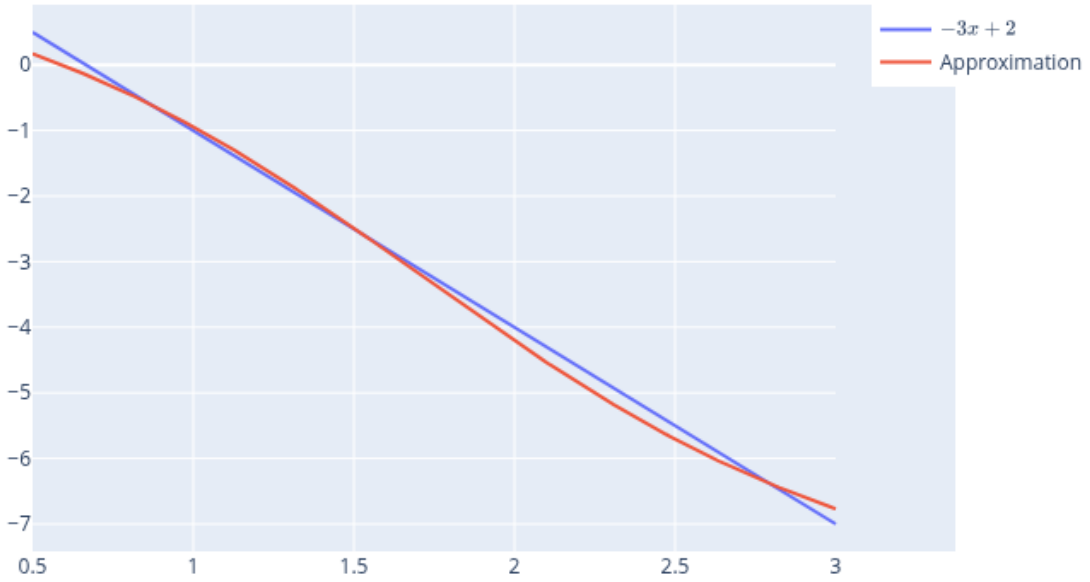
M = 200
grid = jnp.linspace(0.5, 3, num=M)
f_val = f(grid)
```

```
indices = jnp.arange(M)
key = random.key(0)

def train(params, grid, f_val, key, num_epochs=300):
    for epoch in range(num_epochs):
        key, _ = random.split(key)
        random_permutation = random.permutation(random.key(1), indices)
        for x, y in zip(grid[random_permutation], f_val[random_permutation]):
            params = update_la(params, x, y)

    return params
```

```
# Parameters
N = 3  # Number of layers
layer_sizes = [1, ] * (N + 1)
params_ex1 = init_network_params(layer_sizes, key)
```



```
%%time
params_ex1 = train(params_ex1, grid, f_val, key, num_epochs=500)
```

```
CPU times: user 21.1 s, sys: 3.97 s, total: 25.1 s
Wall time: 18.2 s
```

```
predictions = vmap(compute_xδw_seq, in_axes=(None, 0))(params_ex1, grid)[0][:, -1]
```

```
fig = go.Figure()
fig.add_trace(go.Scatter(x=grid, y=f_val, name=r'$-3x+2$'))
fig.add_trace(go.Scatter(x=grid, y=predictions, name='Approximation'))

# Export to PNG file
Image(fig.to_image(format="png"))
# fig.show() will provide interactive plot when running
# notebook locally
```

15.7 How Deep?

It is fun to think about how deepening the neural net for the above example affects the quality of approximation

- If the network is too deep, you'll run into the vanishing gradient problem
- Other parameters such as the step size and the number of epochs can be as important or more important than the number of layers in the situation considered in this lecture.
- Indeed, since f is a linear function of x, a one-layer network with the identity map as an activation would probably work best.

15.8 Example 2

We use the same setup as for the previous example with

$$f(x) = \log(x)$$

```
def f(x):
    return jnp.log(x)

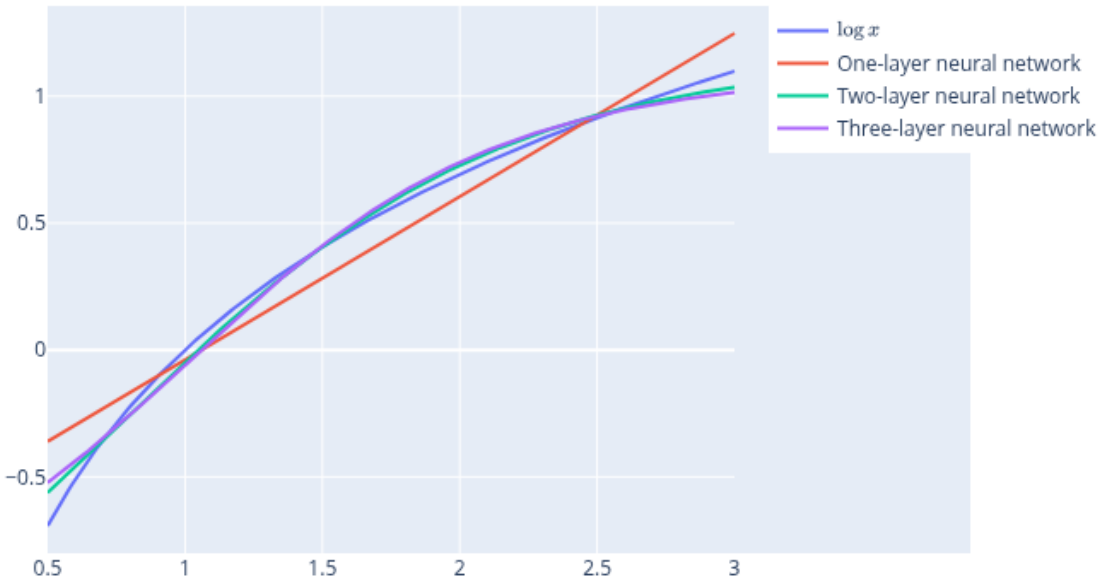
grid = jnp.linspace(0.5, 3, num=M)
f_val = f(grid)
```

```
# Parameters
N = 1  # Number of layers
layer_sizes = [1, ] * (N + 1)
params_ex2_1 = init_network_params(layer_sizes, key)
```

```
# Parameters
N = 2  # Number of layers
layer_sizes = [1, ] * (N + 1)
params_ex2_2 = init_network_params(layer_sizes, key)
```

```
# Parameters
N = 3  # Number of layers
layer_sizes = [1, ] * (N + 1)
params_ex2_3 = init_network_params(layer_sizes, key)
```

```
params_ex2_1 = train(params_ex2_1, grid, f_val, key, num_epochs=300)
```



```
params_ex2_2 = train(params_ex2_2, grid, f_val, key, num_epochs=300)
```

```
params_ex2_3 = train(params_ex2_3, grid, f_val, key, num_epochs=300)
```

```
predictions_1 = vmap(compute_xδw_seq, in_axes=(None, 0))(params_ex2_1, grid)[0][:, -1]
predictions_2 = vmap(compute_xδw_seq, in_axes=(None, 0))(params_ex2_2, grid)[0][:, -1]
predictions_3 = vmap(compute_xδw_seq, in_axes=(None, 0))(params_ex2_3, grid)[0][:, -1]
```

```
fig = go.Figure()
fig.add_trace(go.Scatter(x=grid, y=f_val, name=r'$\log{x}$'))
fig.add_trace(go.Scatter(x=grid, y=predictions_1, name='One-layer neural network'))
fig.add_trace(go.Scatter(x=grid, y=predictions_2, name='Two-layer neural network'))
fig.add_trace(go.Scatter(x=grid, y=predictions_3, name='Three-layer neural network'))

CHAPTER

SIXTEEN

RANDOMIZED RESPONSE SURVEYS

16.1 Overview

Social stigmas can inhibit people from confessing potentially embarrassing activities or opinions.

When people are reluctant to participate a sample survey about personally sensitive issues, they might decline to participate, and even if they do participate, they might choose to provide incorrect answers to sensitive questions.

These problems induce **selection** biases that present challenges to interpreting and designing surveys.

To illustrate how social scientists have thought about estimating the prevalence of such embarrassing activities and opinions, this lecture describes a classic approach of S. L. Warner [Warner, 1965].

Warner used elementary probability to construct a way to protect the privacy of **individual** respondents to surveys while still estimating the fraction of a **collection** of individuals who have a socially stigmatized characteristic or who engage in a socially stigmatized activity.

Warner's idea was to add **noise** between the respondent's answer and the **signal** about that answer that the survey maker ultimately receives.

Knowing about the structure of the noise assures the respondent that the survey maker does not observe his answer.

Statistical properties of the noise injection procedure provide the respondent **plausible deniability**.

Related ideas underlie modern **differential privacy** systems.

(See https://en.wikipedia.org/wiki/Differential_privacy)

16.2 Warner's Strategy

As usual, let's bring in the Python modules we'll be using.

```
import numpy as np
import pandas as pd
```

Suppose that every person in population either belongs to Group A or Group B.

We want to estimate the proportion π who belong to Group A while protecting individual respondents' privacy.

Warner [Warner, 1965] proposed and analyzed the following procedure.

- A random sample of n people is drawn with replacement from the population and each person is interviewed.
- Draw n random samples from the population with replacement and interview each person.
- Prepare a **random spinner** that with p probability points to the Letter A and with $(1-p)$ probability points to the Letter B.

- Each subject spins a random spinner and sees an outcome (A or B) that the interviewer does **not observe**.
- The subject states whether he belongs to the group to which the spinner points.
- If the spinner points to the group that the spinner belongs, the subject reports "yes"; otherwise he reports "no".
- The subject answers the question truthfully.

Warner constructed a maximum likelihood estimators of the proportion of the population in set A.

Let

- π : True probability of A in the population
- p : Probability that the spinner points to A
- $X_i = \begin{cases} 1, \text{ if the } i\text{th subject says yes} \\ 0, \text{ if the } i\text{th subject says no} \end{cases}$

Index the sample set so that the first n_1 report "yes", while the second $n - n_1$ report "no".

The likelihood function of a sample set is

$$L = [\pi p + (1-\pi)(1-p)]^{n_1} [(1-\pi)p + \pi(1-p)]^{n-n_1} \tag{16.1}$$

The log of the likelihood function is:

$$\log(L) = n_1 \log [\pi p + (1-\pi)(1-p)] + (n-n_1) \log [(1-\pi)p + \pi(1-p)] \tag{16.2}$$

The first-order necessary condition for maximizing the log likelihood function with respect to π is:

$$\frac{(n-n_1)(2p-1)}{(1-\pi)p + \pi(1-p)} = \frac{n_1(2p-1)}{\pi p + (1-\pi)(1-p)}$$

or

$$\pi p + (1-\pi)(1-p) = \frac{n_1}{n} \tag{16.3}$$

If $p \neq \frac{1}{2}$, then the maximum likelihood estimator (MLE) of π is:

$$\hat{\pi} = \frac{p-1}{2p-1} + \frac{n_1}{(2p-1)n} \tag{16.4}$$

We compute the mean and variance of the MLE estimator $\hat{\pi}$ to be:

$$\begin{aligned} \mathbb{E}(\hat{\pi}) &= \frac{1}{2p-1} \left[p - 1 + \frac{1}{n} \sum_{i=1}^{n} \mathbb{E} X_i \right] \\ &= \frac{1}{2p-1} [p - 1 + \pi p + (1-\pi)(1-p)] \\ &= \pi \end{aligned} \tag{16.5}$$

and

$$\begin{aligned} Var(\hat{\pi}) &= \frac{nVar(X_i)}{(2p-1)^2 n^2} \\ &= \frac{[\pi p + (1-\pi)(1-p)] [(1-\pi)p + \pi(1-p)]}{(2p-1)^2 n^2} \\ &= \frac{\frac{1}{4} + (2p^2 - 2p + \frac{1}{2})(-2\pi^2 + 2\pi - \frac{1}{2})}{(2p-1)^2 n^2} \\ &= \frac{1}{n} \left[\frac{1}{16(p - \frac{1}{2})^2} - (\pi - \frac{1}{2})^2 \right] \end{aligned} \tag{16.6}$$

Equation (16.5) indicates that $\hat{\pi}$ is an **unbiased estimator** of π while equation (16.6) tell us the variance of the estimator.

To compute a confidence interval, first rewrite (16.6) as:

$$Var(\hat{\pi}) = \frac{\frac{1}{4} - (\pi - \frac{1}{2})^2}{n} + \frac{\frac{1}{16(p-\frac{1}{2})^2} - \frac{1}{4}}{n} \tag{16.7}$$

This equation indicates that the variance of $\hat{\pi}$ can be represented as a sum of the variance due to sampling plus the variance due to the random device.

From the expressions above we can find that:

- When p is $\frac{1}{2}$, expression (16.1) degenerates to a constant.
- When p is 1 or 0, the randomized estimate degenerates to an estimator without randomized sampling.

We shall only discuss situations in which $p \in (\frac{1}{2}, 1)$

(a situation in which $p \in (0, \frac{1}{2})$ is symmetric).

From expressions (16.5) and (16.7) we can deduce that:

- The MSE of $\hat{\pi}$ decreases as p increases.

16.3 Comparing Two Survey Designs

Let's compare the preceding randomized-response method with a stylized non-randomized response method.

In our non-randomized response method, we suppose that:

- Members of Group A tells the truth with probability T_a while the members of Group B tells the truth with probability T_b
- Y_i is 1 or 0 according to whether the sample's ith member's report is in Group A or not.

Then we can estimate π as:

$$\hat{\pi} = \frac{\sum_{i=1}^{n} Y_i}{n} \tag{16.8}$$

We calculate the expectation, bias, and variance of the estimator to be:

$$\mathbb{E}(\hat{\pi}) = \pi T_a + [(1-\pi)(1-T_b)] \tag{16.9}$$

$$\begin{aligned} Bias(\hat{\pi}) &= \mathbb{E}(\hat{\pi} - \pi) \\ &= \pi[T_a + T_b - 2] + [1 - T_b] \end{aligned} \tag{16.10}$$

$$Var(\hat{\pi}) = \frac{[\pi T_a + (1-\pi)(1-T_b)]\,[1 - \pi T_a - (1-\pi)(1-T_b)]}{n} \tag{16.11}$$

It is useful to define a

$$\text{MSE Ratio} = \frac{\text{Mean Square Error Randomized}}{\text{Mean Square Error Regular}}$$

We can compute MSE Ratios for different survey designs associated with different parameter values.

The following Python code computes objects we want to stare at in order to make comparisons under different values of π_A and n:

```
class Comparison:
    def __init__(self, A, n):
        self.A = A
        self.n = n
        TaTb = np.array([[0.95,  1], [0.9,   1], [0.7,    1],
                         [0.5,   1], [1,  0.95], [1,    0.9],
                         [1,   0.7], [1,   0.5], [0.95, 0.95],
                         [0.9, 0.9], [0.7, 0.7], [0.5,  0.5]])
        self.p_arr = np.array([0.6, 0.7, 0.8, 0.9])
        self.p_map = dict(zip(self.p_arr, [f"MSE Ratio: p = {x}" for x in self.p_
↪arr]))
        self.template = pd.DataFrame(columns=self.p_arr)
        self.template[['T_a','T_b']] = TaTb
        self.template['Bias'] = None

    def theoretical(self):
        A = self.A
        n = self.n
        df = self.template.copy()
        df['Bias'] = A * (df['T_a'] + df['T_b'] - 2) + (1 - df['T_b'])
        for p in self.p_arr:
            df[p] = (1 / (16 * (p - 1/2)**2) - (A - 1/2)**2) / n / \
                    (df['Bias']**2 + ((A * df['T_a'] + (1 - A) * (1 - df['T_b'])) *␣
↪(1 - A * df['T_a'] - (1 - A) * (1 - df['T_b'])) / n))
            df[p] = df[p].round(2)
        df = df.set_index(["T_a", "T_b", "Bias"]).rename(columns=self.p_map)
        return df

    def MCsimulation(self, size=1000, seed=123456):
        A = self.A
        n = self.n
        df = self.template.copy()
        rng = np.random.default_rng(seed)
        sample = rng.random((size, self.n)) <= A
        random_device = rng.random((size, n))
        mse_rd = {}
        for p in self.p_arr:
            spinner = random_device <= p
            rd_answer = sample * spinner + (1 - sample) * (1 - spinner)
            n1 = rd_answer.sum(axis=1)
            pi_hat = (p - 1) / (2 * p - 1) + n1 / n / (2 * p - 1)
            mse_rd[p] = np.sum((pi_hat - A)**2)
        for inum, irow in df.iterrows():
            truth_a = rng.random((size, self.n)) <= irow.T_a
            truth_b = rng.random((size, self.n)) <= irow.T_b
            trad_answer = sample * truth_a + (1 - sample) * (1 - truth_b)
            pi_trad = trad_answer.sum(axis=1) / n
            df.loc[inum, 'Bias'] = pi_trad.mean() - A
            mse_trad = np.sum((pi_trad - A)**2)
            for p in self.p_arr:
                df.loc[inum, p] = (mse_rd[p] / mse_trad).round(2)
        df = df.set_index(["T_a", "T_b", "Bias"]).rename(columns=self.p_map)
        return df
```

Let's put the code to work for parameter values

- $\pi_A = 0.6$
- $n = 1000$

We can generate MSE Ratios theoretically using the above formulas.

We can also perform Monte Carlo simulations of a MSE Ratio.

```
cp1 = Comparison(0.6, 1000)
df1_theoretical = cp1.theoretical()
df1_theoretical
```

```
                MSE Ratio: p = 0.6  MSE Ratio: p = 0.7  MSE Ratio: p = 0.8  \
T_a  T_b  Bias
0.95 1.00 -0.03               5.45                1.36                0.60
0.90 1.00 -0.06               1.62                0.40                0.18

```

The theoretical calculations do a good job of predicting Monte Carlo results.

We see that in many situations, especially when the bias is not small, the MSE of the randomized-sampling methods is smaller than that of the non-randomized sampling method.

These differences become larger as p increases.

By adjusting parameters π_A and n, we can study outcomes in different situations.

For example, for another situation described in Warner [Warner, 1965]:

- $\pi_A = 0.5$
- $n = 1000$

we can use the code

```
cp2 = Comparison(0.5, 1000)
df2_theoretical = cp2.theoretical()
df2_theoretical
```

```

```

Evidently, as n increases, the randomized response method does better performance in more situations.

16.4 Concluding Remarks

This QuantEcon lecture describes some alternative randomized response surveys.

That lecture presents a utilitarian analysis of those alternatives conducted by Lars Ljungqvist [Ljungqvist, 1993].

CHAPTER

SEVENTEEN

EXPECTED UTILITIES OF RANDOM RESPONSES

17.1 Overview

This QuantEcon lecture describes randomized response surveys in the tradition of Warner [1965] that are designed to protect respondents' privacy.

Lars Ljungqvist [Ljungqvist, 1993] analyzed how a respondent's decision about whether to answer truthfully depends on **expected utility**.

The lecture tells how Ljungqvist used his framework to shed light on alternative randomized response survey techniques proposed, for example, by [Lanke, 1975], [Lanke, 1976], [Leysieffer and Warner, 1976], [Anderson, 1976], [Fligner *et al.*, 1977], [Greenberg *et al.*, 1977], [Greenberg *et al.*, 1969].

We use the following imports:

```
import matplotlib.pyplot as plt
import numpy as np
```

17.2 Privacy measures

We consider randomized response models with only two possible answers, "yes" and "no."

The design determines probabilities

$$\Pr(\text{yes}|A) = 1 - \Pr(\text{no}|A)$$
$$\Pr(\text{yes}|A^{'}) = 1 - \Pr(\text{no}|A^{'})$$

These design probabilities in turn can be used to compute the conditional probability of belonging to the sensitive group A for a given response, say r:

$$\Pr(A|r) = \frac{\pi_A \Pr(r|A)}{\pi_A \Pr(r|A) + (1 - \pi_A)\Pr(r|A^{'})} \tag{17.1}$$

17.3 Zoo of concepts

At this point, we describe some concepts proposed by various researchers.

17.3.1 Leysieffer and Warner (1976)

The response r is regarded as jeopardizing with respect to A or $A^{'}$ if

$$\begin{aligned} &\Pr(A|r) > \pi_A \\ &\text{or} \\ &\Pr(A^{'}|r) > 1 - \pi_A \end{aligned} \tag{17.2}$$

From Bayes's rule:

$$\frac{\Pr(A|r)}{\Pr(A^{'}|r)} \times \frac{(1-\pi_A)}{\pi_A} = \frac{\Pr(r|A)}{\Pr(r|A^{'})} \tag{17.3}$$

If this expression is greater (less) than unity, it follows that r is jeopardizing with respect to A ($A^{'}$).

Then, the natural measure of jeopardy will be:

$$\begin{aligned} g(r|A) &= \frac{\Pr(r|A)}{\Pr(r|A^{'})} \\ &\text{and} \\ g(r|A^{'}) &= \frac{\Pr(r|A^{'})}{\Pr(r|A)} \end{aligned} \tag{17.4}$$

Suppose, without loss of generality, that $\Pr(\text{yes}|A) > \Pr(\text{yes}|A^{'})$, then a yes (no) answer is jeopardizing with respect to A ($A^{'}$), that is,

$$\begin{aligned} &g(\text{yes}|A) > 1 \\ &\text{and} \\ &g(\text{no}|A^{'}) > 1 \end{aligned}$$

Leysieffer and Warner proved that the variance of the estimate can only be decreased through an increase in one or both of these two measures of jeopardy.

An efficient randomized response model is, therefore, any model that attains the maximum acceptable levels of jeopardy that are consistent with cooperation of the respondents.

As a special example, Leysieffer and Warner considered "a problem in which there is no jeopardy in a no answer"; that is, $g(\text{no}|A^{'})$ can be of unlimited magnitude.

Evidently, an optimal design must have

$$\Pr(\text{yes}|A) = 1$$

which implies that

$$\Pr(A|\text{no}) = 0$$

17.3.2 Lanke (1976)

Lanke [1975] argued that "it is membership in Group A that people may want to hide, not membership in the complementary Group A'."

For that reason, Lanke [1976] argued that an appropriate measure of protection is to minimize

$$\max \{\Pr(A|\text{yes}), \Pr(A|\text{no})\} \tag{17.5}$$

Holding this measure constant, he explained under what conditions the smallest variance of the estimate was achieved with the unrelated question model or the original model of Warner [1965].

17.3.3 Fligner et al. (1977)

Fligner *et al.* [1977] reached a conclusion similar to that of Lanke [1976].

They measured "private protection" as

$$\frac{1 - \max \{\Pr(A|\text{yes}), \Pr(A|\text{no})\}}{1 - \pi_A} \tag{17.6}$$

17.3.4 Greenberg et al. (1977)

Greenberg *et al.* [1977] stressed the importance of examining the risk to respondents who do not belong to A as well as the risk to those who do belong to the sensitive group.

They defined the hazard for an individual in A as the probability that he or she is perceived as belonging to A:

$$\Pr(\text{yes}|A) \times \Pr(A|\text{yes}) + \Pr(\text{no}|A) \times \Pr(A|\text{no}) \tag{17.7}$$

Similarly, the hazard for an individual who does not belong to A would be

$$\Pr(\text{yes}|A^{'}) \times \Pr(A|\text{yes}) + \Pr(\text{no}|A^{'}) \times \Pr(A|\text{no}) \tag{17.8}$$

Greenberg *et al.* [1977] also considered an alternative related measure of hazard that "is likely to be closer to the actual concern felt by a respondent."

The "limited hazard" for an individual in A and $A^{'}$ is

$$\Pr(\text{yes}|A) \times \Pr(A|\text{yes}) \tag{17.9}$$

and

$$\Pr(\text{yes}|A^{'}) \times \Pr(A|\text{yes}) \tag{17.10}$$

This measure is just the first term in (17.7), i.e., the probability that an individual answers "yes" and is perceived to belong to A.

17.4 Respondent's expected utility

17.4.1 Truth border

Key assumptions that underlie a randomized response technique for estimating the fraction of a population that belongs to A are

Assumption 17.4.1 (discomfort)

Respondents feel discomfort from being thought of as belonging to A.

Assumption 17.4.2 (preference for truth)

Respondents prefer to answer questions truthfully than to lie, so long as the cost of doing so is not too high.

The cost is taken to be the discomfort in *Assumption 17.4.1*.

Let r_i denote individual i's response to the randomized question.

r_i can only take values "yes" or "no".

For a given design of a randomized response interview and a given belief about the fraction of the population that belongs to A, the respondent's answer is associated with a conditional probability $\Pr(A|r_i)$ that the individual belongs to A.

Given r_i and complete privacy, the individual's utility is higher if r_i represents a truthful answer rather than a lie.

In terms of a respondent's expected utility as a function of $\Pr(A|r_i)$ and r_i

- The higher is $\Pr(A|r_i)$, the lower is individual i's expected utility.
- Expected utility is higher if r_i represents a truthful answer rather than a lie.

Define:

- $\phi_i \in \{\text{truth}, \text{lie}\}$, a dichotomous variable that indicates whether or not r_i is a truthful statement.
- $U_i\left(\Pr(A|r_i), \phi_i\right)$, a utility function that is differentiable in its first argument, summarizes individual i's expected utility.

Then there is an r_i such that

$$\frac{\partial U_i\left(\Pr(A|r_i), \phi_i\right)}{\partial \Pr(A|r_i)} < 0, \text{ for } \phi_i \in \{\text{truth}, \text{lie}\} \tag{17.11}$$

and

$$U_i\left(\Pr(A|r_i), \text{truth}\right) > U_i\left(\Pr(A|r_i), \text{lie}\right), \text{ for } \Pr(A|r_i) \in [0, 1] \tag{17.12}$$

Suppose now that the correct answer for individual i is "yes".

Individual i would choose to answer truthfully if

$$U_i\left(\Pr(A|\text{yes}), \text{truth}\right) \geq U_i\left(\Pr(A|\text{no}), \text{lie}\right) \tag{17.13}$$

If the correct answer is "no", individual i would volunteer the correct answer only if

$$U_i\left(\Pr(A|\text{no}), \text{truth}\right) \geq U_i\left(\Pr(A|\text{yes}), \text{lie}\right) \tag{17.14}$$

Assume that

$$\Pr(A|\text{yes}) > \pi_A > \Pr(A|\text{no})$$

so that a "yes" answer increases the odds that an individual belongs to A.

Constraint (17.14) holds for sure.

Consequently, constraint (17.13) becomes the single necessary condition for individual i always to answer truthfully.

At equality, constraint (17.13) determines the conditional probabilities that make the individual indifferent between telling the truth and lying when the correct answer is "yes":

$$U_i\left(\Pr(A|\text{yes}), \text{truth}\right) = U_i\left(\Pr(A|\text{no}), \text{lie}\right) \tag{17.15}$$

Equation (17.15) defines a "truth border".

Differentiating (17.15) with respect to the conditional probabilities shows that the truth border has a positive slope in the space of conditional probabilities:

$$\frac{\partial \Pr(A|\text{no})}{\partial \Pr(A|\text{yes})} = \frac{\frac{\partial U_i(\Pr(A|\text{yes}),\text{truth})}{\partial \Pr(A|\text{yes})}}{\frac{\partial U_i(\Pr(A|\text{no}),\text{lie})}{\partial \Pr(A|\text{no})}} > 0 \tag{17.16}$$

The source of the positive relationship is:

- The individual is willing to volunteer a truthful "yes" answer so long as the utility from doing so (i.e., the left side of (17.15)) is at least as high as the utility of lying on the right side of (17.15).
- Suppose now that $\Pr(A|\text{yes})$ increases.
  - This reduces the utility of telling the truth.
  - To preserve indifference between a truthful answer and a lie, $\Pr(A|\text{no})$ must increase to reduce the utility of lying.

17.4.2 Drawing a truth border

We can deduce two things about the truth border:

- The truth border divides the space of conditional probabilities into two subsets: "truth telling" and "lying".
  - Thus, sufficient privacy elicits a truthful answer, whereas insufficient privacy results in a lie.
  - The truth border depends on a respondent's utility function.
- Assumptions in (17.11) and (17.12) are sufficient only to guarantee a positive slope of the truth border.
  - The truth border can have either a concave or a convex shape.

We can draw some truth borders in Fig. 17.1 with the following Python code, writing p for $\Pr(A|r_i)$:

```
x1 = np.arange(0, 1, 0.001)
y1 = x1 - 0.4
x2 = np.arange(0.4**2, 1, 0.001)
y2 = (pow(x2, 0.5) - 0.4)**2
x3 = np.arange(0.4**0.5, 1, 0.001)
y3 = pow(x3**2 - 0.4, 0.5)

fig, ax = plt.subplots()
ax.plot(x1, y1, 'r-', lw=2, label=r'$U_i = -p + f(\phi_i)$')
ax.fill_between(x1, 0, y1, facecolor='red', alpha=0.05)
ax.plot(x2, y2, 'b-', lw=2, label=r'$U_i = -p^2 + f(\phi_i)$')
ax.fill_between(x2, 0, y2, facecolor='blue', alpha=0.05)
ax.plot(x3, y3, 'y-', lw=2, label=r'$U_i = -\sqrt{p} + f(\phi_i)$')
ax.fill_between(x3, 0, y3, facecolor='green', alpha=0.05)
ax.plot(x1, x1, ':', lw=2)
ax.set(xlim=(0, 1), ylim=(0, 1),
       xlabel='Pr(A|yes)', ylabel='Pr(A|no)')
ax.text(0.42, 0.3, "truth telling")
ax.text(0.8, 0.1, "lying")
```

(continues on next page)

(continued from previous page)

```
ax.legend(loc='upper left')
plt.show()
```

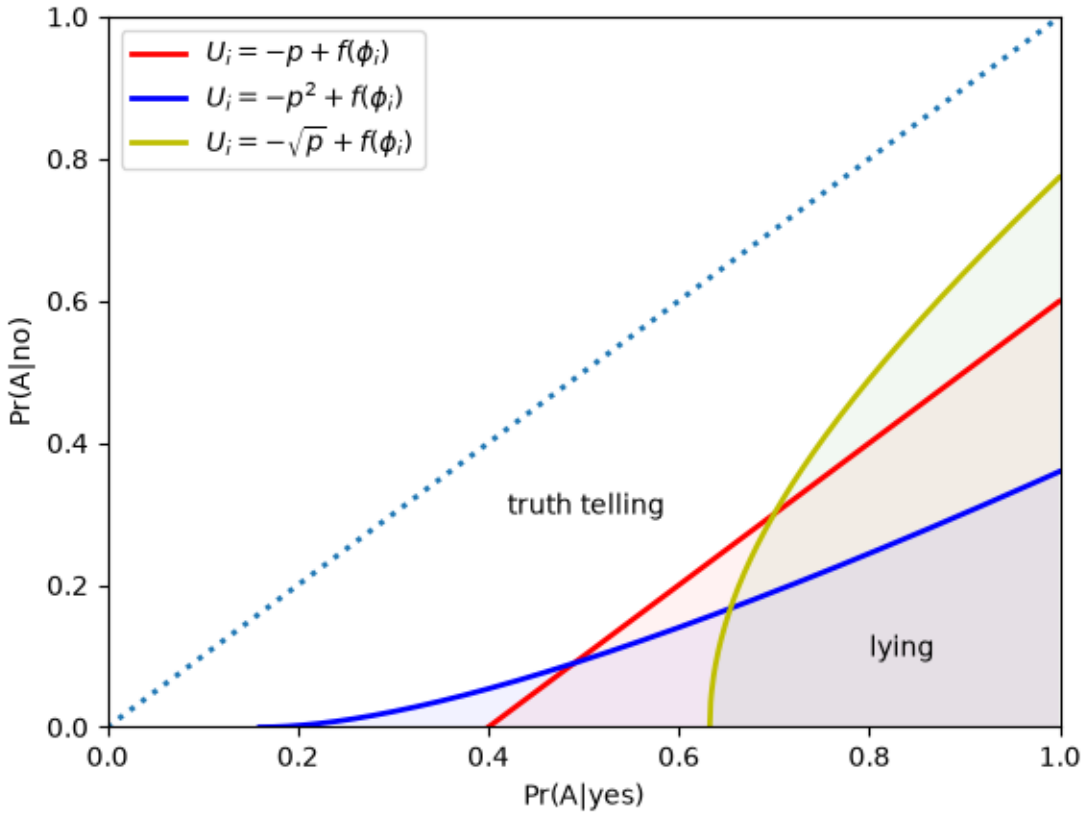

Fig. 17.1: Three types of truth border

Without loss of generality, we consider the truth border:

$$U_i(\Pr(A|r_i), \phi_i) = -\Pr(A|r_i) + f(\phi_i)$$

and plot the "truth telling" and "lying area" of individual i in Fig. 17.2:

```
x1 = np.arange(0, 1, 0.001)
y1 = x1 - 0.4
z1 = x1
z2 = 0

fig, ax = plt.subplots()
ax.plot(x1, y1, 'r-', lw=2, label='truth border')
ax.plot(x1, x1, ':', lw=2)
ax.fill_between(x1, y1, z1, facecolor='blue', alpha=0.05,
                label='truth telling')
ax.fill_between(x1, z2, y1, facecolor='green', alpha=0.05,
                label='lying')
ax.set(xlim=(0, 1), ylim=(0, 1),
       xlabel='Pr(A|yes)', ylabel='Pr(A|no)')
```

(continues on next page)

(continued from previous page)

```
ax.text(0.5, 0.4, "truth telling")
ax.text(0.8, 0.2, "lying")
ax.legend(loc='upper left')
plt.show()
```

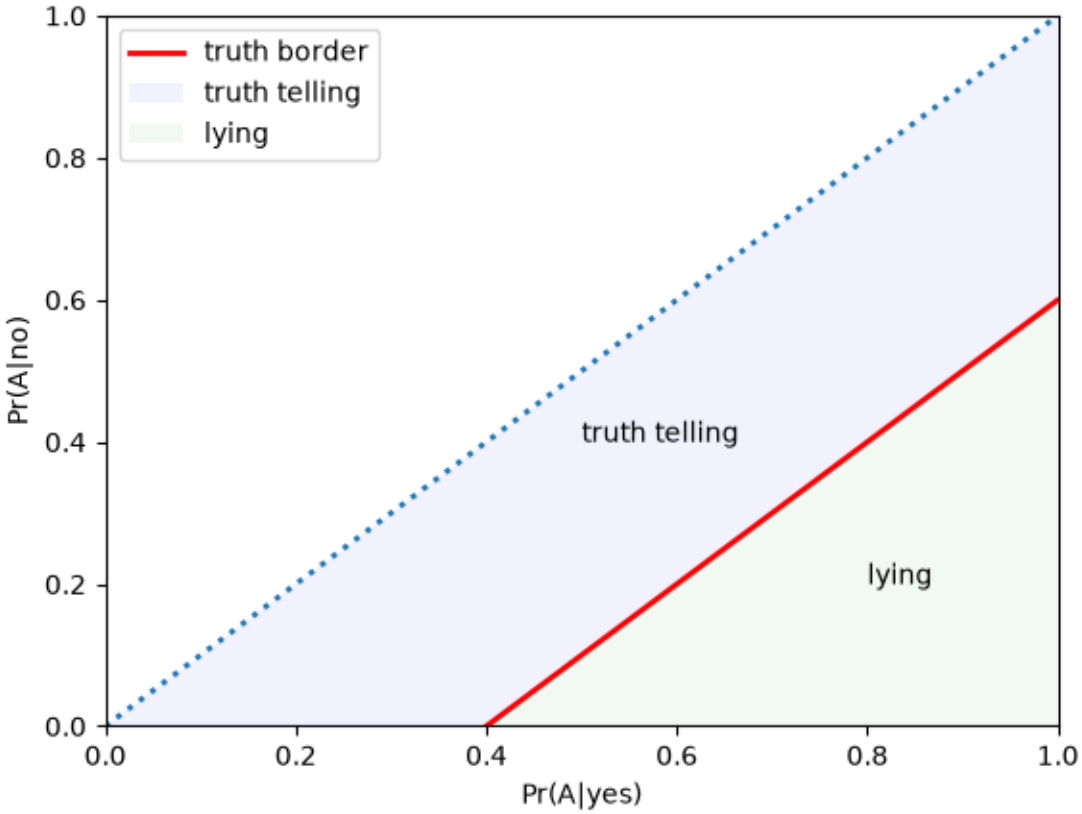

Fig. 17.2: Truth telling and lying areas

17.5 Utilitarian view of survey design

17.5.1 Iso-variance curves

A statistician's objective is

- to find a randomized response survey design that minimizes the bias and the variance of the estimator.

Given a design that ensures truthful answers by all respondents, Anderson [1976] (Theorem 1) showed that the minimum variance estimate in the two-response model has variance

$$V(\Pr(A|\text{yes}), \Pr(A|\text{no})) = \frac{{\pi_A}^2(1-\pi_A)^2}{n} \times \frac{1}{\Pr(A|\text{yes}) - \pi_A} \times \frac{1}{\pi_A - \Pr(A|\text{no})} \tag{17.17}$$

where the random sample with replacement consists of n individuals.

We can use Expression (17.17) to draw iso-variance curves.

The following inequalities restrict the shapes of iso-variance curves:

$$\left.\frac{d\,\Pr(A|\text{no})}{d\,\Pr(A|\text{yes})}\right|_{\text{constant variance}} = \frac{\pi_A - \Pr(A|\text{no})}{\Pr(A|\text{yes}) - \pi_A} > 0 \tag{17.18}$$

$$\left.\frac{d^2\,\Pr(A|\text{no})}{d\,\Pr(A|\text{yes})^2}\right|_{\text{constant variance}} = -\frac{2\left[\pi_A - \Pr(A|\text{no})\right]}{\left[\Pr(A|\text{yes}) - \pi_A\right]^2} < 0 \tag{17.19}$$

From expression (17.17), (17.18) and (17.19) we can see that:

- Variance can be reduced only by increasing the distance of $\Pr(A|\text{yes})$ and/or $\Pr(A|\text{no})$ from r_A.
- Iso-variance curves are always upward-sloping and concave.

17.5.2 Drawing iso-variance curves

We use Python code to draw iso-variance curves.

The pairs of conditional probabilities can be attained using the model of Warner [1965].

Note that:

- Any point on the iso-variance curves can be attained with the unrelated question model as long as the statistician can completely control the model design.
- The original randomized response model of Warner [1965] is less flexible than the unrelated question model.

```
def plot_iso_variance_curves(π, n):
    nv = np.array([0.27, 0.34, 0.49, 0.74, 0.92, 1.1, 1.47, 2.94, 14.7])
    x = np.arange(0, 1, 0.001)
    x0 = np.arange(π, 1, 0.001)
    x2 = np.arange(0, π, 0.001)
    y1 = [π for i in x0]
    y2 = [π for i in x2]
    y0 = 1 / (1 + (x0 * (1 - π)**2) / ((1 - x0) * π**2))

    fig, ax = plt.subplots()
    ax.plot(x0, y0, 'm-', lw=2, label='Warner')
    ax.plot(x, x, 'c:', lw=2)
    ax.plot(x0, y1, 'c:', lw=2)
    ax.plot(y2, x2, 'c:', lw=2)
    for i in range(len(nv)):
        y = π - (π**2 * (1 - π)**2) / (n * (nv[i] / n) * (x0 - π + 1e-8))
        ax.plot(x0, y, 'k--', alpha=1 - 0.07 * i,
                label='iso-variance curves' if i == 0 else None)
    ax.set(xlim=(0, 1), ylim=(0, 0.5),
           xlabel='Pr(A|yes)', ylabel='Pr(A|no)')
    ax.text(0.42, 0.32, "high variance")
    ax.text(0.83, 0.01, "low variance")
    ax.legend(loc='upper left')
    plt.show()
```

Properties of iso-variance curves are:

- All points on one iso-variance curve share the same variance
- Variance increases as the curves move up and to the left, and the curves lighten as variance increases

Suppose the parameters of the iso-variance model follow those in Ljungqvist [Ljungqvist, 1993], which are:

- $\pi = 0.3$
- $n = 100$

Then we can plot the iso-variance curve in Fig. 17.3:

```
plot_iso_variance_curves(π=0.3, n=100)
```

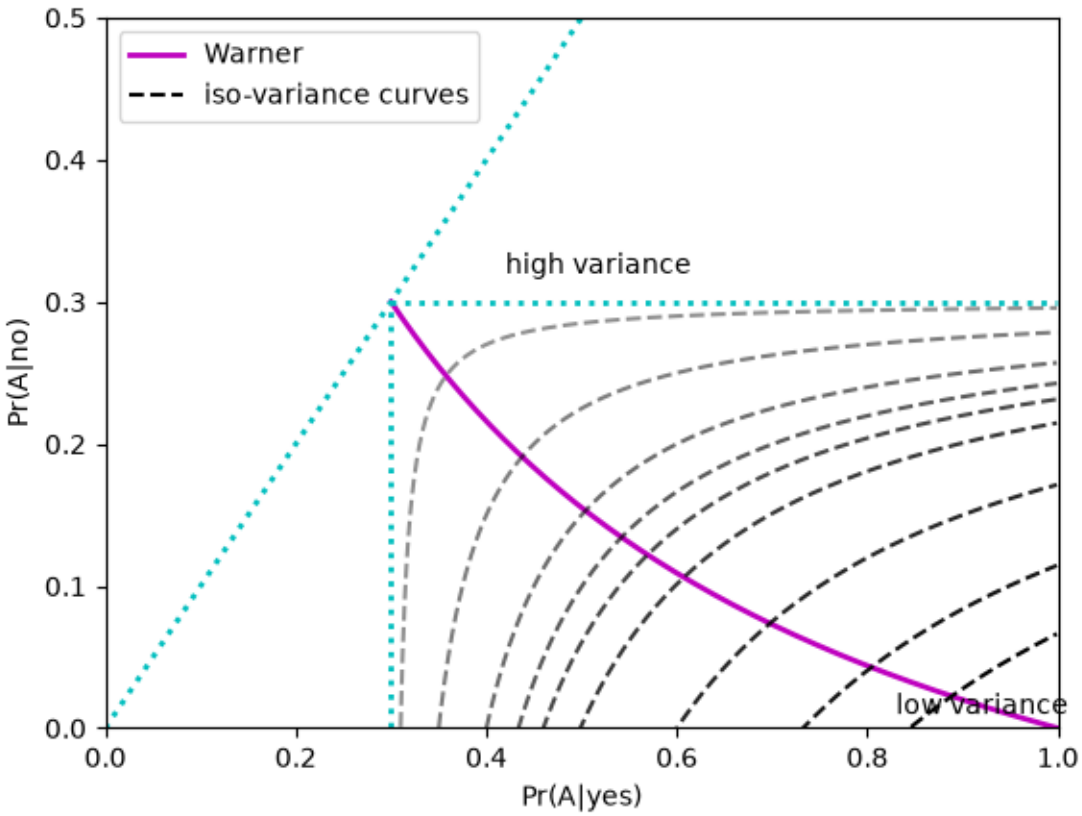

Fig. 17.3: Iso-variance curves

17.5.3 Optimal survey

A point on iso-variance curves can be attained with the unrelated question design.

We now focus on finding an "optimal survey design" that

- Minimizes the variance of the estimator subject to privacy restrictions.

To obtain an optimal design, we first superimpose all individuals' truth borders on the iso-variance mapping.

To construct an optimal design

- The statistician should find the intersection of areas above all truth borders; that is, the set of conditional probabilities ensuring truthful answers from all respondents.
- The point where this set touches the lowest possible iso-variance curve determines an optimal survey design.

Consequently, a minimum variance unbiased estimator is pinned down by an individual who is the least willing to volunteer a truthful answer.

Here are some comments about the model design:

- An individual's decision of whether or not to answer truthfully depends on his or her belief about other respondents' behavior, because this determines the individual's calculation of $\Pr(A|\text{yes})$ and $\Pr(A|\text{no})$.
- An equilibrium of the optimal design model is a Nash equilibrium of a noncooperative game.
- Assumption (17.12) is sufficient to guarantee the existence of an optimal model design.
  - By choosing $\Pr(A|\text{yes})$ and $\Pr(A|\text{no})$ sufficiently close to each other, all respondents will find it optimal to answer truthfully.
  - The closer are these probabilities, the higher the variance of the estimator becomes.
- If respondents experience a large enough increase in expected utility from telling the truth, then there is no need to use a randomized response model.

The smallest possible variance of the estimate is then obtained at $\Pr(A|\text{yes}) = 1$ and $\Pr(A|\text{no}) = 0$; that is, when respondents answer truthfully to direct questioning.

- A more general design problem would be to minimize some weighted sum of the estimator's variance and bias.
  - It would be optimal to accept some lies from the most "reluctant" respondents.

17.6 Criticisms of proposed privacy measures

We can use a utilitarian approach to analyze some privacy measures.

We'll enlist Python code to help us.

17.6.1 Analysis of the method of Lanke (1976)

Lanke [1976] recommends a privacy protection criterion that minimizes:

$$\max\{\Pr(A|\text{yes}), \Pr(A|\text{no})\} \tag{17.20}$$

Following Lanke's suggestion, the statistician should find the highest possible $\Pr(A|\text{yes})$ consistent with truth telling while $\Pr(A|\text{no})$ is fixed at 0.

The variance is then minimized at point X in Fig. 17.4.

However, as shown in Fig. 17.4, point Z offers a smaller variance that still allows cooperation of the respondents, and it is achievable following our earlier discussion of the truth border:

```
π = 0.3
n = 100
nv = [0.27, 0.34, 0.49, 0.74, 0.92, 1.1, 1.47, 2.94, 14.7]
x = np.arange(0, 1, 0.001)
y = x - 0.4
z = x
x0 = np.arange(π, 1, 0.001)
x2 = np.arange(0, π, 0.001)
y1 = [π for i in x0]
y2 = [π for i in x2]
```

(continues on next page)

(continued from previous page)

```
fig, ax = plt.subplots()
ax.plot(x, x, 'c:', lw=2)
ax.plot(x0, y1, 'c:', lw=2)
ax.plot(y2, x2, 'c:', lw=2)
ax.plot(x, y, 'r-', lw=2, label='truth border')
ax.fill_between(x, y, z, facecolor='blue', alpha=0.05,
                label='truth telling')
ax.fill_between(x, 0, y, facecolor='green', alpha=0.05,
                label='lying')
for i in range(len(nv)):
    y = π - (π**2 * (1 - π)**2) / (n * (nv[i] / n) * (x0 - π + 1e-8))
    ax.plot(x0, y, 'k--', alpha=1 - 0.07 * i,
            label='iso-variance curves' if i == 0 else None)
ax.scatter(0.498, 0.1, c='b', marker='*', s=150, label='Z')
ax.scatter(0.4, 0, c='y', s=150, label='X')
ax.set(xlim=(0, 1), ylim=(0, 0.5),
       xlabel='Pr(A|yes)', ylabel='Pr(A|no)')
ax.text(0.45, 0.4, "truth telling")
ax.text(0.85, 0.4, "lying")
ax.text(0.515, 0.095, "optimal design", color='b')
ax.legend(loc='upper left')
plt.show()
```

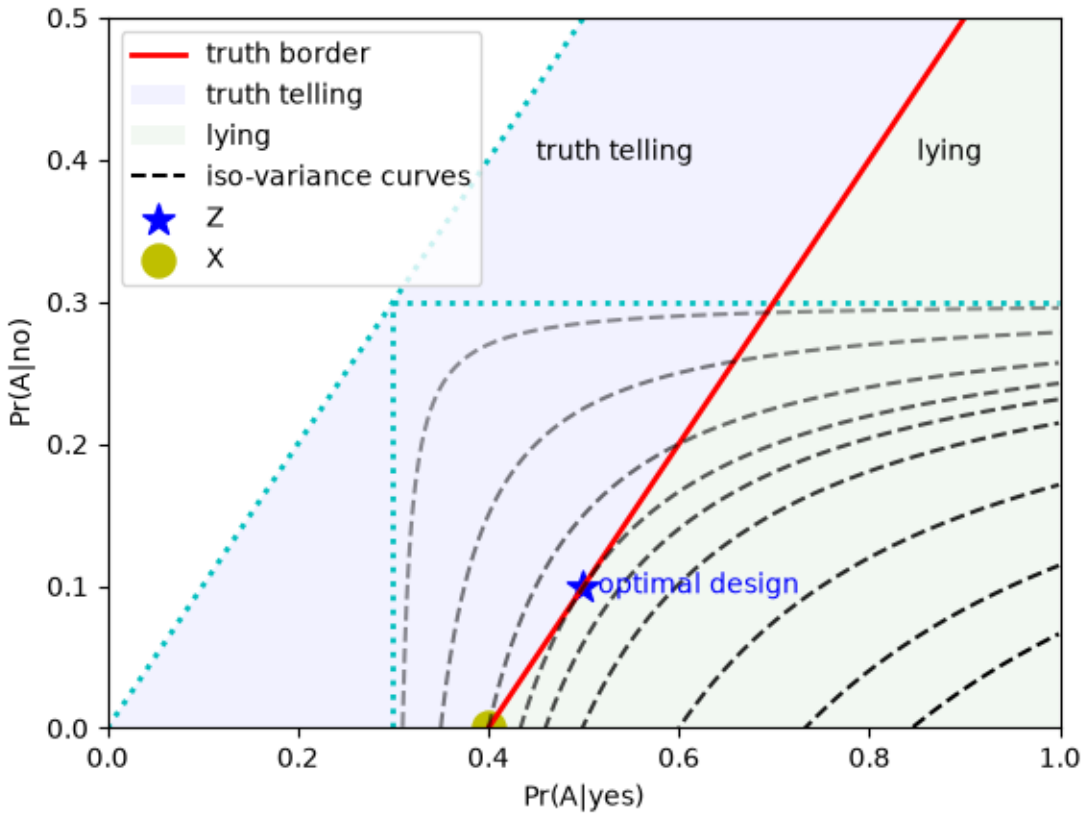

Fig. 17.4: Optimal design under Lanke's criterion

17.6.2 Method of Leysieffer and Warner (1976)

Leysieffer and Warner [1976] recommend a two-dimensional measure of jeopardy that reduces to a single dimension when there is no jeopardy in a 'no' answer, which means that

$$\Pr(\text{yes}|A) = 1$$

and

$$\Pr(A|\text{no}) = 0$$

This is not an optimal choice under a utilitarian approach.

17.6.3 Analysis of the method of Chaudhuri and Mukerjee (1988)

Chaudhuri and Mukerjee [1988] argued that since "yes" may sometimes relate to the sensitive group A, a clever respondent may falsely but safely always be inclined to respond "no".

In this situation, the truth border is such that individuals choose to lie whenever the truthful answer is "yes" and

$$\Pr(A|\text{no}) = 0$$

Here the gain from lying is too high for someone to volunteer a "yes" answer.

This means that

$$U_i\left(\Pr(A|\text{yes}), \text{truth}\right) < U_i\left(\Pr(A|\text{no}), \text{lie}\right)$$

always holds.

As a result, there is no attainable model design.

However, under a utilitarian approach there should exist other survey designs that are consistent with truthful answers.

In particular, respondents will choose to answer truthfully if the relative advantage from lying is eliminated.

We can use Python to show the optimal model design.

```
def f(x):
    "Truth border under the Chaudhuri and Mukerjee assumption."
    return np.where(x < 0.16, 0.0, (np.sqrt(x) - 0.4)**2)
```

```
π = 0.3
n = 100
nv = [0.27, 0.34, 0.49, 0.74, 0.92, 1.1, 1.47, 2.94, 14.7]
x = np.arange(0, 1, 0.001)
y = f(x)
z = x
x0 = np.arange(π, 1, 0.001)
x2 = np.arange(0, π, 0.001)
y1 = [π for i in x0]
y2 = [π for i in x2]
x3 = np.arange(0.16, 1, 0.001)

fig, ax = plt.subplots()
ax.plot(x, x, 'c:', lw=2)
ax.plot(x0, y1, 'c:', lw=2)
```

(continues on next page)

(continued from previous page)

```
ax.plot(y2, x2, 'c:', lw=2)
ax.plot(x3, f(x3), 'b-', lw=2, label='truth border')
ax.fill_between(x, y, z, facecolor='blue', alpha=0.05,
                label='truth telling')
ax.fill_between(x3, 0, f(x3), facecolor='green', alpha=0.05,
                label='lying')
for i in range(len(nv)):
    y = π - (π**2 * (1 - π)**2) / (n * (nv[i] / n) * (x0 - π + 1e-8))
    ax.plot(x0, y, 'k--', alpha=1 - 0.07 * i,
            label='iso-variance curves' if i == 0 else None)
ax.scatter(0.61, 0.146, c='r', marker='*', s=150, label='Q')
ax.set(xlim=(0, 1), ylim=(0, 0.5),
       xlabel='Pr(A|yes)', ylabel='Pr(A|no)')
ax.text(0.45, 0.4, "truth telling")
ax.text(0.85, 0.1, "lying")
ax.text(0.63, 0.141, "optimal design", color='r')
ax.legend(loc='upper left')
plt.show()
```

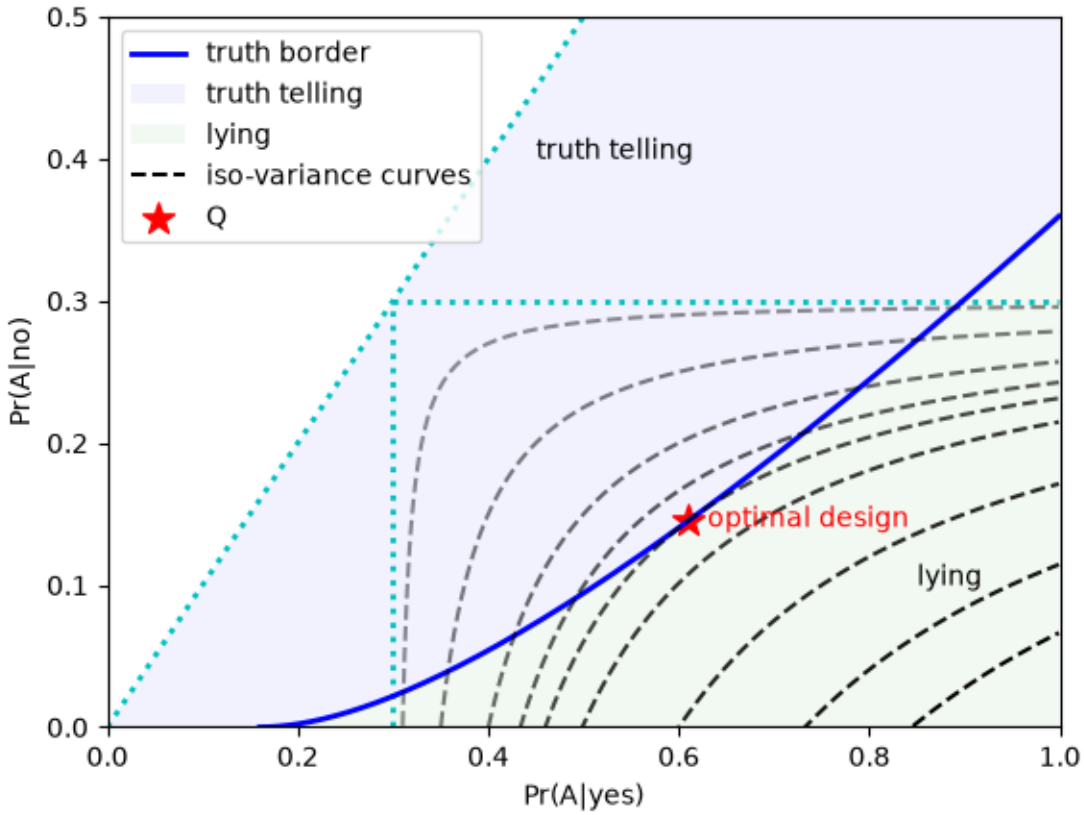

Fig. 17.5: Optimal design under a utilitarian approach

Here the optimal model design corresponds to point Q in Fig. 17.5.

17.6.4 Method of Greenberg et al. (1977)

Greenberg *et al.* [1977] defined the hazard for an individual in A as the probability that he or she is perceived as belonging to A:

$$\Pr(\text{yes}|A) \times \Pr(A|\text{yes}) + \Pr(\text{no}|A) \times \Pr(A|\text{no}) \tag{17.21}$$

The hazard for an individual who does not belong to A is

$$\Pr(\text{yes}|A^{'}) \times \Pr(A|\text{yes}) + \Pr(\text{no}|A^{'}) \times \Pr(A|\text{no}) \tag{17.22}$$

They also considered an alternative related measure of hazard that they said "is likely to be closer to the actual concern felt by a respondent."

Their "limited hazard" for an individual in A and $A^{'}$ is

$$\Pr(\text{yes}|A) \times \Pr(A|\text{yes}) \tag{17.23}$$

and

$$\Pr(\text{yes}|A^{'}) \times \Pr(A|\text{yes}) \tag{17.24}$$

According to Greenberg *et al.* [1977], a respondent commits himself or herself to answer truthfully on the basis of a probability in (17.21) or (17.23) **before** randomly selecting the question to be answered.

Suppose that the appropriate privacy measure is captured by the notion of "limited hazard" in (17.23) and (17.24).

Consider an unrelated question model where the unrelated question is replaced by the instruction "Say the word 'no'", which implies that

$$\Pr(A|\text{yes}) = 1$$

and it follows that:

- Hazard for an individual in $A^{'}$ is 0.
- Hazard for an individual in A can also be made arbitrarily small by choosing a sufficiently small $\Pr(\text{yes}|A)$.

Even though this hazard can be set arbitrarily close to 0, an individual in A will completely reveal his or her identity whenever truthfully answering the sensitive question.

However, under a utilitarian framework, this is obviously contradictory.

If the individuals are willing to volunteer this information, it seems that the randomized response design was not necessary in the first place.

It ignores the fact that respondents retain the option of lying until they have seen the question to be answered.

17.7 Concluding remarks

The justifications for a randomized response procedure are that

- Respondents are thought to feel discomfort from being perceived as belonging to the sensitive group.
- Respondents prefer to answer questions truthfully than to lie, unless it is too revealing.

If a privacy measure is not completely consistent with the rational behavior of the respondents, all efforts to derive an optimal model design are futile.

A utilitarian approach provides a systematic way to model respondents' behavior under the assumption that they maximize their expected utilities.

In a utilitarian analysis:

- A truth border divides the space of conditional probabilities of being perceived as belonging to the sensitive group, $\Pr(A|\text{yes})$ and $\Pr(A|\text{no})$, into the truth-telling region and the lying region.
- The optimal model design is obtained at the point where the truth border touches the lowest possible iso-variance curve.

A practical implication of the analysis of [Ljungqvist, 1993] is that uncertainty about respondents' demands for privacy can be acknowledged by *choosing Pr$(A|yes)$ and Pr$(A|no)$ sufficiently close to each other*.

The designer thus accepts less informative answers in exchange for truthful ones, a trade-off that also appears in *Incentives for Information Transfer*, where a planner can prefer an agent who knows less.

Part III

Bayes Law

CHAPTER

EIGHTEEN

NON-CONJUGATE PRIORS

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install numpyro jax arviz
```

18.1 Overview

This lecture is a sequel to *Two Meanings of Probability*.

In that lecture we adopted a **beta** prior for the unknown probability θ of a coin landing heads, together with a **binomial** likelihood.

That prior and likelihood form a **conjugate pair**: applying Bayes' law returns a posterior of the *same* family as the prior — again a beta distribution.

Conjugacy is convenient because it delivers a posterior in closed form.

But a person's prior beliefs are their own business, and in general they will not happen to be conjugate to the likelihood.

When the prior and likelihood are **not** conjugate, the posterior usually has no closed form, and we must approximate it numerically.

This lecture introduces two widely used ways to do that, both implemented in the probabilistic programming library NumPyro:

- **Markov chain Monte Carlo (MCMC)** — construct a Markov chain whose stationary distribution is the posterior, then sample from it. We use the **No-U-Turn Sampler (NUTS)**, a state-of-the-art form of Hamiltonian Monte Carlo.
- **Variational inference (VI)** — replace sampling with optimization: search within a tractable family of distributions for the member closest to the posterior.

> **Note**
>
> We treat NUTS as a black box in this lecture.
>
> In brief, it is a form of **Hamiltonian Monte Carlo**, which is itself a version of the **Metropolis–Hastings** algorithm: it proposes candidate draws and accepts or rejects them so that the resulting Markov chain has the posterior as its stationary distribution.
>
> What distinguishes it from a basic Metropolis–Hastings sampler is that its proposals are built from *gradient* (derivative) information about the log-posterior, which lets the chain move efficiently through the parameter space; NUTS additionally tunes the length of each proposed move automatically.
>
> For a more advanced introduction to MCMC and the Metropolis–Hastings algorithm, see this lecture.

Our plan is:

1. Confirm that MCMC reproduces the *conjugate* beta posterior that we can compute analytically — this validates the machinery on a problem whose answer we already know.
2. Replace the beta prior with several **non-conjugate** priors and approximate each posterior with MCMC.
3. Introduce variational inference and compare it with MCMC.

Let us start with some imports.

```
import numpy as np
import matplotlib.pyplot as plt
import scipy.stats as st

import jax.numpy as jnp
from jax import random

import numpyro
import numpyro.distributions as dist
from numpyro.infer import MCMC, NUTS, SVI, Trace_ELBO
from numpyro.infer.autoguide import AutoNormal
from numpyro.optim import Adam

import arviz as az
```

18.2 The coin-flipping model

As in *Two Meanings of Probability*, a coin lands heads ($Y = 1$) with probability θ and tails ($Y = 0$) with probability $1 - \theta$.

If we flip the coin n times, the number of heads k has the **binomial** distribution

$$p(k \mid \theta) = \binom{n}{k} \theta^k (1-\theta)^{n-k}.$$

We treat θ as a random variable with a prior density $p(\theta)$, and we want the posterior

$$p(\theta \mid k) \propto p(k \mid \theta)\, p(\theta).$$

18.2.1 Generating data

We simulate a sequence of coin flips from a coin whose true (but unknown to the analyst) probability of heads is $\theta = 0.4$.

```
def simulate_coin_flips(θ=0.4, n=20, seed=1234):
    "Flip a coin n times; return an array of 0s (tails) and 1s (heads)."
    rng = np.random.default_rng(seed)
    return (rng.random(n) < θ).astype(int)

data = simulate_coin_flips()
k, n = int(data.sum()), len(data)
k, n
```

```
(9, 20)
```

We deliberately use a **small** sample ($n = 20$).

The reason is that the prior matters most when data are scarce.

With a large sample the likelihood dominates and almost any reasonable prior leads to the same posterior — exactly the concentration we saw in *Two Meanings of Probability*.

A modest n keeps the influence of the prior visible, which is what we want to study here.

18.2.2 Specifying the model in NumPyro

For most readers this will be a first encounter with NumPyro, whose style takes some getting used to.

To use it we describe our probability model as a Python function — which, a little confusingly, NumPyro calls a **model**.

Such a function does not *compute* anything when called, and it does not return the posterior.

Instead it is a *declaration* of the generative story for the data: which quantities are random, how they are distributed, and how the data depend on them.

An inference algorithm — such as the NUTS sampler below — then *reads* this declaration and works out the posterior for us.

Inside a model, every random quantity is introduced by a call to `numpyro.sample`, and the keyword `obs` decides its role:

- `numpyro.sample("θ", prior)` introduces a **latent** (unobserved) variable named `"θ"`, drawn from `prior` — a quantity we wish to infer.
- `numpyro.sample("k", dist.Binomial(n, θ), obs=k)` introduces an **observed** variable: the keyword `obs=k` pins it to the data, which is how the likelihood $p(k \mid \theta)$ enters.

The string names (`"θ"` and `"k"`) are the labels NumPyro uses to keep track of the variables; we will use them later to pull the posterior draws back out.

We write a *single* model that takes the prior distribution as an argument, so we can reuse it unchanged for every prior we consider — conjugate or not.

```
def binomial_model(prior, k, n):
    "Binomial likelihood with a caller-supplied prior on θ."
    θ = numpyro.sample("θ", prior)
    numpyro.sample("k", dist.Binomial(n, θ), obs=k)
```

Notice that `binomial_model` returns nothing, and that we never call it ourselves.

Instead we hand it to an inference algorithm, which supplies the arguments and traces the two `sample` statements to assemble the posterior.

We also write a small helper that runs NUTS on a given model and returns the fitted sampler.

We request four chains so that we can check convergence below, and run them with `chain_method="vectorized"`, which evaluates all chains together on a single device — so the same code runs unchanged on a CPU or a GPU.

```
def run_nuts(model, *args, seed=0, num_warmup=1000, num_samples=4000, num_chains=4):
    "Sample a NumPyro model with the NUTS sampler."
    mcmc = MCMC(
        NUTS(model),
        num_warmup=num_warmup,
        num_samples=num_samples,
        num_chains=num_chains,
        chain_method="vectorized",
        progress_bar=False,
    )
    mcmc.run(random.key(seed), *args)
    return mcmc
```

NumPyro is built on JAX, which treats randomness explicitly: rather than relying on a global random state, each run needs its own **PRNG key**, created here with `random.key(seed)`.

(This is why we used NumPy's generator to make the data above but JAX keys here.)

`run_nuts` is deliberately generic: it samples whatever model we pass and forwards the extra arguments (`*args`) on to that model through `mcmc.run`. We always call it as `run_nuts(binomial_model, prior, k, n)`, so `prior`, `k`, and `n` reach `binomial_model` unchanged — there is only ever the one prior.

18.3 MCMC reproduces the conjugate posterior

Before trusting MCMC on hard problems, let us check it on an easy one.

With a Beta(α_0, β_0) prior the posterior is known analytically (see *Two Meanings of Probability*):

$$\theta \mid k \sim \text{Beta}(\alpha_0 + k,\ \beta_0 + n - k).$$

We take $\alpha_0 = \beta_0 = 2$ and sample the posterior with NUTS.

```
α0, β0 = 2.0, 2.0
mcmc = run_nuts(binomial_model, dist.Beta(α0, β0), k, n)
```

Before looking at the posterior we should check that the sampler has done its job.

Unlike the independent draws we are used to, MCMC returns a *dependent* sequence — a Markov chain — whose early draws still remember where the chain started.

We can trust the output only once the chain has "forgotten" its starting point and settled into its stationary distribution, which by construction is the posterior we want.

As a safeguard we ran **four** chains from different random starting points (`num_chains=4` in `run_nuts`) and now check that they agree with one another.

ArviZ is a companion library for examining the output of Bayesian samplers.

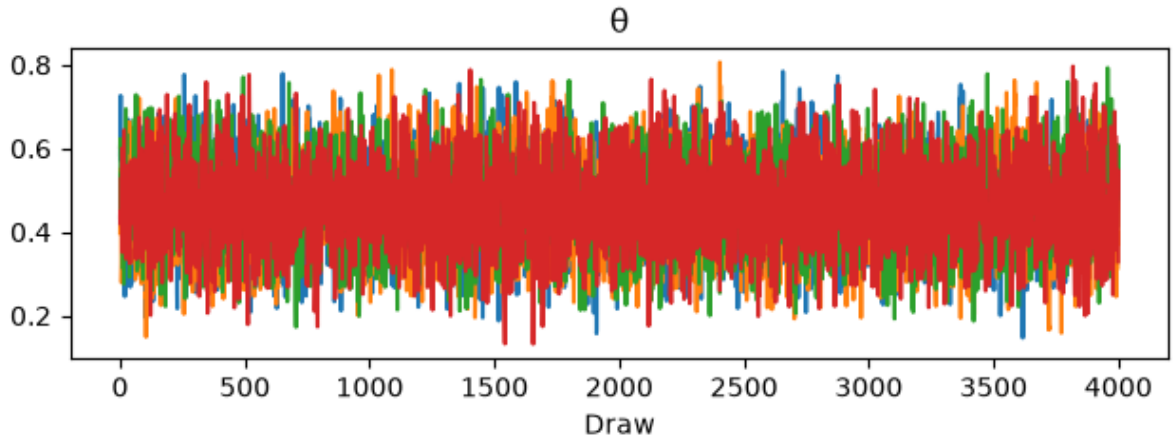
The function `az.from_numpyro` repackages our NumPyro results into ArviZ's standard data structure, and `az.summary` prints a table of per-parameter summaries and convergence diagnostics.

```
idata = az.from_numpyro(mcmc)
az.summary(idata, var_names=["θ"])
```

```
     mean    sd eti89_lb eti89_ub ess_bulk ess_tail r_hat mcse_mean  mcse_sd
θ   0.461   0.1       0.3      0.63     5944     7270  1.00     0.0013  0.00084
```

Two columns of this table are convergence diagnostics worth understanding.

- **`r_hat`** (the Gelman–Rubin statistic) compares the spread of the draws *within* each chain to the spread *between* chains. If the chains have all converged to the same distribution these two match and `r_hat` is close to 1.0; values above roughly 1.01 warn that the chains disagree and the draws cannot yet be trusted.
- **`ess_bulk`** and **`ess_tail`** report the *effective sample size*. Because consecutive MCMC draws are correlated, a chain of length N carries less information than N independent draws would; the effective sample size estimates how many independent draws it is worth (in the bulk and in the tails of the distribution respectively). Larger is better.



Here `r_hat` is essentially 1.0 and the effective sample sizes run into the thousands, so the chains have mixed well.

A **trace plot** gives a visual check of the same thing.

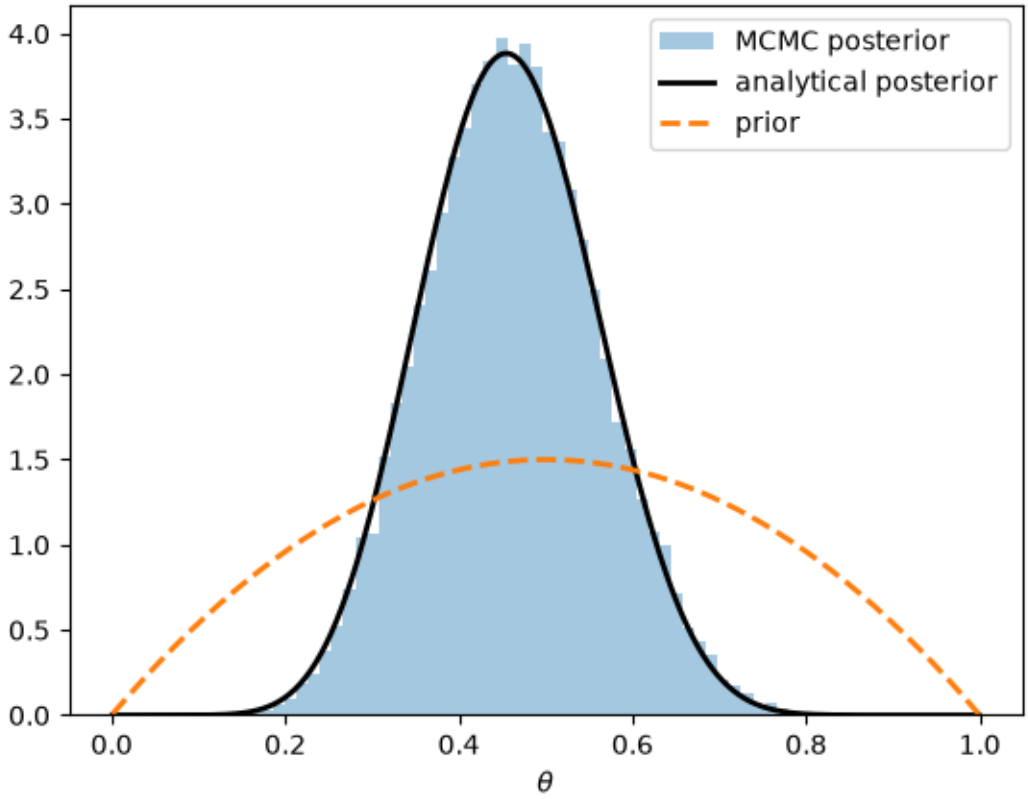
ArviZ's `plot_trace` draws two panels for each parameter: on the right, the sampled value against the iteration number (one coloured line per chain); on the left, a density estimate of the draws from each chain.

Well-mixed chains look like stationary noise on the right — a fuzzy, flat band, with the chains overlapping rather than drifting or wandering — and their densities on the left lie almost on top of one another.

```
az.plot_trace(idata, var_names=["θ"])
plt.tight_layout()
plt.show()
```

Our chains pass both checks, so we can trust the draws and turn to the posterior itself.

Now we compare the MCMC posterior with the analytical beta posterior.



```
θ_grid = np.linspace(0.001, 0.999, 500)
samples = np.asarray(mcmc.get_samples()["θ"])

fig, ax = plt.subplots()
ax.hist(samples, bins=50, density=True, alpha=0.4,
        label="MCMC posterior")
ax.plot(θ_grid, st.beta(α0 + k, β0 + n - k).pdf(θ_grid),
```

(continues on next page)

(continued from previous page)

```
        'k-', lw=2, label="analytical posterior")
ax.plot(θ_grid, st.beta(α0, β0).pdf(θ_grid),
        'C1--', lw=2, label="prior")
ax.set_xlabel(r"$\theta$")
ax.legend()
plt.show()
```

The histogram of MCMC draws sits right on top of the analytical posterior density.

The sampler works, so we can rely on it for priors that have no closed-form posterior.

18.4 Non-conjugate priors

We now keep the binomial likelihood and the same data, but replace the beta prior with priors that are **not** conjugate to it.

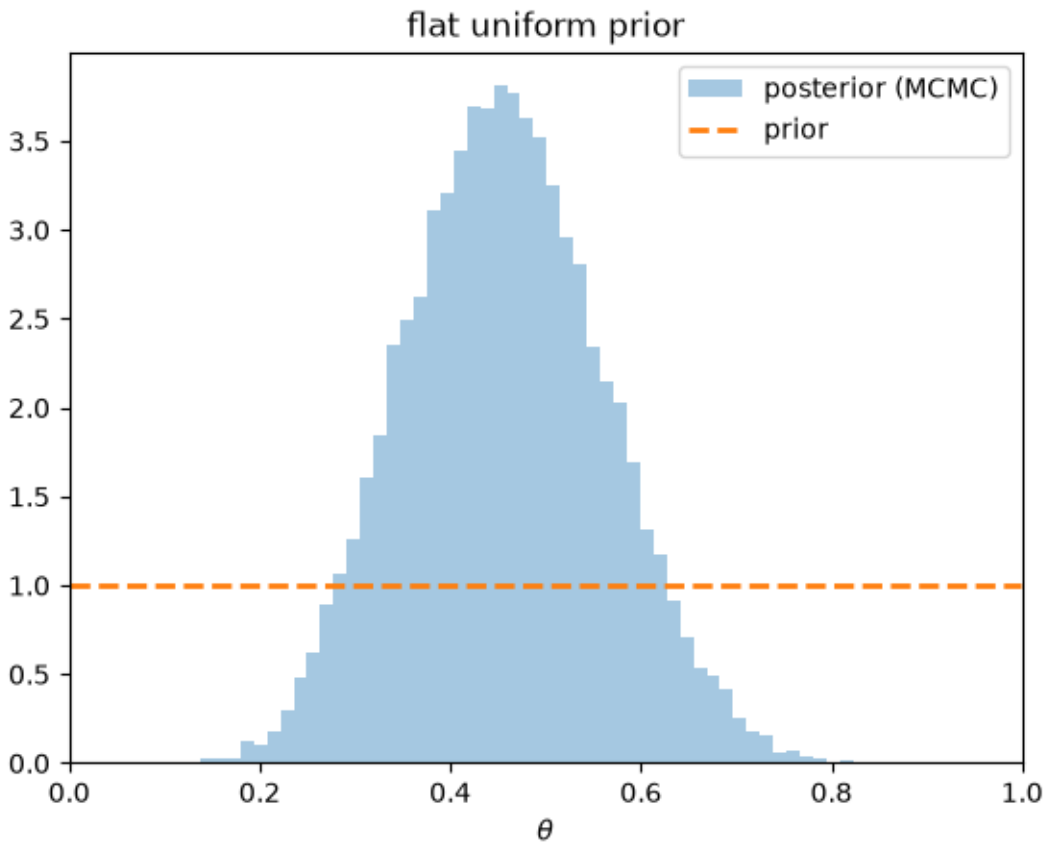
For each prior the recipe is identical:

1. describe the prior and build it as a NumPyro distribution,
2. pass it to `binomial_model` and run NUTS,
3. plot the prior against the resulting posterior.

The following helper draws a prior density and the posterior samples on the same axes.

```
def plot_prior_posterior(prior, samples, title=""):
    "Overlay a prior density and posterior MCMC draws for θ on [0, 1]."
    grid = jnp.linspace(0.001, 0.999, 500)
    # mask the density to the prior's support: dist.Uniform.log_prob
    # returns its constant value even outside [low, high]
    in_support = np.asarray(prior.support(grid))
    prior_pdf = np.where(in_support, np.exp(np.asarray(prior.log_prob(grid))), 0.0)

    fig, ax = plt.subplots()
    ax.hist(np.asarray(samples), bins=50, density=True, alpha=0.4,
            label="posterior (MCMC)")
    ax.plot(np.asarray(grid), prior_pdf, 'C1--', lw=2, label="prior")
    ax.set_xlabel(r"$\theta$")
    ax.set_xlim(0, 1)
    ax.legend()
    if title:
        ax.set_title(title)
    plt.show()
```



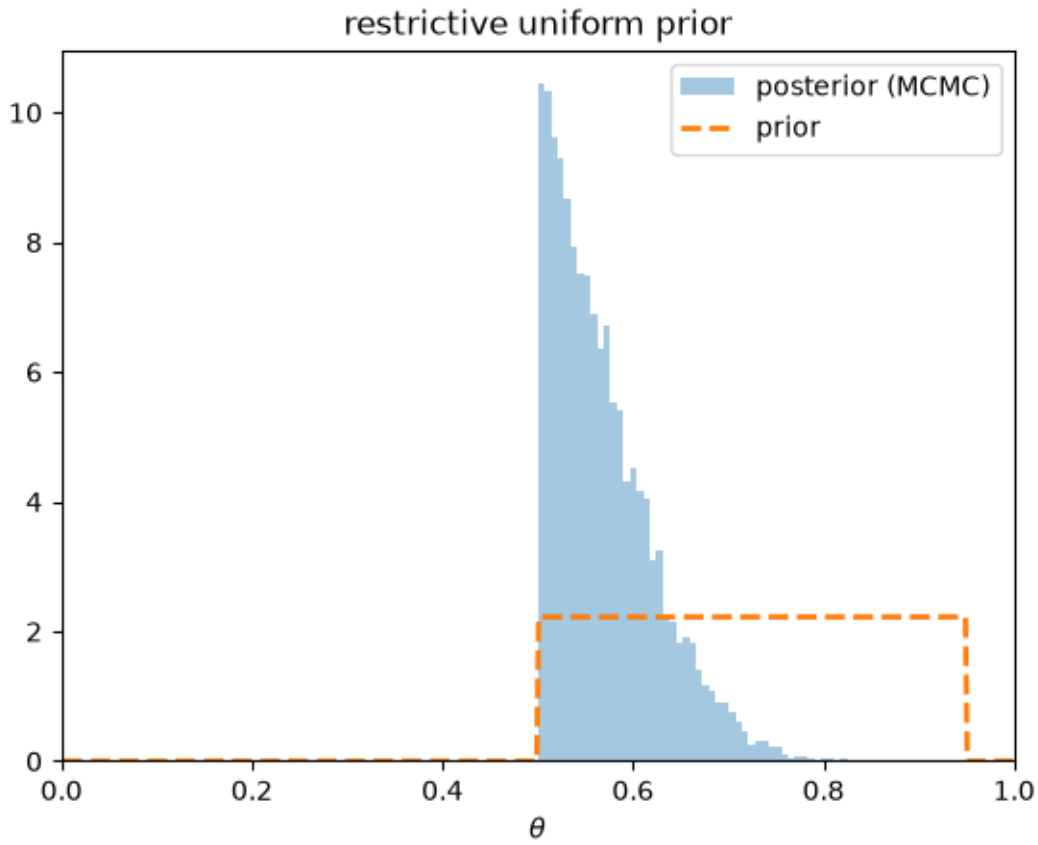
18.4.1 A uniform prior

The simplest non-conjugate prior is **uniform**: the analyst regards every value of θ in some interval as equally likely.

A uniform prior on all of $[0, 1]$ expresses indifference.

Because its density is constant, the posterior is then proportional to the likelihood alone.

```
mcmc_flat = run_nuts(binomial_model, dist.Uniform(0.0, 1.0), k, n)
plot_prior_posterior(dist.Uniform(0.0, 1.0),
                     mcmc_flat.get_samples()["θ"],
                     title="flat uniform prior")
```



The posterior is centered near the sample frequency k/n, just as the likelihood is.

Now suppose instead that the analyst is convinced the coin favors heads, and places a uniform prior on $[0.5, 0.95]$.

This prior assigns *zero* density to the region around the true value $\theta = 0.4$.

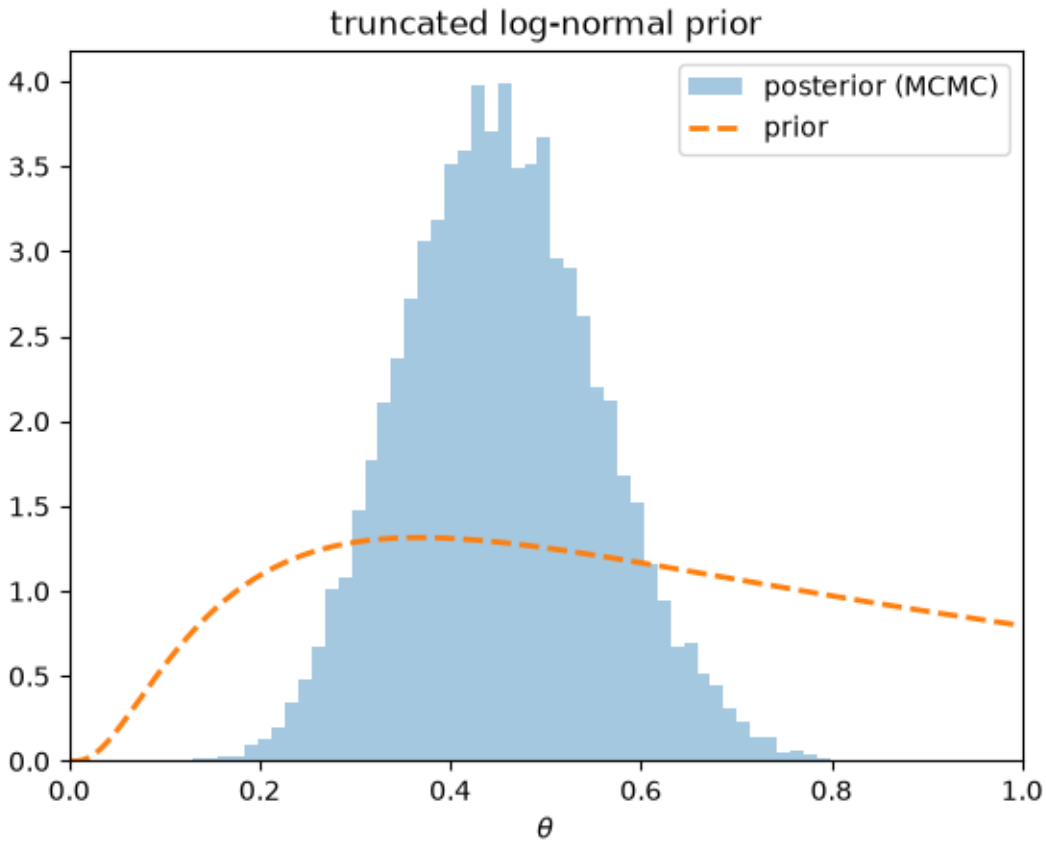
```
mcmc_restr = run_nuts(binomial_model, dist.Uniform(0.5, 0.95), k, n)
plot_prior_posterior(dist.Uniform(0.5, 0.95),
                     mcmc_restr.get_samples()["θ"],
                     title="restrictive uniform prior")
```

```
/tmp/ipykernel_12649/411337751.py:7: UserWarning: Out-of-support values provided␣
↪to log prob method. The value argument should be within the support.
  prior_pdf = np.where(in_support, np.exp(np.asarray(prior.log_prob(grid))), 0.0)
```

The posterior cannot put mass where the prior is zero, so it piles up against the lower boundary 0.5 — as close to the data as the prior permits.

This is a vivid warning: a prior that rules out the truth can never be overturned by data, no matter how much we collect.

18.4.2 A truncated log-normal prior



A uniform prior is flat. A more realistic prior is smooth and asymmetric.

A convenient choice on $[0, 1]$ is a **truncated log-normal**: take $Z \sim N(\mu, \sigma)$ truncated to $Z \leq 0$, and set $\theta = e^Z$, which then lies in $(0, 1]$.

NumPyro builds this by feeding a `TruncatedNormal` through an `ExpTransform`.

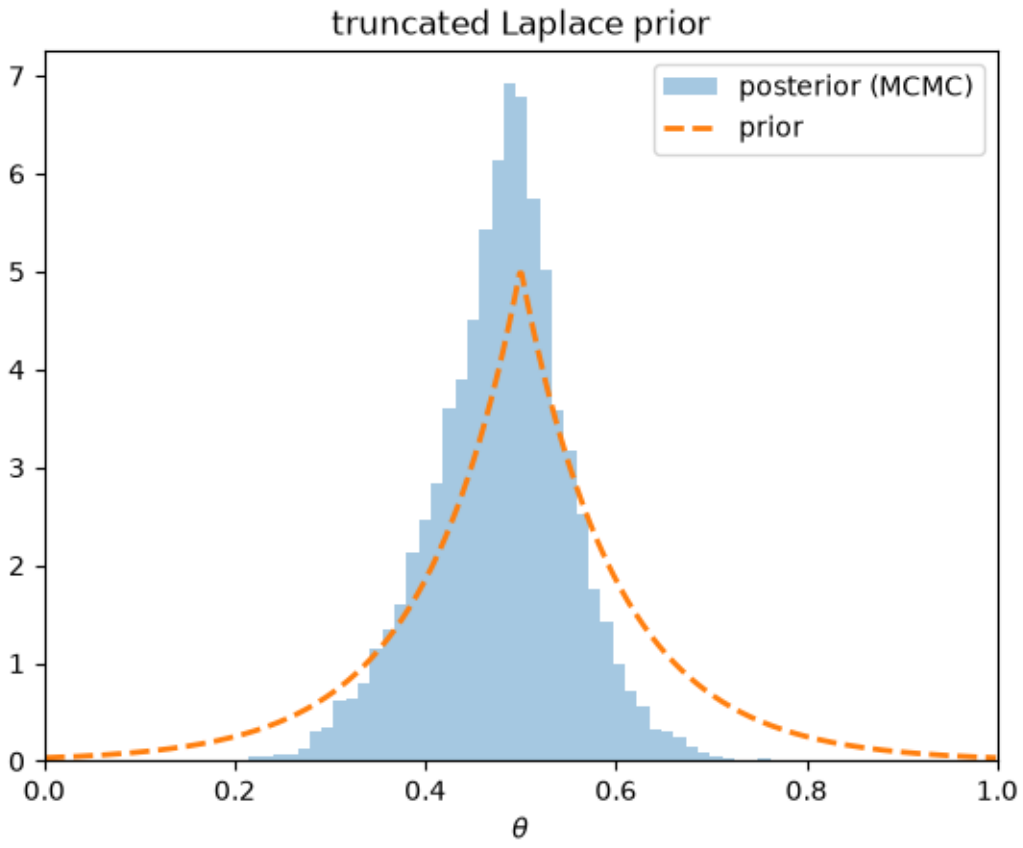
```
def truncated_lognormal(μ, σ):
    "Log-normal distribution truncated to the unit interval (0, 1]."
    base = dist.TruncatedNormal(loc=μ, scale=σ, low=-jnp.inf, high=0.0)
    # Declare the (0, 1] support: ExpTransform alone advertises (0, ∞),
    # which would let the sampler propose θ > 1.
    class _UnitLogNormal(dist.TransformedDistribution):
        support = dist.constraints.interval(0.0, 1.0)
    return _UnitLogNormal(base, dist.transforms.ExpTransform())

prior_ln = truncated_lognormal(0.0, 1.0)
mcmc_ln = run_nuts(binomial_model, prior_ln, k, n)
plot_prior_posterior(prior_ln, mcmc_ln.get_samples()["θ"],
                     title="truncated log-normal prior")
```

The prior favors smaller values of θ, but with $\sigma = 1$ it is diffuse, so the likelihood pulls the posterior toward the sample frequency.

We keep `mcmc_ln` — we will compare it with variational inference below.

18.4.3 A truncated Laplace prior



Our final prior has a sharp, non-smooth peak.

A **Laplace** density $\propto e^{-|\theta-\mu|/b}$ has a kink at its center μ, expressing a strong belief that θ sits near μ while still allowing for surprises in the tails.

We truncate it to $[0, 1]$ and center it at 0.5.

```
def truncated_laplace(μ, b):
    "Laplace distribution truncated to the unit interval [0, 1]."
    return dist.TruncatedDistribution(dist.Laplace(μ, b), low=0.0, high=1.0)

prior_lp = truncated_laplace(0.5, 0.1)
mcmc_lp = run_nuts(binomial_model, prior_lp, k, n)
plot_prior_posterior(prior_lp, mcmc_lp.get_samples()["θ"],
                     title="truncated Laplace prior")
```

The spiked prior tugs the posterior toward 0.5, away from the sample frequency near 0.4.

The pull is gentle here because the prior, though peaked, is not very tight; with a smaller b it would dominate the modest sample.

NUTS handles the kink in the prior without any special tuning — a practical advantage of gradient-based samplers paired with automatic differentiation.

18.5 Variational inference

MCMC approximates the posterior by *sampling* from it.

Variational inference (VI) takes a different route: it turns posterior approximation into an *optimization* problem.

We restrict attention to a tractable family of densities $q_\phi(\theta)$ — the **guide** — indexed by parameters ϕ, and we search for the member of that family closest to the posterior.

18.5.1 Why variational inference?

If NUTS already returns accurate posteriors, why introduce another method?

The answer is **scale**.

MCMC evaluates the likelihood over the entire dataset at every step, and the number of steps it needs tends to grow with the dimension of the parameter.

For large datasets or high-dimensional models — for instance the hierarchical models and neural networks common in machine learning — this can become too slow to be practical.

Variational inference scales much better, because the objective (the ELBO, introduced below) can be maximized with *stochastic* gradients computed on small random subsets of the data — the same machinery that trains deep learning models.

It also yields a compact parametric approximation that is cheap to store and to draw from afterwards.

The price is accuracy: VI returns only the best fit *within the guide family*, and it can understate uncertainty.

As a rule of thumb, prefer MCMC when you need an accurate posterior and the problem is small enough to afford it, and VI when the model is too large for MCMC or a fast, approximate answer is good enough.

18.5.2 The evidence lower bound

Let the prior be $p(\theta)$ and the likelihood be $p(Y \mid \theta)$, where Y denotes the observed data (here the head count k).

By Bayes' rule,

$$p(\theta \mid Y) = \frac{p(Y, \theta)}{p(Y)} = \frac{p(Y \mid \theta)\, p(\theta)}{p(Y)},$$

where

$$p(Y) = \int p(Y \mid \theta)\, p(\theta)\, d\theta. \tag{18.1}$$

The integral in (18.1) is the troublesome one: in the non-conjugate case it has no closed form.

We measure the discrepancy between the guide $q_\phi(\theta)$ and the posterior with the **Kullback–Leibler (KL) divergence**

$$D_{KL}(q_\phi(\theta) \,\|\, p(\theta \mid Y)) = -\int q_\phi(\theta)\, \log \frac{p(\theta \mid Y)}{q_\phi(\theta)}\, d\theta,$$

and we choose ϕ to minimize it.

The KL divergence still involves the intractable posterior, but we can rearrange it. Using $p(\theta \mid Y) = p(\theta, Y)/p(Y)$,

$$\begin{aligned} D_{KL}(q_\phi \,\|\, p(\theta \mid Y)) &= -\int q_\phi(\theta)\, \log \frac{p(\theta, Y)/p(Y)}{q_\phi(\theta)}\, d\theta \\ &= -\int q_\phi(\theta) \left[\log \frac{p(\theta, Y)}{q_\phi(\theta)} - \log p(Y)\right] d\theta \\ &= -\int q_\phi(\theta)\, \log \frac{p(\theta, Y)}{q_\phi(\theta)}\, d\theta + \log p(Y), \end{aligned}$$

where the last line uses $\int q_\phi(\theta)\, d\theta = 1$. Rearranging,

$$\log p(Y) = D_{KL}(q_\phi \,\|\, p(\theta \mid Y)) + \underbrace{\int q_\phi(\theta)\, \log \frac{p(\theta, Y)}{q_\phi(\theta)}\, d\theta}_{\text{ELBO}}.$$

The marginal likelihood $\log p(Y)$ on the left does not depend on ϕ.

Hence **minimizing** the KL divergence is equivalent to **maximizing** the second term, the **evidence lower bound (ELBO)**:

$$\text{ELBO}(\phi) \equiv \int q_\phi(\theta)\, \log \frac{p(\theta, Y)}{q_\phi(\theta)}\, d\theta = \mathbb{E}_{q_\phi(\theta)}\big[\log p(\theta, Y) - \log q_\phi(\theta)\big]. \tag{18.2}$$

Because $D_{KL} \geq 0$, the ELBO is a lower bound on $\log p(Y)$ — hence its name.

Crucially, (18.2) involves only the *joint* density $p(\theta, Y) = p(Y \mid \theta)\, p(\theta)$, which we can evaluate, not the intractable normalizing constant $p(Y)$.

The expectation can be estimated by sampling from q_ϕ, and ϕ improved by gradient ascent — this is **stochastic variational inference (SVI)**.

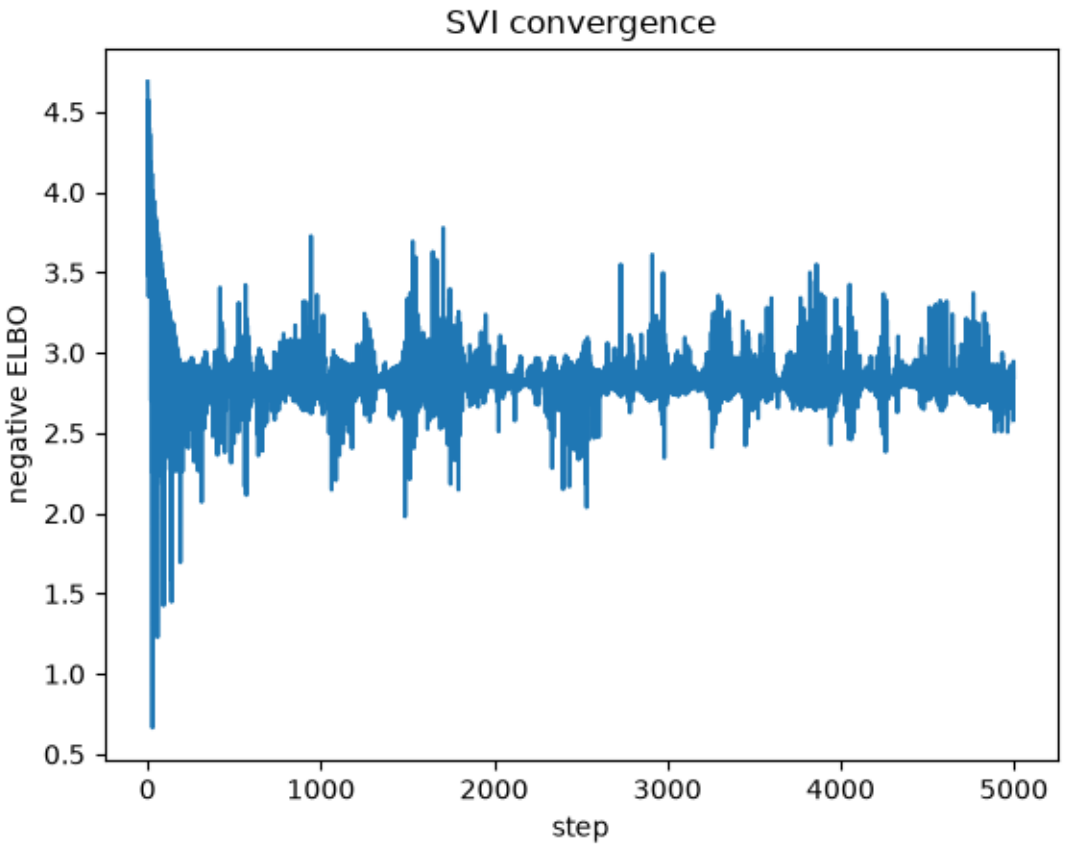
18.5.3 Implementing SVI in NumPyro

We need a guide q_ϕ.

The simplest choice is an **autoguide**: NumPyro inspects the model and automatically constructs a guide for us.

`AutoNormal` places an independent normal distribution on each latent variable, transformed to respect its support — here, to keep θ inside $(0, 1)$.

We apply SVI to the truncated log-normal model from above and maximize the ELBO with the Adam optimizer.



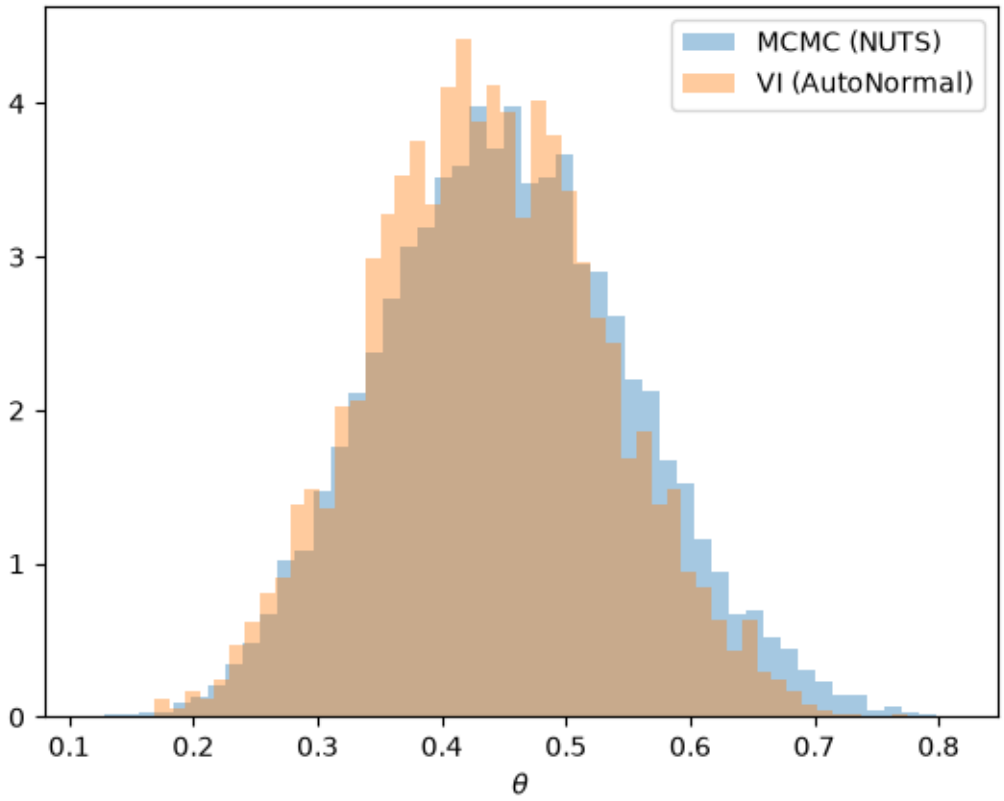
```
guide = AutoNormal(binomial_model)
optimizer = Adam(step_size=0.01)
svi = SVI(binomial_model, guide, optimizer, loss=Trace_ELBO())

svi_result = svi.run(random.key(0), 5000, prior_ln, k, n, progress_bar=False)
```

SVI maximizes the ELBO; equivalently, it minimizes its negative, which is the reported loss.

A loss curve that flattens out indicates convergence.

```
fig, ax = plt.subplots()
ax.plot(svi_result.losses)
ax.set_xlabel("step")
ax.set_ylabel("negative ELBO")
ax.set_title("SVI convergence")
plt.show()
```



18.5.4 Comparing VI with MCMC

To assess the approximation, we draw samples from the fitted guide and compare them with the NUTS posterior for the same (log-normal-prior) model.

```
vi_samples = guide.sample_posterior(
    random.key(1), svi_result.params, sample_shape=(4000,)
)["θ"]
nuts_samples = mcmc_ln.get_samples()["θ"]

fig, ax = plt.subplots()
ax.hist(np.asarray(nuts_samples), bins=50, density=True, alpha=0.4,
        label="MCMC (NUTS)")
ax.hist(np.asarray(vi_samples), bins=50, density=True, alpha=0.4,
        label="VI (AutoNormal)")
ax.set_xlabel(r"$\theta$")
ax.legend()
plt.show()
```

The two approximations broadly agree on the location and spread of the posterior.

They need not agree perfectly.

MCMC samples the true posterior (up to Monte Carlo error), whereas VI reports the best fit *within its guide family*.

A mean-field normal guide is symmetric on the transformed scale and can miss skewness or heavy tails in the true posterior.

The trade-off is one of cost against fidelity: VI replaces sampling with optimization and is often much faster in high dimensions, but it delivers an approximation whose quality is capped by the flexibility of the guide.

18.6 Where to next

This lecture showed how to compute posteriors when prior and likelihood are not conjugate, using NUTS and stochastic variational inference in NumPyro.

The same tools carry over to richer models.

The lectures *Posterior Distributions for AR(1) Parameters* and *Forecasting an AR(1) Process* apply NumPyro to Bayesian estimation and forecasting of autoregressive time series, where the parameter is a vector and conjugate analysis is unavailable.

CHAPTER

NINETEEN

POSTERIOR DISTRIBUTIONS FOR AR(1) PARAMETERS

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

In addition to what's included in base Anaconda, this lecture requires the following libraries.

We first install `numpyro` and `jax`:

```
!pip install numpyro jax
```

We also install `arviz` and `pymc`:

```
!pip install arviz pymc
```

19.1 Overview

This lecture uses Bayesian methods offered by pymc and numpyro to make statistical inferences about two parameters of a univariate first-order autoregression.

The model is a good laboratory for illustrating consequences of alternative ways of modeling the distribution of the initial y_0:

- As a fixed number
- As a random variable drawn from the stationary distribution of the $\{y_t\}$ stochastic process

19.1.1 Setting

The first component of the statistical model is

$$y_{t+1} = \rho y_t + \sigma_x \epsilon_{t+1}, \quad t \geq 0 \tag{19.1}$$

where

- the scalars ρ and σ_x satisfy $|\rho| < 1$ and $\sigma_x > 0$
- $\{\epsilon_{t+1}\}$ is a sequence of IID normal random variables with mean 0 and variance 1.

The second component of the statistical model is

$$y_0 \sim N(\mu_0, \sigma_0^2) \tag{19.2}$$

Unknown parameters are ρ, σ_x.

We have independent *prior probability distributions* for ρ, σ_x and want to compute a posterior probability distribution after observing a sample $\{y_t\}_{t=0}^T$.

We want to study how inferences about the unknown parameters (ρ, σ_x) depend on what is assumed about the parameters μ_0, σ_0 of the distribution of y_0.

We study two assumptions about the initial value y_0, and we refer to them by name throughout the lecture.

Under the **conditioning assumption** we take the observed y_0 as given.

Formally we set $(\mu_0, \sigma_0) = (y_0, 0)$, so the density of y_0 is a spike at its observed value.

This density does not depend on ρ or σ_x, so y_0 carries no information about the parameters; in effect we **condition on** y_0 and model only what happens after it.

Under the **stationary assumption** we treat y_0 as a draw from the stationary distribution of the process,

$$y_0 \sim N\left(0, \frac{\sigma_x^2}{1-\rho^2}\right).$$

This density *does* depend on ρ and σ_x, so now the observed y_0 carries information about the parameters.

The whole lecture is about how this one difference affects our estimates.

> **Note**
>
> We do not treat a third possible case in which μ_0, σ_0 are free parameters to be estimated.

19.1.2 Libraries

We use PyMC and NumPyro to compute the posterior distribution of ρ, σ_x.

We use two libraries because they make different trade-offs.

PyMC offers a mature and highly readable modeling syntax together with a rich set of diagnostic tools, which makes it convenient for learning and prototyping.

NumPyro is built on JAX, so it compiles to fast machine code and can run on a GPU, which helps it scale to larger models and datasets.

Because both libraries fit the same model, running them side by side also lets us check that they agree.

Both libraries support the NUTS sampler, which we use to draw samples from the posterior.

We treat NUTS as a black box here; see the *introduction to NUTS* in *Non-Conjugate Priors* for a brief account of how it works.

19.1.3 Imports

Let's start with some Python imports.

```
import arviz as az
import pymc as pm
import numpyro
from numpyro import distributions as dist

import numpy as np
import jax.numpy as jnp
from jax import random
import matplotlib.pyplot as plt

import logging
logging.basicConfig()
logger = logging.getLogger('pymc')
logger.setLevel(logging.CRITICAL)
```

19.2 Estimation

Let's turn to estimation, starting with the likelihood function.

19.2.1 Likelihood function

For a sample $\{y_t\}_{t=0}^T$ from the AR(1) model, the likelihood function can be *factored* as follows:

$$f(y_T, y_{T-1}, \dots, y_0) = f(y_T|y_{T-1}) f(y_{T-1}|y_{T-2}) \cdots f(y_1|y_0) f(y_0)$$

(We use f to denote a generic probability density.)

The statistical model (19.1)-(19.2) implies

$$\begin{aligned} f(y_t|y_{t-1}) &\sim N(\rho y_{t-1}, \sigma_x^2) \\ f(y_0) &\sim N(\mu_0, \sigma_0^2) \end{aligned}$$

We shall use Bayes' law to construct a posterior distribution under the alternative assumptions.

As discussed above, the way that we select the initial value y_0 matters.

- If we believe y_0 really is a draw from the stationary distribution, the stationary assumption is a good choice, because then y_0 carries useful information about ρ and σ_x.
- If we suspect y_0 is far out in the tail — so that early observations carry a large **transient component** — the conditioning assumption is better.

To illustrate the issue, we'll begin by choosing an initial y_0 that is far out in a tail of the stationary distribution.

19.2.2 Simulation code

We will work with simulated data, fixing parameters ρ and σ_x.

Then we will pretend that we don't know these parameters and try to estimate them under the two assumptions discussed above (conditioning and stationary).

The following function simulates a path of the AR(1) process from a given initial condition.

```
def ar1_simulate(ρ, σ, y0, T, rng):

    # Allocate space and draw shocks
    y = np.empty(T)
    ε = rng.normal(0, σ, T)

    # Initial condition and step forward
    y[0] = y0
    for t in range(1, T):
        y[t] = ρ * y[t-1] + ε[t]

    return y
```

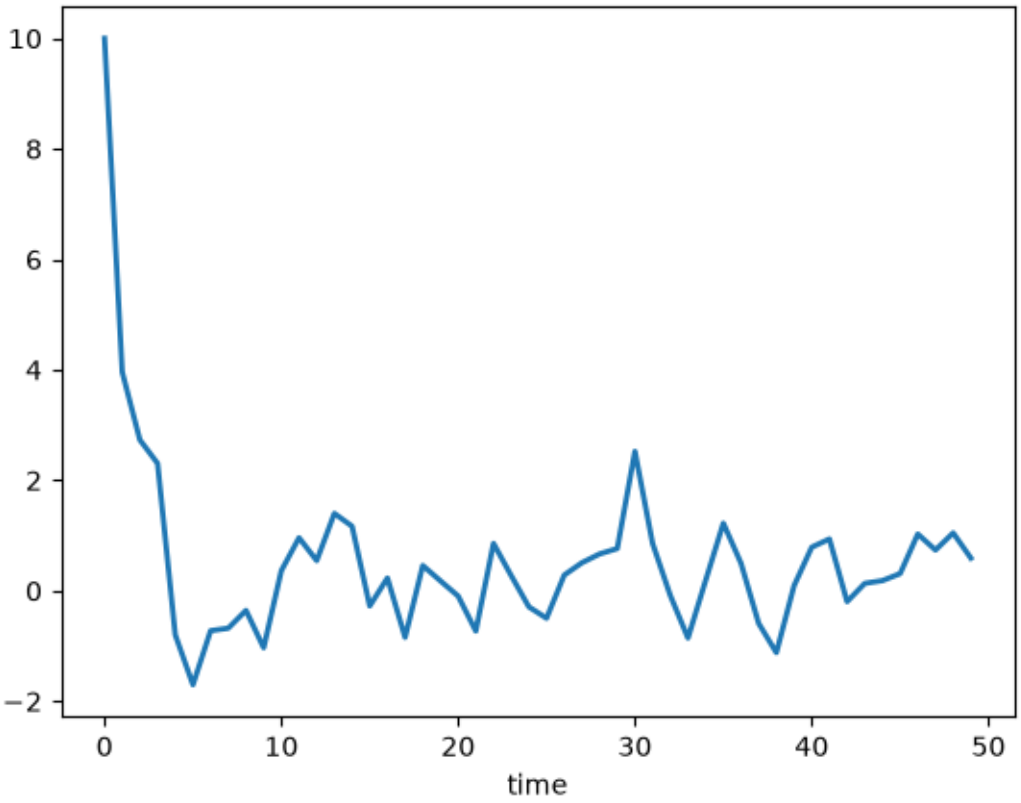
We use the following parameterization.

```
σ_true = 1.0   # Fix a value for σ_x
ρ_true = 0.5   # Fix a value for ρ
```

Our simulated time series will be relatively short, so that the priors matter:

```
T = 50   # Length of time series
```

As mentioned above, we choose an initial y_0 that is far out in a tail of the stationary distribution:



```
y_0 = 10
```

Now let's simulate and generate our data:

```
rng = np.random.default_rng(42)
y = ar1_simulate(ρ_true, σ_true, y_0, T, rng)
```

Here's a plot of the simulated series.

```
fig, ax = plt.subplots()
ax.plot(y, lw=2)
ax.set_xlabel('time')
plt.show()
```

You can see that the initial condition is unusually large — the series moves away from it quickly and fluctuates in a lower band.

19.2.3 PyMC implementation

In this section we use PyMC to compute the posterior under each assumption about y_0 — first the conditioning assumption, then the stationary assumption.

We parameterize each normal distribution in PyMC by its standard deviation σ, via the `sigma` argument.

```
AR1_model = pm.Model()

with AR1_model:

    # Start with priors
    ρ = pm.Uniform('rho', lower=-1., upper=1.)  # Assume stable ρ
    σ = pm.HalfNormal('sigma', sigma=np.sqrt(10))

    # Expected value of y at the next period (ρ * y)
    yhat = ρ * y[:-1]

    # Likelihood of the actual realization
    y_like = pm.Normal('y_obs', mu=yhat, sigma=σ, observed=y[1:])
```

Let's unpack what this model declares.

Inside the `with AR1_model:` block, each `pm` statement adds a random variable to the model.

The first two lines are the **priors** — a uniform prior on ρ over $(-1, 1)$, which builds in stationarity, and a half-normal prior on σ.

The line `yhat = ρ * y[:-1]` is just the vector of conditional means ρy_{t-1} for $t = 1, \ldots, T$.

The last line is the **likelihood**: the keyword `observed=y[1:]` tells PyMC that the values `y[1:]` are data, drawn from $N(\rho y_{t-1}, \sigma^2)$.

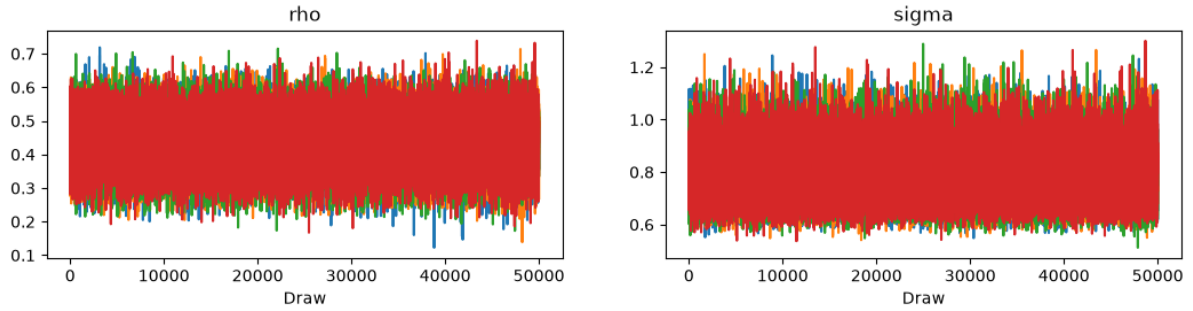
Because `yhat` and `y[1:]` are whole vectors, this single line encodes the entire product $\prod_{t=1}^{T} f(y_t \mid y_{t-1})$ from the factorization above.

PyMC multiplies this likelihood by the priors to form the posterior, which we sample from below.

Note

Notice what is *absent*: we never write down a density for y_0 itself.

It enters the model only inside `y[:-1]`, as the conditioning value for the first transition $f(y_1 \mid y_0)$ — never as something the model has to explain.



Leaving out the $f(y_0)$ factor in this way is precisely the **conditioning assumption**.

pm.sample by default uses the NUTS sampler to generate samples, as shown in the cell below:

```
with AR1_model:
    trace = pm.sample(50000, tune=10000, return_inferencedata=True)
```

We plot the trace and the posterior densities for the two parameters.

```
with AR1_model:
    az.plot_trace(trace)
```

Recall that we generated the data with $\rho = 0.5$ and $\sigma_x = 1$.

The posteriors concentrate near these values, so conditioning on y_0 recovers the parameters reasonably well, even from this short sample.

Note

The fit is good but not exact — the posterior for ρ sits a little below its true value.

This is partly the classic **Hurwicz bias**: in a first-order autoregression the least-squares (and hence posterior) estimate of ρ is biased downward in small samples, with the bias shrinking as the sample grows (see Hurwicz [1950] and [Orcutt and Winokur, 1969]).

Here is a numerical summary of the posterior.

```
with AR1_model:
    summary = az.summary(trace, round_to=4)

summary
```

```
          mean      sd  eti89_lb  eti89_ub     ess_bulk     ess_tail  r_hat  \
rho     0.4369  0.0633    0.3357    0.5378  179840.3608  126763.0507    1.0
sigma   0.7923  0.0834    0.6712    0.9352  184980.0252  135173.3728    1.0

        mcse_mean  mcse_sd
rho        0.0001   0.0002
sigma      0.0002   0.0002
```

Now we switch to the stationary assumption, using the same data.

Recall that this means

$$y_0 \sim N\left(0, \frac{\sigma_x^2}{1-\rho^2}\right).$$

We alter the code as follows:

```
AR1_model_y0 = pm.Model()

with AR1_model_y0:

    # Start with priors
    ρ = pm.Uniform('rho', lower=-1., upper=1.)  # Assume stable ρ
    σ = pm.HalfNormal('sigma', sigma=np.sqrt(10))

    # Standard deviation of the stationary distribution
    y_sd = σ / np.sqrt(1 - ρ**2)

    # Expected value of y at the next period (ρ * y)
    yhat = ρ * y[:-1]
    y_data = pm.Normal('y_obs', mu=yhat, sigma=σ, observed=y[1:])

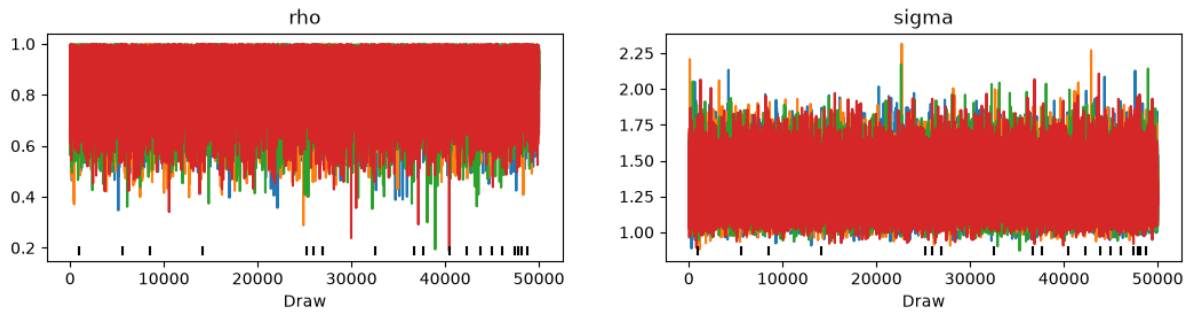
    # Density for y0 -- this term imposes the stationary assumption
    y0_data = pm.Normal('y0_obs', mu=0., sigma=y_sd, observed=y[0])
```

The only change from the first model is that final line.

Note

The new line adds a density for y_0 — the stationary density $N(0, \sigma_x^2/(1-\rho^2))$ — through a second `observed` term.

This restores the $f(y_0)$ factor we dropped before, and so *is* the **stationary assumption**.



Everything else is identical, so any difference between the two posteriors comes entirely from this one term.

As before, we sample from the posterior.

```
with AR1_model_y0:
    trace_y0 = pm.sample(50000, tune=10000, return_inferencedata=True)
```

In the trace plot below, any grey vertical lines mark sampler divergences.

```
with AR1_model_y0:
    az.plot_trace(trace_y0)
```

Here is a summary of the posterior.

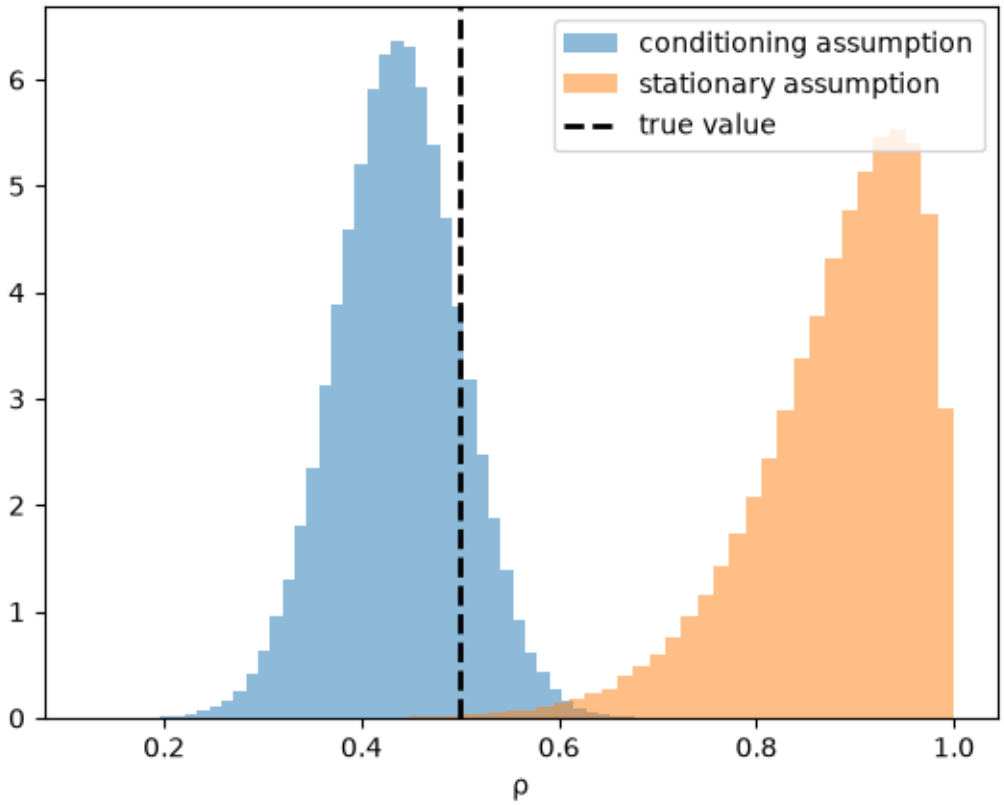
```
with AR1_model_y0:
    summary_y0 = az.summary(trace_y0, round_to=4)

summary_y0
```

```
         mean      sd  eti89_lb  eti89_ub     ess_bulk     ess_tail  r_hat  \
rho    0.8796  0.0851    0.7222    0.9819  114179.2567   89597.1834    1.0
sigma  1.3163  0.1382    1.1157    1.5532  127227.9822  108735.8873    1.0

       mcse_mean  mcse_sd
rho       0.0002   0.0002
sigma     0.0004   0.0004
```

The posterior for ρ has clearly moved when we changed our assumption about y_0.



19.2.4 Comparing the two posteriors

Let's put the two posteriors for ρ side by side to see what changed.

The figure below overlays the posterior for ρ under each assumption, with the true value marked by a dashed line.

```
ρ_cond = trace.posterior['rho'].values.flatten()
ρ_stat = trace_y0.posterior['rho'].values.flatten()

fig, ax = plt.subplots()
ax.hist(ρ_cond, bins=50, density=True, alpha=0.5,
        label='conditioning assumption')
ax.hist(ρ_stat, bins=50, density=True, alpha=0.5,
        label='stationary assumption')
ax.axvline(ρ_true, color='k', linestyle='--', lw=2, label='true value')
ax.set_xlabel('ρ')
ax.legend()
plt.show()
```

The posterior from the conditioning assumption sits close to the true value of 0.5.

It is centred a little below 0.5, which is the small-sample Hurwicz bias mentioned above — a mild downward pull that shrinks as the sample grows.

The posterior from the stationary assumption is different: it is pushed well to the right, toward $\rho = 1$.

Here is why.

We chose a starting value $y_0 = 10$ that lies far out in the tail of the stationary distribution.

If y_0 really were a draw from that distribution, such an extreme value would be very unlikely.

So when we force the model to explain y_0 this way, Bayes' law looks for parameter values that make the extreme y_0 plausible.

It does this by pushing ρ toward 1, because a larger ρ inflates the stationary variance $\sigma_x^2/(1-\rho^2)$ and makes a large y_0 less surprising.

A single unusual starting value therefore drags the whole posterior away from the truth.

This is the sense in which the conditioning assumption is more accurate here: it does not let one atypical observation distort our view of ρ and σ_x.

19.2.5 NumPyro implementation

We now redo both computations with NumPyro.

Because it fits the same two models, we expect its posteriors to match those from PyMC.

The models are the same; only the syntax differs.

NumPyro describes a model as an ordinary Python function rather than a `with` block, each `numpyro.sample('name', distribution)` plays the role that a `pm` random variable did above, and the keyword `obs=` is NumPyro's counterpart of PyMC's `observed=`.

Everything we said about priors, the vectorized likelihood, and how the two assumptions are imposed carries over unchanged; see *Non-Conjugate Priors* for a fuller introduction to NumPyro models.

We start with a helper function that plots the trace and posterior histogram for the sampled parameters.

```
def plot_posterior(sample):
    """
    Plot trace and histogram
    """
    # To np array
    ρs = np.array(sample['rho'])
    σs = np.array(sample['sigma'])

    fig, axs = plt.subplots(2, 2, figsize=(17, 6))
    # Plot trace
    axs[0, 0].plot(ρs, lw=2)
    axs[1, 0].plot(σs, lw=2)

    # Plot posterior
    axs[0, 1].hist(ρs, bins=50, density=True, alpha=0.7)
    axs[0, 1].set_xlim([0, 1])
    axs[1, 1].hist(σs, bins=50, density=True, alpha=0.7)

    axs[0, 0].set_ylabel('ρ')
    axs[1, 0].set_ylabel('σ')
    axs[0, 1].set_xlabel('ρ')
    axs[1, 1].set_xlabel('σ')
    plt.show()
```

The first model uses the conditioning assumption.

```
def AR1_model(data):
    # Set prior
    ρ = numpyro.sample('rho', dist.Uniform(low=-1., high=1.))
    σ = numpyro.sample('sigma', dist.HalfNormal(scale=np.sqrt(10)))

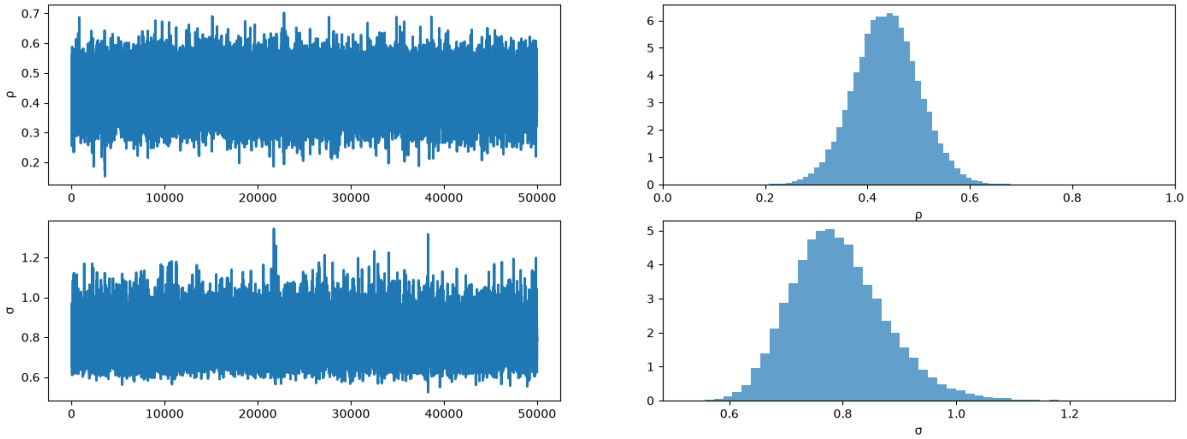
    # Expected value of y at the next period (ρ * y)
    yhat = ρ * data[:-1]

    # Likelihood of the actual realization
    y_data = numpyro.sample('y_obs', dist.Normal(loc=yhat, scale=σ), obs=data[1:])
```

We convert the data to a JAX array, build the NUTS sampler, and run MCMC.

```
# Make jnp array
y = jnp.array(y)
```

(continues on next page)



(continued from previous page)

```
# Set NUTS kernel
NUTS_kernel = numpyro.infer.NUTS(AR1_model)

# Run MCMC
mcmc = numpyro.infer.MCMC(NUTS_kernel, num_samples=50000, num_warmup=10000, progress_
↪bar=False)
mcmc.run(rng_key=random.key(1), data=y)
```

We plot the trace and posterior.

```
plot_posterior(mcmc.get_samples())
```

Here is the posterior summary.

```
mcmc.print_summary()
```

```
                mean       std    median      5.0%      95.0%      n_eff      r_hat
       rho      0.44      0.06      0.44      0.33       0.54   32818.11       1.00
     sigma      0.79      0.08      0.79      0.66       0.93   31929.88       1.00

Number of divergences: 0
```

Next we use the stationary assumption, where

$$y_0 \sim N\left(0, \frac{\sigma_x^2}{1-\rho^2}\right).$$

Here's the new code to achieve this.

```
def AR1_model_y0(data):
    # Set prior
    ρ = numpyro.sample('rho', dist.Uniform(low=-1., high=1.))
    σ = numpyro.sample('sigma', dist.HalfNormal(scale=np.sqrt(10)))

    # Standard deviation of the stationary distribution
    y_sd = σ / jnp.sqrt(1 - ρ**2)

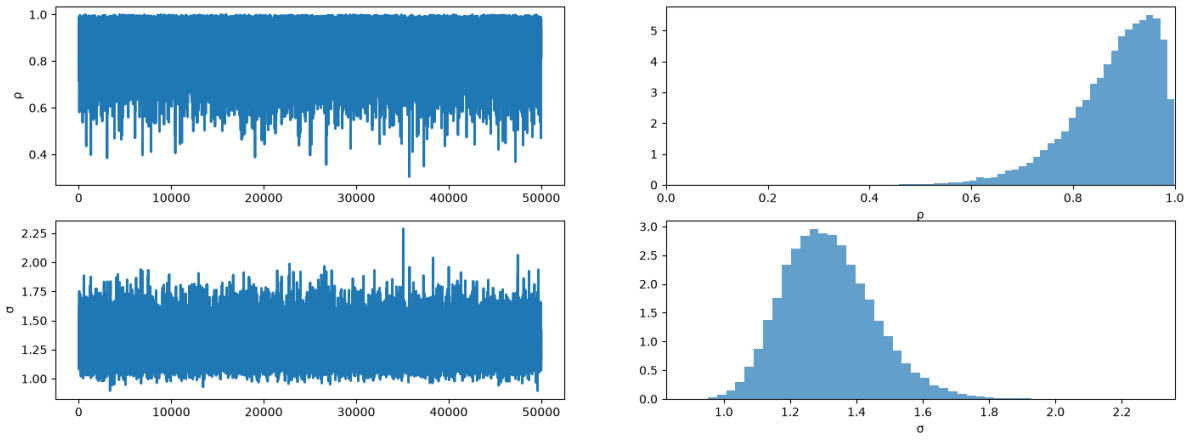
    # Expected value of y at the next period (ρ * y)
    yhat = ρ * data[:-1]
```

(continues on next page)

(continued from previous page)

```
    # Likelihood of the actual realization
    y_data = numpyro.sample('y_obs', dist.Normal(loc=yhat, scale=σ), obs=data[1:])

    # Density for y0 -- this term imposes the stationary assumption
    y0_data = numpyro.sample('y0_obs', dist.Normal(loc=0., scale=y_sd), obs=data[0])
```



We build the sampler for this model and run MCMC.

```
# Set NUTS kernel
NUTS_kernel = numpyro.infer.NUTS(AR1_model_y0)

# Run MCMC
mcmc2 = numpyro.infer.MCMC(NUTS_kernel, num_samples=50000, num_warmup=10000, progress_
↪bar=False)
mcmc2.run(rng_key=random.key(1), data=y)
```

Again we plot the trace and posterior.

```
plot_posterior(mcmc2.get_samples())
```

And here is the posterior summary.

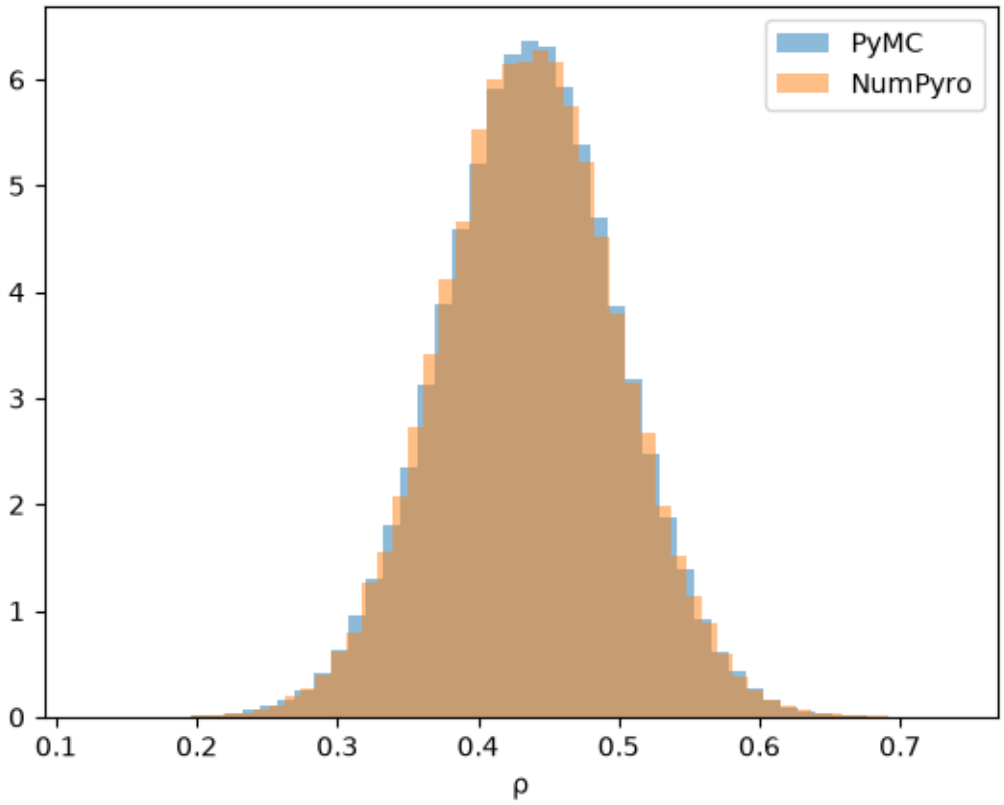
```
mcmc2.print_summary()
```

```
                mean       std    median      5.0%      95.0%     n_eff     r_hat
       rho       0.88      0.09      0.90      0.76       1.00  32252.54      1.00
     sigma       1.32      0.14      1.31      1.09       1.53  24007.40      1.00

Number of divergences: 0
```

As with PyMC, the posterior for ρ shifts toward 1 once we switch to the stationary assumption.

To confirm that the two libraries agree, we overlay their posteriors for ρ under the conditioning assumption.



```
ρ_pymc = trace.posterior['rho'].values.flatten()
ρ_numpyro = np.array(mcmc.get_samples()['rho'])

fig, ax = plt.subplots()
ax.hist(ρ_pymc, bins=50, density=True, alpha=0.5, label='PyMC')
ax.hist(ρ_numpyro, bins=50, density=True, alpha=0.5, label='NumPyro')
ax.set_xlabel('ρ')
```

(continues on next page)

(continued from previous page)

```
ax.legend()
plt.show()
```

The two posteriors line up, as they should.

19.3 Conclusion

This lecture showed that what we assume about the initial value y_0 can have a large effect on our estimates of an AR(1) process.

When the sample is short and y_0 might be unusual, the conditioning assumption is the safer choice.

It lets the data speak about ρ and σ_x without forcing the model to explain the starting value.

The stationary assumption adds information, and that information is valuable when the assumption is true.

But when y_0 is in fact far from typical, the same assumption misleads us — here it pushed ρ toward 1 and away from the truth.

A simple rule of thumb:

- use the conditioning assumption when early observations look transient or the starting point may be atypical;
- use the stationary assumption when you are confident the process has been running near its long-run behaviour.

See also

Forecasting an AR(1) Process builds on the posterior computed here to forecast nonlinear sample-path statistics of an AR(1) process, such as the time until the next turning point.

CHAPTER

TWENTY

FORECASTING AN AR(1) PROCESS

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

```
!pip install numpyro jax arviz
```

This lecture describes methods for forecasting statistics that are functions of future values of a univariate autoregressive process.

The methods are designed to take into account two possible sources of uncertainty about these statistics:

- random shocks that impinge on the transition law
- uncertainty about the parameter values of the AR(1) process

We consider two sorts of statistics:

- prospective values y_{t+j} of a random process $\{y_t\}$ that is governed by the AR(1) process
- sample path properties that are defined as non-linear functions of future values $\{y_{t+j}\}_{j\geq 1}$ at time t

Sample path properties are things like "time to next turning point" or "time to next recession".

To investigate sample path properties we'll use a simulation procedure recommended by Wecker [Wecker, 1979].

To acknowledge uncertainty about parameters, we'll deploy `numpyro` to construct a Bayesian joint posterior distribution for unknown parameters.

This lecture builds on *Posterior Distributions for AR(1) Parameters*, which studies Bayesian inference for the parameters of exactly this AR(1) model in detail.

We recommend reading that lecture first, since here we treat the construction of the posterior more briefly.

Let's start with some imports.

```
import matplotlib.pyplot as plt
import seaborn as sns
from typing import NamedTuple

# numpyro
```

(continues on next page)

(continued from previous page)

```
import numpyro
import numpyro.distributions as dist
from numpyro.infer import MCMC, NUTS

# jax
import jax
import jax.random as random
import jax.numpy as jnp
from jax import lax

# arviz
import arviz as az

sns.set_style('white')
key = random.PRNGKey(0)
```

20.1 A Univariate First-Order Autoregressive Process

Consider the univariate AR(1) model, which is the same model studied in *Posterior Distributions for AR(1) Parameters*:

$$y_{t+1} = \rho y_t + \sigma \epsilon_{t+1}, \quad t \geq 0 \tag{20.1}$$

where

- the scalars ρ and σ satisfy $|\rho| < 1$ and $\sigma > 0$
- $\{\epsilon_{t+1}\}$ is a sequence of IID normal random variables with mean 0 and variance 1.

The initial condition y_0 is a known number.

Equation (20.1) implies that for $t \geq 0$, the conditional density of y_{t+1} is

$$f(y_{t+1}|y_t; \rho, \sigma) \sim \mathcal{N}(\rho y_t, \sigma^2) \tag{20.2}$$

Further, equation (20.1) also implies that for $t \geq 0$, the conditional density of y_{t+j} for $j \geq 1$ is

$$f(y_{t+j}|y_t; \rho, \sigma) \sim \mathcal{N}\left(\rho^j y_t, \sigma^2 \frac{1-\rho^{2j}}{1-\rho^2}\right) \tag{20.3}$$

The predictive distribution (20.3) assumes that the parameters ρ, σ are known, which we express by conditioning on them.

We also want to compute a predictive distribution that does not condition on ρ, σ but instead takes account of our uncertainty about them.

We form this predictive distribution by integrating (20.3) with respect to a joint posterior distribution $\pi_t(\rho, \sigma|y^t)$ that conditions on an observed history $y^t = \{y_s\}_{s=0}^t$:

$$\begin{aligned} f(y_{t+j}|y^t) &= \int f(y_{t+j}|y^t, \rho, \sigma)\pi_t(\rho, \sigma|y^t)d\rho d\sigma \\ &= \int f(y_{t+j}|y_t, \rho, \sigma)\pi_t(\rho, \sigma|y^t)d\rho d\sigma \end{aligned} \tag{20.4}$$

Predictive distribution (20.3) assumes that parameters (ρ, σ) are known.

Predictive distribution (20.4) assumes that parameters (ρ, σ) are uncertain, but have a known probability distribution $\pi_t(\rho, \sigma|y^t)$. Notice the second equality follows because $\{y_t\}$ is an AR(1) process when (ρ, σ) are given.

We also want to compute some predictive distributions of "sample path statistics" that might include, for example

- the time until the next "recession",
- the minimum value of Y over the next 8 periods,
- "severe recession", and
- the time until the next turning point (positive or negative).

To accomplish that for situations in which we are uncertain about parameter values, we shall extend Wecker's [Wecker, 1979] approach in the following way.

- first simulate an initial path of length T_0;
- for a given prior, draw a sample of size N from the posterior joint distribution of parameters (ρ, σ) after observing the initial path;
- for each draw $n = 0, 1, ..., N$, simulate a "future path" of length T_1 with parameters (ρ_n, σ_n) and compute our "sample path statistics";
- finally, plot the desired statistics from the N samples as an empirical distribution.

20.2 Implementation

First, we'll simulate a sample path from which to launch our forecasts.

In addition to plotting the sample path, under the assumption that the true parameter values are known, we'll plot 0.9 and 0.95 coverage intervals using conditional distribution (20.3) described above.

We'll also plot a bunch of samples of sequences of future values and watch where they fall relative to the coverage interval.

```
class AR1(NamedTuple):
    """
    Represents a univariate first-order autoregressive (AR(1)) process.

    Parameters
    ----------
    ρ : float
        Autoregressive coefficient, must satisfy |ρ| < 1 for stationarity.
    σ : float
        Standard deviation of the error term.
    y0 : float
        Initial value of the process at time t=0.
    T0 : int, optional
        Length of the initial observed path (default is 100).
    T1 : int, optional
        Length of the future path to simulate (default is 100).
    """
    ρ: float
    σ: float
    y0: float
    T0: int = 100
    T1: int = 100
```

We create instances through a factory function that validates the parameters.

```
def create_ar1(ρ=0.9, σ=1.0, y0=10.0, T0=100, T1=100):
    """Create an AR(1) instance, checking the parameter restrictions."""
    if not abs(ρ) < 1:
        raise ValueError("ρ must satisfy |ρ| < 1 for stationarity")
```

(continues on next page)

(continued from previous page)

```
    if not σ > 0:
        raise ValueError("σ must be positive")
    return AR1(ρ=ρ, σ=σ, y0=y0, T0=T0, T1=T1)
```

Using the `AR1` class, we can simulate paths more conveniently. The following function simulates an initial path of length T_0.

```
def AR1_simulate_past(ar1: AR1, key=key):
    """
    Simulate a realization of the AR(1) process for T0 periods.

    Parameters
    ----------
    ar1 : AR1
        AR1 named tuple containing parameters (ρ, σ, y0, T0, T1).
    key : jax.random.PRNGKey
        JAX random key for generating random noise.

    Returns
    -------
    initial_path : jax.numpy.ndarray
        Simulated path of the AR(1) process and the initial y0.
    """
    ρ, σ, y0, T0 = ar1.ρ, ar1.σ, ar1.y0, ar1.T0
    # Draw εs
    ε = σ * random.normal(key, (T0,))

    # Set step function
    def ar1_step(y_prev, t_ρ_ε):
        ρ, ε_t = t_ρ_ε
        y_t = ρ * y_prev + ε_t
        return y_t, y_t

    # Scan over time steps
    _, y_seq = lax.scan(ar1_step, y0, (jnp.full(T0, ρ), ε))

    # Concatenate initial value
    initial_path = jnp.concatenate([jnp.array([y0]), y_seq])

    return initial_path
```

Now we define the simulation function that generates a realization of the AR(1) process for the future T_1 periods.

```
def AR1_simulate_future(ar1: AR1, y_T0, N=10, key=key):
    """
    Simulate a realization of the AR(1) process for T1 periods.

    Parameters
    ----------
    ar1 : AR1
        AR1 named tuple containing parameters (ρ, σ, y0, T0, T1).
    y_T0 : float
        Value of the process at time T0.
    N: int
        Number of paths to simulate.
    key : jax.random.PRNGKey
        JAX random key for generating random noise.
```

(continues on next page)

(continued from previous page)

```
    Returns
    -------
    future_path : jax.numpy.ndarray
        Simulated N paths of the AR(1) process of length T1.
    """
    ρ, σ, T1 = ar1.ρ, ar1.σ, ar1.T1

    def single_path_scan(y_T0, subkey):
        ε = σ * random.normal(subkey, (T1,))

        def ar1_step(y_prev, t_ρ_ε):
            ρ, ε_t = t_ρ_ε
            y_t = ρ * y_prev + ε_t
            return y_t, y_t
        _, y = lax.scan(ar1_step, y_T0, (jnp.full(T1, ρ), ε))
        return y

    # Split key to generate different paths
    subkeys = random.split(key, num=N)

    # Simulate N paths
    future_path = jax.vmap(single_path_scan, in_axes=(None, 0))(y_T0, subkeys)

    return future_path
```

The following function plots the initial observed AR(1) path and simulated future paths along with predictive confidence intervals.

```
def plot_path(ar1, initial_path, future_path, ax, key=key):
    """
    Plot the initial observed AR(1) path and simulated future paths,
    along with predictive confidence intervals.

    Parameters
    ----------
    ar1 : AR1
        AR1 named tuple containing process parameters (ρ, σ, T0, T1).
    initial_path : array-like
        Simulated initial path of the AR(1) process, shape(T0+1,).
    future_path : array-like
        Simulated future paths of the AR(1) process, shape (N, T1).
    ax : matplotlib.axes.Axes
        Matplotlib axes object to plot on.
    key : jax.random.PRNGKey, optional
        JAX random key for reproducible sampling.

    Plots
    -----
    - Initial path (historical data)
    - Multiple simulated future paths
    - 90% and 95% predictive confidence intervals
    - Expected future path
    """
    ρ, σ, T0, T1 = ar1.ρ, ar1.σ, ar1.T0, ar1.T1

    # Compute moments and confidence intervals
```

(continues on next page)

(continued from previous page)

```
    y_T0 = initial_path[-1]
    j = jnp.arange(1, T1+1)
    center = ρ**j * y_T0
    vars = σ**2 * (1 - ρ**(2 * j)) / (1 - ρ**2)

initial_path = AR1_simulate_past(ar1)
future_path = AR1_simulate_future(ar1, initial_path[-1])

# Plot
fig, ax = plt.subplots(1, 1)
plot_path(ar1, initial_path, future_path, ax)
plt.show()
```

As functions of forecast horizon, the coverage intervals have shapes like those described in *Permanent Income II: LQ Techniques*

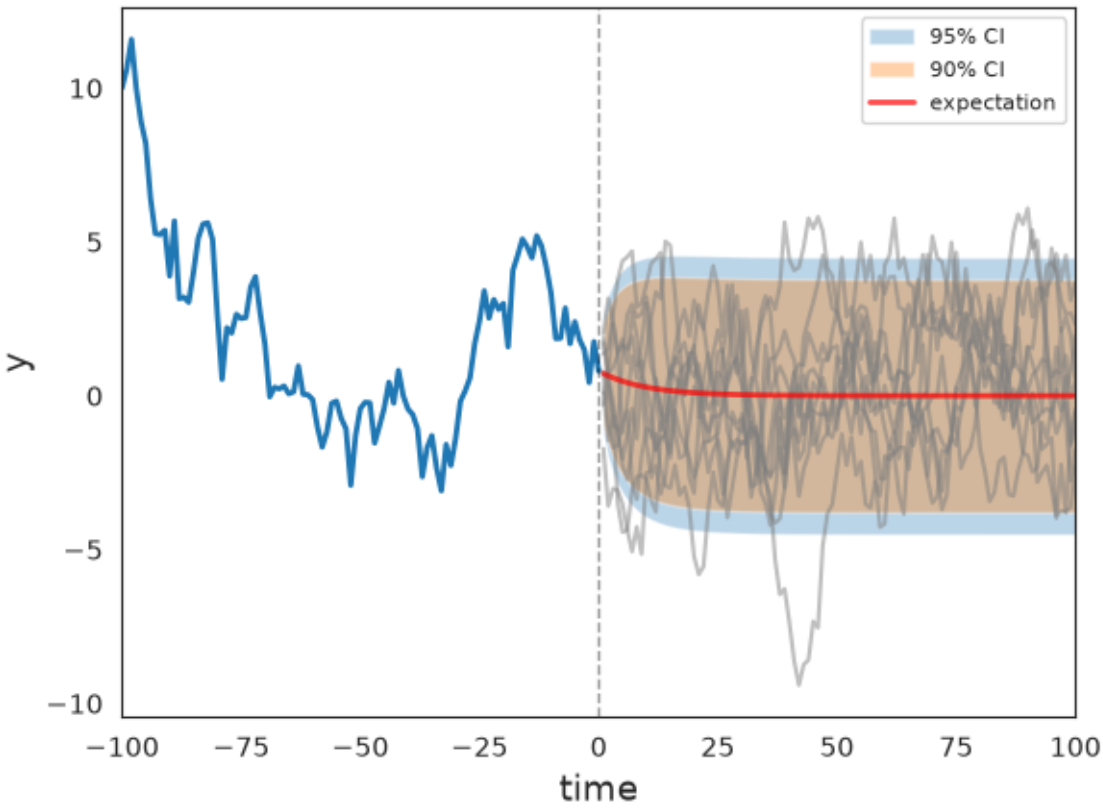

Fig. 20.1: Initial and predictive future paths

20.3 Predictive Distributions of Path Properties

Wecker [Wecker, 1979] proposed using simulation techniques to characterize the predictive distribution of some statistics that are non-linear functions of y.

He called these functions "path properties" to contrast them with properties of single data points.

He studied two special prospective path properties of a given series $\{y_t\}$.

The first was *time until the next turning point*.

- he defined a **"turning point"** to be the date of the second of two successive declines in y.

For example, if $y_t(\omega) < y_{t-1}(\omega) < y_{t-2}(\omega)$, then period t is a turning point.

To examine the *time until the next turning point*, let Z be an indicator process

$$Z_t(\omega) := \begin{cases} 1 & \text{if } Y_t(\omega) < Y_{t-1}(\omega) < Y_{t-2}(\omega) \geq Y_{t-3}(\omega) \\ 0 & \text{otherwise} \end{cases}$$

Here $\omega \in \Omega$ is a sequence of events, and $Y_t : \Omega \to \mathbb{R}$ gives y_t according to ω and the AR(1) process.

By Wecker's definition, period t is a turning point, and $Y_{t-2}(\omega) \geq Y_{t-3}(\omega)$ excludes the possibility that period $t-1$ is a turning point.

Then the random variable **time until the next turning point** is defined as the following *stopping time* with respect to Z:

$$W_t(\omega) := \inf\{k \geq 1 \mid Z_{t+k}(\omega) = 1\}$$

In the following code, we name this statistic *time until the next recession* to distinguish it from another concept of *turning point*.

Moreover, the statistic *time until the next severe recession* is defined in a similar way, except the decline between periods is greater than 0.02.

Wecker [Wecker, 1979] also studied **the minimum value of Y over the next 8 quarters**, which can be defined as the random variable

$$M_t(\omega) := \min\{Y_{t+1}(\omega); Y_{t+2}(\omega); \dots; Y_{t+8}(\omega)\}$$

It is interesting to study yet another possible concept of a **turning point**.

Thus, let

$$T_t(\omega) := \begin{cases} 1 & \text{if } Y_{t-2}(\omega) > Y_{t-1}(\omega) > Y_t(\omega) \text{ and } Y_t(\omega) < Y_{t+1}(\omega) < Y_{t+2}(\omega) \\ -1 & \text{if } Y_{t-2}(\omega) < Y_{t-1}(\omega) < Y_t(\omega) \text{ and } Y_t(\omega) > Y_{t+1}(\omega) > Y_{t+2}(\omega) \\ 0 & \text{otherwise} \end{cases}$$

Define a **positive turning point today or tomorrow** statistic as

$$P_t(\omega) := \begin{cases} 1 & \text{if } T_t(\omega) = 1 \text{ or } T_{t+1}(\omega) = 1 \\ 0 & \text{otherwise} \end{cases}$$

This is designed to express the event

- "after one or two decrease(s), Y will grow for two consecutive quarters"

The **negative turning point today or tomorrow** N_t is defined in the same way.

Following [Wecker, 1979], we can use simulations to calculate probabilities of P_t and N_t for each period t.

However, in the following code, we only use $T_{t+1}(\omega) = 1$ to determine $P_t(\omega)$ and $N_t(\omega)$, because we only want to find the first positive turning point.

20.4 A Wecker-Like Algorithm

The procedure consists of the following steps:

- index a sample path by ω_i
- from a given date t, simulate I sample paths of length N

$$Y(\omega_i) = \{Y_{t+1}(\omega_i), Y_{t+2}(\omega_i), \dots, Y_{t+N}(\omega_i)\}_{i=1}^{I}$$

- for each path ω_i, compute the associated value of $W_t(\omega_i), W_{t+1}(\omega_i), \dots, W_{t+N}$
- consider the sets $\{W_t(\omega_i)\}_{i=1}^{I}$, $\{W_{t+1}(\omega_i)\}_{i=1}^{I}$, ..., $\{W_{t+N}(\omega_i)\}_{i=1}^{I}$ as samples from the predictive distributions $f(W_{t+1} \mid y_t, y_{t-1}, \dots, y_0)$, $f(W_{t+2} \mid y_t, y_{t-1}, \dots, y_0)$, ..., $f(W_{t+N} \mid y_t, y_{t-1}, \dots, y_0)$.

20.5 Using Simulations to Approximate a Posterior Distribution

The next code cells use `numpyro` to compute the time t posterior distribution of ρ, σ.

We construct this posterior just as in *Posterior Distributions for AR(1) Parameters*, to which we refer for a detailed discussion.

As there, in defining the likelihood function we condition on the initial value y_0.

This is the **conditioning assumption** of *Posterior Distributions for AR(1) Parameters*, and it is the appropriate choice here because our initial path starts from an atypical value $y_0 = 10$.

```
def draw_from_posterior(data, size=10000, dis_plot=True, key=key):
    """Draw a sample of the given size from the posterior distribution."""

    def model(data):
        # Start with priors
        ρ = numpyro.sample('ρ', dist.Uniform(-1, 1))  # Assume stable ρ
        σ = numpyro.sample('σ', dist.HalfNormal(jnp.sqrt(10)))

        # Expected value of y at the next period (ρ * y), conditioning on y_0
        yhat = ρ * data[:-1]

        # Likelihood of the actual realization
        numpyro.sample('y_obs', dist.Normal(yhat, σ), obs=data[1:])

    # Compute posterior distribution of parameters
    nuts_kernel = NUTS(model)

    # Define MCMC class to compute the posteriors
    mcmc = MCMC(
        nuts_kernel,
        num_warmup=5000,
        num_samples=size,
        num_chains=4,  # plot 4 chains in the trace
        progress_bar=False,
        chain_method='vectorized'
    )

    # Run MCMC
    mcmc.run(key, data=data)
```

(continues on next page)

(continued from previous page)

```
    # Get posterior samples
    post_sample = {
        'ρ': mcmc.get_samples()['ρ'],
        'σ': mcmc.get_samples()['σ'],
    }

    # Plot posterior distributions and trace plots
    if dis_plot:
        plot_data = az.from_numpyro(posterior=mcmc)
        az.plot_trace(plot_data, var_names=['ρ', 'σ'])

    return post_sample

post_samples = draw_from_posterior(initial_path)
```

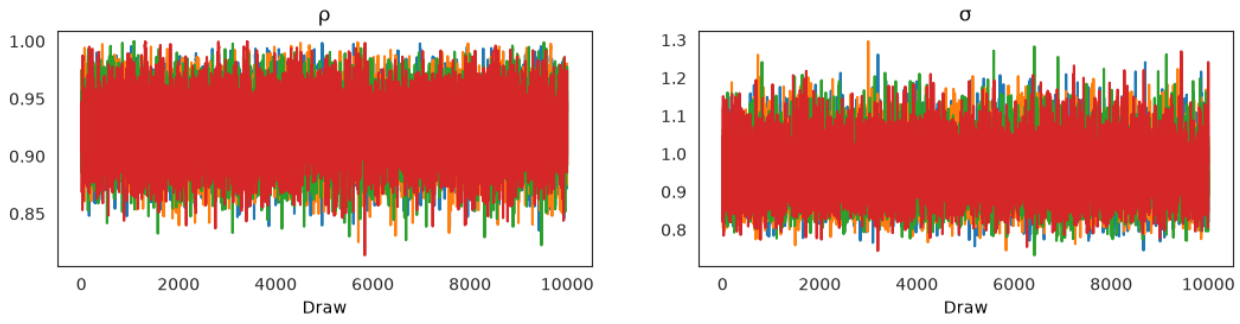

Fig. 20.2: Posterior and trace plots

The graphs above portray posterior distributions and trace plots. The posterior distributions (left column) show the marginal distributions of the parameters after observing the data, while the trace plots (right column) help diagnose MCMC convergence by showing how the sampler explored the parameter space over iterations.

20.6 Calculating Sample Path Statistics

Our next step is to prepare Python code to compute our sample path statistics.

These statistics were originally defined as random variables with respect to ω, but here we use $\{Y_t\}$ as the argument because ω is implicit.

These two kinds of definitions are equivalent because ω determines path statistics only through $\{Y_t\}$.

Moreover, we ignore all equality in the definitions, as equality occurs with zero probability for continuous random variables.

```
@jax.jit
def compute_path_statistics(initial_path, future_path):
    """Compute path statistics for the AR(1) process."""
    # Prepend the last three observed values so we can identify a turn at t=0
    y = jnp.concatenate([initial_path[-3:], future_path])
    n = y.shape[0]
```

(continues on next page)

(continued from previous page)

```
    def step(carry, i):
        # identify recession
        rec_cond = (y[i] < y[i-1]) & (y[i-1] < y[i-2]) & (y[i-2] > y[i-3])
        # identify severe recession
        sev_cond = (
            (y[i] - y[i-1] < -0.02) & (y[i-1] - y[i-2] < -0.02) & (y[i-2] > y[i-3])
            )

        # identify positive turning point
        up_cond = (
            (y[i-2] > y[i-1]) & (y[i-1] > y[i]) & (y[i] < y[i+1]) & (y[i+1] < y[i+2])
        )

        # identify negative turning point
        down_cond = (
            (y[i-2] < y[i-1]) & (y[i-1] < y[i]) & (y[i] > y[i+1]) & (y[i+1] > y[i+2])
        )

        # Convert to int
        rec = jnp.where(rec_cond, 1, 0)
        sev = jnp.where(sev_cond, 1, 0)
        up = jnp.where(up_cond, 1, 0)
        down = jnp.where(down_cond, 1, 0)
        return carry, (rec, sev, up, down)

    _, (rec_seq, sev_seq, up_seq, down_seq) = lax.scan(step, None, jnp.arange(3, n-2))

    # Get the time until the first recession
    next_recession = jnp.where(
        jnp.any(rec_seq == 1), jnp.argmax(rec_seq == 1) + 1, len(y)
    )
    next_severe_recession = jnp.where(
        jnp.any(sev_seq == 1), jnp.argmax(sev_seq == 1) + 1, len(y)
    )

    # Minimum value in the next 8 periods
    min_val_8q = jnp.min(future_path[:8])

    # Get the time until the first turning point
    next_up_turn = jnp.where(
        jnp.any(up_seq == 1),
        jnp.maximum(jnp.argmax(up_seq == 1), 1), # Exclude 0 return
        len(y)
    )
    next_down_turn = jnp.where(
        jnp.any(down_seq == 1),
        jnp.maximum(jnp.argmax(down_seq == 1), 1),
        len(y)
    )
    path_stats = (
        next_recession, next_severe_recession, min_val_8q,
        next_up_turn, next_down_turn
        )
    return path_stats
```

The following function creates visualizations of the path statistics in a subplot grid.

```
def plot_path_stats(next_recession, next_severe_recession, min_val_8q,
                    next_up_turn, next_down_turn, ax, label=None):
    """Plot the path statistics in subplots(3,2)"""
    # ax[0, 0] is for paths of y
    sns.histplot(next_recession, kde=True, stat='density', ax=ax[0, 1],
                 alpha=.8, label=label)
    ax[0, 1].set_xlabel("time until the next recession", fontsize=13)

    sns.histplot(next_severe_recession, kde=True, stat='density', ax=ax[1, 0],
                 alpha=.8, label=label)

    sns.histplot(min_val_8q, kde=True, stat='density', ax=ax[1, 1],
                 alpha=.8, label=label)
    ax[1, 1].set_xlabel("minimum value in next 8 periods", fontsize=13)

    sns.histplot(next_up_turn, kde=True, stat='density', ax=ax[2, 0],
                 alpha=.8, label=label)
    ax[2, 0].set_xlabel("time until the next positive turn", fontsize=13)

    sns.histplot(next_down_turn, kde=True, stat='density', ax=ax[2, 1],
                 alpha=.8, label=label)
    ax[2, 1].set_xlabel("time until the next negative turn", fontsize=13)
```

20.7 Original Wecker Method

Now we apply Wecker's original method by simulating future paths and compute predictive distributions, conditioning on the true parameters associated with the data-generating model.

```
def plot_Wecker(ar1: AR1, initial_path, ax, N=1000, label='true parameters'):
    """
    Plot the predictive distributions from "pure" Wecker's method.

    Parameters
    ----------
    ar1 : AR1
        An AR1 named tuple containing the process parameters (ρ, σ, T0, T1).
    initial_path : array-like
        The initial observed path of the AR(1) process.
    N : int
        Number of future sample paths to simulate for predictive distributions.
    label : str
        Legend label for the plotted distributions.
    """
    # Plot simulated initial and future paths
    y_T0 = initial_path[-1]
    future_path = AR1_simulate_future(ar1, y_T0, N=N)
    plot_path(ar1, initial_path, future_path, ax[0, 0])

    next_reces = jnp.zeros(N)
    severe_rec = jnp.zeros(N)
    min_val_8q = jnp.zeros(N)
    next_up_turn = jnp.zeros(N)
    next_down_turn = jnp.zeros(N)
```

(continues on next page)

(continued from previous page)

```
    # Simulate future paths and compute statistics
    for n in range(N):
        future_temp = future_path[n, :]
        (next_reces_val, severe_rec_val, min_val_8q_val,
        next_up_turn_val, next_down_turn_val
         ) = compute_path_statistics(initial_path, future_temp)

        next_reces = next_reces.at[n].set(next_reces_val)
        severe_rec = severe_rec.at[n].set(severe_rec_val)
        min_val_8q = min_val_8q.at[n].set(min_val_8q_val)
        next_up_turn = next_up_turn.at[n].set(next_up_turn_val)
        next_down_turn = next_down_turn.at[n].set(next_down_turn_val)

    # Plot path statistics
    plot_path_stats(next_reces, severe_rec, min_val_8q,
                    next_up_turn, next_down_turn, ax, label=label)

fig, ax = plt.subplots(3, 2, figsize=(15, 12))
plot_Wecker(ar1, initial_path, ax)
plt.show()
```

Apart from the top-left panel, which repeats the initial path and coverage intervals, each panel shows the predictive distribution of one sample path statistic.

These are computed by simulating many future paths with the parameters held fixed at their true values.

The distributions therefore reflect only the uncertainty that comes from future shocks.

20.8 Extended Wecker Method

Now we apply our "extended" Wecker method based on predictive densities of y defined by (20.4) that acknowledge posterior uncertainty in the parameters ρ, σ.

To approximate the integration on the right side of (20.4), we repeatedly draw parameters from the joint posterior distribution each time we simulate a sequence of future values from model (20.1).

```
def plot_extended_Wecker(
    ar1: AR1, post_samples, initial_path, ax, N=1000,
    label='sampling from posterior'
    ):
    """Plot the extended Wecker's predictive distribution"""
    y0, T1 = ar1.y0, ar1.T1
    y_T0 = initial_path[-1]

    # Select a parameter sample
    index = random.choice(
        key, jnp.arange(len(post_samples['ρ'])), (N,), replace=False
        )
    ρ_sample = post_samples['ρ'][index]
    σ_sample = post_samples['σ'][index]

    # Compute path statistics
```

(continues on next page)

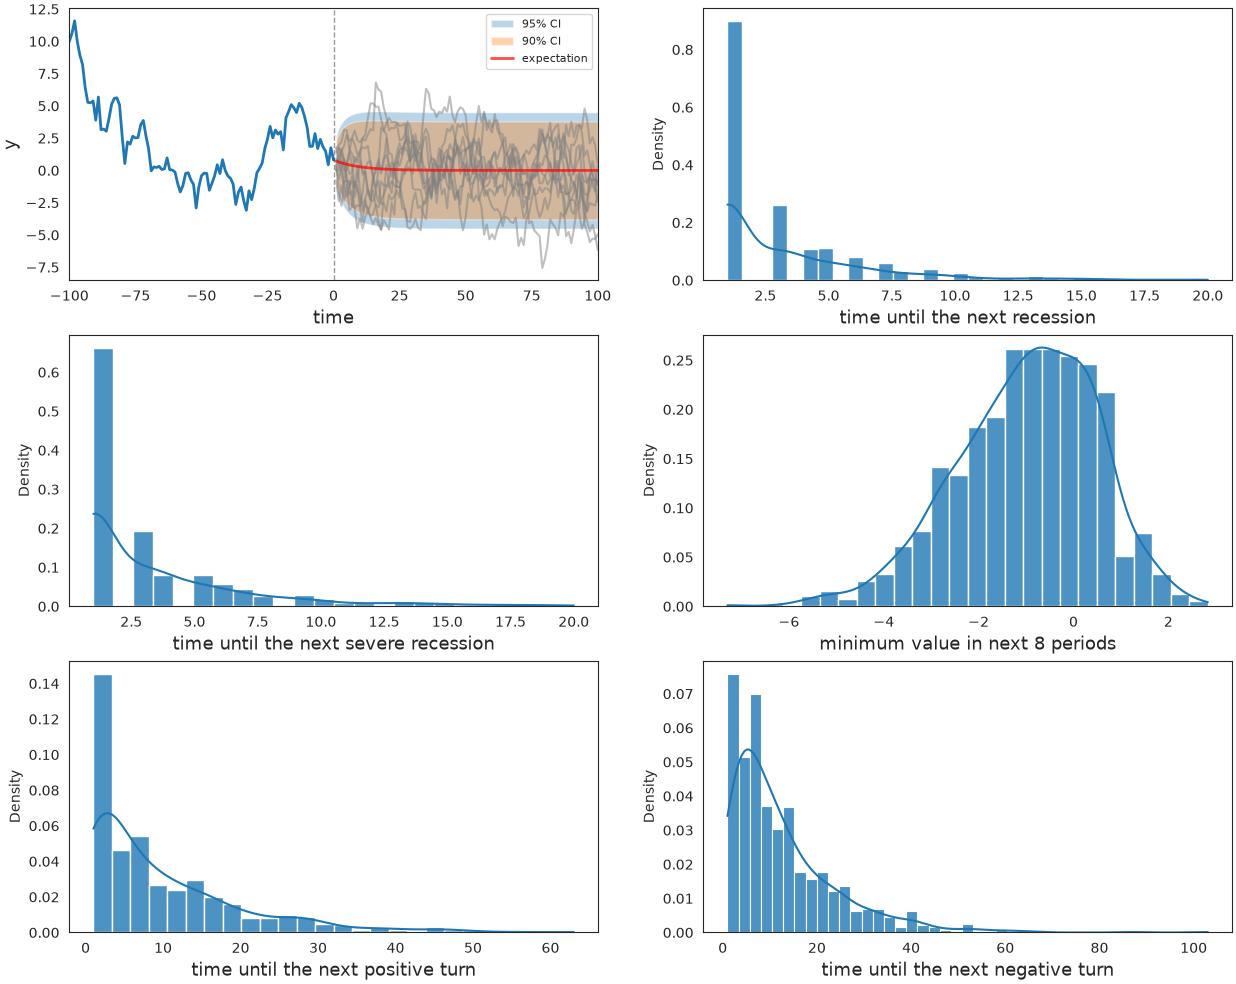

Fig. 20.3: Distributions from Wecker's method

(continued from previous page)

```
    next_reces = jnp.zeros(N)
    severe_rec = jnp.zeros(N)
    min_val_8q = jnp.zeros(N)
    next_up_turn = jnp.zeros(N)
    next_down_turn = jnp.zeros(N)

    subkeys = random.split(key, num=N)

    # Simulate one future path per posterior draw
    future_paths = []
    for n in range(N):
        ar1_n = AR1(ρ=ρ_sample[n], σ=σ_sample[n], y0=y0, T1=T1)
        future_temp = AR1_simulate_future(
            ar1_n, y_T0, N=1, key=subkeys[n]
            ).reshape(-1)
        future_paths.append(future_temp)
        (next_reces_val, severe_rec_val, min_val_8q_val,
        next_up_turn_val, next_down_turn_val
         ) = compute_path_statistics(initial_path, future_temp)

        next_reces = next_reces.at[n].set(next_reces_val)
        severe_rec = severe_rec.at[n].set(severe_rec_val)
        min_val_8q = min_val_8q.at[n].set(min_val_8q_val)
        next_up_turn = next_up_turn.at[n].set(next_up_turn_val)
        next_down_turn = next_down_turn.at[n].set(next_down_turn_val)

    # Plot the initial path and the future paths drawn from the posterior
    future_paths = jnp.stack(future_paths)
    plot_path(ar1, initial_path, future_paths, ax[0, 0])

    # Plot path statistics
    plot_path_stats(next_reces, severe_rec, min_val_8q,
                    next_up_turn, next_down_turn, ax, label=label)

fig, ax = plt.subplots(3, 2, figsize=(12, 15))
plot_extended_Wecker(ar1, post_samples, initial_path, ax)
plt.show()
```

The panels show the same statistics, but now each future path is simulated with parameters drawn from the posterior.

These distributions therefore combine two sources of uncertainty: randomness in future shocks and our uncertainty about (ρ, σ).

20.9 Comparison

Finally, we plot both the original Wecker method and the extended method with parameter values drawn from the posterior together to compare the differences that emerge from pretending to know parameter values when they are actually uncertain.

```
fig, ax = plt.subplots(3, 2, figsize=(12, 15))
plot_Wecker(ar1, initial_path, ax)
ax[0, 0].clear()
plot_extended_Wecker(ar1, post_samples, initial_path, ax)
```

(continues on next page)

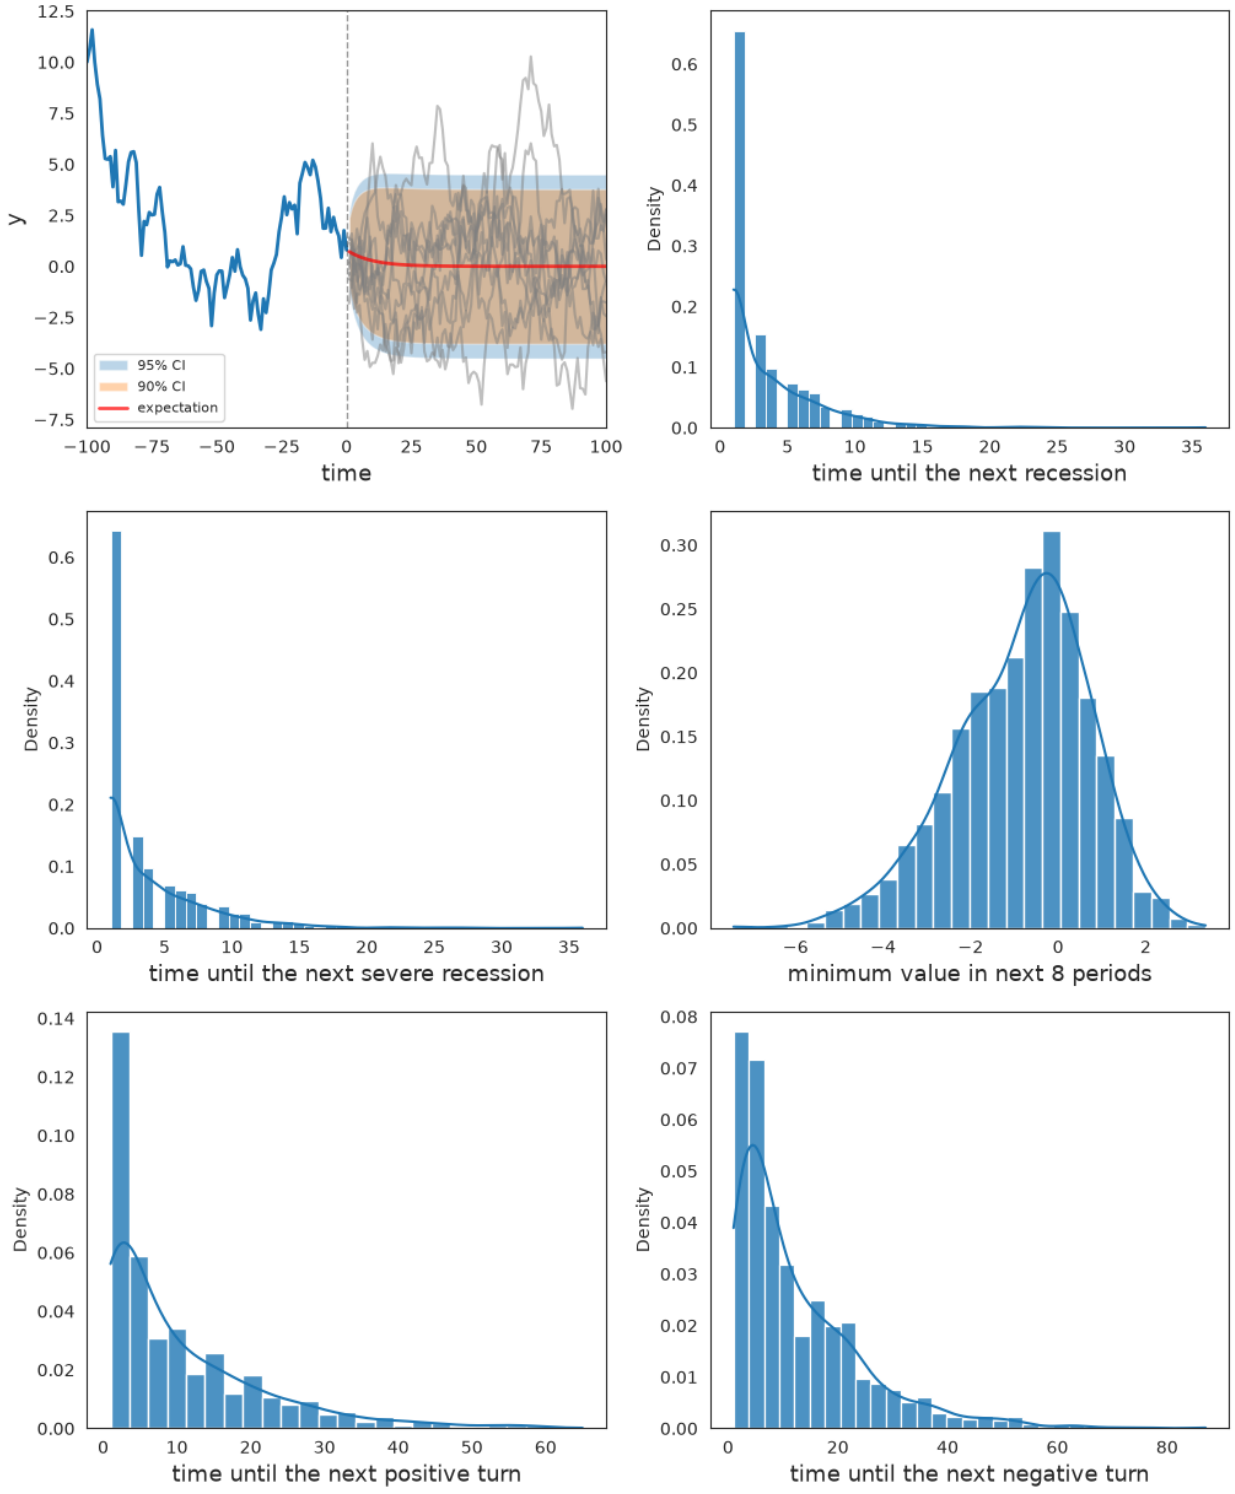

Fig. 20.4: Distributions from extended Wecker's method

(continued from previous page)

```
ax[0, 1].legend(fontsize=10)
plt.show()
```

The two sets of predictive distributions reveal the cost of pretending that we know the parameters.

The extended Wecker method draws (ρ, σ) from their posterior each time it simulates a future path.

It therefore layers parameter uncertainty on top of the shock uncertainty already present in the original method.

As a result, its predictive distributions are more dispersed than those computed with the parameters fixed at their true values.

20.10 Conclusion

This lecture combined two tools to forecast nonlinear functions of the future path of an AR(1) process.

Wecker's simulation method let us approximate predictive distributions of sample path statistics, such as the time until the next turning point.

A Bayesian posterior over (ρ, σ), computed as in *Posterior Distributions for AR(1) Parameters*, let us also account for our uncertainty about the parameters that govern the process.

Putting these together, the extended Wecker method produces predictive distributions that reflect both sources of uncertainty identified at the outset.

Ignoring parameter uncertainty, as the original Wecker method does, yields tighter distributions that overstate how much we really know about these future statistics.

21.1 Overview

A statistical divergence quantifies discrepancies between two distinct probability distributions that can be challenging to distinguish for the following reason:

- every event that has positive probability under one of the distributions also has positive probability under the other distribution
- this means that there is no "smoking gun" event whose occurrence tells a statistician that one of the probability distributions surely governs the data

A statistical divergence is a **function** that maps two probability distributions into a number in $[0, +\infty]$.

The number is zero if and only if the two distributions are equal.

Statistical divergence functions play important roles in statistics, information theory, and what many people now call "machine learning".

This lecture describes three divergence measures:

- **Kullback–Leibler (KL) divergence**

- **Jensen–Shannon (JS) divergence**
- **Chernoff entropy**

These will appear in several quantecon lectures.

Let's start by importing the necessary Python tools.

```
import matplotlib.pyplot as plt
import numpy as np
from numba import vectorize, jit
from math import gamma
from scipy.integrate import quad
from scipy.optimize import minimize_scalar
from scipy.special import betaln, digamma
from scipy.stats import beta as beta_dist
import pandas as pd
from IPython.display import display, Math
```

21.2 Primer on entropy, cross-entropy, KL divergence

Before diving in, we'll introduce some useful concepts in a simple setting.

We'll temporarily assume that f and g are two probability mass functions for discrete random variables on state space $I = \{1, 2, \ldots, n\}$ that satisfy $f_i \geq 0, \sum_i f_i = 1, g_i \geq 0, \sum_i g_i = 1$.

We follow some statisticians and information theorists who define the **surprise** or **surprisal** associated with having observed a single draw $x = i$ from distribution f as

$$\log\left(\frac{1}{f_i}\right)$$

They then define the **information** that you can anticipate to gather from observing a single realization as the expected surprisal

$$H(f) = \sum_i f_i \log\left(\frac{1}{f_i}\right).$$

Claude Shannon [Shannon, 1948] called $H(f)$ the **entropy** of distribution f.

Note

By maximizing $H(f)$ with respect to $\{f_1, f_2, \ldots, f_n\}$ subject to $\sum_i f_i = 1$, we can verify that the distribution that maximizes entropy is the uniform distribution $f_i = \frac{1}{n}$. Entropy $H(f)$ for the uniform distribution equals $\log n$.

Kullback and Leibler [1951] define the amount of information that a single draw $x = i$ provides for distinguishing f from g as the log likelihood ratio

$$\log\frac{f_i}{g_i}$$

The following two concepts are widely used to compare two distributions f and g.

Cross-Entropy:

$$H(f, g) = -\sum_i f_i \log g_i \tag{21.1}$$

Kullback-Leibler (KL) Divergence:

$$D_{KL}(f \parallel g) = \sum_i f_i \log \left[\frac{f_i}{g_i} \right] \tag{21.2}$$

These concepts are related by the following equality.

$$D_{KL}(f \parallel g) = H(f,g) - H(f) \tag{21.3}$$

To prove (21.3), note that

$$\begin{aligned} D_{KL}(f \parallel g) &= \sum_i f_i \log \left[\frac{f_i}{g_i} \right] && (21.4)\\ &= \sum_i f_i \left[\log f_i - \log g_i \right] && (21.5)\\ &= \sum_i f_i \log f_i - \sum_i f_i \log g_i && (21.6)\\ &= -H(f) + H(f,g) && (21.7)\\ &= H(f,g) - H(f) && (21.8) \end{aligned}$$

Remember that $H(f)$ is the anticipated surprisal from drawing x from f.

The cross-entropy $H(f,g) = \sum_i f_i \log(1/g_i)$ is the anticipated surprisal when x is drawn from f but surprisal is computed with g.

Then the above equation tells us that the KL divergence is an anticipated "excess surprise" that comes from anticipating that x is drawn from g when it is actually drawn from f.

21.3 Two Beta distributions: running example

We'll use Beta distributions extensively to illustrate concepts.

The Beta distribution is particularly convenient as it's defined on $[0,1]$ and exhibits diverse shapes by appropriately choosing its two parameters.

The density of a Beta distribution with parameters a and b is given by

$$f(z;a,b) = \frac{\Gamma(a+b) z^{a-1}(1-z)^{b-1}}{\Gamma(a)\Gamma(b)} \quad \text{where} \quad \Gamma(p) := \int_0^\infty x^{p-1} e^{-x} dx$$

We introduce two Beta distributions $f(x)$ and $g(x)$, which we will use to illustrate the different divergence measures.

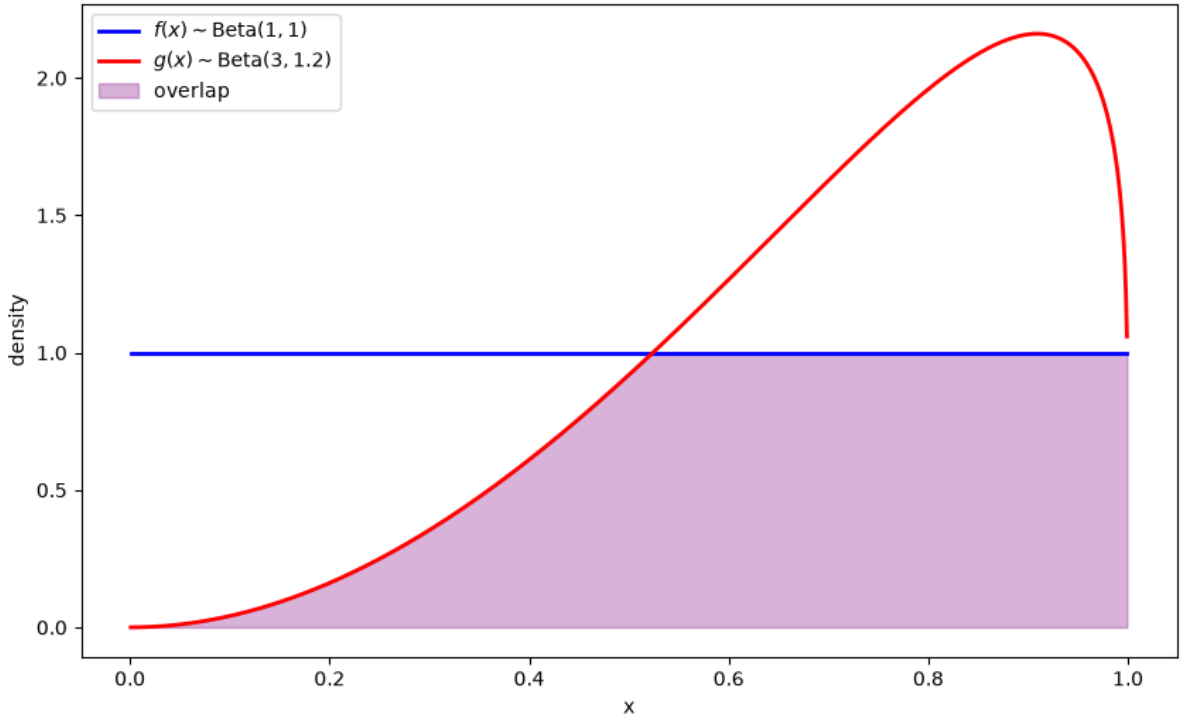
Let's define parameters and density functions in Python

```
# Parameters in the two Beta distributions
F_a, F_b = 1, 1
G_a, G_b = 3, 1.2

@vectorize
def p(x, a, b):
    r = gamma(a + b) / (gamma(a) * gamma(b))
    return r * x** (a-1) * (1 - x) ** (b-1)

# The two density functions
f = jit(lambda x: p(x, F_a, F_b))
g = jit(lambda x: p(x, G_a, G_b))
```

(continues on next page)



(continued from previous page)

```
# Plot the distributions
x_range = np.linspace(0.001, 0.999, 1000)
f_vals = [f(x) for x in x_range]
g_vals = [g(x) for x in x_range]

plt.figure(figsize=(10, 6))
plt.plot(x_range, f_vals, 'b-', linewidth=2, label=r'$f(x) \sim \text{Beta}(1,1)$')
plt.plot(x_range, g_vals, 'r-', linewidth=2, label=r'$g(x) \sim \text{Beta}(3,1.2)$')

# Fill overlap region
overlap = np.minimum(f_vals, g_vals)
plt.fill_between(x_range, 0, overlap, alpha=0.3, color='purple', label='overlap')

plt.xlabel('x')
plt.ylabel('density')
plt.legend()
plt.show()
```

21.4 Kullback–Leibler divergence

Our first divergence function is the **Kullback–Leibler (KL) divergence**.

For probability densities (or pmfs) f and g it is defined by

$$D_{KL}(f\|g) = KL(f,g) = \int f(x) \log \frac{f(x)}{g(x)} \, dx.$$

We can interpret $D_{KL}(f\|g)$ as the expected excess log loss (expected excess surprisal) incurred when we use g while the data are generated by f.

$D_{KL}(f\|g) = +\infty$ unless f is absolutely continuous with respect to g ($f \ll g$), that is, unless $g(x) > 0$ wherever $f(x) > 0$.

It has several important properties:

- Non-negativity (Gibbs' inequality): $D_{KL}(f\|g) \geq 0$ with equality if and only if $f = g$ almost everywhere.
- Asymmetry: $D_{KL}(f\|g) \neq D_{KL}(g\|f)$ in general (hence it is not a metric)
- Information decomposition: $D_{KL}(f\|g) = H(f,g) - H(f)$, where $H(f,g)$ is the cross entropy and $H(f)$ is the Shannon entropy of f.
- Chain rule: For joint distributions $f(x,y)$ and $g(x,y)$, $D_{KL}(f(x,y)\|g(x,y)) = D_{KL}(f(x)\|g(x)) + E_f\left[D_{KL}(f(y|x)\|g(y|x))\right]$
- Data processing inequality: if a Markov kernel κ maps x into a coarser signal y, and $f\kappa$ and $g\kappa$ denote the induced distributions of y, then $D_{KL}(f\kappa\|g\kappa) \leq D_{KL}(f\|g)$.

The data processing inequality says that garbling data cannot make f and g easier to tell apart.

The section on *the data processing inequality and coarse-graining* in *Blackwell's Theorem on Comparing Experiments* connects it to Blackwell's ordering of experiments.

JS divergence and Chernoff entropy, defined below, also satisfy the data processing inequality.

KL divergence plays a central role in statistical inference, including model selection and hypothesis testing.

Likelihood Ratio Processes describes a link between KL divergence and the expected log likelihood ratio.

A Problem that Stumped Milton Friedman connects KL divergence to the expected stopping time of a sequential probability ratio test.

Incorrect Models uses two KL divergences to determine the limit of a Bayesian's posterior probability when the data come from a mixture of f and g that the Bayesian's model excludes.

Let's compute the KL divergence between our example distributions f and g.

A U-shaped Beta density diverges at 0 or 1.

We integrate over all of $(0,1)$ and split the interval at $1/2$ so that `quad` handles one endpoint singularity at a time.

```
def integrate(F):
    """Integrate F over (0, 1), splitting the interval at 1/2."""
    left, _ = quad(F, 0, 0.5, limit=200)
    right, _ = quad(F, 0.5, 1, limit=200)
    return left + right

def compute_KL(f, g):
    """
    Compute KL divergence KL(f, g) via numerical integration
    """
    def integrand(w):
        fw = f(w)
        gw = g(w)
        return fw * np.log(fw / gw)
    return integrate(integrand)

# Compute KL divergences between our example distributions
kl_fg = compute_KL(f, g)
kl_gf = compute_KL(g, f)

print(f"KL(f, g) = {kl_fg:.4f}")
print(f"KL(g, f) = {kl_gf:.4f}")
```

```
KL(f, g) = 0.7592
KL(g, f) = 0.3436
```

The asymmetry of KL divergence has important practical implications.

$D_{KL}(f\|g)$ heavily penalizes regions where $f > 0$ but g is close to zero, because f puts weight on the large values of $\log(f/g)$ there.

$D_{KL}(f\|g)$ barely penalizes regions where $g > 0$ but f is close to zero, because f puts almost no weight there.

$D_{KL}(g\|f)$ reverses these roles.

In our example, g vanishes at $x = 0$ while $f = 1$ there, so $D_{KL}(f\|g)$ exceeds $D_{KL}(g\|f)$.

21.5 Jensen-Shannon divergence

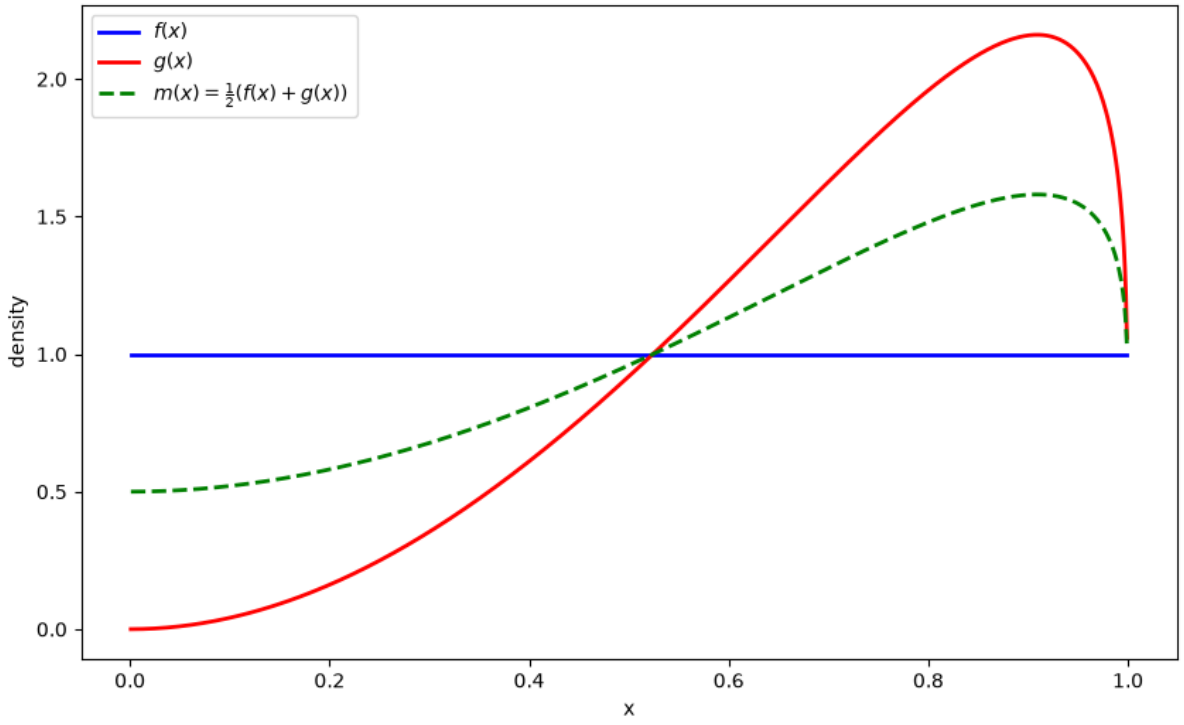
Sometimes we want a symmetric measure of divergence that captures the difference between two distributions without favoring one over the other.

This often arises in applications like clustering, where we want to compare distributions without assuming one is the true model.

The **Jensen-Shannon (JS) divergence** symmetrizes KL divergence by comparing both distributions to their mixture:

$$JS(f, g) = \frac{1}{2} D_{KL}(f\|m) + \frac{1}{2} D_{KL}(g\|m), \quad m = \frac{1}{2}(f + g).$$

where m is a mixture distribution that averages f and g



Let's also visualize the mixture distribution m:

```
def m(x):
    return 0.5 * (f(x) + g(x))

m_vals = [m(x) for x in x_range]

plt.figure(figsize=(10, 6))
plt.plot(x_range, f_vals, 'b-', linewidth=2, label=r'$f(x)$')
plt.plot(x_range, g_vals, 'r-', linewidth=2, label=r'$g(x)$')
plt.plot(x_range, m_vals, 'g--', linewidth=2, label=r'$m(x) = \frac{1}{2}(f(x) + g(x))
↪$')

plt.xlabel('x')
plt.ylabel('density')
plt.legend()
plt.show()
```

The JS divergence has several useful properties:

- Symmetry: $JS(f, g) = JS(g, f)$.
- Boundedness: $0 \leq JS(f, g) \leq \log 2$.
- Its square root $\sqrt{JS}$ is a metric (Jensen–Shannon distance) on the space of probability distributions.
- JS divergence equals the mutual information between a binary random variable $Z \sim \text{Bernoulli}(1/2)$ indicating the source and a sample X drawn from f if $Z = 0$ or from g if $Z = 1$.

The Jensen–Shannon divergence appears in the original formulation of generative adversarial networks: when the discriminator is optimal, the generator minimizes $2\,JS(p_{\text{data}}, p_{\text{model}}) - \log 4$ [Goodfellow *et al.*, 2014].

Boundedness has a cost.

When two distributions have nearly disjoint supports, JS sits near its ceiling $\log 2$ and is nearly flat in the parameters of the model, so gradient-based training stalls [Arjovsky and Bottou, 2017].

Let's compute the JS divergence between our example distributions f and g

```
def compute_JS(f, g):
    """Compute Jensen-Shannon divergence."""
    def integrand(w):
        fw, gw = f(w), g(w)
        mw = 0.5 * (fw + gw)
        return 0.5 * fw * np.log(fw / mw) + 0.5 * gw * np.log(gw / mw)
    return integrate(integrand)

js_div = compute_JS(f, g)
print(f"Jensen-Shannon divergence JS(f,g) = {js_div:.4f}")
```

```
Jensen-Shannon divergence JS(f,g) = 0.0984
```

We can easily generalize to more than two distributions using the generalized Jensen-Shannon divergence with weights $\alpha = (\alpha_i)_{i=1}^n$:

$$JS_\alpha(f_1, \ldots, f_n) = H\left(\sum_{i=1}^n \alpha_i f_i\right) - \sum_{i=1}^n \alpha_i H(f_i)$$

where:

- $\alpha_i \geq 0$ and $\sum_{i=1}^n \alpha_i = 1$, and
- $H(f) = -\int f(x) \log f(x) dx$ is the **differential entropy** of density f

Unlike the entropy of a pmf, differential entropy can be negative: the uniform density on $[0, 1/2]$ has differential entropy $-\log 2$.

JS_α is nonnegative nonetheless, because H is concave.

21.6 Chernoff entropy

Chernoff entropy originates from early applications of the theory of large deviations, which refines central limit approximations by providing exponential decay rates for rare events.

For densities f and g the Chernoff entropy, which Chernoff [1952] introduced and information theorists call the Chernoff information, is

$$C(f, g) = -\log \min_{\phi \in (0,1)} \rho(\phi), \qquad \rho(\phi) = \int f^\phi(x) g^{1-\phi}(x)\, dx.$$

Remarks:

- The integral $\rho(\phi)$ is the **Chernoff coefficient**.
- At $\phi = 1/2$ it becomes the **Bhattacharyya coefficient** $\int \sqrt{fg}$.
- In binary hypothesis testing with T IID observations and equal prior probabilities on f and g, the smallest attainable probability of error $P_e(T)$ decays at exponential rate $C(f, g)$: $-\frac{1}{T} \log P_e(T) \to C(f, g)$.

Merging of Opinions: The Blackwell–Dubins Theorem calls the Bhattacharyya coefficient the Hellinger affinity.

Kakutani's theorem there implies that when $\int \sqrt{fg} < 1$, the distributions of infinite IID sequences drawn from f and from g are mutually singular.

We will see an example of the third point in the lecture *Likelihood Ratio Processes*, where we study the Chernoff entropy in the context of model selection.

Chernoff entropy lies between the Bhattacharyya distance $-\log \int \sqrt{fg}$ and a combination of the two KL divergences:

$$-\log \int \sqrt{fg}\, dx \;\leq\; C(f, g) \;\leq\; \frac{D_{KL}(f\|g)\, D_{KL}(g\|f)}{D_{KL}(f\|g) + D_{KL}(g\|f)} \;\leq\; \min\{D_{KL}(f\|g),\, D_{KL}(g\|f)\}. \tag{21.9}$$

When f and g are positive on the same set, $\log \rho(\phi)$ is a convex function of ϕ that equals 0 at $\phi = 0$ and $\phi = 1$.

Its slope is $-D_{KL}(g\|f)$ at $\phi = 0$ and $D_{KL}(f\|g)$ at $\phi = 1$.

The lower bound in (21.9) evaluates $\log \rho$ at $\phi = 1/2$; the upper bound uses the two tangent lines at the endpoints, which lie below $\log \rho$.

Exercise 21.10.2 asks you to prove these statements.

Let's compute the Chernoff entropy between our example distributions f and g and check the bounds (21.9).

```
def chernoff_integrand(ϕ, f, g):
    """Integral entering Chernoff entropy for a given ϕ."""
    def integrand(w):
        return f(w)**ϕ * g(w)**(1-ϕ)
    return integrate(integrand)

def compute_chernoff_entropy(f, g):
    """Compute Chernoff entropy C(f,g)."""
    def objective(ϕ):
        return chernoff_integrand(ϕ, f, g)
    result = minimize_scalar(objective, bounds=(1e-5, 1-1e-5), method='bounded')
    min_value = result.fun
    ϕ_optimal = result.x
    chernoff_entropy = -np.log(min_value)
    return chernoff_entropy, ϕ_optimal

C_fg, ϕ_optimal = compute_chernoff_entropy(f, g)
print(f"Chernoff entropy C(f,g) = {C_fg:.4f}")
print(f"Optimal ϕ = {ϕ_optimal:.4f}")

bhattacharyya = -np.log(chernoff_integrand(0.5, f, g))
kl_bound = kl_fg * kl_gf / (kl_fg + kl_gf)
print(f"{bhattacharyya:.4f} ≤ {C_fg:.4f} ≤ {kl_bound:.4f} "
      f"≤ {min(kl_fg, kl_gf):.4f}")
```

```
Chernoff entropy C(f,g) = 0.1212
Optimal ϕ = 0.5969
0.1169 ≤ 0.1212 ≤ 0.2365 ≤ 0.3436
```

21.7 Comparing divergence measures

We now compare these measures across several pairs of Beta distributions.

For Beta densities, the KL divergence and the Chernoff coefficient have closed forms.

Let $B(a,b)$ be the Beta function and $\psi = \Gamma'/\Gamma$ the digamma function.

Then

$$D_{KL}(\text{Beta}(a_1,b_1) \,\|\, \text{Beta}(a_2,b_2)) = \log\frac{B(a_2,b_2)}{B(a_1,b_1)} + (a_1-a_2)\psi(a_1) + (b_1-b_2)\psi(b_1) + (a_2-a_1+b_2-b_1)\psi(a_1+b_1)$$

and

$$\rho(\phi) = \frac{B(\phi a_1 + (1-\phi)a_2,\ \phi b_1 + (1-\phi)b_2)}{B(a_1,b_1)^{\phi}\, B(a_2,b_2)^{1-\phi}}.$$

Exercise 21.10.1 asks you to derive these formulas.

JS divergence has no closed form, so we compute it by numerical integration over $(0,1)$.

The integration must cover the whole interval: $\text{Beta}(0.1,0.2)$ puts a quarter of its probability mass outside $[10^{-5}, 1-10^{-5}]$.

```
def KL_beta(a1, b1, a2, b2):
    """KL(Beta(a1, b1) ‖ Beta(a2, b2)) in closed form."""
    return (betaln(a2, b2) - betaln(a1, b1)
```

(continues on next page)

(continued from previous page)

```
            + (a1 - a2) * digamma(a1) + (b1 - b2) * digamma(b1)
            + (a2 - a1 + b2 - b1) * digamma(a1 + b1))

def log_chernoff_coef_beta(ϕ, a1, b1, a2, b2):
    """log ρ(ϕ) for Beta(a1, b1) and Beta(a2, b2) in closed form."""
    return (betaln(ϕ * a1 + (1 - ϕ) * a2, ϕ * b1 + (1 - ϕ) * b2)
            - ϕ * betaln(a1, b1) - (1 - ϕ) * betaln(a2, b2))

def chernoff_beta(a1, b1, a2, b2):
    """Chernoff entropy and minimizing ϕ for two Beta densities."""
    res = minimize_scalar(log_chernoff_coef_beta, bounds=(0, 1),
                          args=(a1, b1, a2, b2), method='bounded')
    return -res.fun, res.x

mass_out = beta_dist.cdf(1e-5, 0.1, 0.2) + beta_dist.sf(1 - 1e-5, 0.1, 0.2)
print(f"Mass of Beta(0.1, 0.2) outside [1e-5, 1-1e-5] = {mass_out:.3f}")
```

```

JS divergence and Chernoff entropy rank the fourteen pairs in the same order.

The two KL divergences rank them differently.

For $g = \text{Beta}(0.1, 0.2)$, $KL(g, f)$ is by far the largest in the table, because g puts most of its mass near the endpoints, where g greatly exceeds $f = 1$.

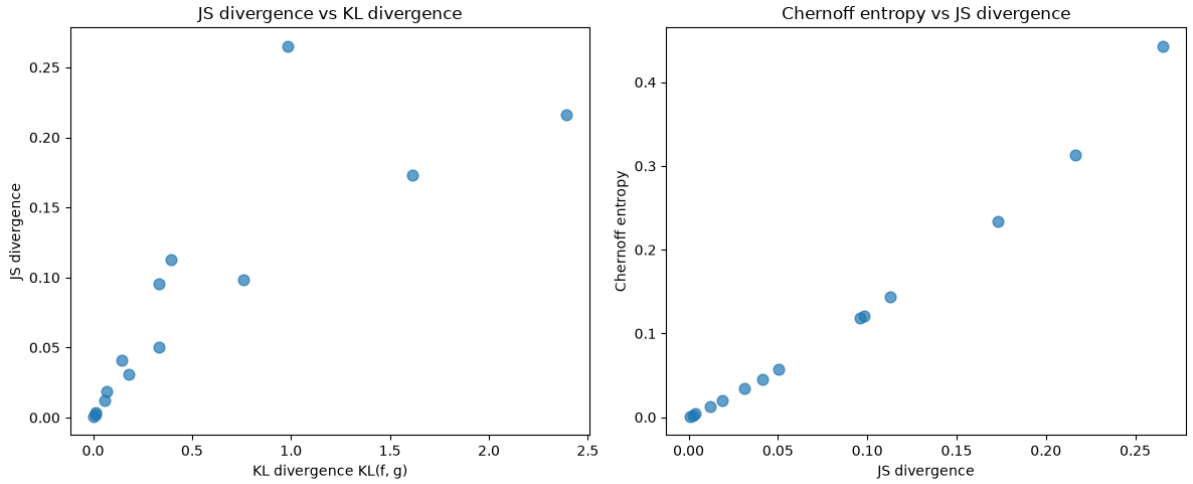
For $g = \text{Beta}(4, 1)$ and $\text{Beta}(5, 1)$, $KL(f, g)$ exceeds its value for $\text{Beta}(0.1, 0.2)$, because these g's vanish at 0, where $f = 1$.

Next we visualize relationships among KL, JS, and Chernoff entropy.

```
kl_fg_values = [result['KL(f, g)'] for result in results]
js_values = [result['JS'] for result in results]
chernoff_values = [result['C'] for result in results]

fig, axes = plt.subplots(1, 2, figsize=(12, 5))

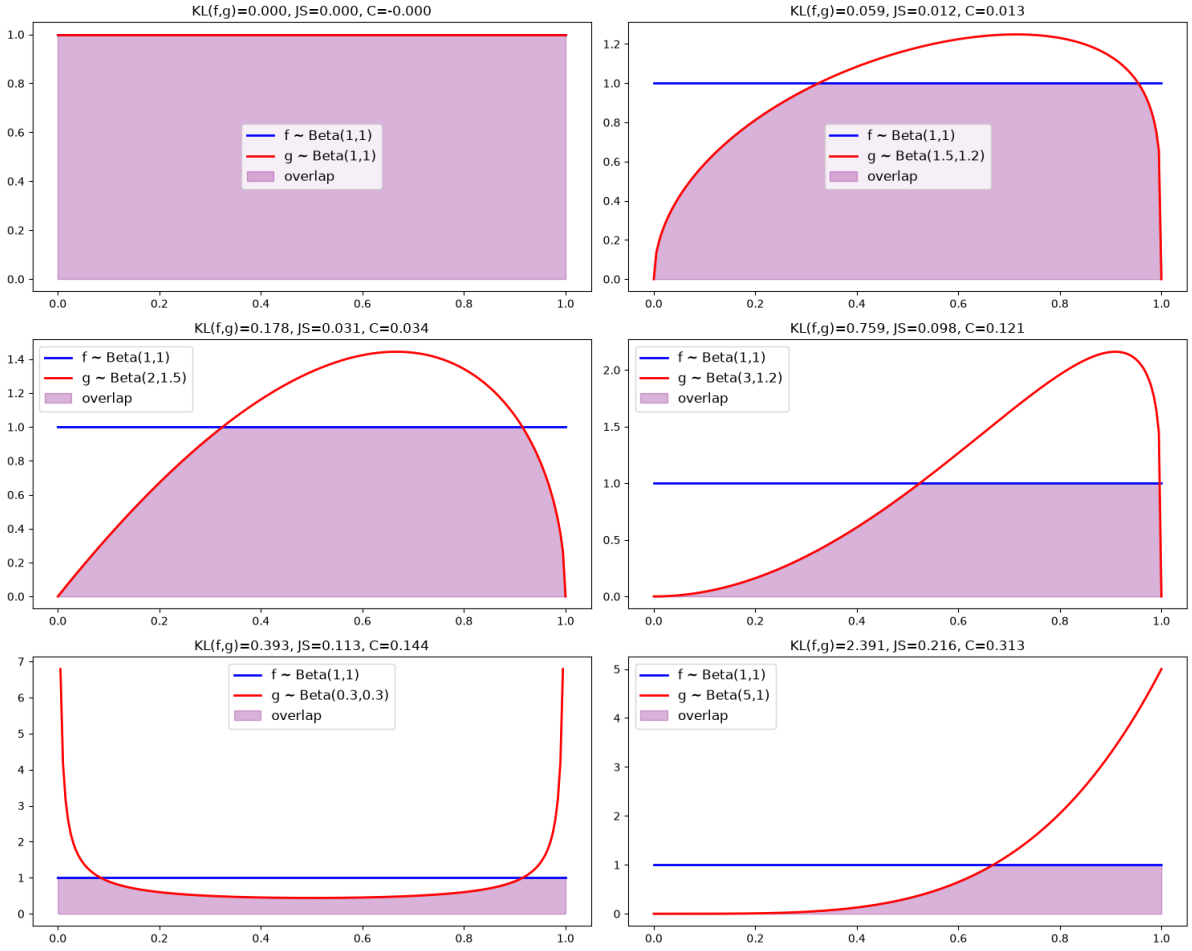
axes[0].scatter(kl_fg_values, js_values, alpha=0.7, s=60)
```



(continues on next page)

(continued from previous page)

```
axes[0].set_xlabel('KL divergence KL(f, g)')
axes[0].set_ylabel('JS divergence')
axes[0].set_title('JS divergence vs KL divergence')



axes[1].scatter(js_values, chernoff_values, alpha=0.7, s=60)
axes[1].set_xlabel('JS divergence')
axes[1].set_ylabel('Chernoff entropy')
axes[1].set_title('Chernoff entropy vs JS divergence')

plt.tight_layout()
plt.show()
```

We now generate plots illustrating how overlap visually diminishes as divergence measures increase.

```
param_grid = [
    ((1, 1), (1, 1)),
    ((1, 1), (1.5, 1.2)),
    ((1, 1), (2, 1.5)),
    ((1, 1), (3, 1.2)),
    ((1, 1), (0.3, 0.3)),
    ((1, 1), (5, 1))
]
```

21.8 KL divergence and maximum-likelihood estimation

Let $x_1, x_2, \ldots, x_N$ be IID draws from a density p_0.

A statistician fits a parametric family of densities $\{p_\theta\}$ by maximum likelihood.

The **empirical distribution** p_e puts probability $1/N$ on each observation:

$$p_e(x) = \frac{1}{N} \sum_{i=1}^{N} \delta(x - x_i),$$

where $\delta(x - x_i)$ is the Dirac delta function centered at x_i; it satisfies $\delta(x - x_i) = 0$ for $x \neq x_i$ and $\int \delta(x - x_i)\, dx = 1$.

The log-likelihood function for parameter θ is

$$\ell_N(\theta) = \sum_{i=1}^{N} \log p_\theta(x_i).$$

The average log likelihood is an expectation under p_e:

$$\frac{1}{N} \ell_N(\theta) = \int p_e(x) \log p_\theta(x)\, dx = -H(p_e, p_\theta),$$

where $H(p_e, p_\theta)$ is the cross-entropy defined in the primer above.

Maximum likelihood chooses θ to minimize the cross-entropy $H(p_e, p_\theta)$.

The KL divergence $D_{KL}(p_e \| p_\theta)$ is of no use here.

When p_θ is a density, p_e puts probability one on the finite set $\{x_1, \ldots, x_N\}$, to which p_θ assigns probability zero.

So p_e is not absolutely continuous with respect to p_θ, and $D_{KL}(p_e \| p_\theta) = +\infty$ for every θ.

KL divergence enters through the population.

By the strong law of large numbers, for each θ

$$\frac{1}{N}\ell_N(\theta) \to E_{p_0} \log p_\theta(X) = -H(p_0) - D_{KL}(p_0 \| p_\theta) \quad \text{almost surely,}$$

where the equality is (21.3) for densities, and we assume that the entropy $H(p_0)$ is finite.

The entropy $H(p_0)$ does not depend on θ.

Maximum likelihood is the sample analogue of minimizing $D_{KL}(p_0 \| p_\theta)$ over θ.

If $p_0 = p_{\theta_0}$ for some θ_0, Gibbs' inequality implies that θ_0 minimizes $D_{KL}(p_0 \| p_\theta)$.

If no member of the family equals p_0, then under regularity conditions the maximum likelihood estimator converges to the **pseudo-true value**

$$\theta^* = \arg\min_\theta D_{KL}(p_0 \| p_\theta),$$

the member of the family closest to p_0 in KL divergence [White, 1982].

Differentiating under the integral sign gives

$$\nabla_\theta D_{KL}(p_0 \| p_\theta) = -E_{p_0} \nabla_\theta \log p_\theta(X).$$

The expected score is the negative gradient of the KL divergence, and it vanishes at θ^*.

Which Moments to Match? builds an estimator on this fact.

Maximum Likelihood Estimation describes how to compute maximum likelihood estimates.

Exercise 21.10.3 fits a misspecified Beta model to data drawn from a mixture.

21.9 Related lectures

This lecture has introduced tools that we'll encounter elsewhere.

- Other quantecon lectures that apply connections between divergence measures and statistical inference include *Likelihood Ratio Processes*, *A Problem that Stumped Milton Friedman*, and *Incorrect Models*.
- Statistical divergence functions also take center stage in *Heterogeneous Beliefs and Financial Markets* that studies Lawrence Blume and David Easley's model of heterogeneous beliefs and financial markets.
- *Mean of a Likelihood Ratio Process* uses the χ^2 divergence $\chi^2(f\|q) = \int (f-q)^2/q\, dx = \int f^2/q\, dx - 1$, which equals the variance under q of the importance weight f/q.
- *Merging of Opinions: The Blackwell–Dubins Theorem* uses the Bhattacharyya coefficient, under the name Hellinger affinity, to decide when two Bayesians' opinions merge.

21.10 Exercises

Exercise 21.10.1

Let $X \sim \text{Beta}(a, b)$, with density $x^{a-1}(1-x)^{b-1}/B(a,b)$ on $(0,1)$.

1. Differentiate $B(a,b) = \int_0^1 x^{a-1}(1-x)^{b-1}dx$ with respect to a and b to show that $E\log X = \psi(a) - \psi(a+b)$ and $E\log(1-X) = \psi(b) - \psi(a+b)$.
2. Use part 1 to derive the closed form for $D_{KL}(\text{Beta}(a_1,b_1) \,\|\, \text{Beta}(a_2,b_2))$ stated above.
3. Show that when f and g are Beta densities, $f^\phi g^{1-\phi}$ is proportional to a Beta density, and use this fact to derive the closed form for $\rho(\phi)$.
4. Let $f = \text{Beta}(1,1)$ and $g = \text{Beta}(0.1, 0.2)$. Compute $KL(g,f)$, $JS(f,g)$, and $C(f,g)$ by applying `quad` to the truncated interval $[10^{-5}, 1-10^{-5}]$. Compare the results with the values in the table above and explain the differences.

Solution

Part 1. Differentiating under the integral sign gives

$$\frac{\partial B(a,b)}{\partial a} = \int_0^1 \log x \; x^{a-1}(1-x)^{b-1}dx = B(a,b)\, E\log X.$$

Since $B(a,b) = \Gamma(a)\Gamma(b)/\Gamma(a+b)$,

$$E\log X = \frac{\partial \log B(a,b)}{\partial a} = \psi(a) - \psi(a+b).$$

The same argument with b in place of a gives $E\log(1-X) = \psi(b) - \psi(a+b)$.

Part 2. Let $f = \text{Beta}(a_1,b_1)$ and $g = \text{Beta}(a_2,b_2)$.

Then

$$\log f(x) - \log g(x) = (a_1 - a_2)\log x + (b_1 - b_2)\log(1-x) + \log B(a_2,b_2) - \log B(a_1,b_1).$$

Taking expectations under f and using part 1 gives

$$D_{KL}(f\|g) = \log\frac{B(a_2,b_2)}{B(a_1,b_1)} + (a_1-a_2)[\psi(a_1) - \psi(a_1+b_1)] + (b_1-b_2)[\psi(b_1) - \psi(a_1+b_1)],$$

which rearranges to the formula in the text.

Part 3. Let $a_\phi = \phi a_1 + (1-\phi)a_2$ and $b_\phi = \phi b_1 + (1-\phi)b_2$.

Then

$$f(x)^\phi g(x)^{1-\phi} = \frac{x^{a_\phi - 1}(1-x)^{b_\phi - 1}}{B(a_1,b_1)^\phi B(a_2,b_2)^{1-\phi}},$$

which is proportional to the $\text{Beta}(a_\phi, b_\phi)$ density.

Integrating over $(0,1)$ gives

$$\rho(\phi) = \frac{B(a_\phi, b_\phi)}{B(a_1,b_1)^\phi B(a_2,b_2)^{1-\phi}}.$$

Part 4. Here is code that repeats the computations on the truncated interval.

```
def KL_truncated(f, g):
    """KL(f, g) by quad over [1e-5, 1-1e-5]."""
    integrand = lambda w: f(w) * np.log(f(w) / g(w))
    return quad(integrand, 1e-5, 1 - 1e-5)[0]

def chernoff_truncated(f, g):
    """Chernoff entropy by quad over [1e-5, 1-1e-5]."""
    ρ = lambda ϕ: quad(lambda w: f(w)**ϕ * g(w)**(1-ϕ),
                       1e-5, 1 - 1e-5)[0]
    res = minimize_scalar(ρ, bounds=(0, 1), method='bounded')
    return -np.log(res.fun)

f_ex = jit(lambda x: p(x, 1, 1))
g_ex = jit(lambda x: p(x, 0.1, 0.2))
m_ex = lambda x: 0.5 * (f_ex(x) + g_ex(x))

truncated = [KL_truncated(g_ex, f_ex),
             0.5 * KL_truncated(f_ex, m_ex) + 0.5 * KL_truncated(g_ex, m_ex),
             chernoff_truncated(f_ex, g_ex)]
accurate = [KL_beta(0.1, 0.2, 1, 1),
            compute_JS(f_ex, g_ex),
            chernoff_beta(1, 1, 0.1, 0.2)[0]]

for name, t, a in zip(['KL(g, f)', 'JS(f, g)', 'C(f, g)'], truncated, accurate):
    print(f"{name}: truncated = {t:.4f}, accurate = {a:.4f}")
print(f"Mass of g outside the truncated interval = {mass_out:.4f}")
```

```
KL(g, f): truncated = 1.0036, accurate = 4.9773
JS(f, g): truncated = 0.1783, accurate = 0.2652
C(f, g): truncated = 0.4556, accurate = 0.4431
Mass of g outside the truncated interval = 0.2509
```

The density $g = \text{Beta}(0.1, 0.2)$ puts a quarter of its mass outside $[10^{-5}, 1 - 10^{-5}]$, where g is enormous and $f = 1$.

The omitted part of $KL(g, f) = \int g \log g$ is large, because $\log g$ is large there.

The omitted part of $JS(f, g)$ is close to $\frac{1}{2} \times 0.25 \times \log 2 \approx 0.087$, because $g \log(2g/(f+g)) \approx g \log 2$ where $g \gg f$.

Truncation also omits part of $\rho(\phi)$, which lowers ρ and raises the computed Chernoff entropy.

Exercise 21.10.2

Let f and g be densities that are positive on the same set, and let $\rho(\phi) = \int f^\phi g^{1-\phi} dx$.

1. Use Hölder's inequality to show that $\log \rho(\phi)$ is convex on $[0, 1]$.
2. Show that $\log \rho(0) = \log \rho(1) = 0$, that the derivative of $\log \rho$ at $\phi = 0$ is $-D_{KL}(g \| f)$, and that its derivative at $\phi = 1$ is $D_{KL}(f \| g)$.
3. Deduce the bounds (21.9).
4. Verify the bounds numerically for every pair in the table above, and plot $-\log \rho(\phi)$ together with the two tangent lines for our example f and g.

Solution

Part 1. Take $\phi_1, \phi_2 \in [0,1]$, $\lambda \in (0,1)$, and $\phi = \lambda\phi_1 + (1-\lambda)\phi_2$.

Write

$$f^{\phi} g^{1-\phi} = \left(f^{\phi_1} g^{1-\phi_1}\right)^{\lambda} \left(f^{\phi_2} g^{1-\phi_2}\right)^{1-\lambda}.$$

Hölder's inequality with exponents $1/\lambda$ and $1/(1-\lambda)$ gives

$$\rho(\phi) \leq \rho(\phi_1)^{\lambda} \rho(\phi_2)^{1-\lambda}.$$

Taking logarithms gives $\log \rho(\phi) \leq \lambda \log \rho(\phi_1) + (1-\lambda) \log \rho(\phi_2)$.

Part 2. Because f and g are positive on the same set, $\rho(0) = \int g = 1$ and $\rho(1) = \int f = 1$.

Differentiating under the integral sign gives

$$\frac{d \log \rho(\phi)}{d\phi} = \frac{1}{\rho(\phi)} \int f^{\phi} g^{1-\phi} \log \frac{f}{g} \, dx.$$

At $\phi = 0$ the derivative is $\int g \log(f/g) = -D_{KL}(g\|f)$.

At $\phi = 1$ the derivative is $\int f \log(f/g) = D_{KL}(f\|g)$.

Part 3. The lower bound holds because $C(f,g) = -\min_{\phi} \log \rho(\phi) \geq -\log \rho(1/2)$.

A convex function lies above its tangent lines, so

$$\log \rho(\phi) \geq -\phi \, D_{KL}(g\|f) \quad \text{and} \quad \log \rho(\phi) \geq -(1-\phi) \, D_{KL}(f\|g).$$

Hence

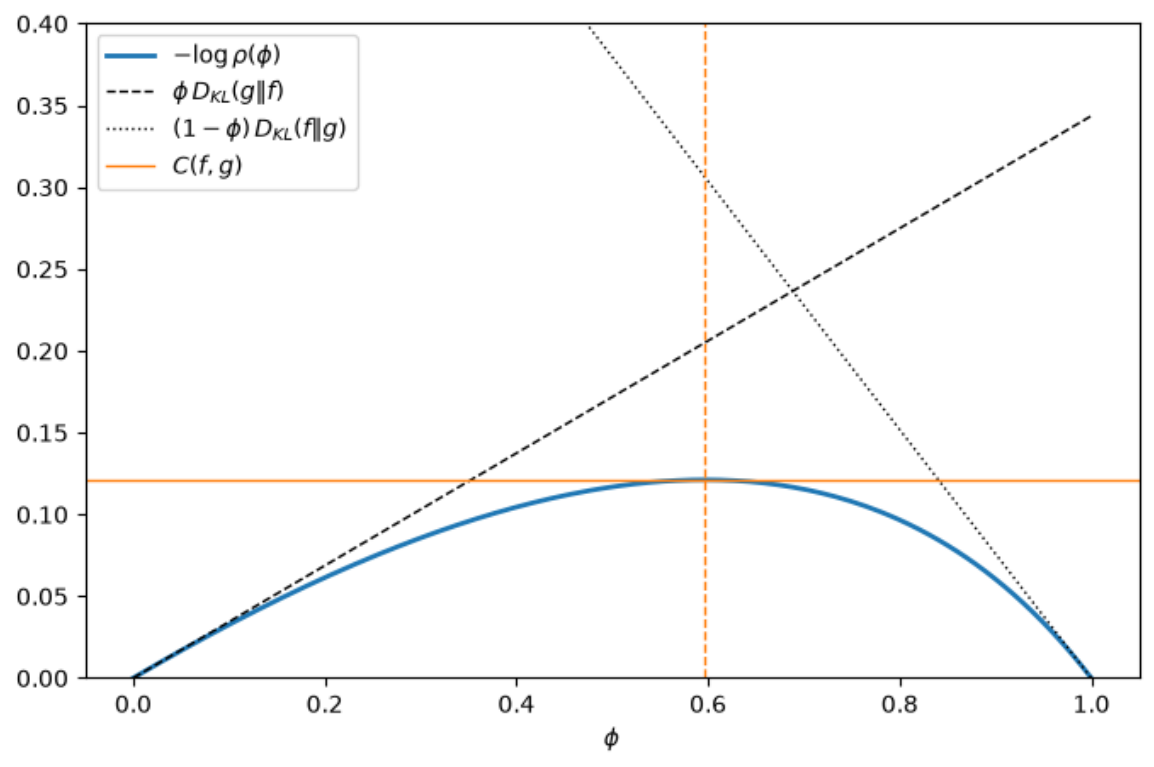
$$-\log \rho(\phi) \leq \min\{\phi \, D_{KL}(g\|f), \; (1-\phi) \, D_{KL}(f\|g)\}.$$

The right side is largest where the two lines cross, at $\phi = D_{KL}(f\|g)/(D_{KL}(f\|g) + D_{KL}(g\|f))$, where it equals $D_{KL}(f\|g) \, D_{KL}(g\|f)/(D_{KL}(f\|g) + D_{KL}(g\|f))$.

Maximizing the left side over ϕ gives the middle inequality.

The last inequality holds because $xy/(x+y) \leq \min\{x, y\}$ for positive x and y.

Part 4. We check the bounds for every pair in the table.



```
for (f_a, f_b), (g_a, g_b) in distribution_pairs:
    K_fg = KL_beta(f_a, f_b, g_a, g_b)
    K_gf = KL_beta(g_a, g_b, f_a, f_b)
    lower = -log_chernoff_coef_beta(0.5, f_a, f_b, g_a, g_b)
    C, _ = chernoff_beta(f_a, f_b, g_a, g_b)
    upper = K_fg * K_gf / (K_fg + K_gf)
    holds = lower <= C <= upper <= min(K_fg, K_gf)
    print(f"Beta({g_a},{g_b}): {lower:.4f} ≤ {C:.4f} ≤ {upper:.4f} "
          f"≤ {min(K_fg, K_gf):.4f}  {holds}")
```

```

Exercise 21.10.3

Let the data $x_1, \ldots, x_N$ be IID draws from the mixture

$$h(x) = \frac{1}{2} f(x) + \frac{1}{2} g(x)$$

of our example densities $f = \text{Beta}(1, 1)$ and $g = \text{Beta}(3, 1.2)$.

A statistician fits the Beta(a, b) family by maximum likelihood.

The family excludes h.

1. Show that the pseudo-true value $(a^*, b^*) = \arg\min_{a,b} D_{KL}(h \,\|\, \text{Beta}(a, b))$ solves $\psi(a) - \psi(a+b) = E_h \log X$ and $\psi(b) - \psi(a+b) = E_h \log(1 - X)$.
2. Show that the maximum likelihood estimator $(\hat{a}_N, \hat{b}_N)$ solves the same equations with the expectations replaced by the sample means of $\log x_i$ and $\log(1 - x_i)$.
3. Compute (a^*, b^*) and plot h against the Beta(a^*, b^*) density.
4. Simulate samples of size $N = 10^2, 10^3, \ldots, 10^6$ and verify that $(\hat{a}_N, \hat{b}_N)$ approaches (a^*, b^*).

Solution

Parts 1 and 2. The log density of Beta(a, b) is

$$\log p_{a,b}(x) = (a-1)\log x + (b-1)\log(1-x) - \log B(a, b).$$

Hence

$$D_{KL}(h \| p_{a,b}) = E_h \log h(X) + Q(a, b; s_1, s_2), \qquad Q(a, b; s_1, s_2) = \log B(a, b) - (a-1)s_1 - (b-1)s_2,$$

with $s_1 = E_h \log X$ and $s_2 = E_h \log(1 - X)$.

The average negative log likelihood is $-\ell_N(a, b)/N = Q(a, b; \hat{s}_1, \hat{s}_2)$, where $\hat{s}_1$ and $\hat{s}_2$ are the sample means of $\log x_i$ and $\log(1 - x_i)$.

The function $\log B(a, b)$ is convex, so Q is convex in (a, b).

By part 1 of Exercise 21.10.1, $\partial \log B(a, b)/\partial a = \psi(a) - \psi(a + b)$ and $\partial \log B(a, b)/\partial b = \psi(b) - \psi(a + b)$.

Setting the gradient of Q to zero gives the stated equations, with (s_1, s_2) for the pseudo-true value and $(\hat{s}_1, \hat{s}_2)$ for the maximum likelihood estimator.

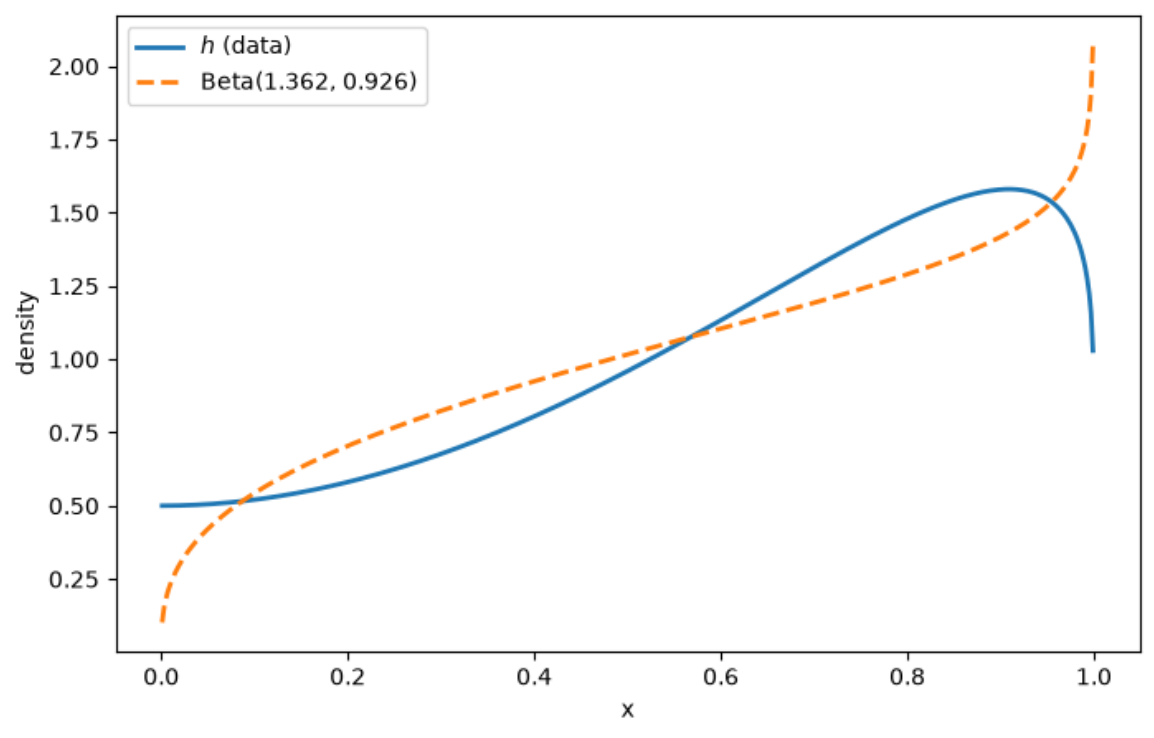
Part 3. Part 1 of Exercise 21.10.1 and linearity of expectations give s_1 and s_2 in closed form.

We minimize Q over $(\log a, \log b)$ to keep a and b positive.

```
from scipy.optimize import minimize

def Q(z, s1, s2):
    a, b = np.exp(z)
    return betaln(a, b) - (a - 1) * s1 - (b - 1) * s2

def fit_beta(s1, s2):
    res = minimize(Q, x0=np.zeros(2), args=(s1, s2), method='BFGS')
    return np.exp(res.x)



E_log_x = lambda a, b: digamma(a) - digamma(a + b)
s1 = 0.5 * E_log_x(F_a, F_b) + 0.5 * E_log_x(G_a, G_b)
s2 = 0.5 * E_log_x(F_b, F_a) + 0.5 * E_log_x(G_b, G_a)

a_star, b_star = fit_beta(s1, s2)
print(f"pseudo-true value: a* = {a_star:.4f}, b* = {b_star:.4f}")

h = lambda x: 0.5 * p(x, F_a, F_b) + 0.5 * p(x, G_a, G_b)
p_star = lambda x: p(x, a_star, b_star)
print(f"KL(h, Beta(a*, b*)) = {compute_KL(h, p_star):.4f}")

x_grid = np.linspace(0.001, 0.999, 500)
plt.figure(figsize=(8, 5))
plt.plot(x_grid, h(x_grid), lw=2, label='$h$ (data)')
plt.plot(x_grid, p_star(x_grid), lw=2, ls='--',
         label=f'Beta({a_star:.3f}, {b_star:.3f})')
plt.xlabel('x')
plt.ylabel('density')
```

```
pseudo-true value: a* = 1.3621, b* = 0.9255
KL(h, Beta(a*, b*)) = 0.0124
```

Part 4. We draw samples from h and compute $(\hat{a}_N, \hat{b}_N)$ from the sample moments.

```
rng = np.random.default_rng(1234)

for N in [10**2, 10**3, 10**4, 10**5, 10**6]:
    from_f = rng.random(N) < 0.5
    x = np.where(from_f, rng.beta(F_a, F_b, N), rng.beta(G_a, G_b, N))
    a_hat, b_hat = fit_beta(np.mean(np.log(x)), np.mean(np.log1p(-x)))
    print(f"N = {N:>7}: a_hat = {a_hat:.4f}, b_hat = {b_hat:.4f}")
```

```
N =     100: a_hat = 1.2524, b_hat = 0.9221
N =    1000: a_hat = 1.5154, b_hat = 0.9324
N =   10000: a_hat = 1.3437, b_hat = 0.9186
N =  100000: a_hat = 1.3472, b_hat = 0.9216
N = 1000000: a_hat = 1.3601, b_hat = 0.9258
```

The estimates approach (a^*, b^*), the member of the Beta family closest to h in KL divergence.

Incorrect Models studies a Bayesian whose model contains only f and g and who sees data from h; KL divergences from h to f and to g determine where that Bayesian's beliefs settle.

Which Moments to Match? uses the pseudo-true value of an auxiliary model as the target of an estimator.

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install --upgrade quantecon
```

22.1 Overview

This lecture describes likelihood ratio processes and some of their uses.

We'll study the same setting that is also used in *this lecture on exchangeability*.

Among the things that we'll learn are

- How a likelihood ratio process is a key ingredient in frequentist hypothesis testing
- How a **receiver operating characteristic curve** summarizes information about a false alarm probability and power in frequentist hypothesis testing
- How a statistician can combine frequentist probabilities of type I and type II errors to form posterior probabilities of mistakes in a model selection or in an individual-classification problem

- How to use a Kullback-Leibler divergence to quantify the difference between two probability distributions with the same support
- How during World War II the United States Navy devised a decision rule for doing quality control on lots of ammunition, a topic that sets the stage for *this lecture*
- A peculiar property of likelihood ratio processes

Let's start by importing some Python tools.

```
import matplotlib.pyplot as plt
import numpy as np
from numba import vectorize, jit
from math import gamma
from scipy.integrate import quad
from scipy.optimize import brentq, minimize_scalar
from scipy.stats import beta as beta_dist
from scipy.special import betaln, digamma
import pandas as pd
from IPython.display import display, Math
import quantecon as qe

rng = np.random.default_rng()
```

22.2 Likelihood Ratio Process

A nonnegative random variable W has one of two probability density functions, either f or g.

Before the beginning of time, nature once and for all decides whether she will draw a sequence of IID draws from either f or g.

We let q be the density that nature chose once and for all, so that q is either f or g, permanently.

Nature knows which density it permanently draws from, but we the observers do not.

We know both f and g but we don't know which density nature chose.

But we want to know.

To do that, we use observations.

We observe a sequence $\{w_t\}_{t=1}^T$ of T IID draws that we know came from either f or g.

We want to use these observations to infer whether nature chose f or g.

A **likelihood ratio process** is a useful tool for this task.

To begin, we define a key component of a likelihood ratio process, namely, the time t likelihood ratio as the random variable

$$\ell(w_t) = \frac{f(w_t)}{g(w_t)}, \quad t \geq 1.$$

We assume that f and g both put positive probabilities on the same intervals of possible realizations of the random variable W.

That means that under the g density, $\ell(w_t) = \frac{f(w_t)}{g(w_t)}$ is a nonnegative random variable with mean 1.

A **likelihood ratio process** for sequence $\{w_t\}_{t=1}^\infty$ is defined as

$$L(w^t) = \prod_{i=1}^t \ell(w_i),$$

where $w^t = \{w_1, \ldots, w_t\}$ is a history of observations up to and including time t.

Sometimes for shorthand we'll write $L_t = L(w^t)$.

Notice that the likelihood process satisfies the *recursion*

$$L(w^t) = \ell(w_t) L(w^{t-1}).$$

The likelihood ratio and its logarithm are key tools for making inferences using a classic frequentist approach due to Neyman and Pearson [Neyman and Pearson, 1933].

To help us appreciate how things work, the following Python code evaluates f and g as two different Beta distributions, then computes and simulates an associated likelihood ratio process by generating a sequence w^t from one of the two probability distributions, for example, a sequence of IID draws from g.

```
# Parameters for the two Beta distributions
F_a, F_b = 1, 1
G_a, G_b = 3, 1.2

@vectorize
def p(x, a, b):
    """Beta distribution density function."""
    r = gamma(a + b) / (gamma(a) * gamma(b))
    return r * x** (a-1) * (1 - x) ** (b-1)

f = jit(lambda x: p(x, F_a, F_b))
g = jit(lambda x: p(x, G_a, G_b))

def create_beta_density(a, b):
    """Create a beta density function with specified parameters."""
    return jit(lambda x: p(x, a, b))

def likelihood_ratio(w, f_func, g_func):
    """Compute likelihood ratio for observation(s) w."""
    return f_func(w) / g_func(w)

@jit
def simulate_likelihood_ratios(a, b, f_func, g_func, rng, T=50, N=500):
    """
    Generate N sets of T observations of the likelihood ratio.
    """
    l_arr = np.empty((N, T))
    for i in range(N):
        for j in range(T):
            w = rng.beta(a, b)
            l_arr[i, j] = f_func(w) / g_func(w)
    return l_arr

def simulate_sequences(distribution, f_func, g_func, rng,
        F_params=(1, 1), G_params=(3, 1.2), T=50, N=500):
    """
    Generate N sequences of T observations from specified distribution.
    """
    if distribution == 'f':
        a, b = F_params
    elif distribution == 'g':
        a, b = G_params
    else:
        raise ValueError("distribution must be 'f' or 'g'")
```

(continues on next page)

(continued from previous page)

```
    l_arr = simulate_likelihood_ratios(a, b, f_func, g_func, rng, T, N)
    l_seq = np.cumprod(l_arr, axis=1)
    return l_arr, l_seq

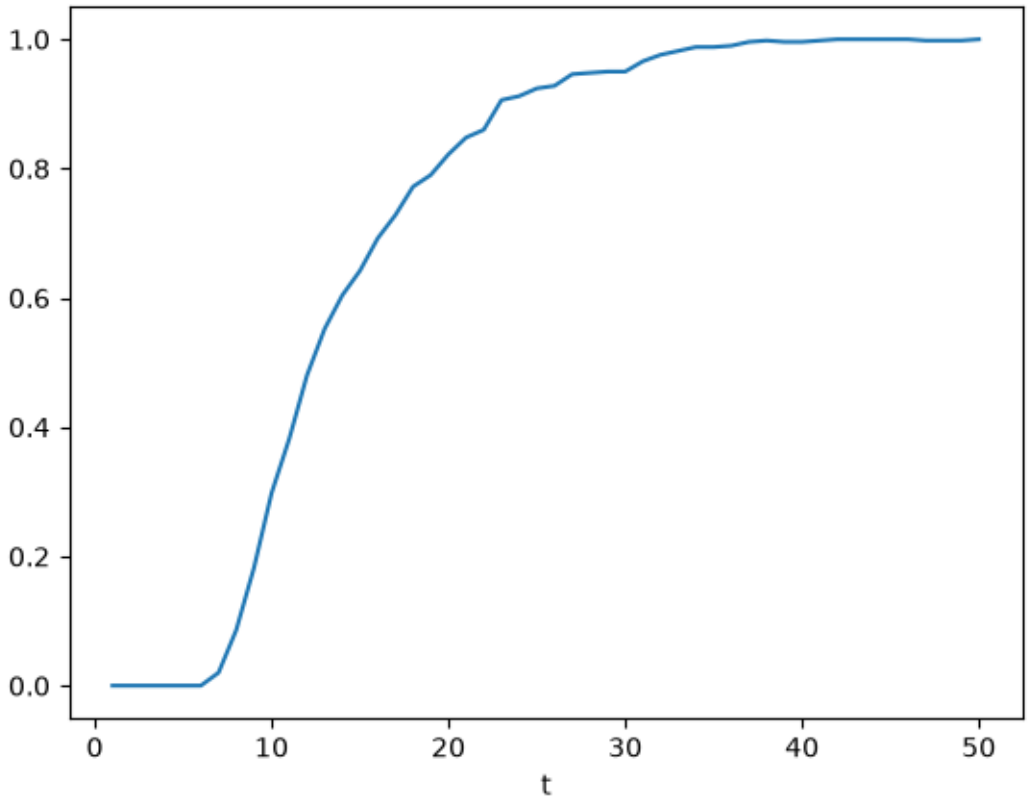
def plot_likelihood_paths(l_seq, title="Likelihood ratio paths",
                          ylim=None, n_paths=None):
    """Plot likelihood ratio paths."""
    N, T = l_seq.shape
    n_show = n_paths or min(N, 100)

    plt.figure(figsize=(10, 6))
    for i in range(n_show):
        plt.plot(np.arange(1, T+1), l_seq[i, :], color='b', lw=0.8, alpha=0.5)

    if ylim:
        plt.ylim(ylim)
    plt.title(title)
    plt.xlabel('t')
    plt.ylabel('$L(w^t)$')
    plt.show()
```

22.3 Nature permanently draws from density g

We first simulate the likelihood ratio process when nature permanently draws from g.



```
# Simulate when nature draws from g
l_arr_g, l_seq_g = simulate_sequences('g', f, g, rng, (F_a, F_b), (G_a, G_b))
plot_likelihood_paths(l_seq_g,
                      title="$L(w^{t})$ paths when nature draws from g",
                      ylim=[0, 3])
```

Evidently, as sample length T grows, most probability mass shifts toward zero.

To see this more clearly, we plot over time the fraction of paths $L\left(w^t\right)$ that fall in the interval $[0, 0.01]$.

```
N, T = l_arr_g.shape
plt.plot(np.arange(1, T+1), np.sum(l_seq_g <= 0.01, axis=0) / N)
plt.xlabel('t')
plt.show()
```

Despite the evident convergence of most probability mass to a very small interval near 0, the unconditional mean of $L(w^t)$ under probability density g is identically 1 for all t.

To verify this assertion, first notice that as mentioned earlier the unconditional mean $E[\ell(w_t) \mid q = g]$ is 1 for all t:

$$\begin{aligned} E[\ell(w_t) \mid q = g] &= \int \frac{f(w_t)}{g(w_t)} g(w_t)\, dw_t \\ &= \int f(w_t)\, dw_t \\ &= 1, \end{aligned}$$

which immediately implies

$$\begin{aligned} E[L(w^1) \mid q = g] &= E[\ell(w_1) \mid q = g] \\ &= 1. \end{aligned}$$

Because $L(w^t) = \ell(w_t) L(w^{t-1})$ and $\{w_t\}_{t=1}^{\infty}$ is an IID sequence, we have

$$\begin{aligned} E[L(w^t) \mid q = g] &= E[L(w^{t-1})\, \ell(w_t) \mid q = g] \\ &= E[L(w^{t-1})\, E[\ell(w_t) \mid q = g, w^{t-1}] \mid q = g] \\ &= E[L(w^{t-1})\, E[\ell(w_t) \mid q = g] \mid q = g] \\ &= E[L(w^{t-1}) \mid q = g] \end{aligned}$$

for any $t \geq 1$.

Mathematical induction implies $E[L(w^t) \mid q = g] = 1$ for all $t \geq 1$.

22.4 Peculiar property

How can $E\left[L\left(w^t\right) \mid q = g\right] = 1$ possibly be true when most probability mass of the likelihood ratio process is piling up near 0 as $t \to +\infty$?

The answer is that as $t \to +\infty$, the distribution of L_t becomes more and more fat-tailed: enough mass shifts to larger and larger values of L_t to make the mean of L_t continue to be one despite most of the probability mass piling up near 0.

Under g, the process $\{L_t\}$ is a nonnegative martingale with mean 1.

By the strong law of large numbers, $\frac{1}{t}\log L_t \to E_g \log \ell(w) = -D_{KL}(g\|f) < 0$ almost surely, so $L_t \to 0$ almost surely.

Thus $E[L_t \mid q = g] = 1$ for every t while $E[\lim_{t\to\infty} L_t \mid q = g] = 0$.

The martingale $\{L_t\}$ converges almost surely but not in mean, because it is not uniformly integrable.

Merging of Opinions: The Blackwell–Dubins Theorem studies this likelihood-ratio martingale.

Kakutani's theorem there states that when $\int \sqrt{fg}\, dw < 1$, the distributions of infinite sequences of IID draws from f and from g are mutually singular, which is another way of saying that $L_t \to 0$ almost surely under g.

To illustrate this peculiar property, we simulate many paths and calculate the unconditional mean of $L\left(w^t\right)$ by averaging across these many paths at each t.

```
l_arr_g, l_seq_g = simulate_sequences('g',
                f, g, rng, (F_a, F_b), (G_a, G_b), N=50000)
```

It would be useful to use simulations to verify that unconditional means $E\left[L\left(w^t\right)\right]$ equal unity by averaging across sample paths.

But it would be too computer-time-consuming for us to do that here simply by applying a standard Monte Carlo simulation approach.

The reason is that the distribution of $L\left(w^t\right)$ is extremely skewed for large values of t.

Because the probability density in the right tail is close to 0, it just takes too much computer time to sample enough points from the right tail.

We explain the problem in more detail in *this lecture*.

There we describe an alternative way to compute the mean of a likelihood ratio by computing the mean of a *different* random variable by sampling from a *different* probability distribution.

22.5 Nature permanently draws from density f

Now suppose that before time 0 nature permanently decided to draw repeatedly from density f.

While the mean of the likelihood ratio $\ell\left(w_t\right)$ under density g is 1, its mean under the density f exceeds one.

To see this, we compute

$$\begin{aligned} E\left[\ell\left(w_t\right) \mid q=f\right] &= \int \frac{f\left(w_t\right)}{g\left(w_t\right)} f\left(w_t\right) dw_t \\ &= \int \frac{f\left(w_t\right)}{g\left(w_t\right)} \frac{f\left(w_t\right)}{g\left(w_t\right)} g\left(w_t\right) dw_t \\ &= \int \ell\left(w_t\right)^2 g\left(w_t\right) dw_t \\ &= E\left[\ell\left(w_t\right)^2 \mid q=g\right] \\ &= E\left[\ell\left(w_t\right) \mid q=g\right]^2 + Var\left(\ell\left(w_t\right) \mid q=g\right) \\ &> E\left[\ell\left(w_t\right) \mid q=g\right]^2 = 1 \end{aligned}$$

For the f and g in our example, $E\left[\ell\left(w_t\right) \mid q=f\right]$ is infinite.

Because f is the uniform density, $E\left[\ell\left(w_t\right) \mid q=f\right] = \int_0^1 1/g(w)\, dw$.

As $w \to 0$, $g(w)$ vanishes like $w^{G_a - 1} = w^2$, so the integral diverges.

Exercise 22.10.4 shows that $E\left[\ell\left(w_t\right) \mid q=f\right] = B(G_a, G_b)B(2-G_a, 2-G_b)$ when $G_a < 2$ and $G_b < 2$, where B is the Beta function, and that it is infinite otherwise.

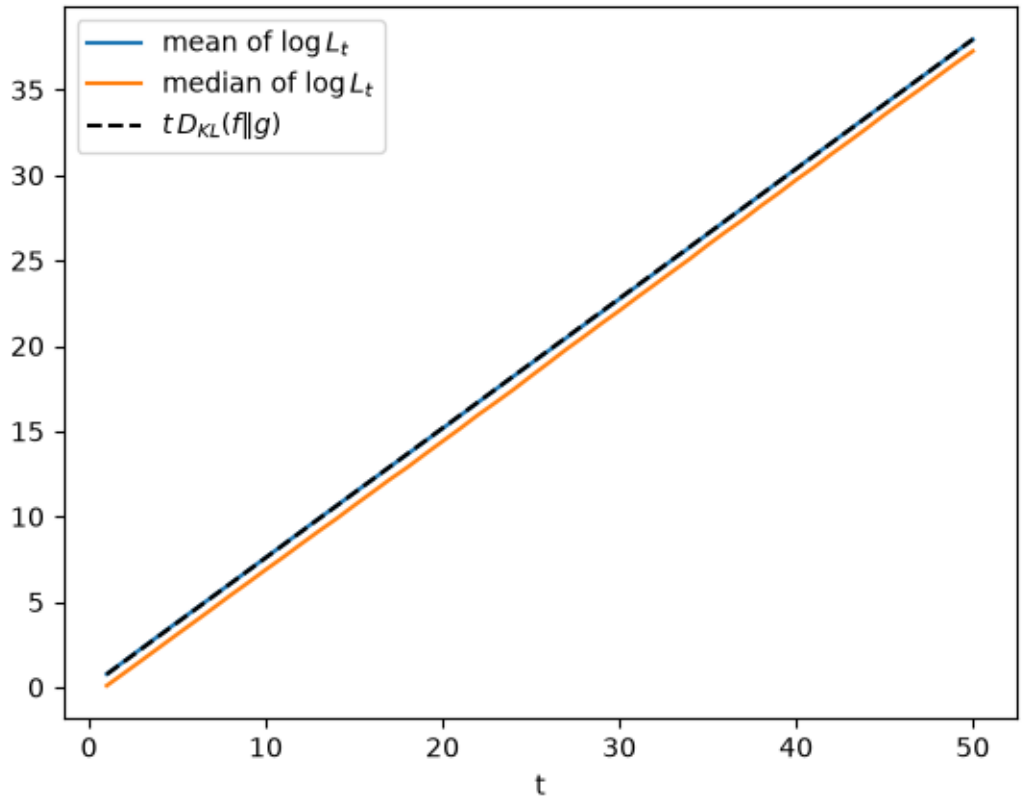
Because the w_t's are IID, $E\left[L\left(w^t\right) \mid q=f\right] = +\infty$ for every $t \geq 1$.

A sample average of $L\left(w^t\right)$ across simulated paths therefore does not settle down as the number of paths grows.

Mean of a Likelihood Ratio Process encounters the same divergent integral as the infinite variance of $\ell(w_t)$ under g, since $E\left[\ell\left(w_t\right)^2 \mid q=g\right] = E\left[\ell\left(w_t\right) \mid q=f\right]$.

The logarithm of $L\left(w^t\right)$ behaves well.

Under f, $E\left[\log L\left(w^t\right) \mid q=f\right] = t\, D_{KL}(f\|g)$, and by the strong law of large numbers $\frac{1}{t}\log L\left(w^t\right) \to D_{KL}(f\|g) > 0$ almost surely, so $L\left(w^t\right) \to +\infty$ almost surely.

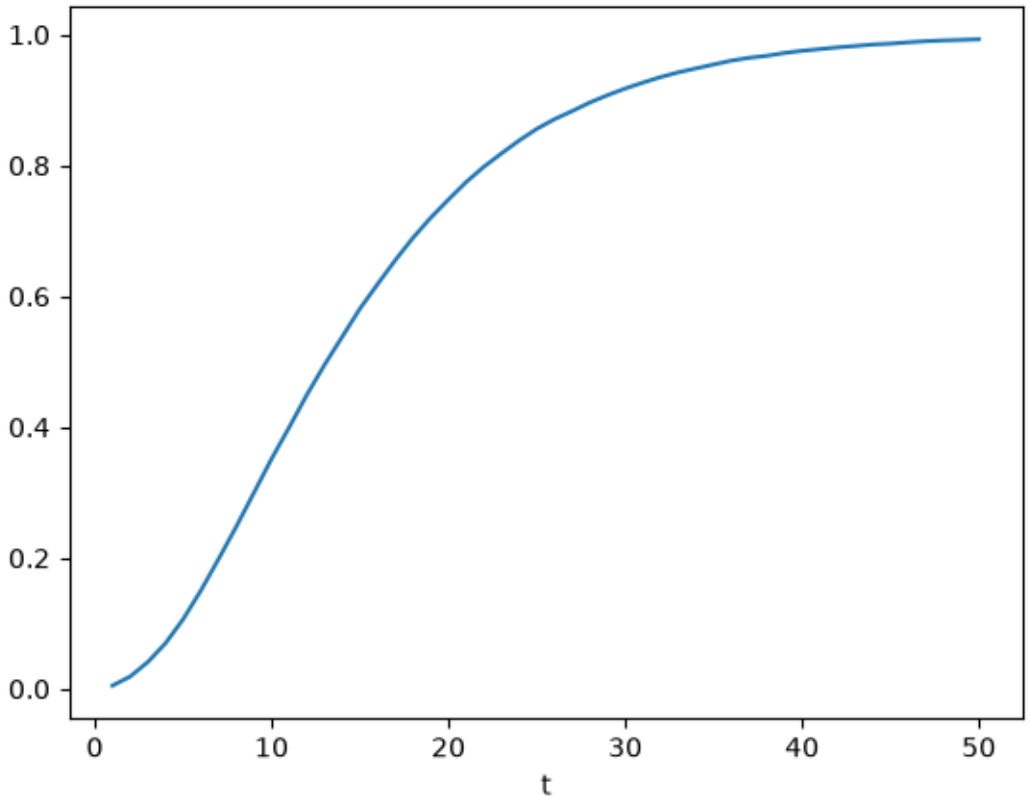


```
# Simulate when nature draws from f
l_arr_f, l_seq_f = simulate_sequences('f', f, g, rng,
                        (F_a, F_b), (G_a, G_b), N=50000)
```

The next figure plots the mean and the median across paths of $\log L\left(w^t\right)$, together with the line $t\, D_{KL}(f\|g)$.

```
N, T = l_arr_f.shape
t_grid = np.arange(1, T+1)
KL_fg, _ = quad(lambda w: f(w) * np.log(f(w) / g(w)), 0, 1)
log_l_seq_f = np.log(l_seq_f)

plt.plot(t_grid, np.mean(log_l_seq_f, axis=0), label=r'mean of $\log L_t$')
plt.plot(t_grid, np.median(log_l_seq_f, axis=0), label=r'median of $\log L_t$')
plt.plot(t_grid, KL_fg * t_grid, 'k--', label=r'$t \, D_{KL}(f\|g)$')
plt.xlabel('t')
plt.legend()
plt.show()



print(f"D_KL(f||g) = {KL_fg:.4f}")
```

```
D_KL(f||g) = 0.7592
```

We also plot the probability that $L\left(w^t\right)$ falls into the interval $[10000, \infty)$ as a function of time and watch how fast probability mass diverges to $+\infty$.

```
plt.plot(t_grid, np.sum(l_seq_f > 10000, axis=0) / N)
plt.xlabel('t')
plt.show()
```

22.6 Likelihood ratio test

We now describe how to employ the machinery of Neyman and Pearson [Neyman and Pearson, 1933] to test the hypothesis that history w^t is generated by repeated IID draws from density f.

Denote q as the data generating process, so that $q = f$ or g.

Upon observing a sample $\{W_i\}_{i=1}^t$, we want to decide whether nature is drawing from g or from f by performing a (frequentist) hypothesis test.

We specify

- Null hypothesis H_0: $q = f$,
- Alternative hypothesis H_1: $q = g$.

Neyman and Pearson proved that the best way to test this hypothesis is to use a **likelihood ratio test** that takes the form:

- accept H_0 if $L(W^t) > c$,
- reject H_0 if $L(W^t) < c$,

where c is a given discrimination threshold.

Setting $c = 1$ is a common choice.

When f and g have equal prior probabilities, $c = 1$ selects the model with the larger posterior probability, which minimizes the probability of selecting the wrong model.

We'll discuss consequences of other choices of c below.

This test is *best* in the sense that it is **most powerful**.

To understand what this means, we have to define probabilities of two important events that allow us to characterize a test associated with a given threshold c.

The two probabilities are:

- Probability of a Type I error in which we reject H_0 when it is true:

$$\alpha \equiv \Pr\{L(w^t) < c \mid q = f\}$$

- Probability of a Type II error in which we accept H_0 when it is false:

$$\beta \equiv \Pr\{L(w^t) > c \mid q = g\}$$

The probability α is also called the probability of false alarm or the significance level.

The probability $1 - \beta = \Pr\{L(w^t) < c \mid q = g\}$ is called the probability of detection or the power of the test.

The Neyman-Pearson Lemma states that among all possible tests, a likelihood ratio test maximizes the probability of detection for a given probability of false alarm.

Another way to say the same thing is that among all possible tests, a likelihood ratio test maximizes **power** for a given **significance level**.

We want a small probability of false alarm and a large probability of detection.

With sample size t fixed, we can change our two probabilities by adjusting c.

A troublesome "that's life" fact is that these two probabilities move in the same direction as we vary the critical value c.

Without specifying quantitative losses from making Type I and Type II errors, there is little that we can say about how we *should* trade off probabilities of the two types of mistakes.

We do know that increasing sample size t improves statistical inference.

The experiment that reveals w^t is more informative in Blackwell's sense than the experiment that reveals w^s for $t > s$, because a statistician can always discard the last $t - s$ observations.

When there are only two hypotheses, one experiment is more informative than another in Blackwell's sense if and only if its receiver operating characteristic curve, defined below, lies everywhere above the other's.

Blackwell's Theorem on Comparing Experiments describes Blackwell's ordering of experiments; its section on *Bayesian likelihood-ratio learning* applies it to the setting of this lecture.

Below we plot some informative figures that illustrate this.

We also present a classical frequentist method for choosing a sample size t.

Let's start with a case in which we fix the threshold c at 1.

```
c = 1
```

Below we plot empirical distributions of logarithms of the cumulative likelihood ratios simulated above, which are generated by either f or g.

Taking logarithms has no effect on calculating the probabilities because the log is a monotonic transformation.

As t increases, the probabilities of making Type I and Type II errors both decrease, which is good.

This is because most of the probability mass of $\log(L(w^t))$ moves toward $-\infty$ when g is the data generating process, while $\log(L(w^t))$ goes to ∞ when data are generated by f.

That disparate behavior of $\log(L(w^t))$ under f and g is what makes it possible eventually to distinguish $q = f$ from $q = g$.

```
def plot_log_histograms(l_seq_f, l_seq_g, c=1, time_points=[1, 7, 14, 21]):
    """Plot log likelihood ratio histograms."""
    fig, axs = plt.subplots(2, 2, figsize=(12, 8))

    for i, t in enumerate(time_points):
        nr, nc = i // 2, i % 2

        axs[nr, nc].axvline(np.log(c), color="k", ls="--")

        # Column t-1 of l_seq holds L(w^t)
        hist_f, x_f = np.histogram(np.log(l_seq_f[:, t-1]), 200, density=True)
        hist_g, x_g = np.histogram(np.log(l_seq_g[:, t-1]), 200, density=True)

        axs[nr, nc].plot(x_f[1:], hist_f, color="C0", label="dist under f")
        axs[nr, nc].plot(x_g[1:], hist_g, color="C1", label="dist under g")

        # Fill error regions
        for j, (x, hist, label) in enumerate(
            zip([x_f, x_g], [hist_f, hist_g],
            ["Type I error", "Type II error"])):
            ind = x[1:] <= np.log(c) if j == 0 else x[1:] > np.log(c)
            axs[nr, nc].fill_between(x[1:][ind], hist[ind], color=f"C{j}",
                                     alpha=0.5, label=label)

        axs[nr, nc].legend()
        axs[nr, nc].set_title(f"t={t}")

    plt.show()

plot_log_histograms(l_seq_f, l_seq_g, c=c)
```

In the above graphs,

- the blue areas equal the probabilities α of a type I error, up to the binning of the histograms
- the orange areas equal the probabilities β of a type II error, up to the binning of the histograms

Because the logarithm is monotone, the event $\{L_t < 1\}$ is the event $\{\log L_t < 0\}$, so the area under the density of $\log L_t$ to the left of 0 is $\Pr\{L_t < 1\}$.

When we hold c fixed at $c = 1$, the following graph shows that

- the probability of detection monotonically increases with increases in t
- the probability of a false alarm monotonically decreases with increases in t.

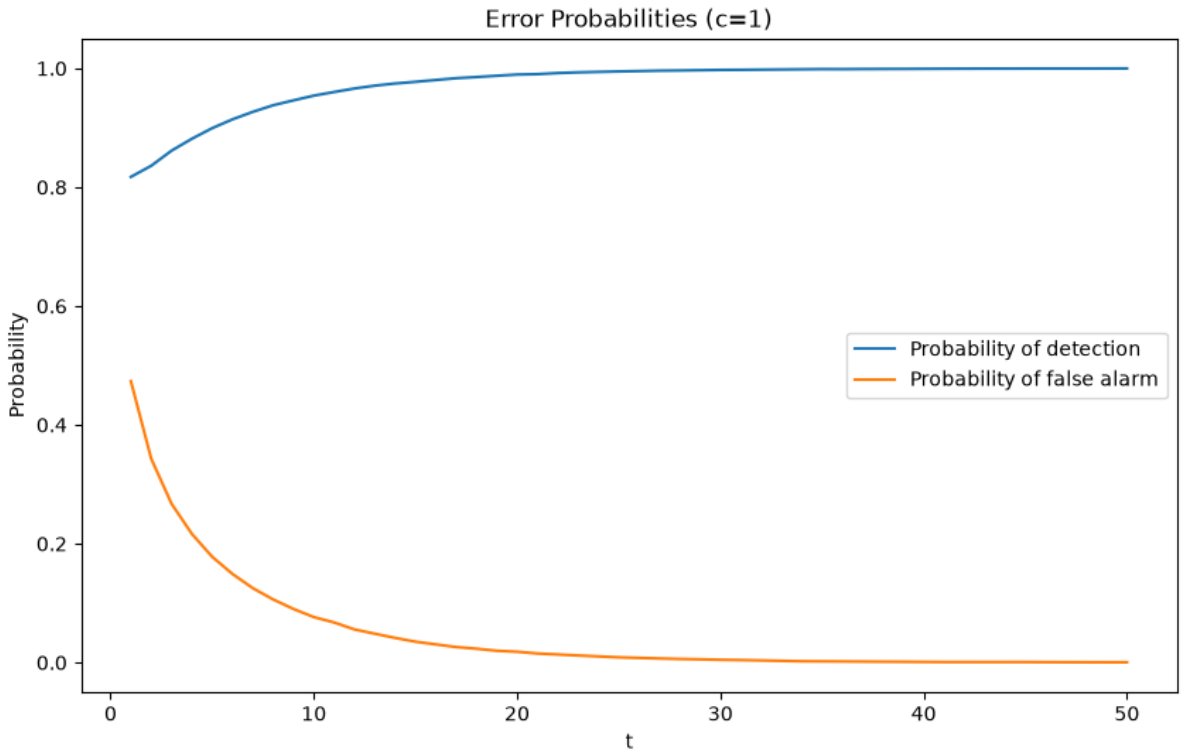
```
def compute_error_probabilities(l_seq_f, l_seq_g, c=1):
    """
    Compute Type I and Type II error probabilities.
    """
    N, T = l_seq_f.shape

    # Type I error (false alarm) - reject H0 when true
    PFA = np.array([np.sum(l_seq_f[:, t] < c) / N for t in range(T)])

    # Type II error - accept H0 when false
    beta = np.array([np.sum(l_seq_g[:, t] >= c) / N for t in range(T)])

    # Probability of detection (power)
    PD = np.array([np.sum(l_seq_g[:, t] < c) / N for t in range(T)])

    return {
        'alpha': PFA,
```



(continues on next page)

(continued from previous page)

```
        'beta': beta,
        'PD': PD,
        'PFA': PFA
    }

def plot_error_probabilities(error_dict, T, c=1, title_suffix=""):
    """Plot error probabilities over time."""
    t_grid = np.arange(1, T+1)
    plt.figure(figsize=(10, 6))
    plt.plot(t_grid, error_dict['PD'], label="Probability of detection")
    plt.plot(t_grid, error_dict['PFA'], label="Probability of false alarm")
    plt.xlabel("t")
    plt.ylabel("Probability")
    plt.title(f"Error Probabilities (c={c}){title_suffix}")
    plt.legend()
    plt.show()

error_probs = compute_error_probabilities(l_seq_f, l_seq_g, c=c)
N, T = l_seq_f.shape
plot_error_probabilities(error_probs, T, c)
```

For a given sample size t, the threshold c uniquely pins down probabilities of both types of error.

If for a fixed t we now free up and move c, we will sweep out the probability of detection as a function of the probability of false alarm.

This produces a receiver operating characteristic curve (ROC curve).

Below, we plot receiver operating characteristic curves for different sample sizes t.

```
def plot_roc_curves(l_seq_f, l_seq_g, t_values=[1, 5, 9, 13], N=None):
    """Plot ROC curves for different sample sizes."""
    if N is None:
        N = l_seq_f.shape[0]

    PFA = np.arange(0, 100, 1)

    plt.figure(figsize=(10, 6))
    for t in t_values:
        # Column t-1 of l_seq holds L(w^t)
        percentile = np.percentile(l_seq_f[:, t-1], PFA)
        PD = [np.sum(l_seq_g[:, t-1] < p) / N for p in percentile]
        plt.plot(PFA / 100, PD, label=f"t={t}")

    plt.scatter(0, 1, label="perfect detection")
    plt.plot([0, 1], [0, 1], color='k', ls='--', label="random detection")

    plt.arrow(0.5, 0.5, -0.15, 0.15, head_width=0.03)
    plt.text(0.35, 0.7, "better")
    plt.xlabel("Probability of false alarm")
    plt.ylabel("Probability of detection")
    plt.legend()
    plt.title("ROC Curve")
    plt.show()

plot_roc_curves(l_seq_f, l_seq_g, t_values=range(1, 15, 4), N=N)
```

Notice that as t increases, we are assured a larger probability of detection and a smaller probability of false alarm associated with a given discrimination threshold c.

For a given sample size t, both α and β change as we vary c.

As we increase c

- $\alpha \equiv \Pr\{L(w^t) < c \mid q = f\}$ increases
- $\beta \equiv \Pr\{L(w^t) > c \mid q = g\}$ decreases

As $t \to +\infty$, we approach the perfect detection curve that is indicated by a right angle hinging on the blue dot.

For a given sample size t, the discrimination threshold c determines a point on the receiver operating characteristic curve.

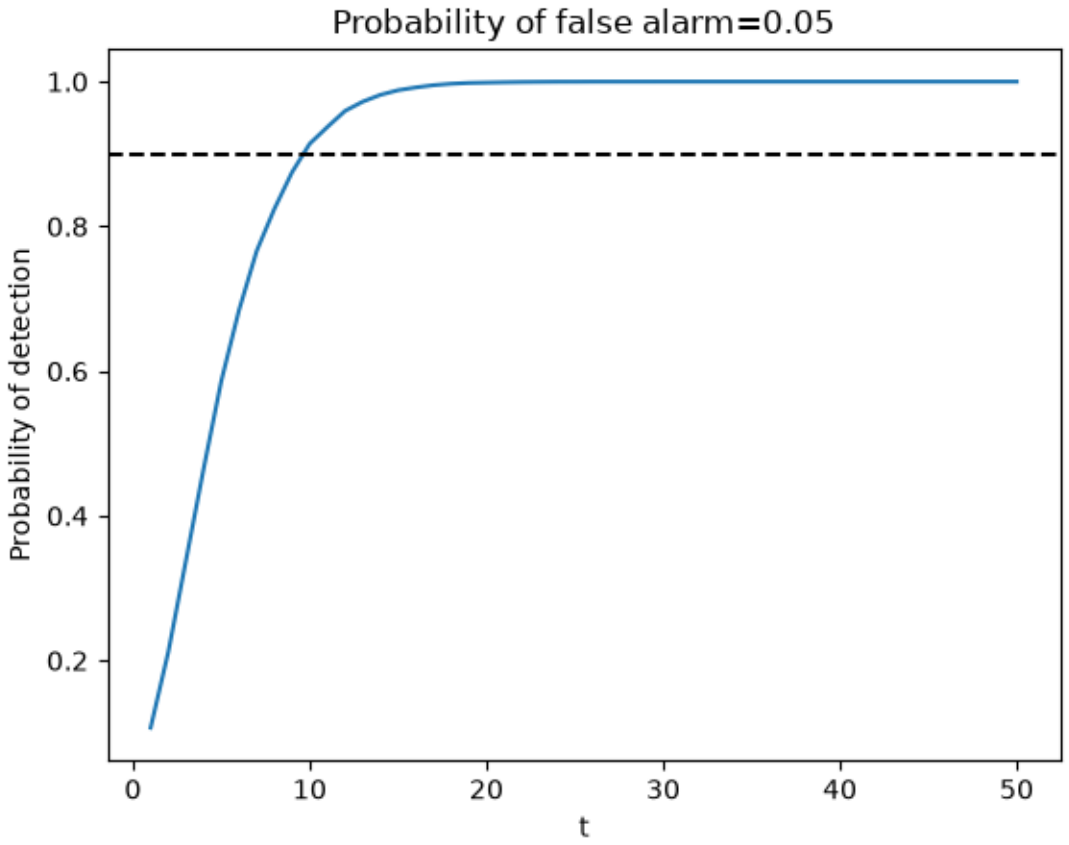
It is up to the test designer to trade off probabilities of making the two types of errors.

But we know how to choose the smallest sample size to achieve given targets for the probabilities.

Typically, frequentists aim for a high probability of detection that respects an upper bound on the probability of false alarm.

Below we show an example in which we fix the probability of false alarm at 0.05.

The required sample size for making a decision is then determined by a target probability of detection, for example, 0.9, as depicted in the following graph.



```
PFA = 0.05
PD = np.empty(T)

for t in range(T):

    c = np.percentile(l_seq_f[:, t], PFA * 100)
    PD[t] = np.sum(l_seq_g[:, t] < c) / N

# PD[t] refers to sample size t+1
plt.plot(np.arange(1, T+1), PD)
plt.axhline(0.9, color="k", ls="--")

plt.xlabel("t")
plt.ylabel("Probability of detection")
plt.title(f"Probability of false alarm={PFA}")
plt.show()
```

The United States Navy evidently used a procedure like this to select a sample size t for doing quality control tests during World War II.

A Navy Captain who had been ordered to perform tests of this kind had doubts about it that he presented to Milton Friedman, as we describe in *this lecture*.

A Bayesian Formulation of Friedman and Wald's Problem formulates the Captain's problem as a Bayesian sequential decision problem, and *Bayesian versus Frequentist Decision Rules* compares the Navy's frequentist rule with the Bayesian decision rule.

22.6.1 A third distribution h

Now let's consider a case in which neither g nor f generates the data.

Instead, a third distribution h does.

Let's study how accumulated likelihood ratios L behave when h governs the data.

A key tool here is called **Kullback–Leibler divergence** we studied in *Statistical Divergence Measures*.

In our application, we want to measure how much f or g diverges from h

Two Kullback–Leibler divergences pertinent for us are K_f and K_g defined as

$$\begin{aligned} K_f = D_{KL}(h\|f) = KL(h,f) &= E_h\left[\log\frac{h(w)}{f(w)}\right] \\ &= \int \log\left(\frac{h(w)}{f(w)}\right) h(w)dw. \end{aligned}$$

$$K_g = D_{KL}(h\|g) = KL(h,g) = E_h\left[\log\frac{h(w)}{g(w)}\right]$$
$$= \int \log\left(\frac{h(w)}{g(w)}\right) h(w)dw.$$

Let's compute the Kullback–Leibler discrepancies using the closed form for Beta densities from *Statistical Divergence Measures*.

```
def KL_beta(a1, b1, a2, b2):
    """KL(Beta(a1, b1) ‖ Beta(a2, b2)) in closed form."""
    return (betaln(a2, b2) - betaln(a1, b1)
            + (a1 - a2) * digamma(a1) + (b1 - b2) * digamma(b1)
            + (a2 - a1 + b2 - b1) * digamma(a1 + b1))

def compute_KL_h(h_params, F_params=(F_a, F_b), G_params=(G_a, G_b)):
    """
    Compute K_f = KL(h, f) and K_g = KL(h, g) for Beta densities h, f, g
    """
    Kf = KL_beta(*h_params, *F_params)
    Kg = KL_beta(*h_params, *G_params)
    return Kf, Kg
```

22.6.2 A helpful formula

There is a mathematical relationship between likelihood ratios and KL divergence.

When data is generated by distribution h, the expected log likelihood ratio is:

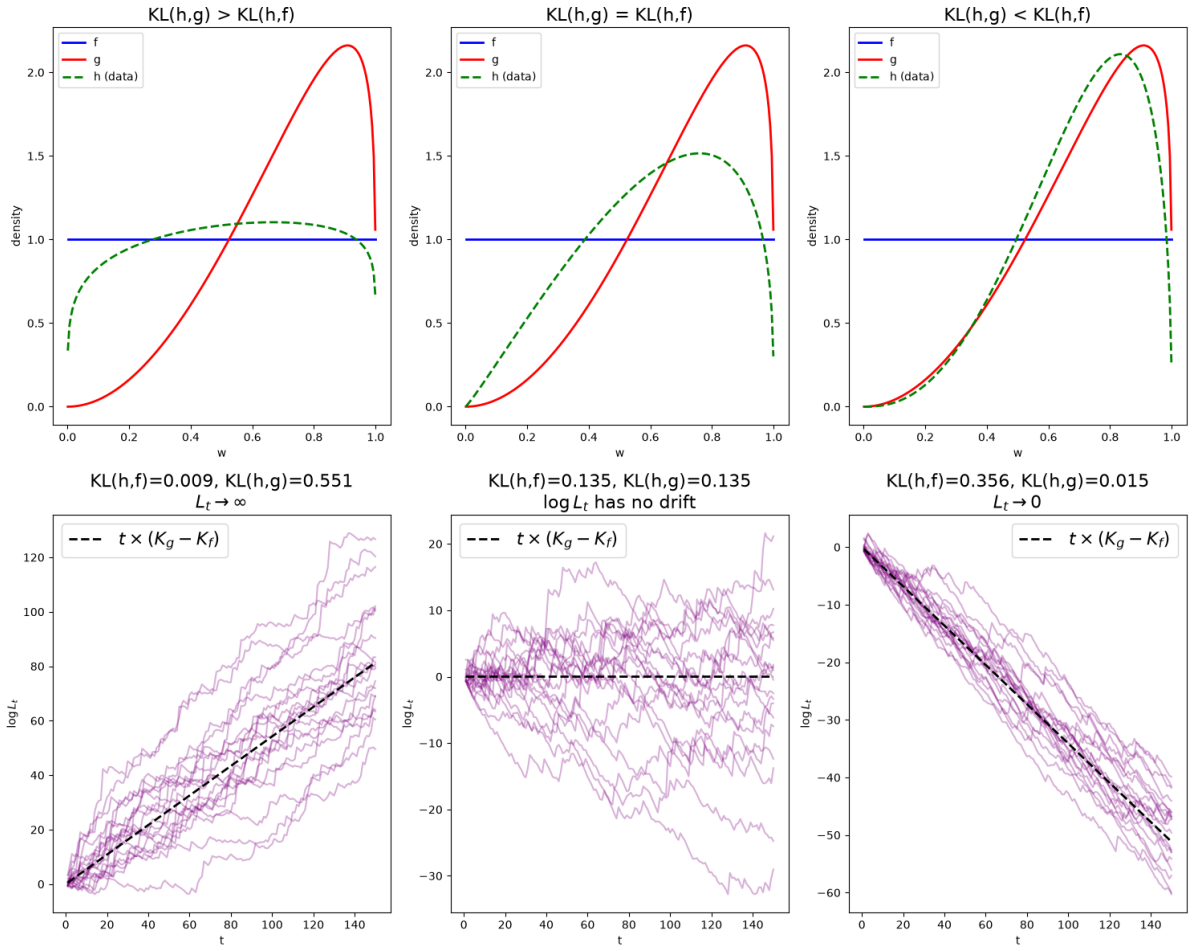
$$\frac{1}{t}E_h[\log L_t] = K_g - K_f \tag{22.1}$$

where $L_t = \prod_{j=1}^{t}\frac{f(w_j)}{g(w_j)}$ is the likelihood ratio process.

Equation (22.1) tells us that:

- When $K_g < K_f$ (i.e., g is closer to h than f is), the expected log likelihood ratio is negative, so $L\left(w^t\right) \to 0$.
- When $K_g > K_f$ (i.e., f is closer to h than g is), the expected log likelihood ratio is positive, so $L\left(w^t\right) \to +\infty$.

Let's verify this using simulation.



In the simulation, we generate multiple paths using Beta distributions f, g, and h, and compute the paths of $\log(L(w^t))$.

First, we write a function to compute the likelihood ratio process

```
def compute_likelihood_ratios(sequences, f, g):
    """Compute likelihood ratios and cumulative products."""
    l_ratios = f(sequences) / g(sequences)
    L_cumulative = np.cumprod(l_ratios, axis=1)
    return l_ratios, L_cumulative
```

We consider three cases: (1) h is closer to f, (2) f and g are equidistant from h, and (3) h is closer to g.

In case (2) we set $h = \text{Beta}(2.1035, 1.35)$, for which K_f and K_g agree to four decimal places.

Note that

- In the first figure, $\log L(w^t)$ diverges to ∞ because $K_g > K_f$.
- In the second figure, $K_g = K_f$, so $\log L(w^t)$ is a random walk with IID increments of mean zero; its paths wander away from zero in both directions, with a spread that grows like $\sqrt{t}$.
- In the last figure, $\log L(w^t)$ diverges to $-\infty$ because $K_g < K_f$.
- The black dashed line, $t\left(D_{KL}(h\|g) - D_{KL}(h\|f)\right)$, passes through the center of the paths, as (22.1) predicts.

These observations align with the theory.

In *Heterogeneous Beliefs and Financial Markets*, we will see an application of these ideas.

22.7 Hypothesis testing and classification

This section discusses another application of likelihood ratio processes.

We describe how a statistician can combine frequentist probabilities of type I and type II errors in order to

- compute an anticipated frequency of selecting a wrong model based on a sample length T
- compute an anticipated error rate in a classification problem

We consider a situation in which nature generates data by mixing known densities f and g with known mixing parameter $\pi_{-1} \in (0, 1)$ so that the random variable w is drawn from the density

$$h(w) = \pi_{-1} f(w) + (1 - \pi_{-1}) g(w)$$

We assume that the statistician knows the densities f and g and also the mixing parameter π_{-1}.

Below, we'll set $\pi_{-1} = .5$, although much of the analysis would follow through with other settings of $\pi_{-1} \in (0, 1)$.

We assume that f and g both put positive probabilities on the same intervals of possible realizations of the random variable W.

In the simulations below, we specify that f is a Beta$(1, 1)$ distribution and that g is Beta$(3, 1.2)$ distribution.

We consider two alternative timing protocols.

- Timing protocol 1 is for the model selection problem
- Timing protocol 2 is for the individual classification problem

Timing Protocol 1: Nature flips a coin only **once** at time $t = -1$ and with probability π_{-1} generates a sequence $\{w_t\}_{t=1}^T$ of IID draws from f and with probability $1 - \pi_{-1}$ generates a sequence $\{w_t\}_{t=1}^T$ of IID draws from g.

Timing Protocol 2: Nature flips a coin **often**. At each time $t \geq 1$, nature flips a coin and with probability π_{-1} draws w_t from f and with probability $1 - \pi_{-1}$ draws w_t from g.

Here is Python code that we'll use to implement timing protocol 1 and 2

```
def protocol_1(π_minus_1, T, rng, N=1000, F_params=(1, 1), G_params=(3, 1.2)):
    """
    Simulate Protocol 1: Nature decides once at t=-1 which model to use.
    """
    F_a, F_b = F_params
    G_a, G_b = G_params

    # Single coin flip for the true model
    true_models_F = rng.random(N) < π_minus_1
    sequences = np.empty((N, T))

    n_f = np.sum(true_models_F)
    n_g = N - n_f

    if n_f > 0:
        sequences[true_models_F, :] = rng.beta(F_a, F_b, (n_f, T))
    if n_g > 0:
        sequences[~true_models_F, :] = rng.beta(G_a, G_b, (n_g, T))

    return sequences, true_models_F

def protocol_2(π_minus_1, T, rng, N=1000, F_params=(1, 1), G_params=(3, 1.2)):
    """
    Simulate Protocol 2: Nature decides at each time step which model to use.
    """
    F_a, F_b = F_params
    G_a, G_b = G_params

    # Coin flips for each time step
    true_models_F = rng.random((N, T)) < π_minus_1
    sequences = np.empty((N, T))

    n_f = np.sum(true_models_F)
```

(continues on next page)

(continued from previous page)

```
    n_g = N * T - n_f

    if n_f > 0:
        sequences[true_models_F] = rng.beta(F_a, F_b, n_f)
    if n_g > 0:
        sequences[~true_models_F] = rng.beta(G_a, G_b, n_g)

    return sequences, true_models_F
```

Remark: Under timing protocol 2, the $\{w_t\}_{t=1}^T$ is a sequence of IID draws from $h(w)$. Under timing protocol 1, the $\{w_t\}_{t=1}^T$ is not IID. It is **conditionally IID** – meaning that with probability π_{-1} it is a sequence of IID draws from $f(w)$ and with probability $1-\pi_{-1}$ it is a sequence of IID draws from $g(w)$. For more about this, see *this lecture about exchangeability*.

Likelihood Ratio Processes and Bayesian Learning studies a Bayesian who knows that timing protocol 1 governs the data and learns which density nature chose.

Incorrect Models studies a Bayesian who wrongly believes timing protocol 1 when timing protocol 2 generates the data.

We again deploy a **likelihood ratio process** with time t component being the likelihood ratio

$$\ell(w_t) = \frac{f(w_t)}{g(w_t)}, \quad t \geq 1.$$

The **likelihood ratio process** for sequence $\{w_t\}_{t=1}^\infty$ is

$$L(w^t) = \prod_{i=1}^t \ell(w_i),$$

For shorthand we'll write $L_t = L(w^t)$.

22.7.1 Model selection mistake probability

We first study a problem that assumes timing protocol 1.

Consider a decision maker who wants to know whether model f or model g governs a data set of length T observations.

The decision maker has observed a sequence $\{w_t\}_{t=1}^T$.

On the basis of that observed sequence, a likelihood ratio test selects model f when $L_T \geq 1$ and model g when $L_T < 1$.

When model f generates the data, the probability that the likelihood ratio test selects the wrong model is

$$p_f = \text{Prob}\left(L_T < 1 \middle| f\right) = \alpha_T.$$

When model g generates the data, the probability that the likelihood ratio test selects the wrong model is

$$p_g = \text{Prob}\left(L_T \geq 1 \middle| g\right) = \beta_T.$$

We can construct a probability that the likelihood ratio selects the wrong model by assigning a Bayesian prior probability of $\pi_{-1} = .5$ that nature selects model f then averaging p_f and p_g to form the prior (ex ante) probability of a detection error equal to

$$p(\text{wrong decision}) = \frac{1}{2}(\alpha_T + \beta_T). \tag{22.2}$$

Now let's simulate timing protocol 1 and compute the error probabilities

```
def compute_protocol_1_errors(π_minus_1, T_max, N_simulations, f_func, g_func,
                              rng, F_params=(1, 1), G_params=(3, 1.2)):
    """
    Compute error probabilities for Protocol 1.
    """
    sequences, true_models = protocol_1(
        π_minus_1, T_max, rng, N_simulations, F_params, G_params)
    l_ratios, L_cumulative = compute_likelihood_ratios(sequences,
                                    f_func, g_func)

    T_range = np.arange(1, T_max + 1)

    mask_f = true_models
    mask_g = ~true_models

    L_f = L_cumulative[mask_f, :]
    L_g = L_cumulative[mask_g, :]

    α_T = np.mean(L_f < 1, axis=0)
    β_T = np.mean(L_g >= 1, axis=0)
    error_prob = 0.5 * (α_T + β_T)

    return {
        'T_range': T_range,
        'alpha': α_T,
        'beta': β_T,
        'error_prob': error_prob,
        'L_cumulative': L_cumulative,
        'true_models': true_models
    }
```

The following code visualizes the error probabilities for timing protocol 1

```
At T=30:
α_30 = 0.0032
β_30 = 0.0038
Model selection error probability = 0.0035
```

Notice how the model selection error probability approaches zero as T grows.

22.7.2 Classification

We now consider a problem that assumes timing protocol 2.

A decision maker wants to classify components of an observed sequence $\{w_t\}_{t=1}^T$ as having been drawn from either f or g.

The decision maker uses the following classification rule:

$$w_t \text{ is from } f \text{ if } l_t \geq 1$$
$$w_t \text{ is from } g \text{ if } l_t < 1.$$

Under this rule, the expected misclassification rate is

$$p(\text{misclassification}) = \frac{1}{2}(\tilde{\alpha}_t + \tilde{\beta}_t) \tag{22.3}$$

where $\tilde{\alpha}_t = \text{Prob}(l_t < 1 \mid f)$ and $\tilde{\beta}_t = \text{Prob}(l_t \geq 1 \mid g)$.

Now let's write some code to simulate it

```
def compute_protocol_2_errors(π_minus_1, T_max, N_simulations, f_func, g_func,
                              rng, F_params=(1, 1), G_params=(3, 1.2)):
    """
    Compute error probabilities for Protocol 2.
    """
    sequences, true_models = protocol_2(π_minus_1,
                        T_max, rng, N_simulations, F_params, G_params)
    l_ratios, _ = compute_likelihood_ratios(sequences, f_func, g_func)

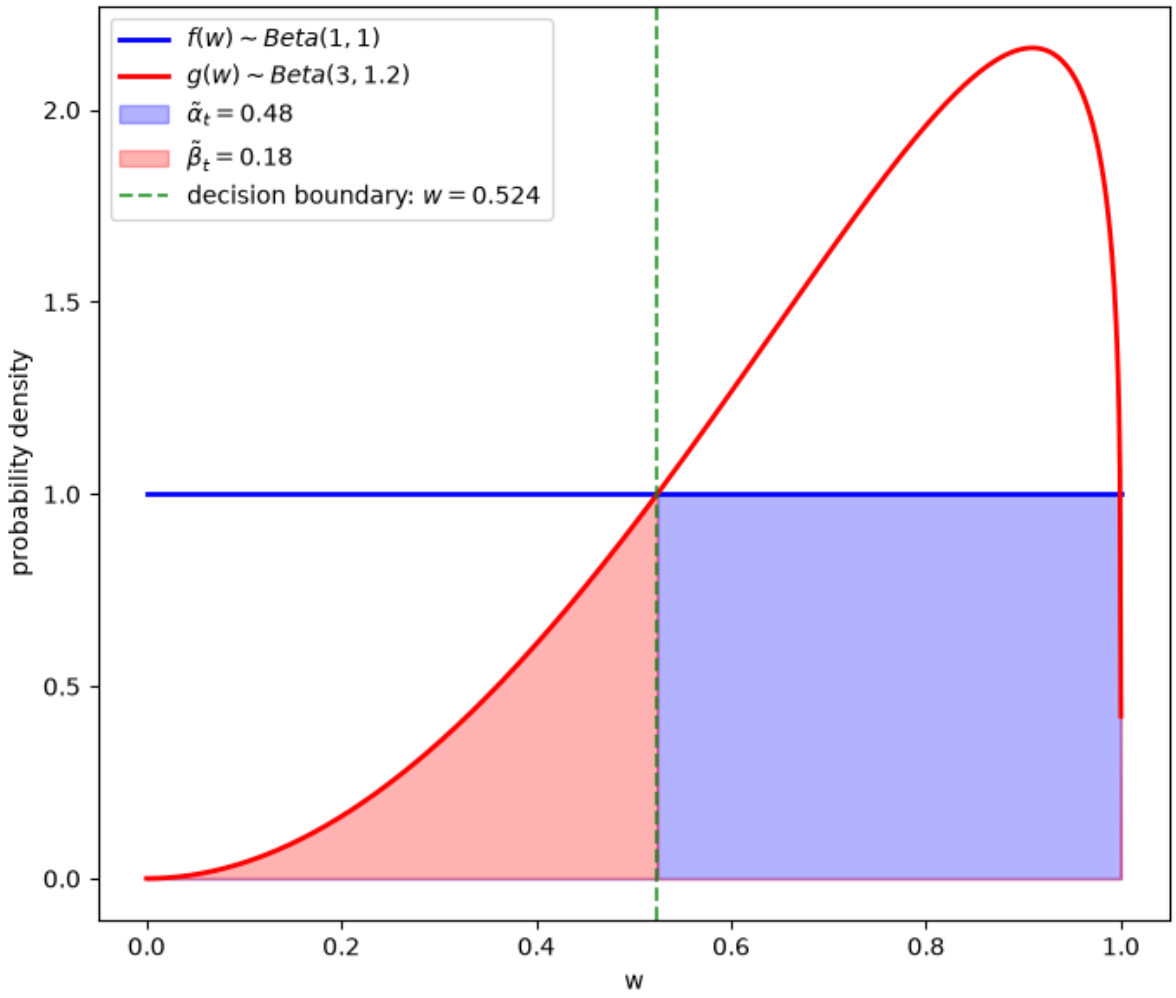
    T_range = np.arange(1, T_max + 1)

    accuracy = np.empty(T_max)
    for t in range(T_max):
        predictions = (l_ratios[:, t] >= 1)
        actual = true_models[:, t]
        accuracy[t] = np.mean(predictions == actual)

    return {
        'T_range': T_range,
        'accuracy': accuracy,
        'l_ratios': l_ratios,
        'true_models': true_models
    }
```

Since for each t, the decision boundary is the same, the decision boundary can be computed as

```
root = brentq(lambda w: f(w) / g(w) - 1, 0.001, 0.99)
root_2 = brentq(lambda w: f(w) / g(w) - 1, 0.99, 1 - 1e-12)
print(f"f/g = 1 at w = {root:.4f} and at w = {root_2:.5f}")
```



```
f/g = 1 at w = 0.5241 and at w = 0.99925
```

The likelihood ratio f/g equals 1 at two points, because g vanishes at both ends of $(0, 1)$.

The rule classifies w_t as coming from g when w_t lies between the two roots and as coming from f otherwise.

The second root lies so close to 1 that the interval to its right has probability below 0.001 under both f and g.

We can plot the distributions of f and g and the decision boundary

To the left of the green vertical line $g < f$, so $l_t > 1$; therefore a w_t that falls to the left of the green line is classified as a type f individual.

- The shaded red area equals $\tilde{\beta}_t$ – the probability of classifying someone as a type f individual when it is really a type g individual.

To the right of the green vertical line and to the left of the second root $w = 0.99925$, $g > f$, so $l_t < 1$; therefore a w_t that falls in this interval is classified as a type g individual.

- The shaded blue area equals $\tilde{\alpha}_t$ – the probability of classifying someone as a type g individual when it is really a type f individual.

This gives us clues about how to compute the theoretical classification error probability

```
# tilde α_t = P(l_t < 1 | f) = P(root < w < root_2 | f)
α_theory = beta_dist.cdf(root_2, F_a, F_b) - beta_dist.cdf(root, F_a, F_b)

# tilde β_t = P(l_t >= 1 | g) = P(w <= root or w >= root_2 | g)
β_theory = beta_dist.cdf(root, G_a, G_b) + beta_dist.sf(root_2, G_a, G_b)

theory_error = 0.5 * (α_theory + β_theory)

print(f"theoretical tilde α_t = {α_theory:.4f}")
```

(continues on next page)

(continued from previous page)

```
print(f"theoretical tilde β_t = {β_theory:.4f}")
print(f"theoretical classification error probability = {theory_error:.4f}")
```

```
theoretical tilde α_t = 0.4752
theoretical tilde β_t = 0.1836
theoretical classification error probability = 0.3294
```

Now we simulate timing protocol 2 and compute the classification error probability.

In the next cell, we also compare the theoretical classification accuracy to the empirical classification accuracy

```
def analyze_protocol_2(π_minus_1, T_max, N_simulations, f_func, g_func, rng,
                       theory_error=None, F_params=(1, 1), G_params=(3, 1.2)):
    """Analyze Protocol 2."""
    result = compute_protocol_2_errors(π_minus_1, T_max, N_simulations,
                                       f_func, g_func, rng, F_params, G_params)

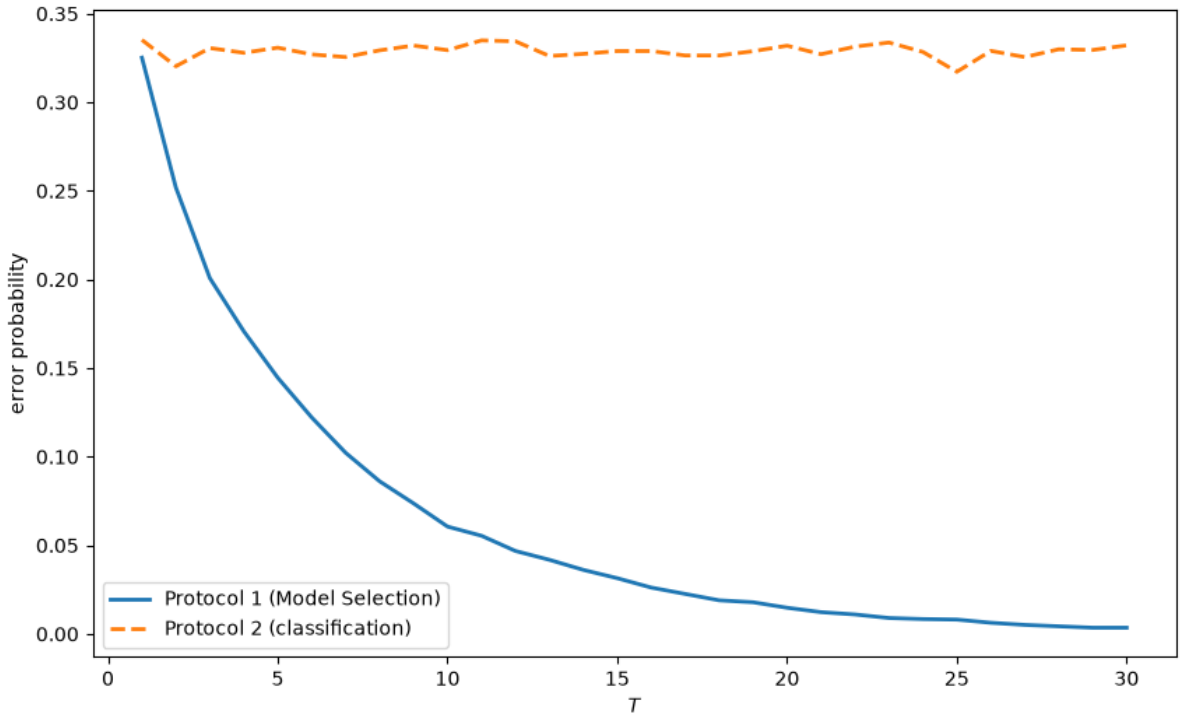
    # Plot results
    plt.figure(figsize=(10, 6))
    plt.plot(result['T_range'], result['accuracy'],
             'b-', linewidth=2, label='empirical accuracy')

    if theory_error is not None:
        plt.axhline(1 - theory_error, color='r', linestyle='--',
                    label=f'theoretical accuracy = {1 - theory_error:.4f}')

    plt.xlabel('$t$')
    plt.ylabel('accuracy')
    plt.legend()
    plt.ylim(0.5, 1.0)
    plt.show()

    return result

# Analyze Protocol 2
result_p2 = analyze_protocol_2(π_minus_1, T_max, N_simulations, f, g, rng,
                               theory_error, (F_a, F_b), (G_a, G_b))
```



Let's watch decisions made by the two timing protocols as more and more observations accrue.

```
def compare_protocols(result1, result2):
    """Compare results from both protocols."""
    plt.figure(figsize=(10, 6))

    plt.plot(result1['T_range'], result1['error_prob'], linewidth=2,
             label='Protocol 1 (Model Selection)')
    plt.plot(result2['T_range'], 1 - result2['accuracy'],
             linestyle='--', linewidth=2,
             label='Protocol 2 (classification)')

    plt.xlabel('$T$')
    plt.ylabel('error probability')
    plt.legend()
    plt.show()

compare_protocols(result_p1, result_p2)
```

From the figure above, we can see:

- For both timing protocols, the error probability starts at the same level, subject to a little randomness.
- For timing protocol 1, the error probability decreases as the sample size increases because we are making just **one** decision – i.e., selecting whether f or g governs **all** individuals. More data provides better evidence.
- For timing protocol 2, the error probability remains constant because we are making **many** decisions – one classification decision for each observation.

Remark: Think about how laws of large numbers are applied to compute error probabilities for the model selection problem and the classification problem.

22.7.3 Error probability and divergence measures

A plausible guess is that the ability of a likelihood ratio to distinguish distributions f and g depends on how "different" they are.

We have learnt some measures of "difference" between distributions in *Statistical Divergence Measures*.

Let's now study two more measures of "difference" between distributions that are useful in the context of model selection and classification.

Recall that Chernoff entropy between probability densities f and g is defined as:

$$C(f,g) = -\log \min_{\phi \in (0,1)} \rho(\phi), \qquad \rho(\phi) = \int f^{\phi}(x) g^{1-\phi}(x) dx$$

Let $f_T(w^T) = \prod_{t=1}^{T} f(w_t)$ and $g_T(w^T) = \prod_{t=1}^{T} g(w_t)$ be the joint densities of w^T under the two models.

The likelihood ratio test selects f when $f_T \geq g_T$ and g when $f_T < g_T$.

Its model selection error probability (22.2) is therefore

$$\frac{1}{2}(\alpha_T + \beta_T) = \frac{1}{2}\int_{f_T<g_T} f_T\, dw^T + \frac{1}{2}\int_{f_T\geq g_T} g_T\, dw^T = \frac{1}{2}\int \min\{f_T, g_T\}\, dw^T.$$

For $x, y \geq 0$ and $\phi \in [0,1]$, $\min\{x,y\} \leq x^\phi y^{1-\phi}$.

Because the w_t's are IID,

$$\frac{1}{2}(\alpha_T + \beta_T) \leq \frac{1}{2}\int f_T^\phi\, g_T^{1-\phi}\, dw^T = \frac{1}{2}\rho(\phi)^T$$

for every $\phi \in [0,1]$.

Minimizing the right side over ϕ gives an upper bound on model selection error probability:

$$\frac{1}{2}(\alpha_T + \beta_T) \leq \frac{1}{2}e^{-C(f,g)T}. \tag{22.4}$$

The weaker bound $e^{-C(f,g)T}$ also holds.

Chernoff [1952] showed that the bound (22.4) delivers the correct exponential rate:

$$-\frac{1}{T}\log\frac{1}{2}(\alpha_T + \beta_T) \to C(f,g).$$

The approach to the limit is slow, because the error probability contains a factor that decays polynomially in T, which the bound omits.

For Beta densities, the Chernoff coefficient $\rho(\phi)$ has a closed form that we derived in *Statistical Divergence Measures*.

Let's compute Chernoff entropy with some Python code

```
def log_chernoff_coef_beta(ϕ, a1, b1, a2, b2):
    """log ρ(ϕ) for Beta(a1, b1) and Beta(a2, b2) in closed form."""
    return (betaln(ϕ * a1 + (1 - ϕ) * a2, ϕ * b1 + (1 - ϕ) * b2)
            - ϕ * betaln(a1, b1) - (1 - ϕ) * betaln(a2, b2))

def chernoff_beta(a1, b1, a2, b2):
    """Chernoff entropy C(f, g) and minimizing ϕ for two Beta densities."""
    res = minimize_scalar(log_chernoff_coef_beta, bounds=(0, 1),
                          args=(a1, b1, a2, b2), method='bounded')
    return -res.fun, res.x

C_fg, ϕ_optimal = chernoff_beta(F_a, F_b, G_a, G_b)
print(f"Chernoff entropy C(f,g) = {C_fg:.4f}")
print(f"Optimal ϕ = {ϕ_optimal:.4f}")
```

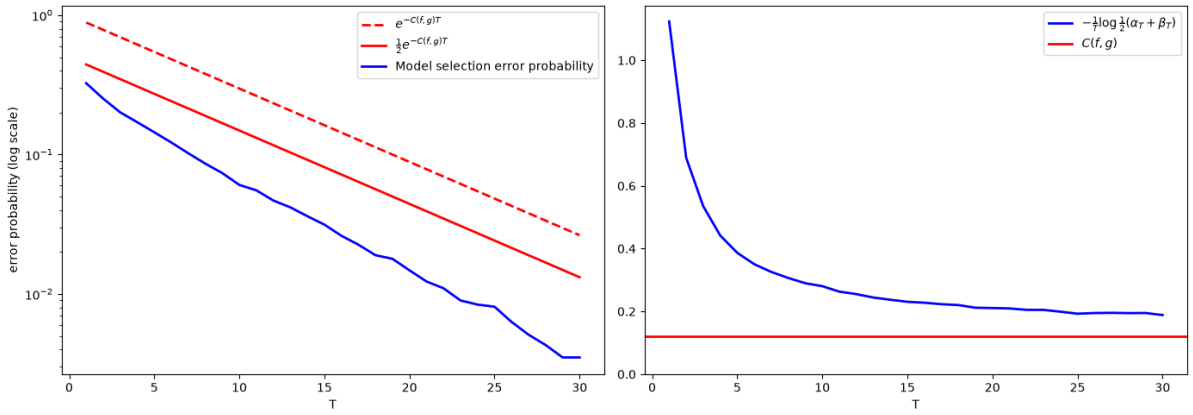
```
Chernoff entropy C(f,g) = 0.1212
Optimal ϕ = 0.5969
```

Now let's compare the model selection error probability that we simulated under timing protocol 1 with the bounds $\frac{1}{2}e^{-C(f,g)T}$ and $e^{-C(f,g)T}$.

The right panel plots $-\frac{1}{T}$ log of the simulated error probability against T.

```
T_range = np.arange(1, T_max+1)
chernoff_bound = 0.5 * np.exp(-C_fg * T_range)

fig, (ax1, ax2) = plt.subplots(1, 2, figsize=(14, 5))
```



(continues on next page)

(continued from previous page)

```
ax1.semilogy(T_range, 2 * chernoff_bound, 'r--', linewidth=2,
             label=f'$e^{{-C(f,g)T}}$')
ax1.semilogy(T_range, chernoff_bound, 'r-', linewidth=2,
             label=r'$\frac{1}{2} e^{-C(f,g)T}$')
ax1.semilogy(T_range, result_p1['error_prob'], 'b-', linewidth=2,
             label='Model selection error probability')
ax1.set_xlabel('T')
ax1.set_ylabel('error probability (log scale)')
ax1.legend()

ax2.plot(T_range, -np.log(result_p1['error_prob']) / T_range, 'b-',
         linewidth=2, label=r'$-\frac{1}{T}\log \frac{1}{2}(\alpha_T + \beta_T)$')
ax2.axhline(C_fg, color='r', linestyle='-', linewidth=2, label='$C(f,g)$')
ax2.set_xlabel('T')
ax2.set_ylim(0, None)
ax2.legend()

plt.tight_layout()
plt.show()
```

The simulated error probability lies below $\frac{1}{2}e^{-C(f,g)T}$, as (22.4) requires.

Its negative log divided by T declines toward $C(f,g)$ slowly.

In *Statistical Divergence Measures*, we also studied **Jensen-Shannon divergence** as a symmetric measure of distance between distributions.

We can use Jensen-Shannon divergence to measure the distance between distributions f and g and compute how it covaries with the model selection error probability.

We also compute Jensen-Shannon divergence numerically with some Python code.

We integrate over all of $(0,1)$, splitting the interval at $1/2$, because U-shaped Beta densities diverge at the endpoints.

```
def compute_JS(f, g):
    """
    Compute Jensen-Shannon divergence
    """
    def integrand(w):
        fw, gw = f(w), g(w)
        mw = 0.5 * (fw + gw)
        return 0.5 * fw * np.log(fw / mw) + 0.5 * gw * np.log(gw / mw)
```

(continues on next page)

(continued from previous page)

```
    left, _ = quad(integrand, 0, 0.5, limit=200)
    right, _ = quad(integrand, 0.5, 1, limit=200)
    return left + right
```

Now let's return to our guess that the error probability at large sample sizes is related to the Chernoff entropy between two distributions.

We verify this by computing the correlation between the log of the error probability at $T = 50$ under Timing Protocol 1 and the divergence measures.

We use the following pairs of Beta distributions for f and g as test cases

```
distribution_pairs = [
    # (f_params, g_params)
    ((1, 1), (0.1, 0.2)),
    ((1, 1), (0.3, 0.3)),
    ((1, 1), (0.3, 0.4)),
    ((1, 1), (0.5, 0.5)),
    ((1, 1), (0.7, 0.6)),
    ((1, 1), (0.9, 0.8)),
    ((1, 1), (1.1, 1.05)),
    ((1, 1), (1.2, 1.1)),
    ((1, 1), (1.5, 1.2)),
    ((1, 1), (2, 1.5)),
    ((1, 1), (2.5, 1.8)),
    ((1, 1), (3, 1.2)),
    ((1, 1), (4, 1)),
    ((1, 1), (5, 1))
]
```

For the most distinct pair, the Chernoff bound (22.4) puts the error probability at $T = 50$ below $\frac{1}{2}e^{-0.443\times 50} \approx 1.2 \times 10^{-10}$.

A simulation of a few thousand sequences from f and from g typically records no errors at all for several of these pairs.

We compute the error probabilities instead by importance sampling, a technique that *Mean of a Likelihood Ratio Process* describes.

We draw w^T from the **tilted density**

$$q(w) = \frac{f(w)^{\phi^*} g(w)^{1-\phi^*}}{\rho(\phi^*)},$$

where ϕ^* attains the minimum in the definition of $C(f, g)$.

For Beta densities f and g, q is again a Beta density, as *Statistical Divergence Measures* shows.

Since $f/q = \rho(\phi^*)\,\ell^{1-\phi^*}$ and $g/q = \rho(\phi^*)\,\ell^{-\phi^*}$,

$$\frac{1}{2}(\alpha_T + \beta_T) = \frac{1}{2}\int \min\left\{\frac{f_T}{q_T}, \frac{g_T}{q_T}\right\} q_T\, dw^T = \frac{1}{2} e^{-C(f,g)T}\, E_q\left[\min\left\{L_T^{1-\phi^*}, L_T^{-\phi^*}\right\}\right],$$

where $q_T(w^T) = \prod_{t=1}^T q(w_t)$.

The random variable inside the expectation lies between 0 and 1.

That fact delivers the bound (22.4) once more and gives the sample average of $\min\{L_T^{1-\phi^*}, L_T^{-\phi^*}\}$ a small variance.

```
def log_beta_pdf(w, a, b):
    """Log density of Beta(a, b)."""
    return (a - 1) * np.log(w) + (b - 1) * np.log1p(-w) - betaln(a, b)

def error_prob_tilted(f_params, g_params, T, N, rng):
    """
    Model selection error probability (α_T + β_T) / 2 by
    importance sampling from the Chernoff-tilted density.
    """
    (f_a, f_b), (g_a, g_b) = f_params, g_params
    C, ϕ = chernoff_beta(f_a, f_b, g_a, g_b)
    q_a, q_b = ϕ * f_a + (1 - ϕ) * g_a, ϕ * f_b + (1 - ϕ) * g_b

    # Keep draws off the boundary, where the log densities are infinite
    w = np.clip(rng.beta(q_a, q_b, (N, T)), 1e-300, 1 - 1e-16)
    log_L = np.sum(log_beta_pdf(w, f_a, f_b)
                   - log_beta_pdf(w, g_a, g_b), axis=1)
    weights = np.exp(np.minimum((1 - ϕ) * log_L, -ϕ * log_L))
    return 0.5 * np.exp(-C * T) * np.mean(weights)
```

As a check, we apply the importance sampling estimator to our f and g at $T = 30$ and compare it with the simulation of timing protocol 1 above.

```
is_estimate = error_prob_tilted((F_a, F_b), (G_a, G_b), T_max, 5000, rng)
print(f"Importance sampling estimate at T={T_max}: {is_estimate:.5f}")
print(f"Simulated protocol 1 error at T={T_max}:   "
      f"{result_p1['error_prob'][-1]:.5f}")
```

```
Importance sampling estimate at T=30: 0.00368
Simulated protocol 1 error at T=30:   0.00350
```

Now we compute the divergence measures and the error probability at $T = 50$ for every pair

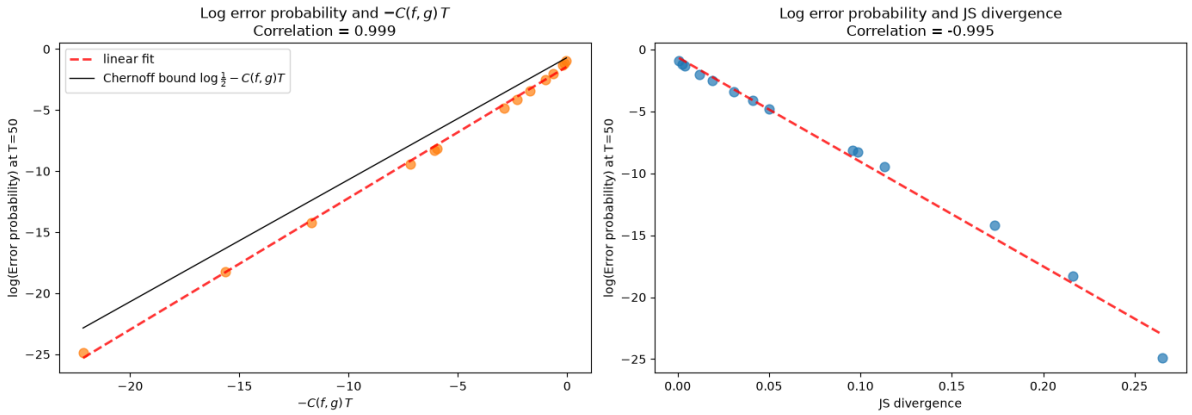
```
# Parameters for simulation
T_large = 50
N_sims = 5000

# Initialize arrays
n_pairs = len(distribution_pairs)
kl_fg_vals = np.zeros(n_pairs)
kl_gf_vals = np.zeros(n_pairs)
js_vals = np.zeros(n_pairs)
chernoff_vals = np.zeros(n_pairs)
error_probs = np.zeros(n_pairs)
pair_names = []

for i, ((f_a, f_b), (g_a, g_b)) in enumerate(distribution_pairs):
    # Create density functions
    f_pair = jit(lambda x, a=f_a, b=f_b: p(x, a, b))
    g_pair = jit(lambda x, a=g_a, b=g_b: p(x, a, b))

    # Compute divergence measures
    kl_fg_vals[i] = KL_beta(f_a, f_b, g_a, g_b)
    kl_gf_vals[i] = KL_beta(g_a, g_b, f_a, f_b)
    js_vals[i] = compute_JS(f_pair, g_pair)
    chernoff_vals[i], _ = chernoff_beta(f_a, f_b, g_a, g_b)
```

(continues on next page)



(continued from previous page)

```
    # Error probability by importance sampling
    error_probs[i] = error_prob_tilted((f_a, f_b), (g_a, g_b),
                                       T_large, N_sims, rng)
    pair_names.append(f"Beta({f_a},{f_b}) and Beta({g_a},{g_b})")

cor_data = {
    'kl_fg': kl_fg_vals,
    'kl_gf': kl_gf_vals,
    'js': js_vals,
    'chernoff': chernoff_vals,
    'error_prob': error_probs,
    'names': pair_names,
    'T': T_large}
```

Now let's visualize the correlations.

The left panel plots the log error probability against $-C(f,g)T$, together with the Chernoff bound $\log \frac{1}{2} - C(f,g)T$.

All fourteen points lie below the Chernoff bound.

Evidently, Chernoff entropy and Jensen-Shannon divergence each covary tightly with the model selection error probability.

The vertical distance between the points and the Chernoff bound is the log of $E_q\left[\min\left\{L_T^{1-\phi^*}, L_T^{-\phi^*}\right\}\right]$, which varies across pairs much less than $C(f,g)T$ does.

We'll encounter related ideas in *A Problem that Stumped Milton Friedman* very soon.

22.8 Markov chains

Let's now look at a likelihood ratio process for a sequence of random variables that is not independently and identically distributed.

Here we assume that the sequence is generated by a Markov chain on a finite state space.

We consider two n-state irreducible and aperiodic Markov chain models on the same state space $\{1, 2, \ldots, n\}$ with positive transition matrices $P^{(f)}$, $P^{(g)}$ and initial distributions $\pi_0^{(f)}$, $\pi_0^{(g)}$.

We assume that nature samples from chain f.

For a sample path $(x_0, x_1, \ldots, x_T)$, let N_{ij} count transitions from state i to j.

The likelihood process under model $m \in \{f, g\}$ is

$$L_T^{(m)} = \pi_{0,x_0}^{(m)} \prod_{i=1}^{n} \prod_{j=1}^{n} \left(P_{ij}^{(m)}\right)^{N_{ij}}$$

Hence,

$$\log L_T^{(m)} = \log \pi_{0,x_0}^{(m)} + \sum_{i,j} N_{ij} \log P_{ij}^{(m)}$$

The log-likelihood ratio is

$$\log \frac{L_T^{(f)}}{L_T^{(g)}} = \log \frac{\pi_{0,x_0}^{(f)}}{\pi_{0,x_0}^{(g)}} + \sum_{i,j} N_{ij} \log \frac{P_{ij}^{(f)}}{P_{ij}^{(g)}} \tag{22.5}$$

22.8.1 KL divergence rate

By the ergodic theorem for irreducible Markov chains, we have

$$\frac{N_{ij}}{T} \xrightarrow{a.s.} \pi_i^{(f)} P_{ij}^{(f)} \quad \text{as } T \to \infty$$

where $\pi^{(f)}$ is the stationary distribution satisfying $\pi^{(f)} = \pi^{(f)} P^{(f)}$.

Therefore,

$$\frac{1}{T} \log \frac{L_T^{(f)}}{L_T^{(g)}} = \frac{1}{T} \log \frac{\pi_{0,x_0}^{(f)}}{\pi_{0,x_0}^{(g)}} + \frac{1}{T} \sum_{i,j} N_{ij} \log \frac{P_{ij}^{(f)}}{P_{ij}^{(g)}}$$

Taking the limit as $T \to \infty$, we have:

- The first term: $\frac{1}{T} \log \frac{\pi_{0,x_0}^{(f)}}{\pi_{0,x_0}^{(g)}} \to 0$
- The second term: $\frac{1}{T} \sum_{i,j} N_{ij} \log \frac{P_{ij}^{(f)}}{P_{ij}^{(g)}} \xrightarrow{a.s.} \sum_{i,j} \pi_i^{(f)} P_{ij}^{(f)} \log \frac{P_{ij}^{(f)}}{P_{ij}^{(g)}}$

Define the **KL divergence rate** as

$$h_{KL}(f, g) = \sum_{i=1}^{n} \pi_i^{(f)} \underbrace{\sum_{j=1}^{n} P_{ij}^{(f)} \log \frac{P_{ij}^{(f)}}{P_{ij}^{(g)}}}_{=: KL(P_{i\cdot}^{(f)}, P_{i\cdot}^{(g)})}$$

where $KL(P_{i\cdot}^{(f)}, P_{i\cdot}^{(g)})$ is the row-wise KL divergence.

By the ergodic theorem, we have

$$\frac{1}{T} \log \frac{L_T^{(f)}}{L_T^{(g)}} \xrightarrow{a.s.} h_{KL}(f, g) \quad \text{as } T \to \infty$$

Taking expectations and using the dominated convergence theorem, we obtain

$$\frac{1}{T} E_f \left[\log \frac{L_T^{(f)}}{L_T^{(g)}} \right] \to h_{KL}(f, g) \quad \text{as } T \to \infty$$

Here we invite readers to pause and compare this result with (22.1).

Likelihood Processes For VAR Models extends these calculations to vector autoregressions.

Let's confirm this in the simulation below.

22.8.2 Simulations

Let's implement simulations to illustrate these concepts with a three-state Markov chain.

We start by writing functions to compute the stationary distribution and the KL divergence rate for Markov chain models.

Now let's create an example with two different 3-state Markov chains.

We are now ready to simulate paths and visualize how likelihood ratios evolve.

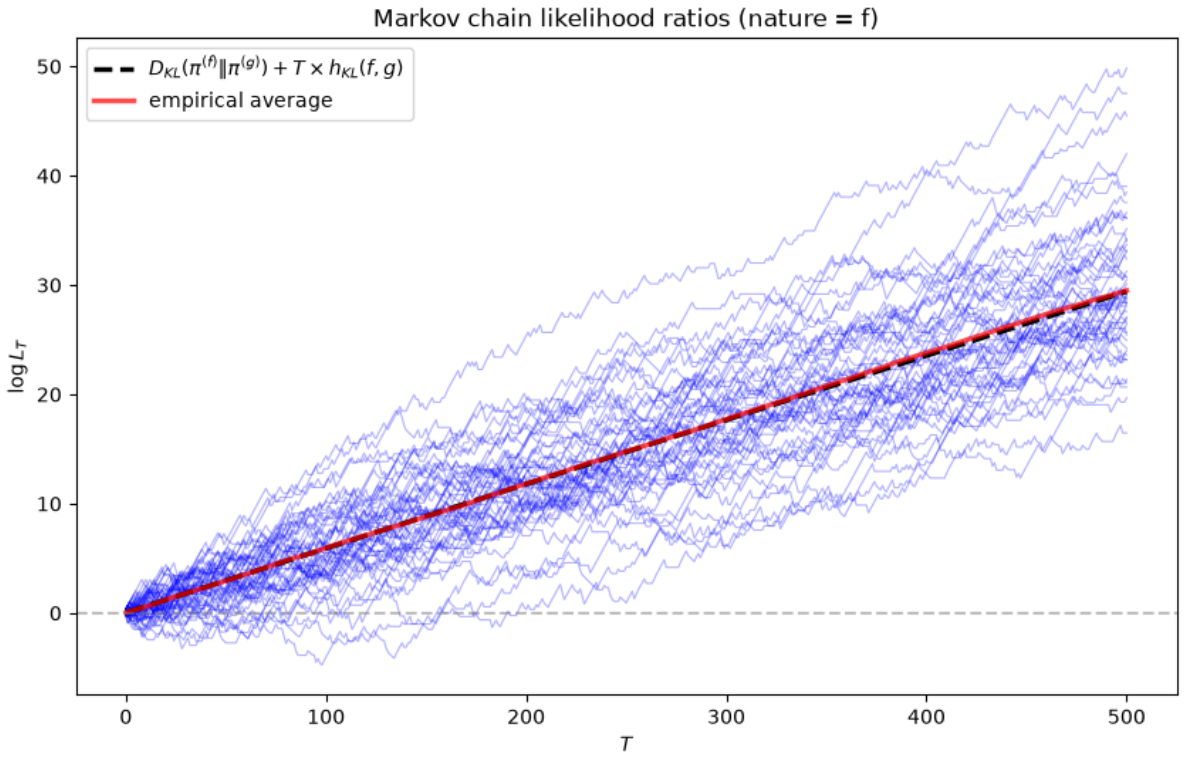
We draw x_0 from the stationary distribution $\pi^{(f)}$ and set $\pi_0^{(f)} = \pi^{(f)}$ and $\pi_0^{(g)} = \pi^{(g)}$.

The chain is then stationary under f, so $E_f N_{ij} = T\pi_i^{(f)} P_{ij}^{(f)}$ and (22.5) implies

$$E_f\left[\log \frac{L_T^{(f)}}{L_T^{(g)}}\right] = D_{KL}(\pi^{(f)} \| \pi^{(g)}) + T\, h_{KL}(f, g)$$

for every T.

We verify this formula by plotting both the empirical average and the line predicted by the theory



```
# Define example Markov chain transition matrices
P_f = np.array([[0.7, 0.2, 0.1],
                [0.3, 0.5, 0.2],
                [0.1, 0.3, 0.6]])

P_g = np.array([[0.5, 0.3, 0.2],
                [0.2, 0.6, 0.2],
                [0.2, 0.2, 0.6]])

markov_results = analyze_markov_chains(P_f, P_g, rng)
```

```
Stationary distribution (f): [0.41176471 0.32352941 0.26470588]
Stationary distribution (g): [0.28571429 0.38095238 0.33333333]

KL divergence rate h(f, g): 0.0588
KL divergence rate h(g, f): 0.0563
KL(π_f, π_g): 0.0366
```

22.9 Related lectures

Likelihood processes play an important role in Bayesian learning, as described in *Likelihood Ratio Processes and Bayesian Learning* and as applied in *Job Search IX: Search with Learning*.

Likelihood ratio processes are central to Lawrence Blume and David Easley's answer to their question "If you're so smart, why aren't you rich?" [Blume and Easley, 2006], the subject of the lecture *Heterogeneous Beliefs and Financial Markets*.

Likelihood ratio processes also appear in Additive and Multiplicative Functionals, which contains another illustration of the **peculiar property** of likelihood ratio processes described above.

22.10 Exercises

Exercise 22.10.1

Consider the setting where nature generates data from a third density h.

Let $\{w_t\}_{t=1}^T$ be IID draws from h, and let $L_t = L(w^t)$ be the likelihood ratio process defined as in the lecture.

Assume that K_f and K_g are finite and that $E_h|\log f(W)| < \infty$ and $E_h|\log g(W)| < \infty$.

Show that:

$$\frac{1}{t} E_h[\log L_t] = K_g - K_f$$

Hint: Start by expressing $\log L_t$ as a sum of $\log \ell(w_i)$ terms and compare with the definition of K_f and K_g.

Solution

Since $w_1, \ldots, w_t$ are IID draws from h, we can write

$$\log L_t = \log \prod_{i=1}^{t} \ell(w_i) = \sum_{i=1}^{t} \log \ell(w_i) = \sum_{i=1}^{t} \log \frac{f(w_i)}{g(w_i)}$$

Taking the expectation under h

$$E_h[\log L_t] = E_h\left[\sum_{i=1}^{t} \log \frac{f(w_i)}{g(w_i)}\right] = \sum_{i=1}^{t} E_h\left[\log \frac{f(w_i)}{g(w_i)}\right]$$

Since the w_i are identically distributed

$$E_h[\log L_t] = t \cdot E_h\left[\log \frac{f(w)}{g(w)}\right]$$

where $w \sim h$.

Therefore

$$\frac{1}{t} E_h[\log L_t] = E_h\left[\log \frac{f(w)}{g(w)}\right] = E_h[\log f(w)] - E_h[\log g(w)]$$

Now, from the definition of Kullback-Leibler divergence

$$K_f = \int h(w) \log \frac{h(w)}{f(w)} dw = E_h[\log h(w)] - E_h[\log f(w)]$$

This gives us

$$E_h[\log f(w)] = E_h[\log h(w)] - K_f$$

Similarly

$$E_h[\log g(w)] = E_h[\log h(w)] - K_g$$

Substituting back

$$\begin{aligned} \frac{1}{t} E_h[\log L_t] &= E_h[\log f(w)] - E_h[\log g(w)] \\ &= [E_h[\log h(w)] - K_f] - [E_h[\log h(w)] - K_g] \\ &= K_g - K_f \end{aligned}$$

Exercise 22.10.2

Building on Exercise 22.10.1, use the result to explain what happens to L_t as $t \to \infty$ in the following cases:

1. When $K_g > K_f$ (i.e., f is "closer" to h than g is)
2. When $K_g < K_f$ (i.e., g is "closer" to h than f is)

Relate your answer to the simulation results shown in *this section*.

Solution

From Exercise 22.10.1, we know that:

$$\frac{1}{t}E_h[\log L_t] = K_g - K_f$$

Case 1: When $K_g > K_f$

Here, f is "closer" to h than g is. Since $K_g - K_f > 0$

$$E_h[\log L_t] = t \cdot (K_g - K_f) \to +\infty \text{ as } t \to \infty$$

By the strong law of large numbers, $\frac{1}{t}\log L_t \to K_g - K_f > 0$ almost surely.

Therefore $L_t \to +\infty$ almost surely.

Case 2: When $K_g < K_f$

Here, g is "closer" to h than f is. Since $K_g - K_f < 0$

$$E_h[\log L_t] = t \cdot (K_g - K_f) \to -\infty \text{ as } t \to \infty$$

Therefore by similar reasoning $L_t \to 0$ almost surely.

Exercise 22.10.3

This exercise extends the Chernoff bound (22.4) to the Markov chains of *this section*.

Let x_0 be drawn from $\pi_0^{(f)}$ under model f and from $\pi_0^{(g)}$ under model g.

The likelihood ratio test selects f when $L_T^{(f)}/L_T^{(g)} \geq 1$ and g otherwise; let α_T and β_T be its two error probabilities.

For $\phi \in [0,1]$, let Q_ϕ be the $n \times n$ matrix with entries $Q_\phi(i,j) = (P_{ij}^{(f)})^{\phi}(P_{ij}^{(g)})^{1-\phi}$, and let $\lambda(\phi)$ be its largest eigenvalue (the Perron root).

1. Show that

$$\frac{1}{2}(\alpha_T + \beta_T) \leq \frac{1}{2}v_\phi^\top Q_\phi^T \mathbf{1},$$

   where $v_\phi(i) = (\pi_{0,i}^{(f)})^{\phi}(\pi_{0,i}^{(g)})^{1-\phi}$ and $\mathbf{1}$ is a vector of ones.

2. Use the Perron–Frobenius theorem to conclude that the error probability decays at least at the exponential rate $C_M = -\log \min_{\phi\in[0,1]} \lambda(\phi)$.

3. Compute C_M and the minimizing ϕ for the matrices $P^{(f)}$ and $P^{(g)}$ in the lecture, and compare C_M with the KL divergence rates $h_{KL}(f,g)$ and $h_{KL}(g,f)$.

4. Set $\pi_0^{(f)} = \pi^{(f)}$ and $\pi_0^{(g)} = \pi^{(g)}$. Use `compute_markov_selection_error` to simulate the error probability for several values of T, and plot it together with the bound in part 1.

Solution

Part 1. Let $p_f(x^T) = \pi_{0,x_0}^{(f)} \prod_{t=1}^{T} P_{x_{t-1}x_t}^{(f)}$ and define $p_g(x^T)$ in the same way.

As in the IID case, the error probability equals $\frac{1}{2}\sum_{x^T}\min\{p_f(x^T), p_g(x^T)\}$.

Since $\min\{x, y\} \leq x^\phi y^{1-\phi}$,

$$\frac{1}{2}(\alpha_T + \beta_T) \leq \frac{1}{2}\sum_{x_0,\ldots,x_T} v_\phi(x_0)\prod_{t=1}^{T} Q_\phi(x_{t-1}, x_t) = \frac{1}{2} v_\phi^\top Q_\phi^T \mathbf{1}.$$

Part 2. The matrix Q_ϕ has positive entries.

By the Perron–Frobenius theorem, $Q_\phi^T = \lambda(\phi)^T(r_\phi \ell_\phi^\top + o(1))$ as $T \to \infty$, where r_ϕ and ℓ_ϕ are positive right and left eigenvectors normalized so that $\ell_\phi^\top r_\phi = 1$.

Hence $\frac{1}{T}\log(v_\phi^\top Q_\phi^T \mathbf{1}) \to \log\lambda(\phi)$, and the error probability decays at least at rate $-\log\lambda(\phi)$ for every ϕ.

The best rate comes from the ϕ that minimizes $\lambda(\phi)$.

Because $P^{(f)}$ and $P^{(g)}$ are stochastic matrices, $\lambda(0) = \lambda(1) = 1$.

Large deviation theory for Markov chains implies that C_M is the exact rate [Dembo and Zeitouni, 1998].

Part 3.

```
def perron_root(ϕ, P_f, P_g):
    """Largest eigenvalue of the matrix with entries P_f^ϕ P_g^(1-ϕ)."""
    Q = P_f**ϕ * P_g**(1 - ϕ)
    return np.max(np.abs(np.linalg.eigvals(Q)))

res = minimize_scalar(perron_root, bounds=(0, 1), args=(P_f, P_g),
                      method='bounded')
C_M, ϕ_M = -np.log(res.fun), res.x

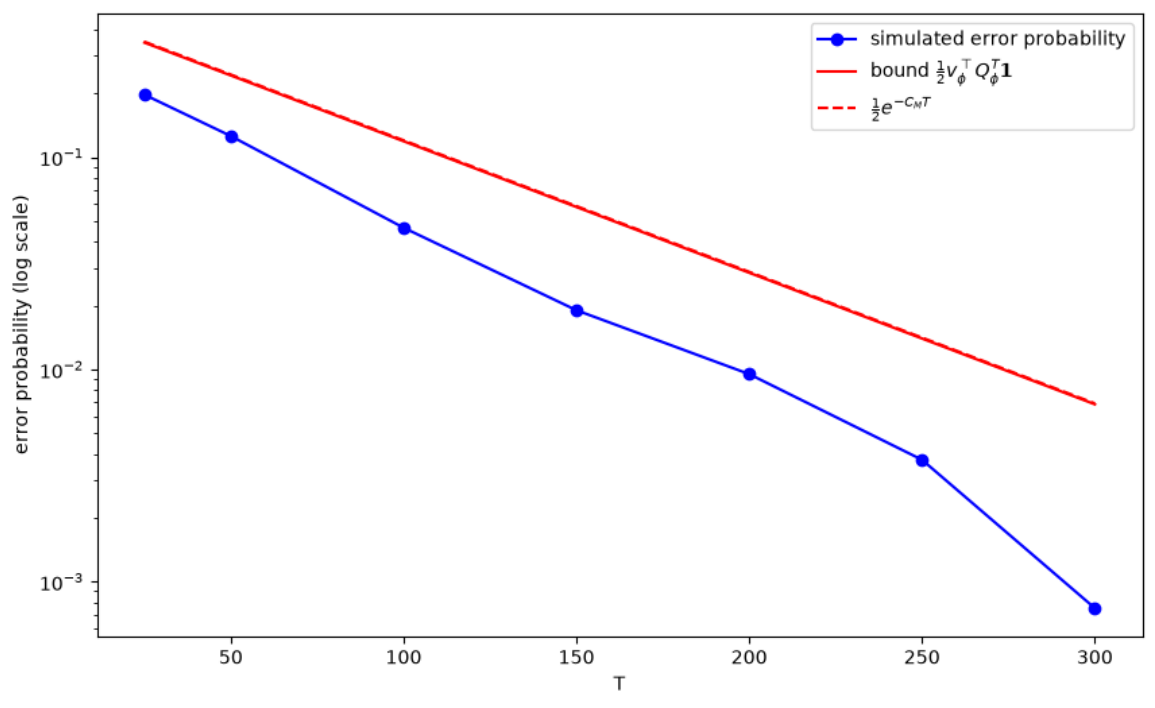
print(f"C_M = {C_M:.5f} at ϕ = {ϕ_M:.4f}")
print(f"h_KL(f, g) = {markov_results['kl_rate_fg']:.4f}, "
      f"h_KL(g, f) = {markov_results['kl_rate_gf']:.4f}")
```

```
C_M = 0.01427 at ϕ = 0.5055
h_KL(f, g) = 0.0588, h_KL(g, f) = 0.0563
```

The Chernoff rate $C_M = 0.0143$ is about a quarter of either KL divergence rate.

The error probability therefore falls much more slowly than $\log L_T^{(f)}/L_T^{(g)}$ drifts.

Part 4.



```
π_f = markov_results['stationary_f']
π_g = markov_results['stationary_g']
T_values = np.array([25, 50, 100, 150, 200, 250, 300])

errors = compute_markov_selection_error(T_values, P_f, P_g, π_f, π_g,
                                        rng, N_sim=4000)

Q_M = P_f**ϕ_M * P_g**(1 - ϕ_M)
v_M = π_f**ϕ_M * π_g**(1 - ϕ_M)
bound = [0.5 * v_M @ np.linalg.matrix_power(Q_M, T) @ np.ones(3)
         for T in T_values]

plt.figure(figsize=(10, 6))
plt.semilogy(T_values, errors, 'bo-', label='simulated error probability')
plt.semilogy(T_values, bound, 'r-',
             label=r'bound $\frac{1}{2} v_\phi^\top Q_\phi^T \mathbf{1}$')
plt.semilogy(T_values, 0.5 * np.exp(-C_M * T_values), 'r--',
             label=r'$\frac{1}{2} e^{-C_M T}$')
```

```
plt.xlabel('T')
plt.ylabel('error probability (log scale)')
plt.legend()
plt.show()
```

The bound from part 1 nearly coincides with $\frac{1}{2}e^{-C_M T}$.

The simulated error probabilities lie below the bound.

On the log scale they decline roughly in parallel with the bound, a little faster because of a polynomial factor that the bound omits.

Exercise 22.10.4

Let $f = \text{Beta}(1,1)$ and $g = \text{Beta}(G_a, G_b)$.

1. Show that

$$E\left[\ell(w_t) \mid q = f\right] = \int_0^1 \frac{f(w)^2}{g(w)} dw = B(G_a, G_b)\, B(2 - G_a, 2 - G_b)$$

   when $G_a < 2$ and $G_b < 2$, and that $E\left[\ell(w_t) \mid q = f\right] = +\infty$ otherwise.

2. Compute $E\left[\ell(w_t) \mid q = f\right]$ for $g = \text{Beta}(1.5, 1.2)$ and for the lecture's $g = \text{Beta}(3, 1.2)$.

3. For each g, draw $w_1, w_2, \ldots, w_N$ from f and plot the running sample average $\frac{1}{n}\sum_{i=1}^n \ell(w_i)$ against n. Explain the difference between the two plots.

Solution

Part 1. Since $f = 1$ on $(0, 1)$,

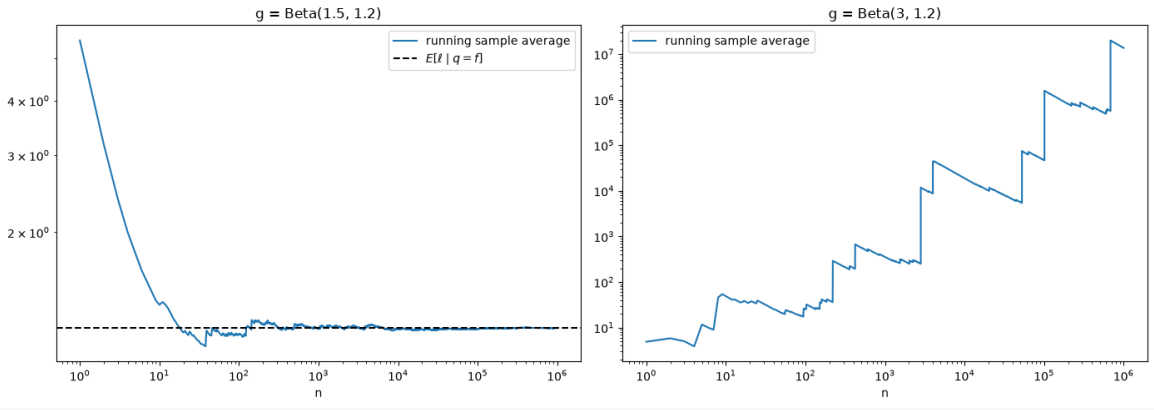
$$\int_0^1 \frac{f(w)^2}{g(w)} dw = B(G_a, G_b) \int_0^1 w^{1-G_a}(1-w)^{1-G_b} dw.$$

The integral converges if and only if $1 - G_a > -1$ and $1 - G_b > -1$, that is, if and only if $G_a < 2$ and $G_b < 2$.

When it converges, it equals $B(2 - G_a, 2 - G_b)$.

Part 2.

```
def mean_ell_under_f(G_a, G_b):
    """E[ℓ(w) | q=f] for f = Beta(1, 1) and g = Beta(G_a, G_b)."""
    if G_a < 2 and G_b < 2:
        return np.exp(betaln(G_a, G_b) + betaln(2 - G_a, 2 - G_b))
    return np.inf



for G_params in [(1.5, 1.2), (3, 1.2)]:
    print(f"g = Beta{G_params}: E[ℓ | f] = {mean_ell_under_f(*G_params):.4f}")
```

```
g = Beta(1.5, 1.2): E[ℓ | f] = 1.2112
g = Beta(3, 1.2): E[ℓ | f] = inf
```

Part 3.

```
N = 1_000_000
n_grid = np.arange(1, N+1)

fig, axes = plt.subplots(1, 2, figsize=(14, 5))
for ax, (g_a, g_b) in zip(axes, [(1.5, 1.2), (3, 1.2)]):
    w = rng.uniform(size=N)
    ℓ = np.exp(-log_beta_pdf(w, g_a, g_b))
    ax.plot(n_grid, np.cumsum(ℓ) / n_grid, lw=1.5,
            label='running sample average')
    mean = mean_ell_under_f(g_a, g_b)
    if np.isfinite(mean):
        ax.axhline(mean, color='k', ls='--', label=r'$E[\ell \mid q=f]$')
    ax.set_xscale('log')
    ax.set_yscale('log')
    ax.set_xlabel('n')
    ax.set_title(f'g = Beta({g_a}, {g_b})')
    ax.legend()
plt.tight_layout()
plt.show()
```

For $g = \text{Beta}(1.5, 1.2)$, the mean of ℓ under f is finite and the strong law of large numbers drives the running average to 1.2112.

For $g = \text{Beta}(3, 1.2)$, the mean is infinite.

Rare draws near $w = 0$ produce enormous values of $\ell = 1/g$, and the running average keeps jumping upward without settling.

For this reason we plotted $\log L_t$ in *the section in which nature draws from f*.

23.1 Overview

A likelihood ratio process lies behind Lawrence Blume and David Easley's answer to their question "If you're so smart, why aren't you rich?" [Blume and Easley, 2006].

Blume and Easley constructed formal models to study how differences of opinions about probabilities governing risky income processes would influence outcomes and be reflected in prices of stocks, bonds, and insurance policies that individuals use to share and hedge risks.

Note

[Alchian, 1950] and [Friedman, 1953] conjectured that, by rewarding traders with more realistic probability models, competitive markets in financial securities put wealth in the hands of better informed traders and help make prices of risky assets reflect realistic probability assessments.

Here we'll provide an example that illustrates basic components of Blume and Easley's analysis.

Our main tools are the likelihood ratio processes and Kullback–Leibler divergences studied in *Likelihood Ratio Processes*.

We'll focus only on their analysis of an environment with complete markets in which trades in all conceivable risky securities are possible.

We'll study two alternative arrangements:

- perfect socialism in which individuals surrender their endowments of consumption goods each period to a central planner who then dictatorially allocates those goods
- a decentralized system of competitive markets in which selfish price-taking individuals voluntarily trade with each other in competitive markets

The fundamental theorems of welfare economics will apply and assure us that these two arrangements end up producing exactly the same allocation of consumption goods to individuals **provided** that the social planner assigns an appropriate set of **Pareto weights**.

Note

You can learn about how the two welfare theorems are applied in modern macroeconomic models in *this lecture on a planning problem* and *this lecture on a related competitive equilibrium*. *This quantecon lecture* presents a recursive formulation of complete markets models with homogeneous beliefs.

Let's start by importing some Python tools.

```
import matplotlib.pyplot as plt
import numpy as np
from numba import vectorize, jit
from math import gamma
from scipy.integrate import quad
from scipy.special import expit

rng = np.random.default_rng()
```

23.2 Review: likelihood ratio processes

Likelihood Ratio Processes studies likelihood ratio processes in detail.

We recall the facts that we use here.

A nonnegative random variable W has one of two probability density functions, either f or g.

We assume that f and g both put positive probabilities on the same intervals of possible realizations of the random variable W.

For a sequence $\{w_t\}_{t=1}^{\infty}$ of IID draws, the time t likelihood ratio is

$$\ell(w_t) = \frac{f(w_t)}{g(w_t)}, \quad t \geq 1,$$

and the **likelihood ratio process** is

$$L(w^t) = \prod_{i=1}^{t} \ell(w_i),$$

where $w^t = \{w_1, \ldots, w_t\}$ is a history of observations up to and including time t.

We write $L_t = L(w^t)$.

The likelihood ratio process satisfies the recursion $L(w^t) = \ell(w_t) L(w^{t-1})$.

Suppose that a density h generates the data.

Let $K_f = KL(h, f)$ and $K_g = KL(h, g)$ be the Kullback–Leibler divergences of f and g from h.

The strong law of large numbers applied to $\log L_t = \sum_{i=1}^{t} \log \ell(w_i)$ implies

$$\frac{1}{t} \log L_t \to K_g - K_f \quad \text{almost surely under } h.$$

A helpful formula in *Likelihood Ratio Processes* derives the corresponding formula for $\frac{1}{t} E_h[\log L_t]$.

When $K_f < K_g$, $L_t \to +\infty$; when $K_f > K_g$, $L_t \to 0$.

When $h = f$, the drift of $\log L_t$ is $KL(f, g) > 0$; when $h = g$, it is $-KL(g, f) < 0$.

The following Python code defines f and g as two Beta densities.

```
# Parameters in the two Beta distributions.
F_a, F_b = 1, 1
G_a, G_b = 3, 1.2

@vectorize
def p(x, a, b):
    r = gamma(a + b) / (gamma(a) * gamma(b))
    return r * x** (a-1) * (1 - x) ** (b-1)

# The two density functions.
f = jit(lambda x: p(x, F_a, F_b))
g = jit(lambda x: p(x, G_a, G_b))
```

23.3 Blume and Easley's setting

Let the random variable $s_t \in (0, 1)$ at time $t = 0, 1, 2, \ldots$ be distributed according to the same Beta distribution with parameters $\theta = \{\theta_1, \theta_2\}$.

We'll denote this probability density as

$$\pi(s_t | \theta)$$

Below, we'll often just write $\pi(s_t)$ instead of $\pi(s_t|\theta)$ to save space.

Let $s_t \equiv y_t^1$ be the endowment of a nonstorable consumption good that a person we'll call "agent 1" receives at time t.

Let a history $s^t = [s_t, s_{t-1}, \ldots, s_0]$ be a sequence of i.i.d. random variables with joint distribution

$$\pi_t(s^t) = \pi(s_t)\pi(s_{t-1}) \cdots \pi(s_0)$$

So in our example, the history s^t is a comprehensive record of agent 1's endowments of the consumption good from time 0 up to time t.

If agent 1 were to live on an island by himself, agent 1's consumption $c^1(s_t)$ at time t is

$$c^1(s_t) = y_t^1 = s_t.$$

But in our model, agent 1 is not alone.

23.4 Nature and agents' beliefs

Nature draws i.i.d. sequences $\{s_t\}_{t=0}^{\infty}$ from $\pi_t(s^t)$.

- so π without a superscript is nature's model
- but in addition to nature, there are other entities inside our model – artificial people that we call "agents"
- each agent has a sequence of probability distributions over s^t for $t = 0, \ldots$
- agent i thinks that nature draws i.i.d. sequences $\{s_t\}_{t=0}^{\infty}$ from $\{\pi_t^i(s^t)\}_{t=0}^{\infty}$
  - agent i is mistaken unless $\pi_t^i(s^t) = \pi_t(s^t)$

Note

A **rational expectations** model would set $\pi_t^i(s^t) = \pi_t(s^t)$ for all agents i.

There are two agents named $i = 1$ and $i = 2$.

At time t, agent 1 receives an endowment

$$y_t^1 = s_t$$

of a nonstorable consumption good, while agent 2 receives an endowment of

$$y_t^2 = 1 - s_t$$

The aggregate endowment of the consumption good is

$$y_t^1 + y_t^2 = 1$$

at each date $t \geq 0$.

At date t agent i consumes $c_t^i(s^t)$ of the good.

A (non wasteful) feasible allocation of the aggregate endowment of 1 each period satisfies

$$c_t^1 + c_t^2 = 1.$$

23.5 A socialist risk-sharing arrangement

In order to share risks, a benevolent social planner dictates a history-dependent consumption allocation that takes the form of a sequence of functions

$$c_t^i = c_t^i(s^t)$$

that satisfy

$$c_t^1(s^t) + c_t^2(s^t) = 1 \tag{23.1}$$

for all s^t for all $t \geq 0$.

To design a socially optimal allocation, the social planner wants to know what each agent i believes about the endowment sequence and how they feel about bearing risks.

As for the endowment sequences, agent i believes that nature draws i.i.d. sequences from joint densities

$$\pi_t^i(s^t) = \pi^i(s_t)\pi^i(s_{t-1})\cdots\pi^i(s_0)$$

As for attitudes toward bearing risks, agent i has a one-period utility function

$$u(c_t^i) = \ln(c_t^i)$$

with marginal utility of consumption in period t

$$u'(c_t^i) = \frac{1}{c_t^i}$$

Putting its beliefs about its random endowment sequence and its attitudes toward bearing risks together, agent i has intertemporal utility function

$$V^i = \sum_{t=0}^{\infty}\sum_{s^t}\delta^t u(c_t^i(s^t))\pi_t^i(s^t), \tag{23.2}$$

where $\delta \in (0,1)$ is an intertemporal discount factor, and $u(\cdot)$ is a strictly increasing, concave one-period utility function.

Because s_t has a density, $\sum_{s^t}$ stands for an integral $\int\cdots ds^t$ over histories s^t, here and below.

23.6 Social planner's allocation problem

The benevolent dictator has all the information it requires to choose a consumption allocation that maximizes the social welfare criterion

$$W = \lambda V^1 + (1-\lambda)V^2 \tag{23.3}$$

where $\lambda \in [0,1]$ is a Pareto weight that tells how much the planner likes agent 1 and $1-\lambda$ is a Pareto weight that tells how much the social planner likes agent 2.

Setting $\lambda = .5$ expresses "egalitarian" social preferences.

Notice how social welfare criterion (23.3) takes into account both agents' preferences as represented by formula (23.2).

This means that the social planner knows and respects

- each agent's one period utility function $u(\cdot) = \ln(\cdot)$
- each agent i's probability model $\{\pi_t^i(s^t)\}_{t=0}^{\infty}$

Consequently, it is natural to anticipate that these objects will appear in the social planner's rule for allocating the aggregate endowment each period.

Let $\theta_t(s^t)$ be a Lagrange multiplier on feasibility constraint (23.1) at history s^t.

First-order necessary conditions for maximizing welfare criterion (23.3) subject to the feasibility constraint (23.1) are

$$\lambda\delta^t\frac{\pi_t^1(s^t)}{c_t^1(s^t)} = \theta_t(s^t), \qquad (1-\lambda)\delta^t\frac{\pi_t^2(s^t)}{c_t^2(s^t)} = \theta_t(s^t). \tag{23.4}$$

Dividing the second condition by the first gives

$$\frac{\pi_t^2(s^t)}{\pi_t^1(s^t)}\frac{(1/c_t^2(s^t))}{(1/c_t^1(s^t))} = \frac{\lambda}{1-\lambda}$$

which can be rearranged to become

$$\frac{c_t^1(s^t)}{c_t^2(s^t)} = \frac{\lambda}{1-\lambda} l_t(s^t) \tag{23.5}$$

where

$$l_t(s^t) = \frac{\pi_t^1(s^t)}{\pi_t^2(s^t)}$$

is the likelihood ratio of agent 1's joint density to agent 2's joint density.

The cumulative likelihood ratio $l_t(s^t)$ is the counterpart of L_t in the review above, with $f = \pi^1$, $g = \pi^2$, and histories that start at date 0.

The one-period likelihood ratio is $\pi^1(s_t)/\pi^2(s_t)$.

Using

$$c_t^1(s^t) + c_t^2(s^t) = 1$$

we can rewrite allocation rule (23.5) as

$$\frac{c_t^1(s^t)}{1 - c_t^1(s^t)} = \frac{\lambda}{1-\lambda} l_t(s^t)$$

or

$$c_t^1(s^t) = \frac{\lambda}{1-\lambda} l_t(s^t)(1 - c_t^1(s^t))$$

which implies that the social planner's allocation rule is

$$c_t^1(s^t) = \frac{\lambda l_t(s^t)}{1 - \lambda + \lambda l_t(s^t)} \tag{23.6}$$

If we define a temporary or **continuation Pareto weight** process as

$$\lambda_t(s^t) = \frac{\lambda l_t(s^t)}{1 - \lambda + \lambda l_t(s^t)},$$

then we can represent the social planner's allocation rule as

$$c_t^1(s^t) = \lambda_t(s^t)$$

and of course

$$c_t^2(s^t) = 1 - \lambda_t(s^t).$$

Substituting $c_t^1(s^t) = \lambda_t(s^t)$ into the first condition in (23.4) gives

$$\theta_t(s^t) = \delta^t \left[\lambda \pi_t^1(s^t) + (1-\lambda)\pi_t^2(s^t)\right]. \tag{23.7}$$

The multiplier $\theta_t(s^t)$ is the planner's **shadow price** of one unit of consumption at date t after history s^t, measured in units of social welfare W.

23.7 If you're so smart, …

Let's compute some values of limiting allocations (23.6) for some interesting possible limiting values of the likelihood ratio process $l_t(s^t)$.

As our first case, let's suppose that the two agents have identical beliefs, $\pi^1 = \pi^2$, so that

$$l_t(s^t) = 1 \text{ for all } t; \quad c_t^1 = \lambda$$

- In this case, the consumption allocation stays put at a $\lambda, 1-\lambda$ split between the two agents.

As our second case, let's suppose that

$$l_\infty(s^\infty) = 0; \quad c_\infty^1 = 0$$

- In this case, agent 2 is "smarter" than agent 1, and agent 1's share of the aggregate endowment converges to zero.

As our third case, let's suppose that

$$l_\infty(s^\infty) = \infty; \quad c_\infty^1 = 1$$

- In this case, agent 1 is smarter than agent 2, and agent 1's share of the aggregate endowment converges to 1.

Kullback–Leibler divergences of the agents' beliefs from nature's density determine which case occurs.

Let

$$KL(\pi, \pi^i) = \int \pi(s) \log \frac{\pi(s)}{\pi^i(s)} \, ds.$$

When nature draws s_t IID from π, $\log l_t(s^t) = \sum_{j=0}^t \log[\pi^1(s_j)/\pi^2(s_j)]$ is a sum of IID random variables with mean

$$E_\pi \left[\log \frac{\pi^1(s)}{\pi^2(s)} \right] = KL(\pi, \pi^2) - KL(\pi, \pi^1).$$

The strong law of large numbers implies

$$\frac{1}{t} \log l_t(s^t) \to KL(\pi, \pi^2) - KL(\pi, \pi^1) \quad \text{almost surely.} \tag{23.8}$$

Formula (23.8) is the formula in *A helpful formula* of *Likelihood Ratio Processes* with $h = \pi$, $f = \pi^1$, and $g = \pi^2$.

It implies:

- if $KL(\pi, \pi^1) < KL(\pi, \pi^2)$, then $l_t \to +\infty$ and $c_t^1 \to 1$
- if $KL(\pi, \pi^1) > KL(\pi, \pi^2)$, then $l_t \to 0$ and $c_t^1 \to 0$
- if $KL(\pi, \pi^1) = KL(\pi, \pi^2)$ and $\pi^1 \neq \pi^2$, then $\log l_t$ is a random walk with zero drift and positive variance; its lim sup is $+\infty$ and its lim inf is $-\infty$, so c_t^1 swings between values near 0 and values near 1 and never settles down

Exercise 23.11.3 studies the third case.

"Smarter" means closer to nature's π in Kullback–Leibler divergence.

An agent with correct beliefs, $\pi^i = \pi$, has $KL(\pi, \pi^i) = 0$ and drives out any agent whose beliefs differ.

Sandroni [2000] and Blume and Easley [2006] prove market selection results of this kind for more general economies.

Note

These three cases are somehow telling us about how relative **wealths** of the agents evolve as time passes.

- when the two agents have identical beliefs and $\lambda \in (0, 1)$, agent 1's wealth share stays at λ perpetually.
- when agent 1 is smarter and $\lambda \in (0, 1)$, agent 1 eventually "owns" the entire continuation endowment and agent 2 eventually "owns" nothing.
- when agent 2 is smarter and $\lambda \in (0, 1)$, agent 2 eventually "owns" the entire continuation endowment and agent 1 eventually "owns" nothing.

We define continuation wealths precisely after we construct a competitive equilibrium **price** system below.

Soon we'll do some simulations that will shed further light on possible outcomes.

But before we do that, let's take a detour and study the "shadow prices" $\theta_t(s^t)$ in (23.7) for the social planning problem.

We shall soon see that these shadow prices can readily be converted to "equilibrium prices" for a competitive equilibrium.

Doing this will allow us to connect our analysis with claims by [Alchian, 1950] and [Friedman, 1953] that transfers of wealth coming from trades in competitive asset markets eventually make prices of risky assets reflect realistic probability assessments.

23.8 Competitive equilibrium prices

Two fundamental welfare theorems for general equilibrium models lead us to anticipate that there is a connection between the allocation that solves the social planning problem we have been studying and the allocation in a **competitive equilibrium** with complete markets in contingent claims to time- and history-dependent consumption goods.

Note

For the two welfare theorems and their history, see https://en.wikipedia.org/wiki/Fundamental_theorems_of_welfare_economics. Again, for applications to a classic macroeconomic growth model, see *this lecture on a planning problem* and *this lecture on a related competitive equilibrium*

Such a connection prevails for our model.

We'll sketch it now.

In a competitive equilibrium, no social planner dictatorially collects everybody's endowments and then reallocates them.

Instead, there is a comprehensive centralized market that meets at one point in time.

There are **prices** at which price-taking agents can buy or sell whatever goods that they want.

Trade is multilateral in the sense that a "Walrasian auctioneer" who lives outside the model finds prices at which supply equals demand for every good.

Each agent faces a budget constraint.

That budget constraint requires that the total value of the agent's endowment stream be at least as large as the total value of its consumption stream.

These values are computed at price vectors that the agents take as given – the agents are "price-takers" who assume that they can buy or sell whatever quantities that they want at those prices.

Suppose that at time -1, before time 0 starts, agent i can purchase one unit $c_t(s^t)$ of consumption at time t after history s^t at price $p_t(s^t)$.

The price **vector** is very long:

- there is one price $p_t(s^t)$ for each history s^t at every date $t = 0, 1, \ldots,$.
- so there are as many prices as there are histories and dates.

The auctioneer sets these prices at time -1, before the economy starts.

The market meets once at time -1.

At times $t = 0, 1, 2, \ldots$ trades made at time -1 are simply executed, i.e., the promised deliveries are made.

- in the background, there is an "enforcement" procedure that forces agents to carry out the exchanges or "deliveries" that they agreed to at time -1.

We want to study how agents' probability models influence equilibrium prices.

Agent i faces a **single** intertemporal budget constraint

$$\sum_{t=0}^{\infty} \sum_{s^t} p_t(s^t) c_t^i(s^t) \leq \sum_{t=0}^{\infty} \sum_{s^t} p_t(s^t) y_t^i(s^t) \tag{23.9}$$

Because s_t has a density, $p_t(s^t)$ is a price density: $p_t(s^t)\, ds^t$ is the time -1 price of one unit of consumption at date t delivered if the history lands in a small set ds^t around s^t.

According to budget constraint (23.9), trade is **multilateral** in the following sense

- imagine that agent i first sells his random endowment stream $\{y_t^i(s^t)\}$ and then uses the proceeds (i.e., his "wealth") to purchase a random consumption stream $\{c_t^i(s^t)\}$.

Agent i attaches a Lagrange multiplier μ_i to budget constraint (23.9) and once-and-for-all chooses a consumption plan $\{c_t^i(s^t)\}_{t=0}^{\infty}$ that maximizes criterion (23.2) subject to budget constraint (23.9).

This means that the agent i chooses many objects, namely, $c_t^i(s^t)$ for all s^t for $t = 0, 1, 2, \ldots$.

For convenience, let's remind ourselves of criterion V^i defined in (23.2):

$$V^i = \sum_{t=0}^{\infty} \sum_{s^t} \delta^t u(c_t^i(s^t)) \pi_t^i(s^t)$$

First-order necessary conditions for maximizing objective V^i defined in (23.2) with respect to $c_t^i(s^t)$ are

$$\delta^t u'(c_t^i(s^t)) \pi_t^i(s^t) = \mu_i p_t(s^t),$$

which we can rearrange to obtain

$$p_t(s^t) = \frac{\delta^t \pi_t^i(s^t)}{\mu_i c_t^i(s^t)} \tag{23.10}$$

for $i = 1, 2$.

If we divide equation (23.10) for agent 1 by the appropriate version of equation (23.10) for agent 2, impose the feasibility condition $c_t^2(s^t) = 1 - c_t^1(s^t)$, and do some algebra, we'll obtain

$$c_t^1(s^t) = \frac{\mu_2 l_t(s^t)}{\mu_1 + \mu_2 l_t(s^t)}. \tag{23.11}$$

We now embark on an extended "guess-and-verify" exercise that involves matching objects in our competitive equilibrium with objects in our social planning problem.

- we'll match consumption allocations in the planning problem with equilibrium consumption allocations in the competitive equilibrium
- we'll match "shadow" prices in the planning problem with competitive equilibrium prices.

Formula (23.11) has the same form as formula (23.6) with $\lambda/(1-\lambda) = \mu_2/\mu_1$.

Setting $\mu_1 = 1-\lambda$ and $\mu_2 = \lambda$ makes the two formulas agree.

Only the ratio μ_2/μ_1 matters for the allocation.

- multiplying μ_1 and μ_2 by a positive constant and dividing all prices $p_t(s^t)$ by the same constant leaves budget constraints and first-order conditions unchanged
- choosing that constant amounts to choosing a **numeraire** or normalization for the price system $\{p_t(s^t)\}_{t=0}^{\infty}$

Note

For information about how a numeraire must be chosen to pin down the absolute price level in a model like ours that determines only relative prices, see https://en.wikipedia.org/wiki/Numéraire.

The ratio μ_2/μ_1 is not a normalization.

Budget constraints (23.9) pin it down, and with it the Pareto weight λ, as we show below.

If we set $\mu_1 = 1-\lambda$ and $\mu_2 = \lambda$, substitute formula (23.11) for $c_t^1(s^t)$ into formula (23.10), and rearrange, we obtain

$$p_t(s^t) = \frac{\delta^t}{\lambda(1-\lambda)}\pi_t^2(s^t)[1-\lambda+\lambda l_t(s^t)]$$

or

$$p_t(s^t) = \frac{\delta^t}{\lambda(1-\lambda)}[(1-\lambda)\pi_t^2(s^t) + \lambda\pi_t^1(s^t)] \tag{23.12}$$

Comparing (23.12) with (23.7) shows that $p_t(s^t) = \theta_t(s^t)/(\lambda(1-\lambda))$.

Competitive equilibrium prices are proportional to the planner's shadow prices.

The normalization $\mu_1 = 1/\lambda$ and $\mu_2 = 1/(1-\lambda)$ makes them equal: $p_t(s^t) = \theta_t(s^t)$.

According to formula (23.12), we have the following possible limiting cases:

- when $l_\infty = 0$, $c_\infty^1 = 0$ and tails of competitive equilibrium prices reflect agent 2's probability model $\pi_t^2(s^t)$ according to $p_t(s^t) \propto \delta^t\pi_t^2(s^t)$
- when $l_\infty = \infty$, $c_\infty^1 = 1$ and tails of competitive equilibrium prices reflect agent 1's probability model $\pi_t^1(s^t)$ according to $p_t(s^t) \propto \delta^t\pi_t^1(s^t)$
- for small t's, competitive equilibrium prices reflect both agents' probability models.

23.8.1 The competitive equilibrium Pareto weight

Let $E^i[s] = \int s\,\pi^i(s)\,ds$ be agent i's expected value of s_t.

Substituting allocation (23.6) and prices (23.12) into agent 1's budget constraint (23.9) with $y_t^1 = s_t$ and imposing equality gives

$$\lambda = \lambda E^1[s] + (1-\lambda)E^2[s],$$

or

$$\lambda = \frac{E^2[s]}{1 - E^1[s] + E^2[s]}. \tag{23.13}$$

Exercise 23.11.1 asks you to verify this.

Agent 2's budget constraint then holds by Walras' law.

Finding Pareto weights at which the planner's allocation satisfies every agent's budget constraint is the method of Negishi [1960].

The left side of the first equation is agent 1's share of total wealth at time -1.

The right side is the market value of agent 1's endowment stream divided by the market value of the aggregate endowment stream.

For $\pi^1 = f = \text{Beta}(1, 1)$ and $\pi^2 = g = \text{Beta}(3, 1.2)$, $E^1[s] = 1/2$, $E^2[s] = 5/7$, and $\lambda = 10/17 \approx 0.588$.

Agent 2 expects agent 1's endowment to be high.

Agent 2's beliefs raise the price of claims on agent 1's endowment and make agent 1 rich.

The simulations below set $\lambda = 0.5$.

By the second welfare theorem, that allocation is a competitive equilibrium after a time -1 transfer of wealth from agent 1 to agent 2.

23.8.2 Wealth

Agent i's **continuation wealth** at history s^t is the value of its continuation consumption plan in units of date t consumption:

$$W_t^i(s^t) = \frac{1}{p_t(s^t)} \sum_{\tau=t}^{\infty} \int p_\tau(s^\tau) c_\tau^i(s^\tau)\, ds_{t+1} \cdots ds_\tau.$$

With logarithmic utility, first-order condition (23.10) implies

$$W_t^i(s^t) = \frac{c_t^i(s^t)}{1 - \delta}. \tag{23.14}$$

Total wealth $W_t^1(s^t) + W_t^2(s^t) = 1/(1 - \delta)$ is the value of a claim to the aggregate endowment.

Agent 1's wealth share equals its consumption share $c_t^1(s^t) = \lambda_t(s^t)$.

The limiting cases above describe wealth shares as well as consumption shares.

23.8.3 Arrow prices and market selection

Let $q(s_{t+1}|s^t) = p_{t+1}(s^{t+1})/p_t(s^t)$ be the Arrow price density at history s^t of claims to consumption at $t+1$ contingent on s_{t+1}, measured in units of date t consumption.

Formula (23.12) and $\pi_{t+1}^i(s^{t+1}) = \pi^i(s_{t+1})\pi_t^i(s^t)$ imply

$$q(s_{t+1}|s^t) = \delta\big[\lambda_t(s^t)\pi^1(s_{t+1}) + (1 - \lambda_t(s^t))\pi^2(s_{t+1})\big]. \tag{23.15}$$

Arrow prices equal δ times a mixture of the two agents' one-period densities.

Wealth shares are the mixing weights.

Integrating (23.15) over s_{t+1} shows that a one-period riskless bond costs δ at every history.

The continuation Pareto weight

$$\lambda_t(s^t) = \frac{\lambda l_t(s^t)}{\lambda l_t(s^t) + 1 - \lambda}$$

is the posterior probability on model π^1 of a Bayesian who puts prior probability λ on model π^1 and $1-\lambda$ on model π^2 and then observes s^t, as in *Likelihood Ratio Processes and Bayesian Learning*.

The bracketed term in (23.15) is that Bayesian's predictive density of s_{t+1}.

Competitive markets price risks as if such a Bayesian set prices.

Formula (23.15) makes the Alchian–Friedman conjecture precise.

When agent 1's beliefs are correct, $\pi^1 = \pi$, formula (23.8) implies $\lambda_t \to 1$.

Arrow prices then converge to $\delta\pi(s_{t+1})$ and reflect true probabilities.

When neither agent's beliefs are correct and $KL(\pi, \pi^1) \neq KL(\pi, \pi^2)$, Arrow prices converge to δ times the one-period density of the agent whose beliefs are closer to π in Kullback–Leibler divergence.

Markets then select the less wrong model, and prices do not converge to the truth.

23.9 Simulations

Now let's implement some simulations when agent 1 believes marginal density

$$\pi^1(s_t) = f(s_t)$$

and agent 2 believes marginal density

$$\pi^2(s_t) = g(s_t)$$

where f and g are Beta distributions like ones that we used in earlier sections of this lecture.

Meanwhile, we'll assume that nature believes a marginal density

$$\pi(s_t) = h(s_t)$$

where $h(s_t)$ is perhaps a mixture of f and g.

First, we write a function to compute the likelihood ratio process

```
def compute_likelihood_ratios(sequences, f, g):
    """Compute likelihood ratios and cumulative products."""
    l_ratios = f(sequences) / g(sequences)
    L_cumulative = np.cumprod(l_ratios, axis=1)
    return l_ratios, L_cumulative
```

Let's compute the Kullback–Leibler discrepancies by quadrature integration.

```
def compute_KL(f, g):
    """
    Compute KL divergence KL(f, g)
    """
    integrand = lambda w: f(w) * np.log(f(w) / g(w))
    val, _ = quad(integrand, 1e-5, 1-1e-5)
    return val
```

We also create a helper function to compute KL divergence with respect to a reference distribution h

```
def compute_KL_h(h, f, g):
    """
    Compute KL divergence with reference distribution h
    """

    Kf = compute_KL(h, f)
    Kg = compute_KL(h, g)

    return Kf, Kg
```

Let's write a Python function that computes agent 1's consumption share

```
def simulate_blume_easley(sequences, f_belief=f, g_belief=g, λ=0.5):
    """Simulate Blume-Easley model consumption shares."""
    l_ratios, l_cumulative = compute_likelihood_ratios(sequences, f_belief, g_belief)
    c1_share = λ * l_cumulative / (1 - λ + λ * l_cumulative)
    return l_cumulative, c1_share
```

Now let's use this function to generate sequences in which

- nature draws from f each period, or
- nature draws from g each period, or
- nature flips a fair coin each period to decide whether to draw from f or g

```
λ = 0.5
T = 100
N = 10000

# Nature follows f, g, or mixture
s_seq_f = rng.beta(F_a, F_b, (N, T))
s_seq_g = rng.beta(G_a, G_b, (N, T))

h = jit(lambda x: 0.5 * f(x) + 0.5 * g(x))
model_choices = rng.random((N, T)) < 0.5
s_seq_h = np.empty((N, T))
s_seq_h[model_choices] = rng.beta(F_a, F_b, size=model_choices.sum())
s_seq_h[~model_choices] = rng.beta(G_a, G_b, size=(~model_choices).sum())

l_cum_f, c1_f = simulate_blume_easley(s_seq_f)
l_cum_g, c1_g = simulate_blume_easley(s_seq_g)
l_cum_h, c1_h = simulate_blume_easley(s_seq_h)
```

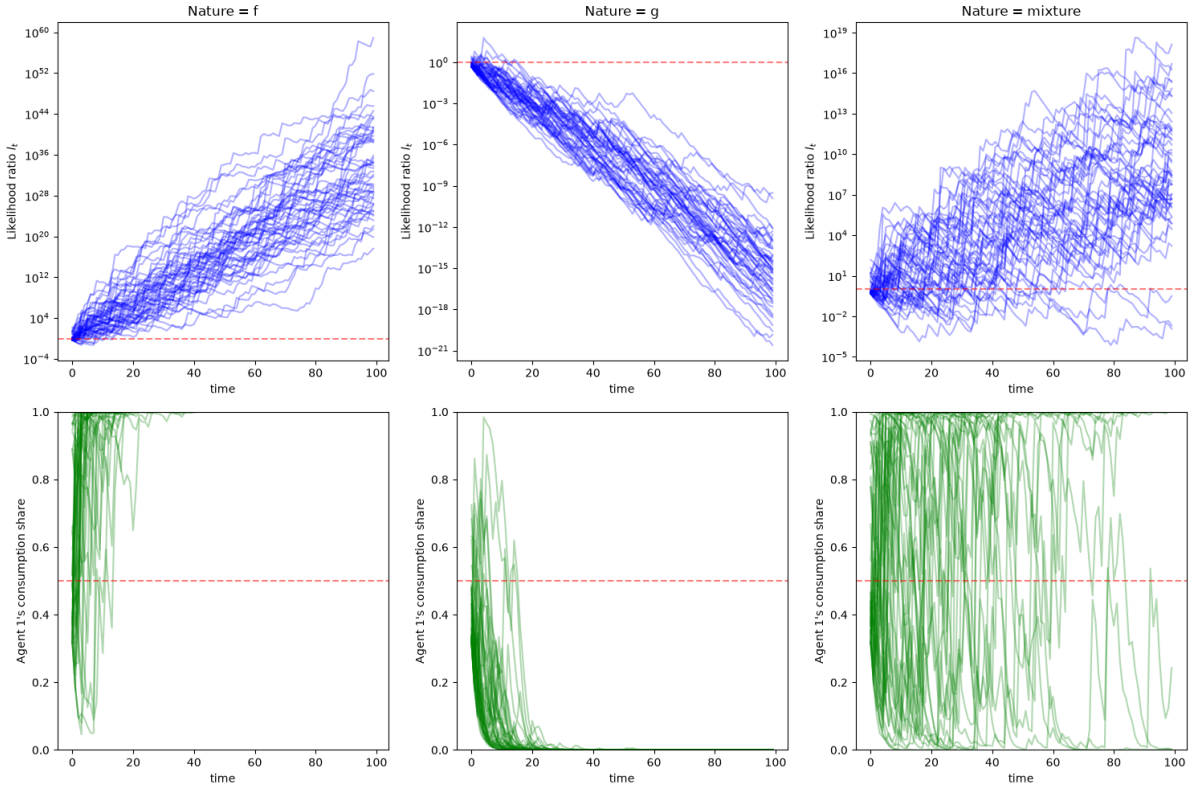
Before looking at the figure below, have some fun by guessing whether agent 1 or agent 2 will have a larger and larger consumption share as time passes in our three cases.

To make better guesses, let's visualize instances of the likelihood ratio processes in the three cases.

```
fig, axes = plt.subplots(2, 3, figsize=(15, 10))

titles = ["Nature = f", "Nature = g", "Nature = mixture"]
data_pairs = [(l_cum_f, c1_f), (l_cum_g, c1_g), (l_cum_h, c1_h)]

for i, ((l_cum, c1), title) in enumerate(zip(data_pairs, titles)):
    # Likelihood ratios
    ax = axes[0, i]
```



(continues on next page)

(continued from previous page)

```
    for j in range(min(50, l_cum.shape[0])):
        ax.plot(l_cum[j, :], alpha=0.3, color='blue')
    ax.set_yscale('log')
    ax.set_xlabel('time')
    ax.set_ylabel('Likelihood ratio $l_t$')
    ax.set_title(title)
    ax.axhline(y=1, color='red', linestyle='--', alpha=0.5)

    # Consumption shares
    ax = axes[1, i]
    for j in range(min(50, c1.shape[0])):
        ax.plot(c1[j, :], alpha=0.3, color='green')
    ax.set_xlabel('time')
    ax.set_ylabel("Agent 1's consumption share")
    ax.set_ylim([0, 1])
    ax.axhline(y=λ, color='red', linestyle='--', alpha=0.5)

plt.tight_layout()
plt.show()
```

In the left panel, nature chooses f. Agent 1's consumption reaches 1 very quickly.

In the middle panel, nature chooses g. Agent 1's consumption ratio tends to move towards 0 but not as fast as in the first case.

In the right panel, nature flips coins each period. Agent 1's consumption share again moves toward 1, more slowly than in the left panel.

The figures in the top panel remind us of the discussion in *this section* of *Likelihood Ratio Processes*.

We invite readers to revisit *that section* and try to infer the relationships among $D_{KL}(f\|g)$, $D_{KL}(g\|f)$, $D_{KL}(h\|f)$, and

$D_{KL}(h\|g)$.

Let's compute values of KL divergence

```
shares = [np.mean(c1_f[:, -1]), np.mean(c1_g[:, -1]), np.mean(c1_h[:, -1])]
Kf_g, Kg_f = compute_KL(f, g), compute_KL(g, f)
Kf_h, Kg_h = compute_KL_h(h, f, g)

print(f"Final shares: f={shares[0]:.3f}, g={shares[1]:.3f}, mix={shares[2]:.3f}")
print(f"KL divergences: \nKL(f,g)={Kf_g:.3f}, KL(g,f)={Kg_f:.3f}")
print(f"KL(h,f)={Kf_h:.3f}, KL(h,g)={Kg_h:.3f}")
```

```
Final shares: f=1.000, g=0.000, mix=0.927
KL divergences:
KL(f,g)=0.759, KL(g,f)=0.344
KL(h,f)=0.073, KL(h,g)=0.281
```

We find that $KL(f,g) > KL(g,f)$ and $KL(h,g) > KL(h,f)$.

The first inequality tells us that the average "surprise" from having belief g when nature chooses f is greater than the "surprise" from having belief f when nature chooses g.

This explains the difference between the first two panels we noted above.

The second inequality tells us that agent 1's belief distribution f is closer to nature's pick than agent 2's belief g.

By formula (23.8), $\log l_t$ drifts upward at rate $KL(f,g) = 0.759$ per period when nature draws from f and at rate $KL(h,g) - KL(h,f) = 0.208$ per period when nature draws from the mixture h.

The drift has the same sign in the left and right panels and is about 3.6 times smaller in the right panel.

To make this idea more concrete, let's compare two cases:

- agent 1's belief distribution f is close to agent 2's belief distribution g;
- agent 1's belief distribution f is far from agent 2's belief distribution g.

We use the two distributions visualized below

```
def plot_distribution_overlap(ax, x_range, f_vals, g_vals,
                              f_label='f', g_label='g',
                              f_color='blue', g_color='red'):
    """Plot two distributions with their overlap region."""
    ax.plot(x_range, f_vals, color=f_color, linewidth=2, label=f_label)
    ax.plot(x_range, g_vals, color=g_color, linewidth=2, label=g_label)

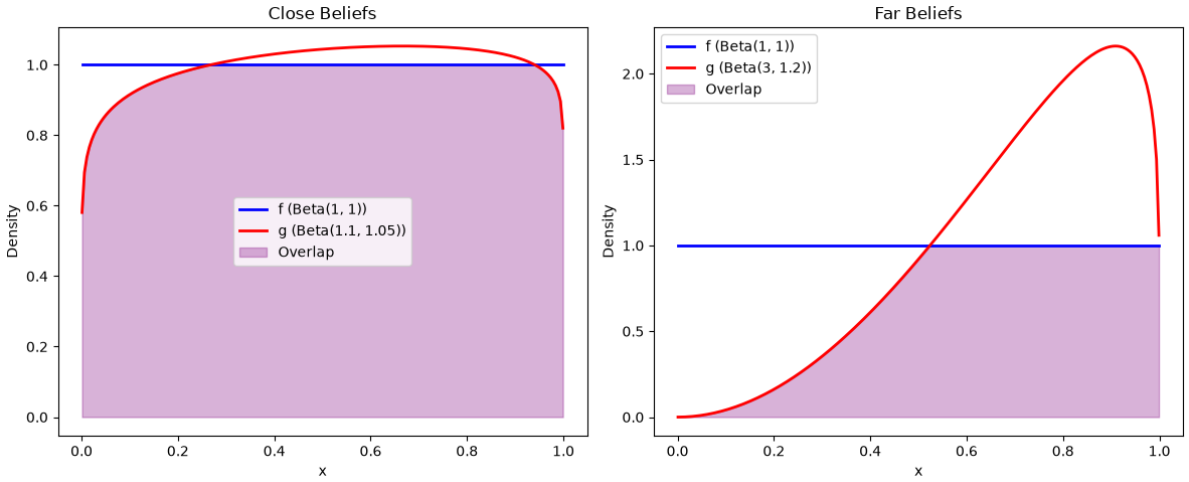
    overlap = np.minimum(f_vals, g_vals)
    ax.fill_between(x_range, 0, overlap, alpha=0.3, color='purple', label='Overlap')
    ax.set_xlabel('x')
    ax.set_ylabel('Density')
    ax.legend()

# Define close and far belief distributions
f_close = jit(lambda x: p(x, 1, 1))
g_close = jit(lambda x: p(x, 1.1, 1.05))

f_far = jit(lambda x: p(x, 1, 1))
g_far = jit(lambda x: p(x, 3, 1.2))

# Visualize the belief distributions
fig, (ax1, ax2) = plt.subplots(1, 2, figsize=(12, 5))
```

(continues on next page)



(continued from previous page)

```
x_range = np.linspace(0.001, 0.999, 200)

# Close beliefs
f_close_vals = [f_close(x) for x in x_range]
g_close_vals = [g_close(x) for x in x_range]
plot_distribution_overlap(ax1, x_range, f_close_vals, g_close_vals,
                          f_label='f (Beta(1, 1))', g_label='g (Beta(1.1, 1.05))')
ax1.set_title(f'Close Beliefs')

# Far beliefs
f_far_vals = [f_far(x) for x in x_range]
g_far_vals = [g_far(x) for x in x_range]
plot_distribution_overlap(ax2, x_range, f_far_vals, g_far_vals,
                          f_label='f (Beta(1, 1))', g_label='g (Beta(3, 1.2))')
ax2.set_title(f'Far Beliefs')

plt.tight_layout()
plt.show()
```

Let's draw the same consumption ratio plots as above for agent 1.

We replace the simulation paths with median and percentiles to make the figure cleaner.

In the third column, nature draws from $h = \text{Beta}(2, 1.5)$, a different h from the mixture used above.

Staring at the figure below, can we infer the relation between $KL(f, g)$ and $KL(g, f)$?

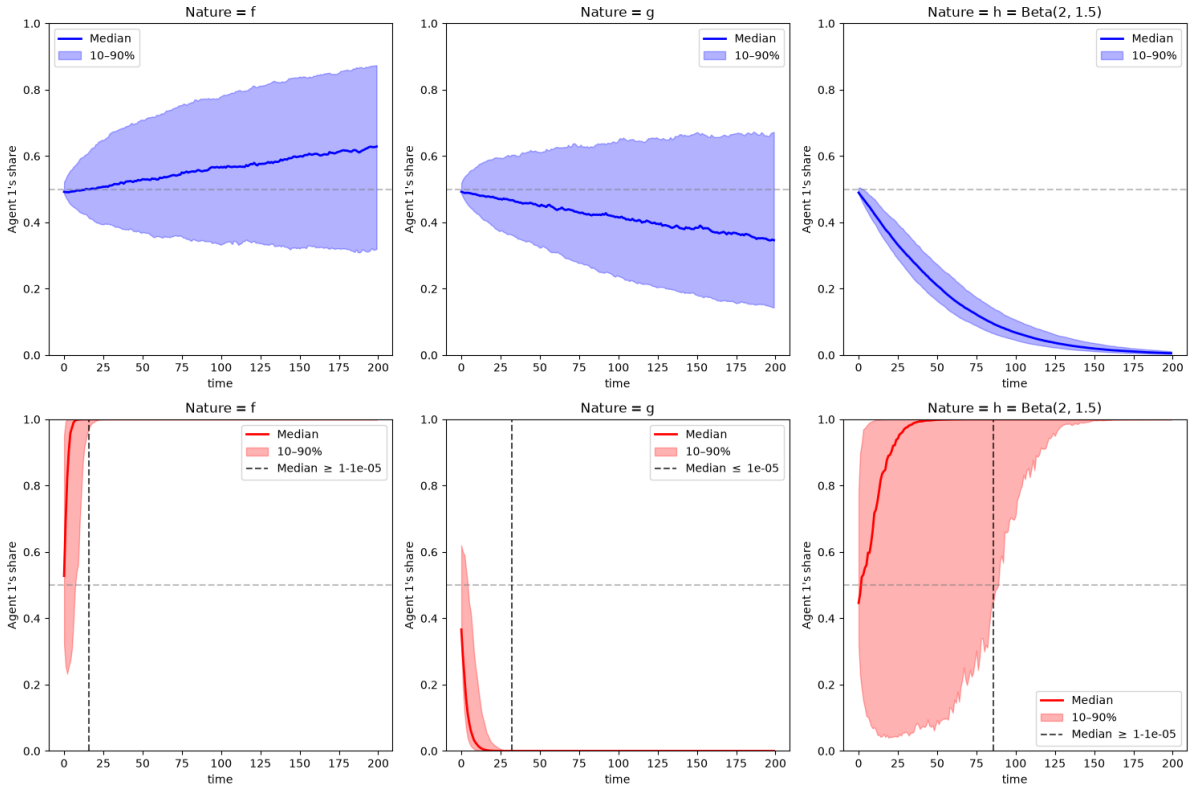
From the right panel, can we infer the relation between $KL(h, g)$ and $KL(h, f)$?

```
fig, axes = plt.subplots(2, 3, figsize=(15, 10))
nature_params = {'close': [(1, 1), (1.1, 1.05), (2, 1.5)],
                 'far':   [(1, 1), (3, 1.2),    (2, 1.5)]}
nature_labels = ["Nature = f", "Nature = g", "Nature = h = Beta(2, 1.5)"]
colors = {'close': 'blue', 'far': 'red'}

threshold = 1e-5  # "close to zero" cutoff

for row, (f_belief, g_belief, label) in enumerate([
                        (f_close, g_close, 'close'),
                        (f_far, g_far, 'far')]):
```

(continues on next page)



(continued from previous page)

```
    for col, nature_label in enumerate(nature_labels):
        params = nature_params[label][col]
        s_seq = rng.beta(params[0], params[1], (1000, 200))
        _, c1 = simulate_blume_easley(s_seq, f_belief, g_belief, λ)

        median_c1 = np.median(c1, axis=0)
        p10, p90 = np.percentile(c1, [10, 90], axis=0)

        ax = axes[row, col]
        color = colors[label]
        ax.plot(median_c1, color=color, linewidth=2, label='Median')
        ax.fill_between(range(len(median_c1)), p10, p90, alpha=0.3, color=color,␣
↪label='10-90%')
        ax.set_xlabel('time')
        ax.set_ylabel("Agent 1's share")
        ax.set_ylim([0, 1])
        ax.set_title(nature_label)
        ax.axhline(y=λ, color='gray', linestyle='--', alpha=0.5)
        below = np.where(median_c1 < threshold)[0]
        above = np.where(median_c1 > 1-threshold)[0]
        if below.size > 0: first_zero = (below[0], True)
        elif above.size > 0: first_zero = (above[0], False)
        else: first_zero = None
        if first_zero is not None:
            ax.axvline(x=first_zero[0], color='black', linestyle='--',
                       alpha=0.7,
                       label=fr'Median $\leq$ {threshold}' if first_zero[1]
                       else fr'Median $\geq$ 1-{threshold}')
        ax.legend()

plt.tight_layout()
plt.show()
```

Holding to our guesses, let's calculate the four values

```
# Nature's density in the third column
h_beta = jit(lambda x: p(x, 2, 1.5))

# Close case
Kf_g, Kg_f = compute_KL(f_close, g_close), compute_KL(g_close, f_close)
Kf_h, Kg_h = compute_KL_h(h_beta, f_close, g_close)

print(f"KL divergences (close): \nKL(f,g)={Kf_g:.3f}, KL(g,f)={Kg_f:.3f}")
print(f"KL(h,f)={Kf_h:.3f}, KL(h,g)={Kg_h:.3f}")

# Far case
Kf_g, Kg_f = compute_KL(f_far, g_far), compute_KL(g_far, f_far)
Kf_h, Kg_h = compute_KL_h(h_beta, f_far, g_far)

print(f"KL divergences (far): \nKL(f,g)={Kf_g:.3f}, KL(g,f)={Kg_f:.3f}")
print(f"KL(h,f)={Kf_h:.3f}, KL(h,g)={Kg_h:.3f}")
```

```
KL divergences (close):
KL(f,g)=0.003, KL(g,f)=0.003
KL(h,f)=0.108, KL(h,g)=0.082
KL divergences (far):
KL(f,g)=0.759, KL(g,f)=0.344
KL(h,f)=0.108, KL(h,g)=0.241
```

We find that in the first case, $KL(f,g) \approx KL(g,f)$ and both are relatively small, so although either agent 1 or agent 2 will eventually consume everything, convergence displayed in the first two panels on the top is pretty slow.

In the first two panels at the bottom, we see convergence occurring faster (as indicated by the black dashed line) because the divergence gaps $KL(f,g)$ and $KL(g,f)$ are larger.

Since $KL(f,g) > KL(g,f)$, we see faster convergence in the first panel at the bottom when nature chooses f than in the second panel where nature chooses g.

The third column holds nature's h and agent 1's f fixed and changes agent 2's g.

In both rows, $KL(h,f) = 0.108$.

The close g has $KL(h,g) = 0.082 < KL(h,f)$, so agent 1's consumption share drifts toward 0.

The far g has $KL(h,g) = 0.241 > KL(h,f)$, so agent 1's consumption share goes to 1.

Agent 1 loses to the close g and wins against the far g.

In each case the winner is the agent whose beliefs have the smaller KL divergence from h.

These outcomes agree with formula (23.8) and with *A helpful formula* in *Likelihood Ratio Processes*.

Complete markets models with homogeneous beliefs, a kind often used in macroeconomics and finance, are studied in this quantecon lecture *Competitive Equilibria with Arrow Securities*.

[Blume *et al.*, 2018] discuss a paternalistic case against complete markets. They study the consequences of assuming that a social planner disregards individuals preferences in the sense that it ignores the subjective belief components of their preferences and replaces it with the social planner's beliefs about probabilities.

Survival and Long-Run Dynamics under Recursive Preferences studies Borovička [2020], who shows that market selection can fail when agents have Epstein–Zin recursive preferences: agents with distorted beliefs can survive and can even dominate.

Merging of Opinions: The Blackwell–Dubins Theorem presents the merging-of-opinions theorem of Blackwell and Dubins [1962].

In Exercise 23.11.4 and Exercise 23.11.6, nature's probability law is absolutely continuous with respect to each agent's subjective probability law, each agent's predictions merge with the truth, and both agents survive.

In Exercise 23.11.7, agent 2's dogmatic prior breaks absolute continuity, and agent 2 does not survive.

Incorrect Models studies what a Bayesian learns when nature draws from a mixture h of f and g, the case in the right panels of our first figure.

Statistical Divergence Measures describes Kullback–Leibler divergence and other statistical divergences.

Likelihood processes play an important role in Bayesian learning, as described in *Likelihood Ratio Processes and Bayesian Learning* and as applied in *Job Search IX: Search with Learning*.

Likelihood ratio processes appear again in Additive and Multiplicative Functionals.

23.11 Exercises

Exercise 23.11.1

Agent 1's endowment is $y_t^1 = s_t$ and agent 2's endowment is $y_t^2 = 1 - s_t$.

Let $E^i[s] = \int s\,\pi^i(s)\,ds$.

Take prices (23.12) and allocation (23.6) as given.

1. Show that agent 1's budget constraint (23.9) holds with equality if and only if λ satisfies (23.13).

2. Show that λ is agent 1's share of total wealth at time -1.
3. Show that continuation wealth satisfies (23.14).
4. Derive Arrow-price formula (23.15).
5. Set $\pi^1 = f = \text{Beta}(1,1)$, $\pi^2 = g = \text{Beta}(3, 1.2)$, and $\delta = 0.9$. Compute λ from (23.13). Use Monte Carlo simulation to compute the values of agent 1's consumption and endowment streams when λ satisfies (23.13) and when $\lambda = 0.5$.

Solution

Part 1. Allocation (23.6) is

$$c_t^1(s^t) = \frac{\lambda \pi_t^1(s^t)}{\lambda \pi_t^1(s^t) + (1-\lambda)\pi_t^2(s^t)}.$$

Multiplying by prices (23.12) gives

$$p_t(s^t) c_t^1(s^t) = \frac{\delta^t \pi_t^1(s^t)}{1-\lambda}.$$

Because $\int \pi_t^1(s^t)\, ds^t = 1$, the value of agent 1's consumption stream is

$$\sum_{t=0}^{\infty} \int p_t(s^t) c_t^1(s^t)\, ds^t = \frac{1}{(1-\delta)(1-\lambda)}.$$

Integrating over all dates except t gives $\int \pi_t^i(s^t) s_t\, ds^t = E^i[s]$.

The value of agent 1's endowment stream is

$$\sum_{t=0}^{\infty} \int p_t(s^t) s_t\, ds^t = \frac{\lambda E^1[s] + (1-\lambda) E^2[s]}{(1-\delta)\lambda(1-\lambda)}.$$

Equating the two values gives $\lambda = \lambda E^1[s] + (1-\lambda) E^2[s]$.

Solving for λ gives (23.13).

Part 2. The value of the aggregate endowment stream is

$$\sum_{t=0}^{\infty} \int p_t(s^t) \cdot 1\, ds^t = \frac{1}{(1-\delta)\lambda(1-\lambda)}.$$

Dividing the value of agent 1's consumption stream by this value gives λ.

Part 3. First-order condition (23.10) gives $p_\tau(s^\tau) c_\tau^i(s^\tau) = \delta^\tau \pi_\tau^i(s^\tau)/\mu_i$.

Integrating over $s_{t+1}, \ldots, s_\tau$ gives $\delta^\tau \pi_t^i(s^t)/\mu_i$.

Summing over $\tau \geq t$ gives $\delta^t \pi_t^i(s^t)/(\mu_i(1-\delta))$.

Dividing by $p_t(s^t) = \delta^t \pi_t^i(s^t)/(\mu_i c_t^i(s^t))$ gives $W_t^i(s^t) = c_t^i(s^t)/(1-\delta)$.

Part 4. Using $\pi_{t+1}^i(s^{t+1}) = \pi_t^i(s^t)\pi^i(s_{t+1})$ in (23.12),

$$\begin{aligned} q(s_{t+1}|s^t) &= \frac{p_{t+1}(s^{t+1})}{p_t(s^t)} \\ &= \delta \frac{\lambda \pi_t^1(s^t)\pi^1(s_{t+1}) + (1-\lambda)\pi_t^2(s^t)\pi^2(s_{t+1})}{\lambda \pi_t^1(s^t) + (1-\lambda)\pi_t^2(s^t)} \\ &= \delta\big[\lambda_t(s^t)\pi^1(s_{t+1}) + (1-\lambda_t(s^t))\pi^2(s_{t+1})\big], \end{aligned}$$

where the last line uses $\lambda_t(s^t) = \lambda\pi_t^1(s^t)/[\lambda\pi_t^1(s^t) + (1-\lambda)\pi_t^2(s^t)]$.

Arrow prices from s^t onward have the same form as prices at time -1, with $\lambda_t(s^t)$ in place of λ.

Part 2 applied at s^t gives agent 1's wealth share $\lambda_t(s^t)$, which agrees with part 3.

Part 5. Prices (23.12) turn the value of any stream $x_t(s^t)$ into a mixture of expectations under the two agents' models:

$$\sum_{t=0}^{\infty} \int p_t(s^t) x_t(s^t)\, ds^t = \frac{1}{\lambda(1-\lambda)} \sum_{t=0}^{\infty} \delta^t \left(\lambda E^1[x_t] + (1-\lambda) E^2[x_t]\right).$$

We estimate $E^i[x_t]$ by averaging over histories drawn from π^i.

We report values as shares of the value of the aggregate endowment, which removes the factor $1/(\lambda(1-\lambda))$.

```
f = jit(lambda x: p(x, 1, 1))
g = jit(lambda x: p(x, 3, 1.2))

E1 = quad(lambda s: s * f(s), 0, 1)[0]
E2 = quad(lambda s: s * g(s), 0, 1)[0]
λ_ce = E2 / (1 - E1 + E2)

print(f"E^1[s] = {E1:.4f}, E^2[s] = {E2:.4f}, λ = {λ_ce:.4f}")
```

```
E^1[s] = 0.5000, E^2[s] = 0.7143, λ = 0.5882
```

```

```
λ = 0.588: value of c^1 = 0.586 (exact 0.588), value of y^1 = 0.589 (exact 0.
↪588)
λ = 0.500: value of c^1 = 0.500 (exact 0.500), value of y^1 = 0.607 (exact 0.
↪607)
```

At $\lambda = 10/17$, the values of agent 1's consumption and endowment streams agree.

At $\lambda = 0.5$, agent 1's endowment stream is worth more than its consumption stream.

Agent 1 can then afford more consumption, so $\lambda = 0.5$ is not a competitive equilibrium Pareto weight without a transfer.

Exercise 23.11.2

Suppose that agent i has its own discount factor δ_i, so that

$$V^i = \sum_{t=0}^{\infty} \sum_{s^t} \delta_i^t u(c_t^i(s^t)) \pi_t^i(s^t).$$

Keep all other assumptions of the planning problem.

1. Show that the planner's allocation satisfies

$$\frac{c_t^1(s^t)}{c_t^2(s^t)} = \frac{\lambda}{1-\lambda} \left(\frac{\delta_1}{\delta_2}\right)^t l_t(s^t).$$

2. Show that when nature draws s_t IID from π,

$$\frac{1}{t} \log \frac{c_t^1(s^t)}{c_t^2(s^t)} \to [\log \delta_1 - KL(\pi, \pi^1)] - [\log \delta_2 - KL(\pi, \pi^2)] \quad \text{almost surely.}$$

   The quantity $\log \delta_i - KL(\pi, \pi^i)$ is agent i's **survival index**.

3. Let nature draw from the mixture $h = 0.5f + 0.5g$ with $f = \text{Beta}(1,1)$ and $g = \text{Beta}(3, 1.2)$, as in the right panels of our first figure. Agent 1 believes f and agent 2 believes g. For which values of δ_1/δ_2 does agent 1's consumption share converge to 1?

4. Set $\delta_2 = 0.99$ and $\lambda = 0.5$. Simulate agent 1's consumption share for values of δ_1 on both sides of the threshold you found.

Solution

Part 1. The planner's first-order conditions become

$$\lambda \delta_1^t \frac{\pi_t^1(s^t)}{c_t^1(s^t)} = \theta_t(s^t) = (1-\lambda)\delta_2^t \frac{\pi_t^2(s^t)}{c_t^2(s^t)}.$$

Equating the first and third expressions and rearranging gives the result.

Part 2. Taking logarithms gives

$$\log \frac{c_t^1(s^t)}{c_t^2(s^t)} = \log \frac{\lambda}{1-\lambda} + t \log \frac{\delta_1}{\delta_2} + \log l_t(s^t).$$

Dividing by t and applying (23.8) gives the result.

Part 3. Agent 1's consumption share converges to 1 when its survival index exceeds agent 2's:

$$\log \frac{\delta_1}{\delta_2} + KL(h, g) - KL(h, f) > 0,$$

or

$$\frac{\delta_1}{\delta_2} > \exp(-[KL(h, g) - KL(h, f)]).$$

```
f = jit(lambda x: p(x, 1, 1))
g = jit(lambda x: p(x, 3, 1.2))
h = jit(lambda x: 0.5 * f(x) + 0.5 * g(x))

Kh_f, Kh_g = compute_KL_h(h, f, g)
ratio_threshold = np.exp(-(Kh_g - Kh_f))

print(f"KL(h,g) - KL(h,f) = {Kh_g - Kh_f:.3f}")
print(f"agent 1's share converges to 1 if δ_1/δ_2 > {ratio_threshold:.3f}")
```

```
KL(h,g) - KL(h,f) = 0.208
agent 1's share converges to 1 if δ_1/δ_2 > 0.812
```

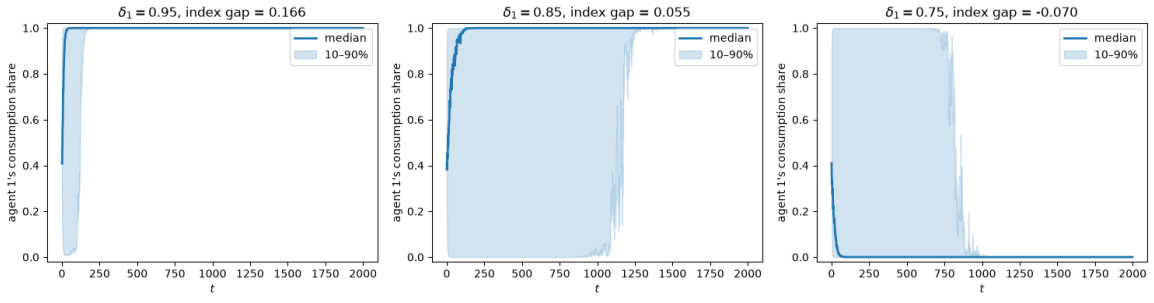
Agent 1 has better beliefs.

A more patient agent 2 drives agent 1 out when $\delta_1/\delta_2 < 0.81$.

An agent can make up for worse beliefs by saving more.

Part 4. With $\delta_2 = 0.99$, the threshold is $\delta_1 = 0.99 \times 0.81 \approx 0.80$.

We simulate $\delta_1 = 0.95$ and $\delta_1 = 0.85$ above the threshold and $\delta_1 = 0.75$ below it.



```
def simulate_patience(sequences, δ_1, δ_2, λ=0.5):
    """Agent 1's consumption share when agents discount at δ_1 and δ_2."""
    log_l = np.cumsum(np.log(f(sequences) / g(sequences)), axis=1)
    t = np.arange(sequences.shape[1])
    return expit(np.log(λ / (1 - λ)) + t * np.log(δ_1 / δ_2) + log_l)

T, N = 2000, 1000
δ_2 = 0.99

# Nature draws from the mixture h
draw_f = rng.random((N, T)) < 0.5
s_seq_h = np.where(draw_f, rng.beta(1, 1, (N, T)), rng.beta(3, 1.2, (N, T)))

fig, axes = plt.subplots(1, 3, figsize=(15, 4))
for ax, δ_1 in zip(axes, [0.95, 0.85, 0.75]):
    c1 = simulate_patience(s_seq_h, δ_1, δ_2)
    gap = np.log(δ_1 / δ_2) + Kh_g - Kh_f
    p10, p50, p90 = np.percentile(c1, [10, 50, 90], axis=0)
    ax.plot(p50, color='C0', linewidth=2, label='median')
    ax.fill_between(range(T), p10, p90, color='C0', alpha=0.2, label='10-90%')
    ax.set_title(rf'$\delta_1 = {δ_1}$, index gap = {gap:.3f}')
    ax.set_xlabel('$t$')
    ax.set_ylabel("agent 1's consumption share")
    ax.set_ylim([-0.02, 1.02])
    ax.legend()

plt.tight_layout()
plt.show()
```

The panel titles report the difference between agent 1's and agent 2's survival indexes.

When the difference is positive, agent 1's consumption share goes to 1.

When it is negative, agent 1's consumption share goes to 0 even though agent 1 has better beliefs.

Exercise 23.11.3

Let nature draw s_t IID from $\pi = \text{Beta}(2, 2)$, let agent 1 believe $\pi^1 = \text{Beta}(2, 3)$, and let agent 2 believe $\pi^2 = \text{Beta}(3, 2)$.

Set $\lambda = 0.5$.

1. Show that $KL(\pi, \pi^1) = KL(\pi, \pi^2)$.
2. Show that agent 1's consumption share c_t^1 does not converge.
3. Simulate many paths and plot histograms of c_t^1 at $t = 10, 100, 2000$.

Solution

Part 1. The densities satisfy $\pi^1(s) = \pi^2(1-s)$ and $\pi(s) = \pi(1-s)$.

The change of variables $s \mapsto 1 - s$ maps $KL(\pi, \pi^1)$ into $KL(\pi, \pi^2)$.

Part 2. Both densities have normalizing constant 12, so

$$\log \frac{\pi^1(s)}{\pi^2(s)} = \log \frac{s(1-s)^2}{s^2(1-s)} = \log \frac{1-s}{s}.$$

Under π, this random variable has mean 0 by symmetry and variance $\sigma^2 > 0$.

The log likelihood ratio $\log l_t$ is a random walk with zero drift and increment variance σ^2.

The law of the iterated logarithm implies $\limsup_t \log l_t = +\infty$ and $\liminf_t \log l_t = -\infty$ almost surely.

With $\lambda = 0.5$, $c_t^1 = l_t/(1 + l_t)$, so $\limsup_t c_t^1 = 1$ and $\liminf_t c_t^1 = 0$.

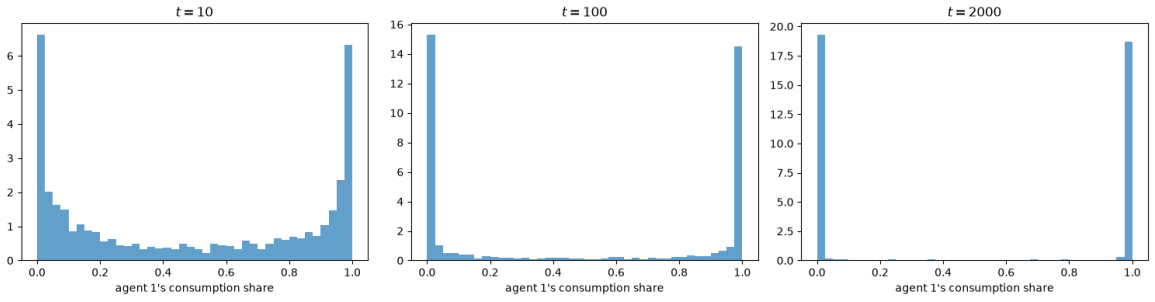
By the central limit theorem, $\log l_t$ is approximately normal with mean 0 and variance $(t+1)\sigma^2$.

The probability that c_t^1 lies near 0.5 shrinks at rate $1/\sqrt{t}$, and the distribution of c_t^1 piles up near 0 and 1.

Part 3.

```
rng = np.random.default_rng(1234)

nature = jit(lambda x: p(x, 2, 2))
f = jit(lambda x: p(x, 2, 3))
g = jit(lambda x: p(x, 3, 2))



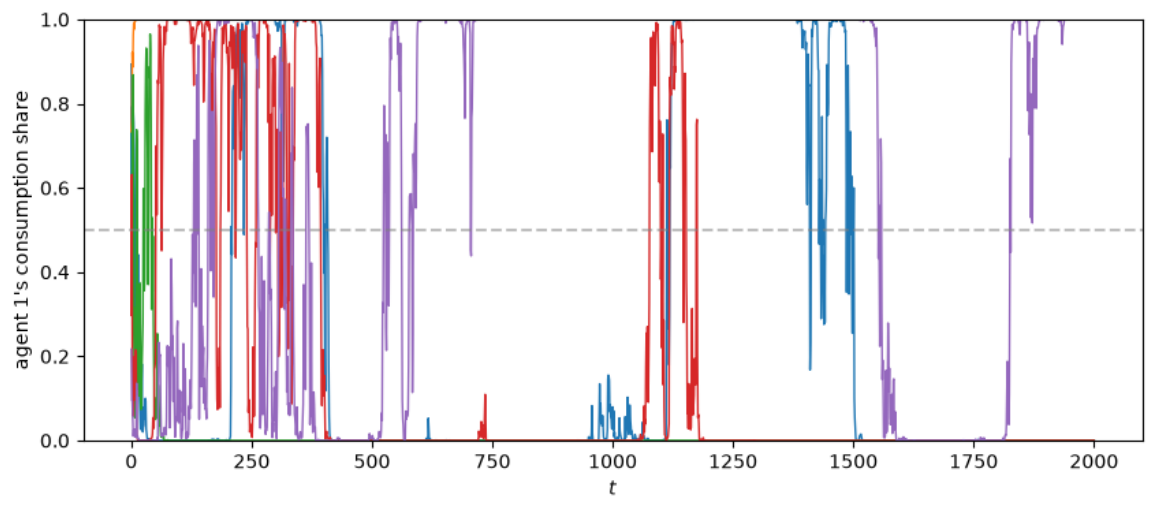
K1, K2 = compute_KL_h(nature, f, g)
σ2 = quad(lambda s: nature(s) * np.log((1 - s) / s)**2, 0, 1)[0]
print(f"KL(π, π^1) = {K1:.4f}, KL(π, π^2) = {K2:.4f}, σ^2 = {σ2:.3f}")
```

```
KL(π, π^1) = 0.1402, KL(π, π^2) = 0.1402, σ^2 = 1.290
```

```
N, T = 2000, 2001
s_seq = rng.beta(2, 2, (N, T))
log_l = np.cumsum(np.log(f(s_seq) / g(s_seq)), axis=1)
c1 = expit(log_l)      # λ = 0.5

fig, axes = plt.subplots(1, 3, figsize=(15, 4))
for ax, t in zip(axes, [10, 100, 2000]):
    ax.hist(c1[:, t], bins=40, range=(0, 1), density=True, alpha=0.7)
    ax.set_title(f'$t = {t}$')
    ax.set_xlabel("agent 1's consumption share")
plt.tight_layout()
plt.show()

for t in [10, 100, 2000]:
    near_half = np.mean(np.abs(c1[:, t] - 0.5) < 0.05)
    extreme = np.mean((c1[:, t] < 0.05) | (c1[:, t] > 0.95))
    print(f"t = {t:4d}: P(|c1 - 0.5| < 0.05) = {near_half:.3f}, "
          f"P(c1 < 0.05 or c1 > 0.95) = {extreme:.3f}")
```



```
t =   10: P(|c1 - 0.5| < 0.05) = 0.035, P(c1 < 0.05 or c1 > 0.95) = 0.433
t =  100: P(|c1 - 0.5| < 0.05) = 0.011, P(c1 < 0.05 or c1 > 0.95) = 0.794
t = 2000: P(|c1 - 0.5| < 0.05) = 0.003, P(c1 < 0.05 or c1 > 0.95) = 0.961
```

As t grows, the histograms put more mass near 0 and 1 and less near 0.5.

The next figure shows five sample paths.

```
fig, ax = plt.subplots(figsize=(10, 4))
for j in range(5):
    ax.plot(c1[j, :], linewidth=1)
ax.axhline(y=0.5, color='gray', linestyle='--', alpha=0.5)
ax.set_xlabel('$t$')
ax.set_ylabel("agent 1's consumption share")
ax.set_ylim([0, 1])
plt.show()
```

Each path keeps crossing 0.5 and spends long spells near 0 or near 1.

Neither agent is driven out, and neither agent's share settles down.

Exercise 23.11.4

In this exercise, each of our two agents is a Bayesian who does not know whether nature draws from f or from g.

In this exercise and the following ones, dates start at $t = 1$: the history is $s^t = (s_1, \ldots, s_t)$.

The following two models are on the table

$$f(s^t) = f(s_1)f(s_2)\cdots f(s_t)$$

and

$$g(s^t) = g(s_1)g(s_2)\cdots g(s_t)$$

as is an associated likelihood ratio process

$$L(s^t) = \frac{f(s^t)}{g(s^t)}.$$

The two agents share f and g but have different prior probabilities $\pi_0^1, \pi_0^2 \in (0, 1)$ on model f.

Agent i's joint density of s^t is the prior-weighted mixture

$$m^i(s^t) = \pi_0^i f(s^t) + (1 - \pi_0^i)g(s^t). \tag{23.16}$$

As in *Likelihood Ratio Processes and Bayesian Learning*, Bayes' law implies that agent i's posterior probability on model f after observing s^t is

$$\pi_t^i = \frac{\pi_0^i L(s^t)}{\pi_0^i L(s^t) + 1 - \pi_0^i}.$$

Joint density (23.16) is a product of one-step-ahead predictive densities:

$$m^i(s^t) = \prod_{j=1}^{t} \left[\pi_{j-1}^i f(s_j) + (1 - \pi_{j-1}^i)g(s_j)\right].$$

The predictive density of s_j uses the posterior π^i_{j-1} that agent i forms before observing s_j.

We now hand probability models (23.16) for $i = 1, 2$ to the social planner.

1. Show that the likelihood ratio $l_t(s^t) = m^1(s^t)/m^2(s^t)$ satisfies

$$l_t(s^t) = \frac{\pi^1_0 L(s^t) + 1 - \pi^1_0}{\pi^2_0 L(s^t) + 1 - \pi^2_0},$$

   and find the limits of agent 1's consumption share when nature draws from f and when nature draws from g.

2. Set $f \sim \text{Beta}(1.5, 1)$, $g \sim \text{Beta}(1, 1.5)$, and $\lambda = 0.5$. Write Python code that simulates posteriors and consumption shares for prior pairs $(\pi^1_0, \pi^2_0) = (0.3, 0.7), (0.7, 0.3), (0.1, 0.9)$ when nature draws from f and when nature draws from g.

3. Does either agent's consumption share converge to zero? How do the priors π^1_0 and π^2_0 affect outcomes?

Solution

Part 1. Dividing the numerator and the denominator of $m^1(s^t)/m^2(s^t)$ by $g(s^t)$ gives the formula for $l_t(s^t)$.

When nature draws from f, $L(s^t) \to +\infty$ and $l_t \to \pi^1_0/\pi^2_0$, so

$$c^1_t \to \frac{\lambda\pi^1_0}{\lambda\pi^1_0 + (1-\lambda)\pi^2_0}.$$

When nature draws from g, $L(s^t) \to 0$ and $l_t \to (1-\pi^1_0)/(1-\pi^2_0)$, so

$$c^1_t \to \frac{\lambda(1-\pi^1_0)}{\lambda(1-\pi^1_0) + (1-\lambda)(1-\pi^2_0)}.$$

Both limits lie strictly between 0 and 1.

Both agents survive.

Part 2. The following function computes posteriors, the likelihood ratio l_t, and agent 1's consumption share.

It builds l_t from one-step-ahead predictive densities that use posteriors formed before s_t is observed.

```
def simulate_learning_blume_easley(sequences, f_belief, g_belief,
                                   π_0_1, π_0_2, λ=0.5):
    """
    Simulate the Blume-Easley model with two Bayesian agents.

    Column t-1 of `sequences` holds s_t.
    """
    N, T = sequences.shape
    f_vals = f_belief(sequences)
    g_vals = g_belief(sequences)

    π_1_seq = np.empty((N, T))
    π_2_seq = np.empty((N, T))
    l_agents_seq = np.empty((N, T))

    # Priors and l_0 = 1
    π_1 = np.full(N, π_0_1)
    π_2 = np.full(N, π_0_2)
    l_agents = np.ones(N)
```

```
    for t in range(T):
        # Predictive densities of s_{t+1} use posteriors given s^t
        m1 = π_1 * f_vals[:, t] + (1 - π_1) * g_vals[:, t]
        m2 = π_2 * f_vals[:, t] + (1 - π_2) * g_vals[:, t]
        l_agents = l_agents * m1 / m2

        # Bayes' law after observing s_{t+1}
        π_1 = π_1 * f_vals[:, t] / m1
        π_2 = π_2 * f_vals[:, t] / m2

        π_1_seq[:, t] = π_1
        π_2_seq[:, t] = π_2
        l_agents_seq[:, t] = l_agents

    c1_share = λ * l_agents_seq / (1 - λ + λ * l_agents_seq)

    return {
        'π_1': π_1_seq,
        'π_2': π_2_seq,
        'c1_share': c1_share,
        'l_agents': l_agents_seq
    }
```

The next function computes the limits of agent 1's consumption share from part 1.

```
def c1_limit(π_0_1, π_0_2, nature_type, λ=0.5):
    """Limit of agent 1's consumption share."""
    if nature_type == 'f':
        w_1, w_2 = π_0_1, π_0_2
    else:
        w_1, w_2 = 1 - π_0_1, 1 - π_0_2
    return λ * w_1 / (λ * w_1 + (1 - λ) * w_2)
```

Let's run simulations for different scenarios.

We use $\lambda = 0.5$, $T = 40$, and $N = 1000$.

```
λ = 0.5
T = 40
N = 1000

F_a, F_b = 1.5, 1
G_a, G_b = 1, 1.5

f = jit(lambda x: p(x, F_a, F_b))
g = jit(lambda x: p(x, G_a, G_b))
```

We'll start with different initial priors $\pi_0^i \in (0, 1)$ and widen the gap between them.

```
# Different initial priors
π_0_scenarios = [
    (0.3, 0.7),
    (0.7, 0.3),
    (0.1, 0.9),
]
```

Now we can run simulations for different scenarios

```
rng = np.random.default_rng()

# Nature follows f
s_seq_f = rng.beta(F_a, F_b, (N, T))

# Nature follows g
s_seq_g = rng.beta(G_a, G_b, (N, T))

results_f = {}
results_g = {}

for i, (π_0_1, π_0_2) in enumerate(π_0_scenarios):
    # When nature follows f
    results_f[i] = simulate_learning_blume_easley(
            s_seq_f, f, g, π_0_1, π_0_2, λ)
    # When nature follows g
    results_g[i] = simulate_learning_blume_easley(
            s_seq_g, f, g, π_0_1, π_0_2, λ)
```

The recursion reproduces the closed form for l_t in part 1

```
_, L = compute_likelihood_ratios(s_seq_f, f, g)
π_0_1, π_0_2 = π_0_scenarios[0]
l_closed = (π_0_1 * L + 1 - π_0_1) / (π_0_2 * L + 1 - π_0_2)
print(np.max(np.abs(results_f[0]['l_agents'] / l_closed - 1)))
```

```
1.1546319456101628e-13
```

Let's visualize the results

```
def plot_learning_results(results, π_0_scenarios, nature_type, λ=0.5):
    """
    Plot median posteriors and consumption shares for learning agents.
    """
    fig, axes = plt.subplots(3, 2, figsize=(10, 15))
    truth = 1.0 if nature_type == 'f' else 0.0

    for row, (π_0_1, π_0_2) in enumerate(π_0_scenarios):
        res = results[row]
        t_grid = np.arange(1, res['c1_share'].shape[1] + 1)
        scenario_label = rf'$\pi_0^1 = {π_0_1}, \pi_0^2 = {π_0_2}$'

        # Posterior probabilities on f
        ax = axes[row, 0]
        ax.plot(t_grid, np.median(res['π_1'], axis=0), 'C0',
                label='agent 1', linewidth=2)
        ax.plot(t_grid, np.median(res['π_2'], axis=0), 'C1',
                label='agent 2', linewidth=2)
        ax.axhline(y=truth, color='gray', linestyle='--',
                   alpha=0.5, label=f'truth ({nature_type})')
        ax.set_title(f'Beliefs when nature = {nature_type}\n{scenario_label}')
        ax.set_ylabel(r'median $\pi^i_t$')
        ax.set_ylim([-0.05, 1.05])
        ax.legend()

        # Consumption shares and their limit
        ax = axes[row, 1]
        ax.plot(t_grid, np.median(res['c1_share'], axis=0), 'g-',
                linewidth=2, label='median')
```

```
        ax.axhline(y=c1_limit(π_0_1, π_0_2, nature_type, λ),
                   color='k', linestyle='--', alpha=0.7, label='limit')
        ax.set_title(f'Agent 1 consumption share (Nature = {nature_type})')
        ax.set_ylabel('consumption share')
        ax.set_ylim([0, 1])
        ax.legend()

        for col in range(2):
            axes[row, col].set_xlabel('$t$')

    plt.tight_layout()
    return fig, axes

def print_limits(results, π_0_scenarios, nature_type, λ=0.5):
    """Compare median final consumption shares with their limits."""
    for i, (π_0_1, π_0_2) in enumerate(π_0_scenarios):
        c1_T = np.median(results[i]['c1_share'][:, -1])
        limit = c1_limit(π_0_1, π_0_2, nature_type, λ)
        print(f"nature = {nature_type}, priors = ({π_0_1}, {π_0_2}): "
              f"median c1 at T = {c1_T:.3f}, limit = {limit:.3f}")
```

Now we'll plot outcomes when nature follows f:

```
fig_f, axes_f = plot_learning_results(results_f, π_0_scenarios, 'f', λ)
plt.show()
print_limits(results_f, π_0_scenarios, 'f', λ)
```

Beliefs when nature = f
$\pi_0^1 = 0.3, \pi_0^2 = 0.7$
median π_t^i
agent 1
agent 2
truth (f)
t
Agent 1 consumption share (Nature = f)
consumption share
median
limit
Beliefs when nature = f
$\pi_0^1 = 0.7, \pi_0^2 = 0.3$
Agent 1 consumption share (Nature = f)
Beliefs when nature = f
$\pi_0^1 = 0.1, \pi_0^2 = 0.9$
Agent 1 consumption share (Nature = f)

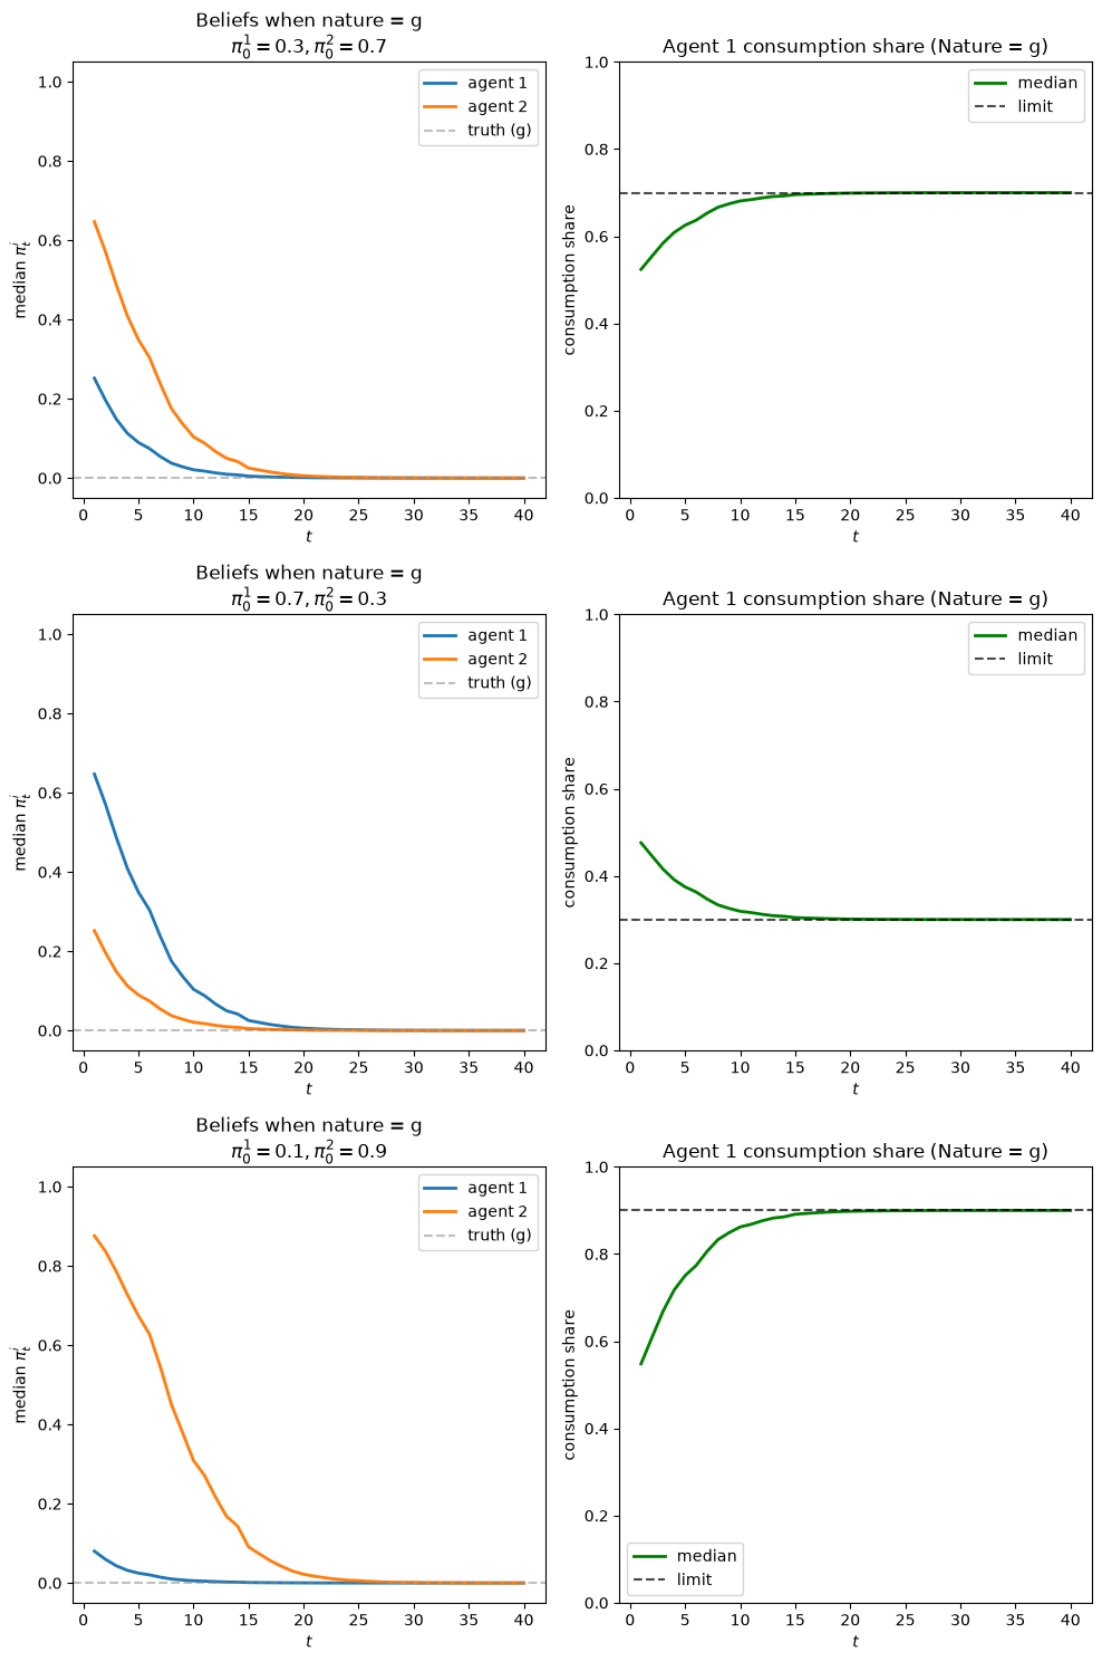
```
nature = f, priors = (0.3, 0.7): median c1 at T = 0.300, limit = 0.300
nature = f, priors = (0.7, 0.3): median c1 at T = 0.700, limit = 0.700
nature = f, priors = (0.1, 0.9): median c1 at T = 0.100, limit = 0.100
```

Agent 1's median consumption share settles at the limit from part 1 in each scenario.

Neither agent's consumption share goes to zero.

Both agents learn that nature draws from f.

Their posterior log odds $\log[\pi_t^i/(1-\pi_t^i)] = \log[\pi_0^i/(1-\pi_0^i)] + \log L(s^t)$ move in parallel.



The agent with the larger prior on f has the larger posterior on f at every date.

Once both agents have learned, their predictive densities agree and l_t stops moving.

The agent who puts more prior probability on the true model keeps the larger consumption share.

Now let's plot outcomes when nature follows g:

```
fig_g, axes_g = plot_learning_results(results_g, π_0_scenarios, 'g', λ)
plt.show()
print_limits(results_g, π_0_scenarios, 'g', λ)
```

limit
consumption share
t

```
nature = g, priors = (0.3, 0.7): median c1 at T = 0.700, limit = 0.700
nature = g, priors = (0.7, 0.3): median c1 at T = 0.300, limit = 0.300
nature = g, priors = (0.1, 0.9): median c1 at T = 0.900, limit = 0.900
```

We observe symmetrical outcomes.

Bayesian learners who put positive prior probability on the true model all survive.

Nature's probability law $f(s^t)$ or $g(s^t)$ is absolutely continuous with respect to each agent's joint density $m^i(s^t)$.

As *Merging of Opinions: The Blackwell–Dubins Theorem* explains, each agent's predictions then merge with the truth.

Exercise 23.11.5

In the previous exercise, we purposefully set the two beta distributions to be relatively close to each other.

That made it challenging to distinguish the distributions.

Now let's study outcomes when the distributions are further apart.

Let's set $f \sim \text{Beta}(2, 5)$ and $g \sim \text{Beta}(5, 2)$.

Please use the Python code you have written to study outcomes.

Solution

Here is one solution

```
λ = 0.5
T = 40
N = 1000

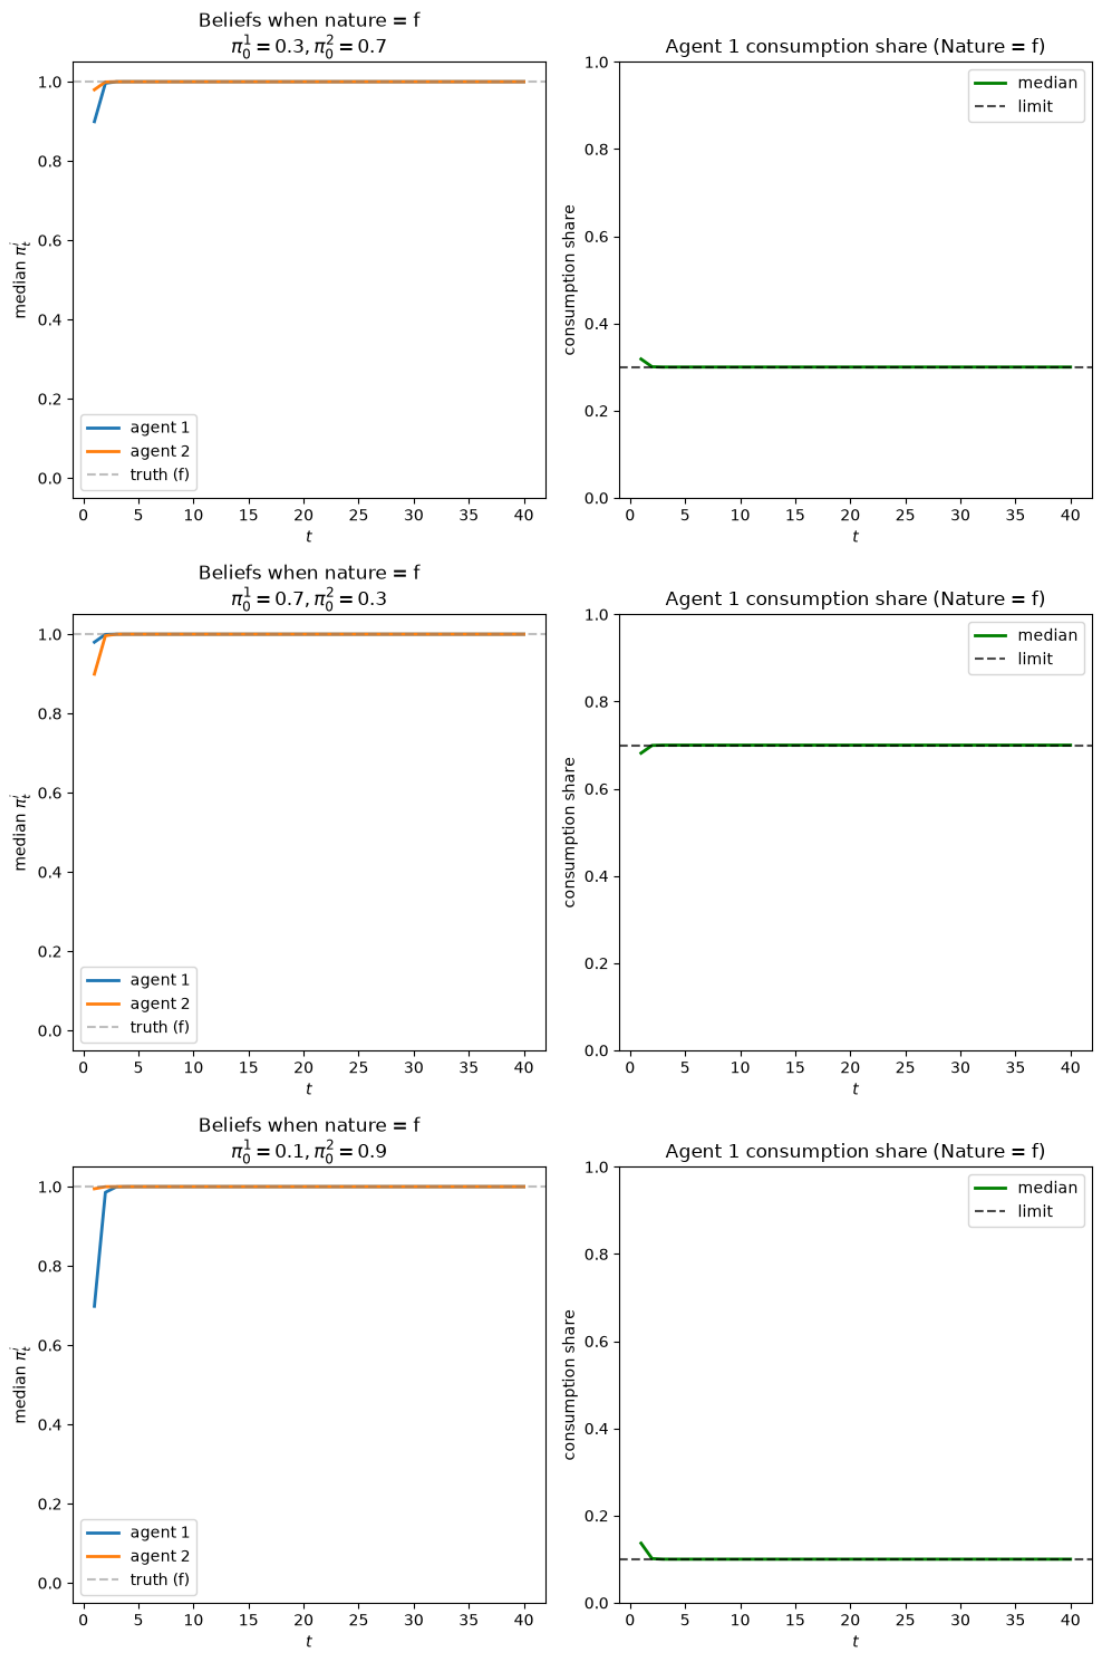
rng = np.random.default_rng()

F_a, F_b = 2, 5
G_a, G_b = 5, 2

f = jit(lambda x: p(x, F_a, F_b))
g = jit(lambda x: p(x, G_a, G_b))

π_0_scenarios = [
    (0.3, 0.7),
    (0.7, 0.3),
    (0.1, 0.9),
]

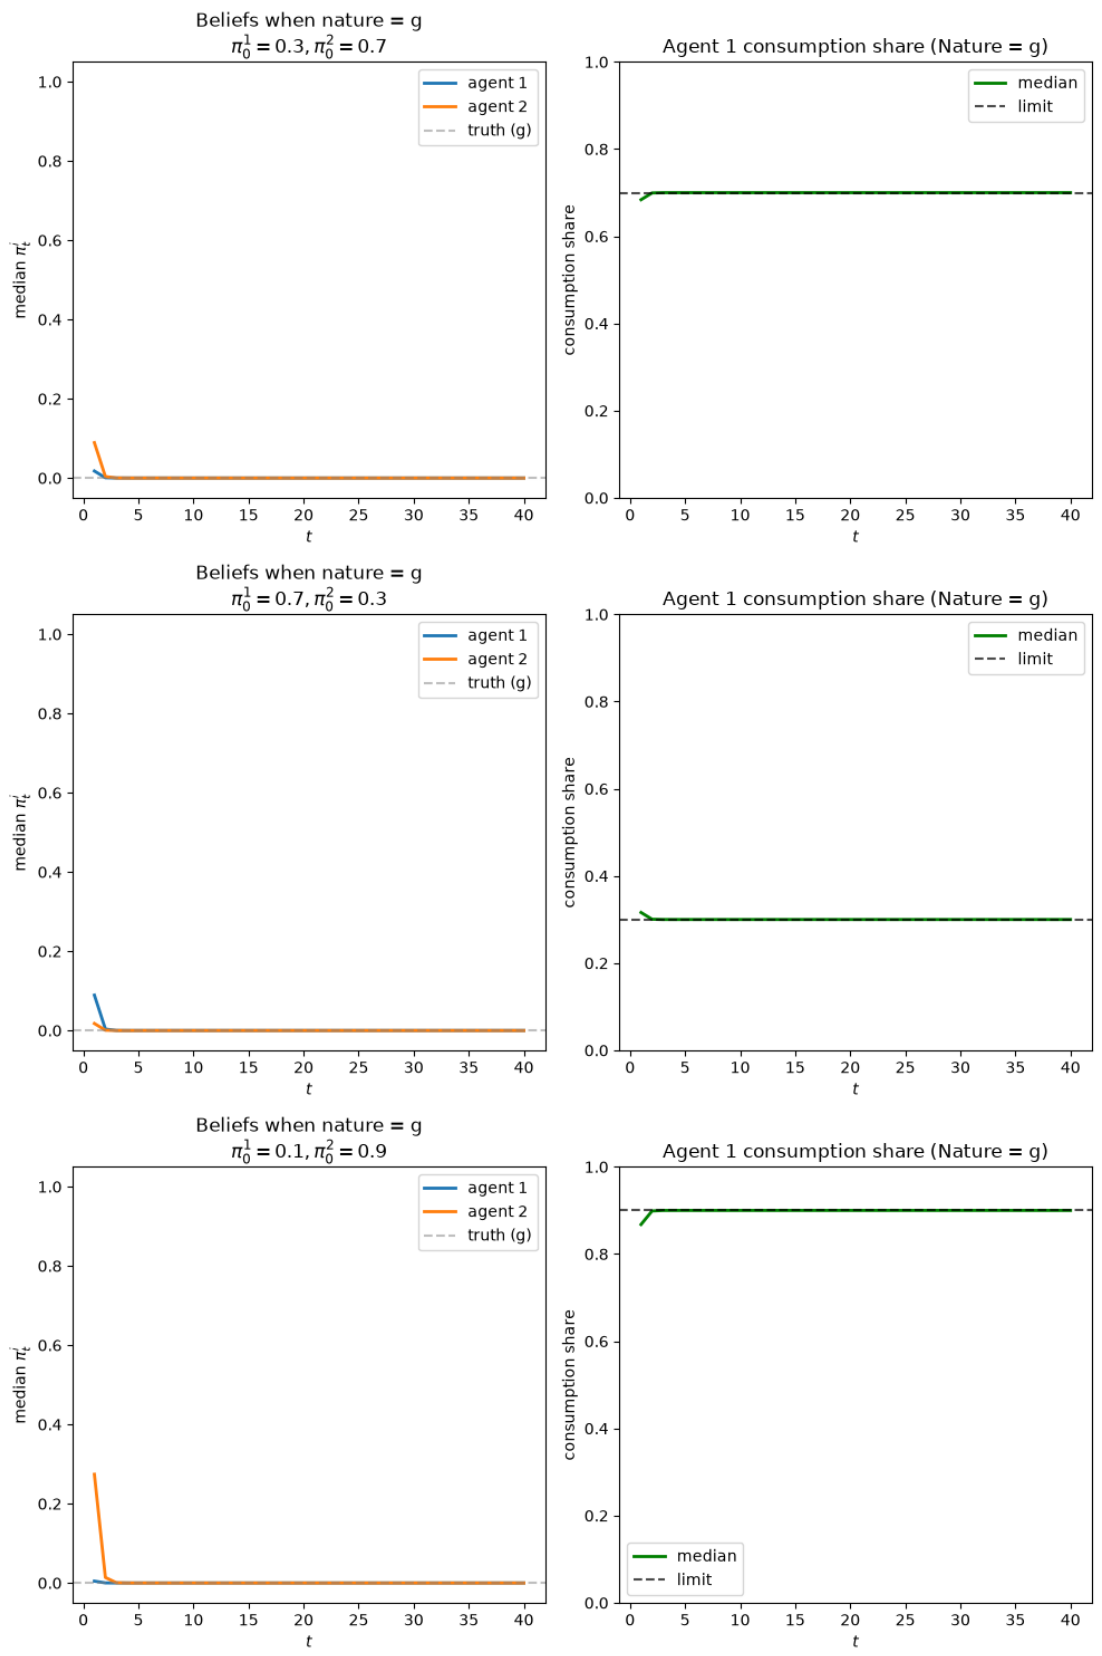
s_seq_f = rng.beta(F_a, F_b, (N, T))
s_seq_g = rng.beta(G_a, G_b, (N, T))



results_f = {}
results_g = {}

for i, (π_0_1, π_0_2) in enumerate(π_0_scenarios):
    # When nature follows f
    results_f[i] = simulate_learning_blume_easley(
            s_seq_f, f, g, π_0_1, π_0_2, λ)
    # When nature follows g
```

```
    results_g[i] = simulate_learning_blume_easley(
            s_seq_g, f, g, π_0_1, π_0_2, λ)
```



Now let's visualize the results

```
fig_f, axes_f = plot_learning_results(results_f, π_0_scenarios, 'f', λ)
plt.show()
print_limits(results_f, π_0_scenarios, 'f', λ)
```

Beliefs when nature = f

```
nature = g, priors = (0.3, 0.7): median c1 at T = 0.700, limit = 0.700
nature = g, priors = (0.7, 0.3): median c1 at T = 0.300, limit = 0.300
nature = g, priors = (0.1, 0.9): median c1 at T = 0.900, limit = 0.900
```

Evidently, because the two distributions are further apart, it is easier to distinguish them.

So learning occurs more quickly.

So does convergence of consumption shares.

The limits are the same as in Exercise 23.11.4 because they depend only on λ and the priors.

Exercise 23.11.6

Two agents have different beliefs about three possible models.

Assume $f(x) \geq 0$, $g(x) \geq 0$, and $h(x) \geq 0$ for $x \in X$ with:

- $\int_X f(x)dx = 1$
- $\int_X g(x)dx = 1$
- $\int_X h(x)dx = 1$

Each model asserts that s_t is IID, so that $f(s^t) = f(s_1) \cdots f(s_t)$, and similarly for g and h.

Let $\pi_0^{f,i}$, $\pi_0^{g,i}$, and $\pi_0^{h,i}$ be agent i's prior probabilities on models f, g, and h.

We'll consider two agents:

- Agent 1: $\pi_0^{f,1} = \pi_0^{g,1} = 1/2$, $\pi_0^{h,1} = 0$ (attaches positive probability only to models f and g)
- Agent 2: $\pi_0^{f,2} = \pi_0^{g,2} = \pi_0^{h,2} = 1/3$ (attaches equal weights to all three models)

Let f and g be two beta distributions with $f \sim \text{Beta}(3, 2)$ and $g \sim \text{Beta}(2, 3)$, and set $h = xf + (1 - x)g$ with $x = 0.5$.

Agent i's joint density of s^t is

$$m^i(s^t) = \pi_0^{f,i} f(s^t) + \pi_0^{g,i} g(s^t) + \pi_0^{h,i} h(s^t).$$

Bayes' Law tells us that agent i's posterior probabilities on models f and g are

$$\pi^{f,i}(s^t) = \frac{\pi_0^{f,i} f(s^t)}{m^i(s^t)}$$

and

$$\pi^{g,i}(s^t) = \frac{\pi_0^{g,i} g(s^t)}{m^i(s^t)}.$$

Please simulate and visualize evolutions of posterior probabilities and consumption allocations when:

- Nature permanently draws from f
- Nature permanently draws from g

Solution

Let's implement this three-model case with two agents having different beliefs.

Let's define f and g far apart, with h being a mixture of f and g.

```
F_a, F_b = 3, 2
G_a, G_b = 2, 3
λ = 0.5
x = 0.5     # weight on f in the mixture h

f = jit(lambda s: p(s, F_a, F_b))
g = jit(lambda s: p(s, G_a, G_b))
h = jit(lambda s: x * f(s) + (1 - x) * g(s))
```

The following function computes each agent's joint density $m^i(s^t)$, posterior probabilities, and agent 1's consumption share.

It works with logarithms of joint densities to avoid overflow and underflow over long histories.

```
def simulate_three_model_allocation(sequences, f_func, g_func, h_func,
                                    priors_1, priors_2, λ=0.5):
    """
    Simulate the Blume-Easley model with two Bayesian agents
    whose prior probabilities on models (f, g, h) are priors_1 and priors_2.

    Column t-1 of `sequences` holds s_t.
    """
    # log f(s^t), log g(s^t), log h(s^t), with shape (3, N, T)
    log_dens = np.stack([np.cumsum(np.log(dens(sequences)), axis=1)
                         for dens in (f_func, g_func, h_func)])

    results = {}
    log_m = []
    for i, priors in enumerate((priors_1, priors_2), start=1):
        # log of prior × joint density; a zero prior gives -inf
        with np.errstate(divide='ignore'):
            log_w = np.log(np.asarray(priors))[:, None, None] + log_dens
        w_max = log_w.max(axis=0)
        log_m_i = w_max + np.log(np.exp(log_w - w_max).sum(axis=0))

        # Posterior probabilities after observing s^t
        posteriors = np.exp(log_w - log_m_i)
        for k, model in enumerate(['f', 'g', 'h']):
            results[f'π_{model}_{i}'] = posteriors[k]
        log_m.append(log_m_i)

    # log l_t = log m^1(s^t) - log m^2(s^t)
    log_l = log_m[0] - log_m[1]
    results['c1_share'] = expit(np.log(λ / (1 - λ)) + log_l)
    return results
```

The following code cell defines a plotting function to show evolutions of beliefs and consumption ratios

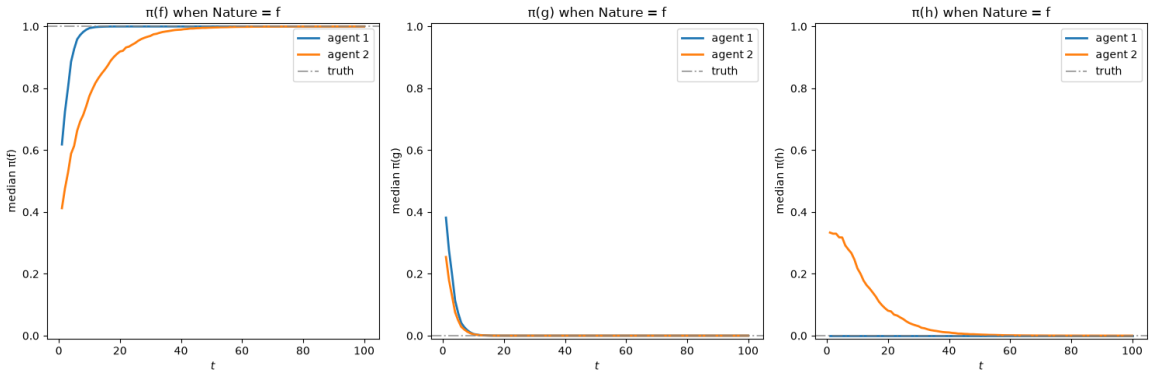
Now let's run the simulation.

In the simulation below, agent 1 assigns positive probabilities only to f and g, while agent 2 puts equal weights on all three models.

```
T = 100
N = 1000

rng = np.random.default_rng()

# Generate sequences for nature f and g
s_seq_f = rng.beta(F_a, F_b, (N, T))
s_seq_g = rng.beta(G_a, G_b, (N, T))



priors_1 = (0.5, 0.5, 0.0)
priors_2 = (1/3, 1/3, 1/3)

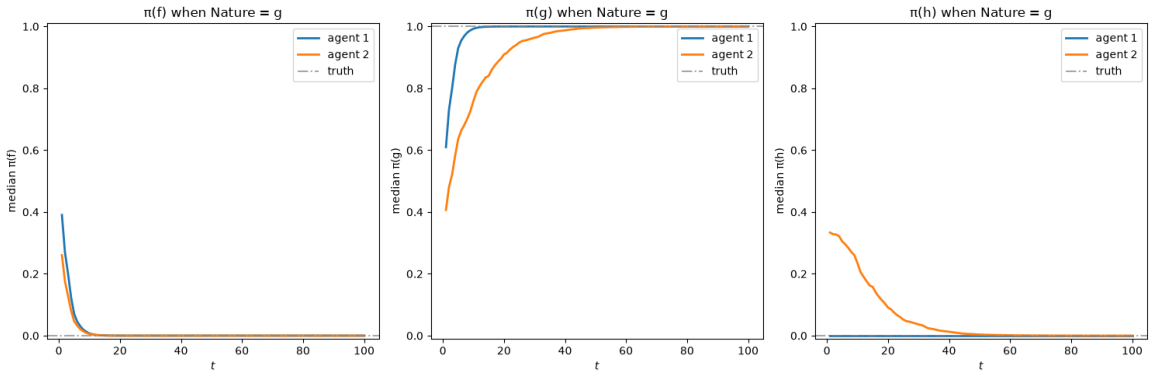
# Run simulations
results_f = simulate_three_model_allocation(s_seq_f, f, g, h,
                                            priors_1, priors_2, λ)
results_g = simulate_three_model_allocation(s_seq_g, f, g, h,
                                            priors_1, priors_2, λ)
```

Plots below show the evolution of beliefs for each model (f, g, h) separately.

First we show the figure when nature chooses f

```
plot_belief_evolution(results_f, nature='f', figsize=(15, 5))
plt.show()
```

Agent 1's posterior beliefs are depicted in blue and agent 2's posterior beliefs are depicted in orange.



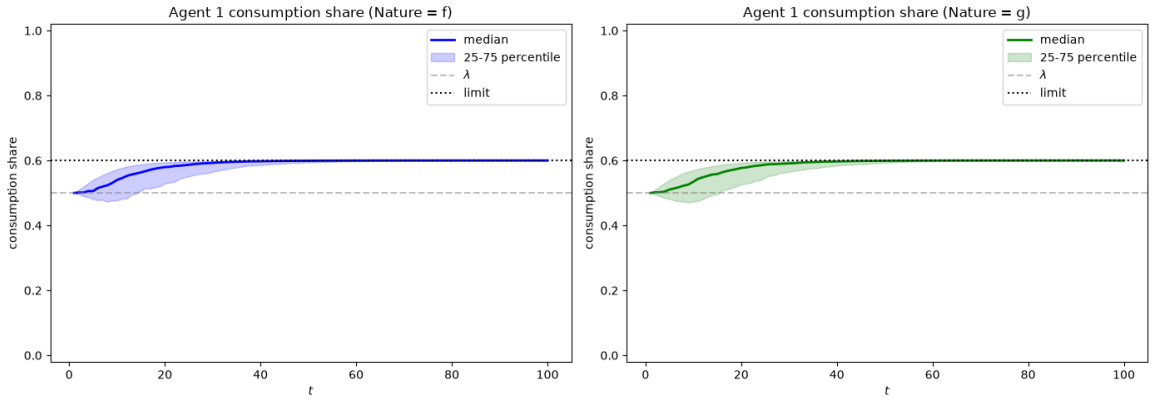
Evidently, when nature draws from f, agent 1 learns faster than agent 2, who, unlike agent 1, attaches a positive prior probability to model h:

- In the leftmost panel, both agents' beliefs for $\pi(f)$ converge toward 1 (the truth)
- Agent 2's belief in model h (rightmost panel) equals $1/3$ after the first draw and then falls toward 0

Agent 2's posterior on h after one draw is $h(s_1)/[f(s_1) + g(s_1) + h(s_1)] = 1/3$ because $f + g = 2h$.

Now let's plot the belief evolution when nature chooses g:

```
plot_belief_evolution(results_g, nature='g', figsize=(15, 5))
plt.show()
```



Again, agent 1 learns faster than agent 2.

Before reading the next figure, please guess how consumption shares evolve.

Remember that agent 1 reaches the correct model faster than agent 2

```
c1_lim = λ * priors_1[0] / (λ * priors_1[0] + (1 - λ) * priors_2[0])
plot_consumption_dynamics(results_f, results_g, λ=0.5,
                          c1_limits=(c1_lim, c1_lim), figsize=(14, 5))
plt.show()

for name, res in [('f', results_f), ('g', results_g)]:
    print(f"nature = {name}: median c1 at T = "
          f"{np.median(res['c1_share'][:, -1]):.3f}, limit = {c1_lim:.3f}")
```

```
nature = f: median c1 at T = 0.600, limit = 0.600
nature = g: median c1 at T = 0.600, limit = 0.600
```

As we expected, agent 1 has a higher consumption share compared to agent 2.

In this exercise, the "truth" is among possible outcomes according to both agents.

Agent 2's model is "more general" because it allows a possibility – that nature is drawing from h – that agent 1's model does not include.

When nature draws from f, $g(s^t)/f(s^t) \to 0$ and $h(s^t)/f(s^t) \to 0$, so $m^i(s^t)/f(s^t) \to \pi_0^{f,i}$.

The likelihood ratio l_t converges to $\pi_0^{f,1}/\pi_0^{f,2} = (1/2)/(1/3) = 1.5$, and agent 1's consumption share converges to $0.5 \times 1.5/(0.5 \times 1.5 + 0.5) = 0.6$.

The same limit prevails when nature draws from g.

Both agents survive.

Agent 1's limiting share exceeds agent 2's because agent 1 puts prior probability $1/2$ on the true model while agent 2 puts $1/3$.

Agent 2 pays for model h with prior probability taken from the true model.

Exercise 23.11.7

Now consider two agents with extreme priors about three models.

Consider the same setup as the previous exercise, but now:

- Agent 1: $\pi_0^{f,1} = \pi_0^{g,1} = \frac{\epsilon}{2} > 0$ and $\pi_0^{h,1} = 1 - \epsilon$, where ϵ is close to 0 (e.g., $\epsilon = 0.01$)
- Agent 2: $\pi_0^{f,2} = \pi_0^{g,2} = 0$ and $\pi_0^{h,2} = 1$ (rigid belief in model h)

Set $f \sim \text{Beta}(1, 1)$, $g \sim \text{Beta}(3, 1.2)$, and $h \sim \text{Beta}(1.2, 1.1)$.

Model h is close to f and far from g as measured by KL divergence.

Please simulate and visualize evolutions of posterior probabilities and consumption allocations when:

- Nature permanently draws from f
- Nature permanently draws from g

Solution

To explore this exercise, we increase T to 1000.

Let's specify f, g, and h and verify that h and f are closer than h and g

```
F_a, F_b = 1, 1
G_a, G_b = 3, 1.2
H_a, H_b = 1.2, 1.1

f = jit(lambda x: p(x, F_a, F_b))
g = jit(lambda x: p(x, G_a, G_b))
h = jit(lambda x: p(x, H_a, H_b))

Kh_f = compute_KL(h, f)
Kh_g = compute_KL(h, g)
Kf_h = compute_KL(f, h)
Kg_h = compute_KL(g, h)

print(f"KL divergences:")
print(f"KL(h,f) = {Kh_f:.4f}, KL(h,g) = {Kh_g:.4f}")
print(f"KL(f,h) = {Kf_h:.4f}, KL(g,h) = {Kg_h:.4f}")
```

```
KL divergences:
KL(h,f) = 0.0092, KL(h,g) = 0.5514
KL(f,h) = 0.0105, KL(g,h) = 0.2919
```

Now we can set the belief models for the two agents

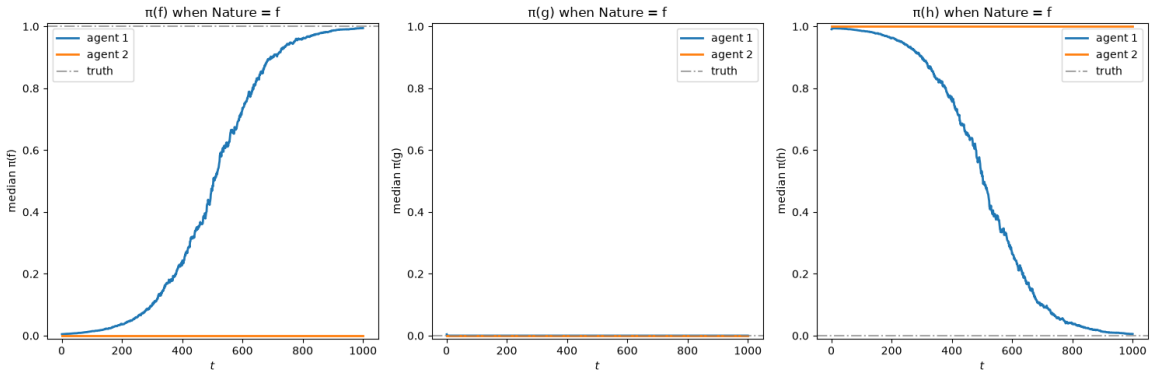
```
ε = 0.01
λ = 0.5

# Agent 1: π_f = ε/2, π_g = ε/2, π_h = 1-ε
# (almost rigid about h)
priors_1 = (ε/2, ε/2, 1 - ε)

# Agent 2: π_f = 0, π_g = 0, π_h = 1
# (fully rigid about h)
priors_2 = (0.0, 0.0, 1.0)
```

Now we can run the simulation

```
T = 1000
N = 1000



rng = np.random.default_rng()

# Generate sequences for different nature scenarios
s_seq_f = rng.beta(F_a, F_b, (N, T))
s_seq_g = rng.beta(G_a, G_b, (N, T))

# Run simulations for both scenarios
results_f = simulate_three_model_allocation(s_seq_f, f, g, h,
                                            priors_1, priors_2, λ)
results_g = simulate_three_model_allocation(s_seq_g, f, g, h,
                                            priors_1, priors_2, λ)
```

Let's plot the belief evolution when nature chooses f

```
plot_belief_evolution(results_f, nature='f', figsize=(15, 5))
plt.show()
```

Agent 1 learns the truth slowly in the leftmost panel showing $\pi(f)$.

Agent 2 does not update at all.

Bayes' law cannot revise a prior probability of zero, so agent 2's posterior probability on h stays at 1 whatever the data.

Agent 2's dogmatic prior keeps it from learning.

The closeness of h to f sets only how long agent 1 takes to overcome its own small prior on f.

Agent 1's posterior on f reaches $1/2$ roughly when $\log[f(s^t)/h(s^t)]$ reaches $\log[2(1-\epsilon)/\epsilon]$.

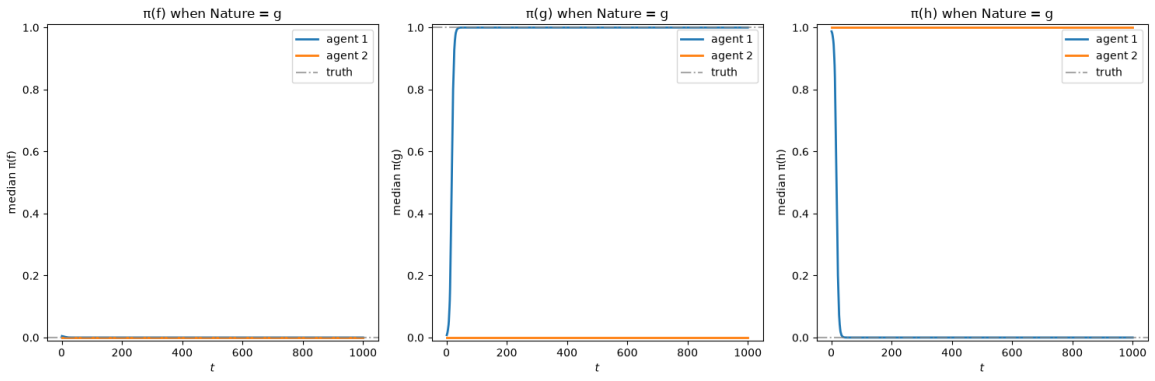
When nature draws from f, $\log[f(s^t)/h(s^t)]$ grows at rate $KL(f,h)$ per period.

The following code computes the implied waiting times, along with the waiting times for a nearly dogmatic agent who puts prior probability 10^{-10} on each of f and g.

```
def first_crossing(post, level=0.5):
    """First date at which the median posterior exceeds level."""
    above = np.where(np.median(post, axis=0) > level)[0]
    return above[0] + 1 if above.size > 0 else None

for nature, K in [('f', Kf_h), ('g', Kg_h)]:
    print(f"nature = {nature}: log(2(1-ε)/ε)/KL = {np.log(2*(1-ε)/ε)/K:.0f}, "
          f"log(1e10)/KL = {np.log(1e10)/K:.0f}")

print("first t with median π(f) of agent 1 > 1/2 when nature = f:",
      first_crossing(results_f['π_f_1']))
print("first t with median π(g) of agent 1 > 1/2 when nature = g:",
      first_crossing(results_g['π_g_1']))
```



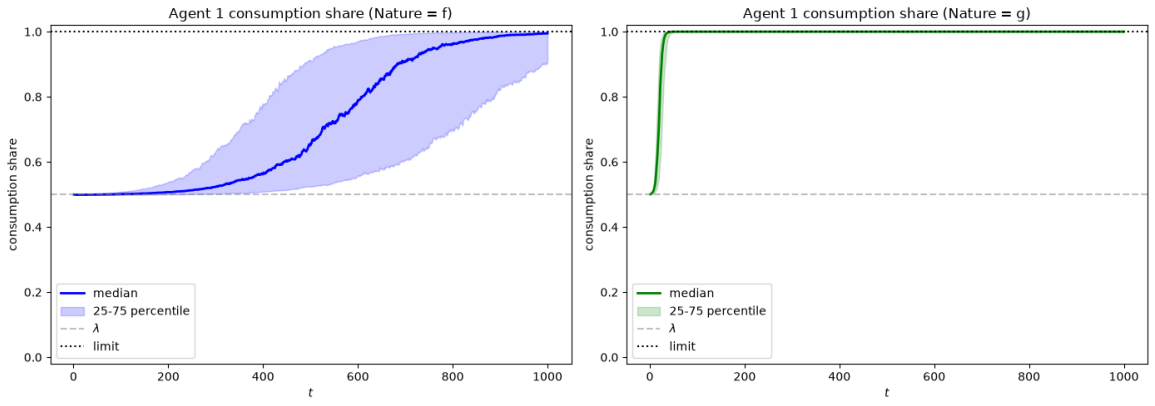
```
nature = f: log(2(1-ε)/ε)/KL = 502, log(1e10)/KL = 2186
nature = g: log(2(1-ε)/ε)/KL = 18, log(1e10)/KL = 79
first t with median π(f) of agent 1 > 1/2 when nature = f: 504
first t with median π(g) of agent 1 > 1/2 when nature = g: 18
```

Agent 1 needs about 500 periods to put probability $1/2$ on f when nature draws from f.

A nearly dogmatic agent 2 would need about 2200 periods.

Now let's plot the belief evolution when nature chooses g

```
plot_belief_evolution(results_g, nature='g', figsize=(15, 5))
plt.show()
```



When nature draws from g, $KL(g,h) = 0.2919$ is much larger than $KL(f,h) = 0.0105$.

Agent 1 puts probability $1/2$ on g after about 18 periods.

Agent 2 again does not update.

A nearly dogmatic agent 2 would need about 79 periods.

```
plot_consumption_dynamics(results_f, results_g, λ=0.5,
                          c1_limits=(1.0, 1.0), figsize=(14, 5))
plt.show()
```

Agent 1's consumption share converges to 1 both when nature permanently draws from f and when nature permanently draws from g.

Agent 2's probability law over infinite histories puts probability zero on a set of histories that has probability one when nature draws from f, and likewise for g.

Nature's probability law is not absolutely continuous with respect to agent 2's, and agent 2's predictions never merge with the truth (see *Merging of Opinions: The Blackwell–Dubins Theorem*).

The likelihood ratio $l_t = m^1(s^t)/h(s^t)$ eventually grows at rate $KL(f,h)$ when nature draws from f and at rate $KL(g,h)$ when nature draws from g.

A nearly dogmatic agent 2 with prior probability 10^{-10} on each of f and g would eventually learn the truth and survive.

Its limiting consumption share would be $(1-\lambda)10^{-10}/[\lambda\epsilon/2 + (1-\lambda)10^{-10}] \approx 2 \times 10^{-8}$.

24.1 Overview

This lecture extends our analysis of likelihood ratio processes to Vector Autoregressions (VARs).

We'll

- Construct likelihood functions for VAR models
- Form likelihood ratio processes for comparing two VAR models
- Visualize the evolution of likelihood ratios over time
- Compute the Kullback–Leibler divergence rate that governs the drift of a log likelihood ratio
- Connect VAR likelihood ratios to the Samuelson multiplier-accelerator model

Our analysis builds on concepts from:

- *Likelihood Ratio Processes*
- *Statistical Divergence Measures*
- *Linear State Space Models*
- *Samuelson Multiplier-Accelerator*

Let's start by importing helpful libraries:

```
import numpy as np
import matplotlib.pyplot as plt
from scipy import linalg
from scipy.stats import multivariate_normal as mvn
from collections import namedtuple

rng = np.random.default_rng(1234)
```

24.2 VAR model setup

Consider a VAR model of the form:

$$x_{t+1} = Ax_t + Cw_{t+1}$$
$$x_0 \sim \mathcal{N}(\mu_0, \Sigma_0)$$

where:

- x_t is an $n \times 1$ state vector
- $w_{t+1} \sim \mathcal{N}(0, I)$ is an $m \times 1$ vector of shocks
- A is an $n \times n$ transition matrix
- C is an $n \times m$ volatility matrix

Let's define the necessary data structures for the VAR model

```
VARModel = namedtuple('VARModel', ['A', 'C', 'μ_0', 'Σ_0',
                                   'CC', 'CC_inv', 'log_det_CC',
                                   'Σ_0_inv', 'log_det_Σ_0'])
def compute_stationary_var(A, C):
    """
    Compute stationary mean and covariance for VAR model
    """
    n = A.shape[0]

    # Check stability
    eigenvalues = np.linalg.eigvals(A)
    if np.max(np.abs(eigenvalues)) >= 1:
        raise ValueError("VAR is not stationary")

    μ_0 = np.zeros(n)

    # Stationary covariance: solve discrete Lyapunov equation
    # Σ_0 = A @ Σ_0 @ A.T + C @ C.T
    CC = C @ C.T
    Σ_0 = linalg.solve_discrete_lyapunov(A, CC)

    return μ_0, Σ_0

def create_var_model(A, C, μ_0=None, Σ_0=None, stationary=True):
    """
    Create a VAR model with parameters and precomputed matrices
    """
    A = np.asarray(A)
```

(continues on next page)

(continued from previous page)

```
    C = np.asarray(C)
    n = A.shape[0]
    CC = C @ C.T

    if stationary:
        μ_0_comp, Σ_0_comp = compute_stationary_var(A, C)
    else:
        μ_0_comp = μ_0 if μ_0 is not None else np.zeros(n)
        Σ_0_comp = Σ_0 if Σ_0 is not None else np.eye(n)

    # Check if CC is singular
    det_CC = np.linalg.det(CC)
    if np.abs(det_CC) < 1e-10:
        # Use pseudo-inverse for singular case
        CC_inv = np.linalg.pinv(CC)
        CC_reg = CC + 1e-10 * np.eye(CC.shape[0])
        log_det_CC = np.log(np.linalg.det(CC_reg))
    else:
        CC_inv = np.linalg.inv(CC)
        log_det_CC = np.log(det_CC)

    # Same check for Σ_0
    det_Σ_0 = np.linalg.det(Σ_0_comp)
    if np.abs(det_Σ_0) < 1e-10:
        Σ_0_inv = np.linalg.pinv(Σ_0_comp)
        Σ_0_reg = Σ_0_comp + 1e-10 * np.eye(Σ_0_comp.shape[0])
        log_det_Σ_0 = np.log(np.linalg.det(Σ_0_reg))
    else:
        Σ_0_inv = np.linalg.inv(Σ_0_comp)
        log_det_Σ_0 = np.log(det_Σ_0)

    return VARModel(A=A, C=C, μ_0=μ_0_comp, Σ_0=Σ_0_comp,
                    CC=CC, CC_inv=CC_inv, log_det_CC=log_det_CC,
                    Σ_0_inv=Σ_0_inv, log_det_Σ_0=log_det_Σ_0)
```

24.2.1 Joint distribution

The joint probability density $p(x_T, x_{T-1}, \dots, x_0)$ can be factored as:

$$p(x_T, \dots, x_0) = p(x_T|x_{T-1})p(x_{T-1}|x_{T-2}) \cdots p(x_1|x_0)p(x_0)$$

Since the VAR is Markovian, $p(x_{t+1}|x_t, \dots, x_0) = p(x_{t+1}|x_t)$.

We write p for a generic density and reserve f and g for the names of two models.

24.2.2 Conditional densities

Given the Gaussian structure, the conditional distribution $p(x_{t+1}|x_t)$ is Gaussian with:

- Mean: Ax_t
- Covariance: $CC^\top$

The log conditional density is

$$\log p(x_{t+1}|x_t) = -\frac{n}{2}\log(2\pi) - \frac{1}{2}\log\det(CC^\top) - \frac{1}{2}(x_{t+1} - Ax_t)^\top (CC^\top)^{-1}(x_{t+1} - Ax_t) \tag{24.1}$$

```
def log_likelihood_transition(x_next, x_curr, model):
    """
    Compute log likelihood of transition from x_curr to x_next
    """
    x_next = np.atleast_1d(x_next)
    x_curr = np.atleast_1d(x_curr)
    n = len(x_next)
    diff = x_next - model.A @ x_curr
    return -0.5 * (n * np.log(2 * np.pi) + model.log_det_CC +
                   diff @ model.CC_inv @ diff)
```

The log density of the initial state is:

$$\log p(x_0) = -\frac{n}{2}\log(2\pi) - \frac{1}{2}\log\det(\Sigma_0) - \frac{1}{2}(x_0 - \mu_0)^\top \Sigma_0^{-1}(x_0 - \mu_0) \tag{24.2}$$

```
def log_likelihood_initial(x_0, model):
    """
    Compute log likelihood of initial state
    """
    x_0 = np.atleast_1d(x_0)
    n = len(x_0)
    diff = x_0 - model.μ_0
    return -0.5 * (n * np.log(2 * np.pi) + model.log_det_Σ_0 +
                   diff @ model.Σ_0_inv @ diff)
```

The following function simulates paths from a VAR model

```
def simulate_var(model, T, rng, N_paths=1):
    """
    Simulate paths from the VAR model
    """
    n = model.A.shape[0]
    m = model.C.shape[1]
    paths = np.zeros((N_paths, T+1, n))

    for i in range(N_paths):
        # Draw initial state
        x = mvn.rvs(mean=model.μ_0, cov=model.Σ_0, random_state=rng)
        x = np.atleast_1d(x)
        paths[i, 0] = x

        # Simulate forward
        for t in range(T):
            w = rng.standard_normal(m)
            x = model.A @ x + model.C @ w
```

(continues on next page)

(continued from previous page)

```
            paths[i, t+1] = x

    return paths if N_paths > 1 else paths[0]
```

24.3 Likelihood ratio process

Now let's compute likelihood ratio processes for comparing two VAR models f and g.

Let p_f and p_g denote densities under models f and g respectively.

As in *Likelihood Ratio Processes*, L_t denotes the likelihood ratio of the sample $x_0, x_1, \ldots, x_t$:

$$L_t = \frac{p_f(x_t, \ldots, x_0)}{p_g(x_t, \ldots, x_0)} = \frac{p_f(x_0)}{p_g(x_0)} \prod_{s=1}^{t} \frac{p_f(x_s|x_{s-1})}{p_g(x_s|x_{s-1})}$$

where the conditional densities are given by (24.1) and the densities of x_0 by (24.2).

The log likelihood ratio process is

$$\log L_t = \log \frac{p_f(x_0)}{p_g(x_0)} + \sum_{s=1}^{t} \ell_s, \qquad \ell_s = \log \frac{p_f(x_s|x_{s-1})}{p_g(x_s|x_{s-1})} \tag{24.3}$$

It obeys the recursion $\log L_t = \log L_{t-1} + \ell_t$ with initial condition $\log L_0 = \log p_f(x_0) - \log p_g(x_0)$.

Let's write those equations in Python

```
def compute_likelihood_ratio_var(paths, model_f, model_g):
    """
    Compute likelihood ratio process for VAR models
    """
    if paths.ndim == 2:
        paths = paths[np.newaxis, :]

    N_paths, T_plus_1, n = paths.shape
    T = T_plus_1 - 1
    log_L_ratios = np.zeros((N_paths, T+1))

    for i in range(N_paths):
        X = paths[i]

        # Initial log likelihood ratio
        log_L_f_0 = log_likelihood_initial(X[0], model_f)
        log_L_g_0 = log_likelihood_initial(X[0], model_g)
        log_L_ratios[i, 0] = log_L_f_0 - log_L_g_0

        # Recursive computation
        for t in range(1, T+1):
            log_L_f_t = log_likelihood_transition(X[t], X[t-1], model_f)
            log_L_g_t = log_likelihood_transition(X[t], X[t-1], model_g)

            # Update log likelihood ratio
            log_diff = log_L_f_t - log_L_g_t

            log_L_prev = log_L_ratios[i, t-1]
            log_L_new = log_L_prev + log_diff
```

(continues on next page)

(continued from previous page)

```
            log_L_ratios[i, t] = log_L_new

    return log_L_ratios if N_paths > 1 else log_L_ratios[0]
```

24.4 Example 1: two AR(1) processes

Let's start with a simple example comparing two univariate AR(1) processes with $A_f = 0.8$, $A_g = 0.5$, and $C_f = 0.3$, $C_g = 0.4$

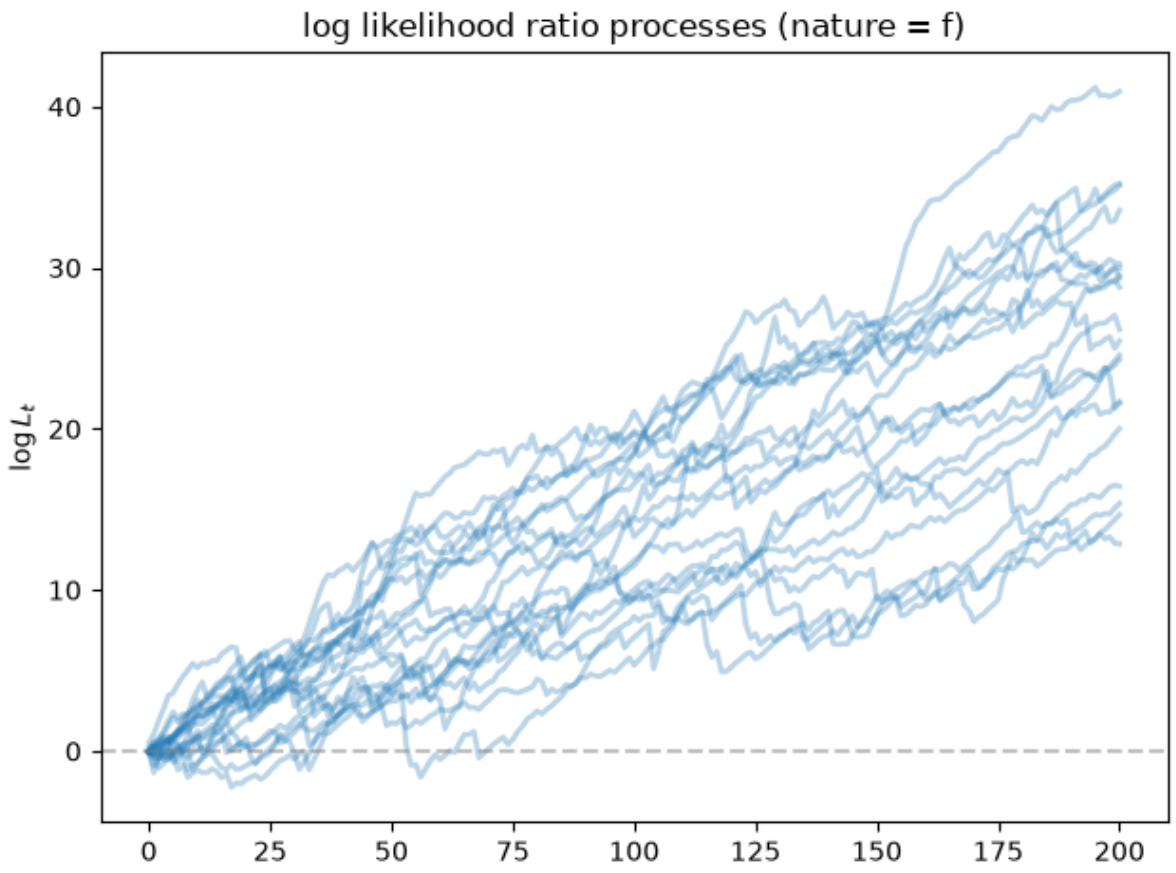
```
# Model f: AR(1) with persistence ρ = 0.8
A_f = np.array([[0.8]])
C_f = np.array([[0.3]])

# Model g: AR(1) with persistence ρ = 0.5
A_g = np.array([[0.5]])
C_g = np.array([[0.4]])

# Create VAR models
model_f = create_var_model(A_f, C_f)
model_g = create_var_model(A_g, C_g)
```

Let's generate 100 paths of length 200 from model f and compute the likelihood ratio processes

```
# Simulate from model f
T = 200
N_paths = 100
paths_from_f = simulate_var(model_f, T, rng, N_paths)



L_ratios_f = compute_likelihood_ratio_var(paths_from_f, model_f, model_g)

fig, ax = plt.subplots()

for i in range(min(20, N_paths)):
    ax.plot(L_ratios_f[i], alpha=0.3, color='C0', lw=2)

ax.axhline(y=0, color='gray', linestyle='--', alpha=0.5)
ax.set_ylabel(r'$\log L_t$')
ax.set_title('log likelihood ratio processes (nature = f)')

plt.tight_layout()
plt.show()
```

As we expected, the log likelihood ratio processes go to $+\infty$ as t increases, indicating that model f is chosen correctly by our algorithm.

24.5 Example 2: bivariate VAR models

Now let's consider an example with bivariate VAR models with

$$A_f = \begin{bmatrix} 0.7 & 0.2 \\ 0.1 & 0.6 \end{bmatrix}, \quad C_f = \begin{bmatrix} 0.3 & 0.1 \\ 0.1 & 0.3 \end{bmatrix}$$

and

$$A_g = \begin{bmatrix} 0.5 & 0.3 \\ 0.2 & 0.5 \end{bmatrix}, \quad C_g = \begin{bmatrix} 0.4 & 0.0 \\ 0.0 & 0.4 \end{bmatrix}$$

```
A_f = np.array([[0.7, 0.2],
                [0.1, 0.6]])

C_f = np.array([[0.3, 0.1],
                [0.1, 0.3]])

A_g = np.array([[0.5, 0.3],
                [0.2, 0.5]])

C_g = np.array([[0.4, 0.0],
```

(continues on next page)

(continued from previous page)

```
                [0.0, 0.4]])

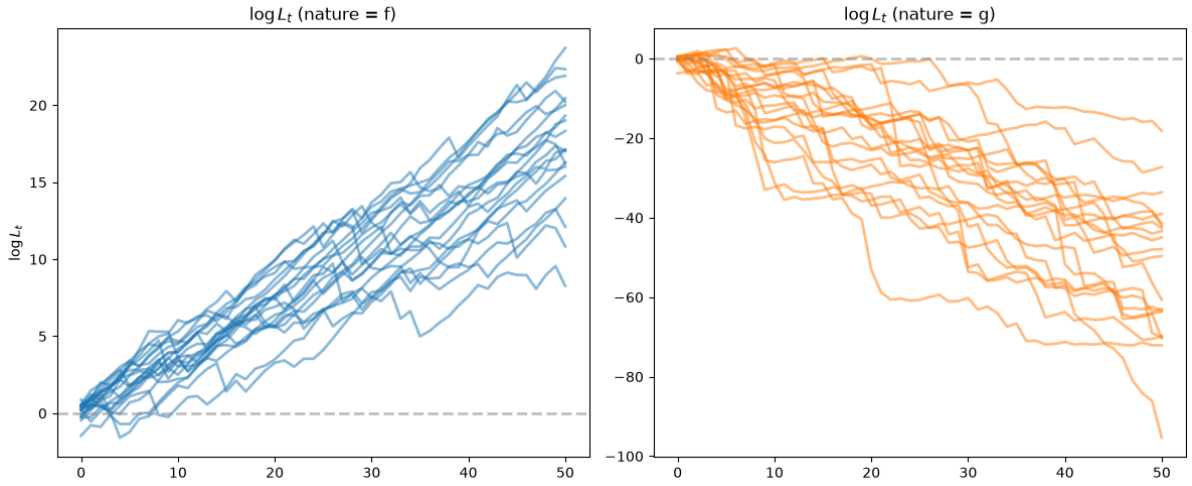
# Create VAR models
model2_f = create_var_model(A_f, C_f)
model2_g = create_var_model(A_g, C_g)

# Check stationarity
print("model f eigenvalues:", np.linalg.eigvals(A_f))
print("model g eigenvalues:", np.linalg.eigvals(A_g))
```

```
model f eigenvalues: [0.8 0.5]
model g eigenvalues: [0.74494897 0.25505103]
```

Let's generate 50 paths of length 50 from both models and compute the likelihood ratio processes

```
# Simulate from both models
T = 50
N_paths = 50



paths_from_f = simulate_var(model2_f, T, rng, N_paths)
paths_from_g = simulate_var(model2_g, T, rng, N_paths)

# Compute likelihood ratios
L_ratios_ff = compute_likelihood_ratio_var(paths_from_f, model2_f, model2_g)
L_ratios_gf = compute_likelihood_ratio_var(paths_from_g, model2_f, model2_g)
```

```
# Visualize the results
fig, axes = plt.subplots(1, 2, figsize=(12, 5))

ax = axes[0]
for i in range(min(20, N_paths)):
    ax.plot(L_ratios_ff[i], alpha=0.5, color='C0', lw=2)
ax.axhline(y=0, color='gray', linestyle='--', alpha=0.5, lw=2)
ax.set_title(r'$\log L_t$ (nature = f)')
ax.set_ylabel(r'$\log L_t$')

ax = axes[1]
for i in range(min(20, N_paths)):
    ax.plot(L_ratios_gf[i], alpha=0.5, color='C1', lw=2)
ax.axhline(y=0, color='gray', linestyle='--', alpha=0.5, lw=2)
ax.set_title(r'$\log L_t$ (nature = g)')
plt.tight_layout()
plt.show()
```

For paths generated from model f, the log likelihood ratio processes tend to go to $+\infty$, while for paths from model g, they tend to go to $-\infty$.

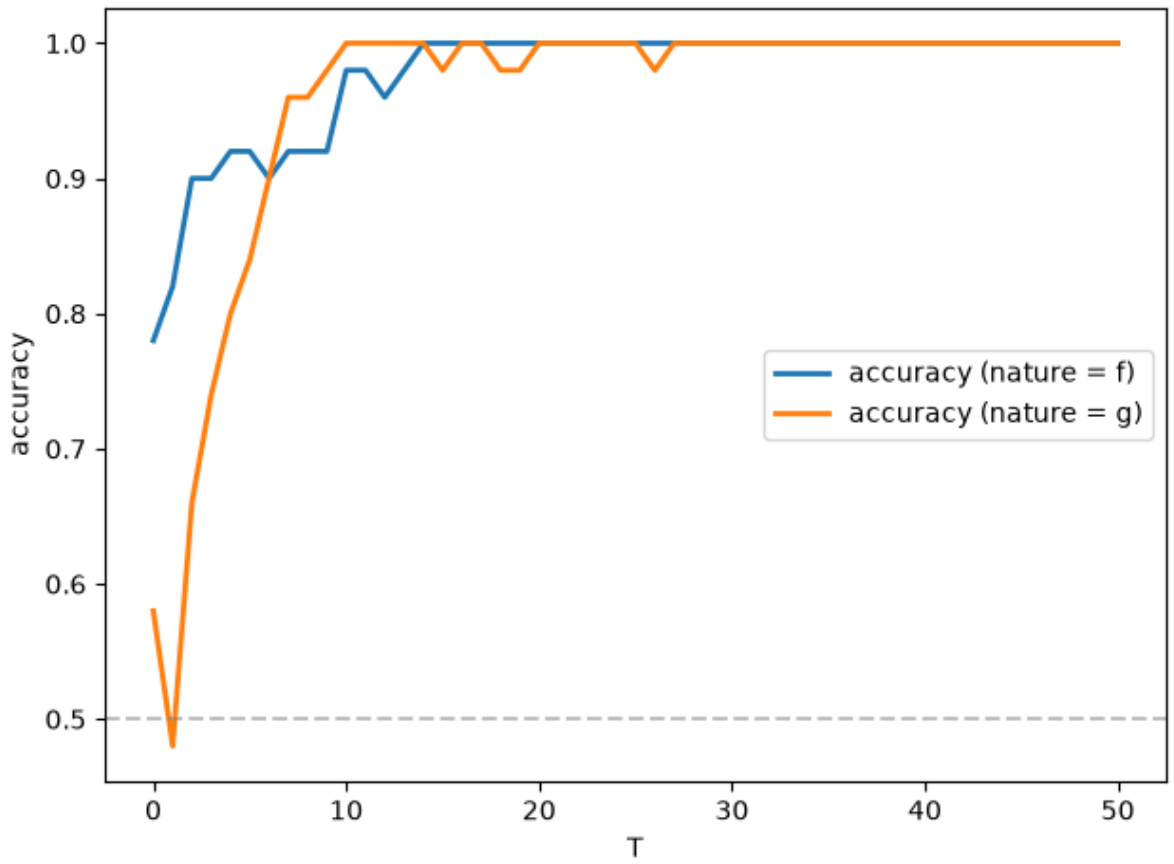
The paths fall faster under g than they rise under f; the section *KL divergence rate* explains why.

Let's apply the decision rule described in the section on *model selection mistake probability* in *Likelihood Ratio Processes*: select model f when $\log L_T \geq 0$ and model g when $\log L_T < 0$.

This rule is a likelihood ratio test with threshold $L_T = 1$.

Suppose that a Bayesian puts prior probability $1/2$ on each model.

Then the posterior probability of model f is $L_T/(1 + L_T)$, as in *Likelihood Ratio Processes and Bayesian Learning*.



The rule selects the model with the higher posterior probability, so it minimizes the probability $\frac{1}{2}(\alpha_T + \beta_T)$ of selecting the wrong model, where $\alpha_T = \text{Prob}(\log L_T < 0|f)$ and $\beta_T = \text{Prob}(\log L_T \geq 0|g)$.

```
fig, ax = plt.subplots()
T_values = np.arange(0, T+1)
accuracy_f = np.zeros(len(T_values))
accuracy_g = np.zeros(len(T_values))

for i, t in enumerate(T_values):
    # Correct selection when data from f
    accuracy_f[i] = np.mean(L_ratios_ff[:, t] > 0)
    # Correct selection when data from g
    accuracy_g[i] = np.mean(L_ratios_gf[:, t] < 0)

ax.plot(T_values, accuracy_f, 'C0', linewidth=2, label='accuracy (nature = f)')
ax.plot(T_values, accuracy_g, 'C1', linewidth=2, label='accuracy (nature = g)')
ax.axhline(y=0.5, color='gray', linestyle='--', alpha=0.5)
ax.set_xlabel('T')
ax.set_ylabel('accuracy')
ax.legend()

plt.tight_layout()
plt.show()
```

Evidently, the accuracy approaches 1 as T increases, and it does so very quickly.

Let's also check the type I and type II errors α_T and β_T as functions of T

```
def model_selection_analysis(T_values, model_f, model_g, N_sim=500):
    """
    Analyze model selection performance for different sample sizes
    """
    errors_f = []  # Type I errors
    errors_g = []  # Type II errors

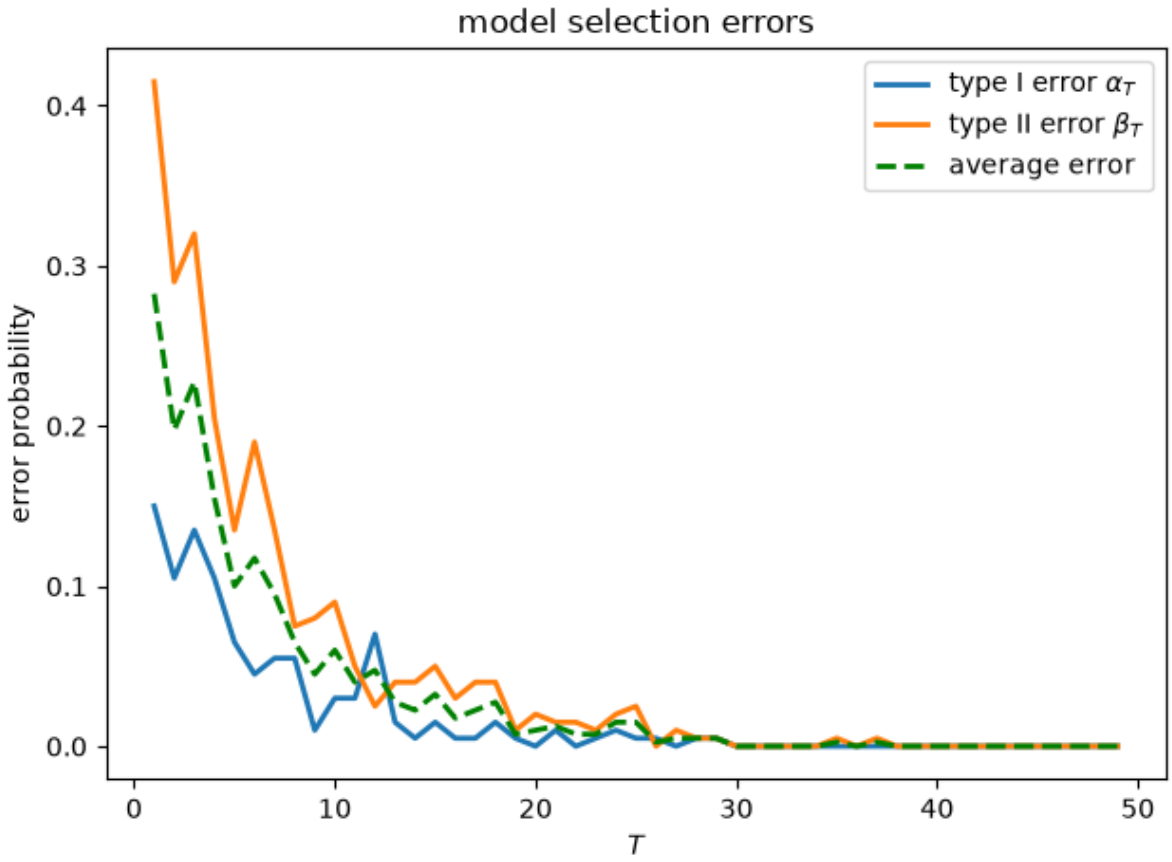
    for T in T_values:
        # Simulate from model f
        paths_f = simulate_var(model_f, T, rng, N_sim//2)
        L_ratios_f = compute_likelihood_ratio_var(paths_f, model_f, model_g)

        # Simulate from model g
        paths_g = simulate_var(model_g, T, rng, N_sim//2)
        L_ratios_g = compute_likelihood_ratio_var(paths_g, model_f, model_g)

        # Decision rule: choose f if log L_T >= 0
        errors_f.append(np.mean(L_ratios_f[:, -1] < 0))
        errors_g.append(np.mean(L_ratios_g[:, -1] >= 0))

    return np.array(errors_f), np.array(errors_g)

T_values = np.arange(1, 50, 1)
```



(continues on next page)

(continued from previous page)

```
errors_f, errors_g = model_selection_analysis(T_values, model2_f, model2_g, N_sim=400)

fig, ax = plt.subplots()

ax.plot(T_values, errors_f, 'C0', linewidth=2, label=r'type I error $\alpha_T$')
ax.plot(T_values, errors_g, 'C1', linewidth=2, label=r'type II error $\beta_T$')
ax.plot(T_values, 0.5 * (errors_f + errors_g), 'g--',
linewidth=2, label='average error')
ax.set_xlabel('$T$')
ax.set_ylabel('error probability')
ax.set_title('model selection errors')
ax.legend()
plt.tight_layout()
plt.show()
```

The decision rule above fixes the sample size T in advance.

Wald's sequential probability ratio test, described in *A Problem that Stumped Milton Friedman*, instead stops sampling the first time $\log L_t$ leaves an interval.

Exercise Exercise **??** of that lecture applies it to two VAR models.

24.6 KL divergence rate

The average slopes of the log likelihood ratio paths in the figures above are Kullback–Leibler divergence rates.

They are VAR counterparts of the *KL divergence rate for Markov chains* in *Likelihood Ratio Processes*.

Statistical Divergence Measures describes Kullback–Leibler divergence.

Let $\Sigma_f = C_f C_f^\top$ and $\Sigma_g = C_g C_g^\top$, and let V_f solve the discrete Lyapunov equation

$$V_f = A_f V_f A_f^\top + \Sigma_f$$

so that $\mathcal{N}(0, V_f)$ is the stationary distribution of x_t under model f.

Suppose that model f generates the data and that x_0 is drawn from $\mathcal{N}(0, V_f)$, as in Examples 1 and 2.

Then every increment ℓ_t in (24.3) has the same expected value

$$\begin{aligned} h_{KL}(f,g) &= E_f\left[\log \frac{p_f(x_t|x_{t-1})}{p_g(x_t|x_{t-1})}\right] \\ &= \frac{1}{2}\left[\operatorname{tr}(\Sigma_g^{-1}\Sigma_f) - n + \log\frac{\det\Sigma_g}{\det\Sigma_f} + \operatorname{tr}\left(\Sigma_g^{-1}(A_f - A_g)V_f(A_f - A_g)^\top\right)\right] \end{aligned} \tag{24.4}$$

The first three terms in the brackets measure the discrepancy between the shock covariance matrices Σ_f and Σ_g.

The last term measures the discrepancy between the conditional means $A_f x_{t-1}$ and $A_g x_{t-1}$, averaged over the stationary distribution of x_{t-1}.

Because $\{x_t\}$ is ergodic under f,

$$\frac{1}{t}\log L_t \to h_{KL}(f,g) \quad \text{almost surely as } t \to \infty$$

When model g generates the data, $\frac{1}{t}\log L_t \to -h_{KL}(g,f)$, where $h_{KL}(g,f)$ is (24.4) with the roles of f and g reversed.

Exercise Exercise 24.8.1 asks you to derive (24.4) and to verify these limits by simulation.

The function below computes the two parts of (24.4).

It takes V_f from `model_f.Σ_0`, so `model_f` must be created with `stationary=True`.

```
def kl_rate_terms(model_f, model_g):
    """
    Covariance and conditional-mean terms of the KL divergence rate
    h_KL(f, g), with x_t drawn from the stationary distribution of model f
    """
    n = model_f.A.shape[0]
    D = model_f.A - model_g.A
    V_f = model_f.Σ_0
    cov_term = 0.5 * (np.trace(model_g.CC_inv @ model_f.CC) - n
                      + model_g.log_det_CC - model_f.log_det_CC)
    mean_term = 0.5 * np.trace(model_g.CC_inv @ D @ V_f @ D.T)
    return cov_term, mean_term

def kl_rate_var(model_f, model_g):
    """
    KL divergence rate h_KL(f, g) between two stationary Gaussian VARs
    """
    return sum(kl_rate_terms(model_f, model_g))
```

(continues on next page)

(continued from previous page)

```
examples = [("Example 1", model_f, model_g),
            ("Example 2", model2_f, model2_g)]

for name, m_f, m_g in examples:
    for label, m1, m2 in [("h_KL(f, g)", m_f, m_g), ("h_KL(g, f)", m_g, m_f)]:
        cov_term, mean_term = kl_rate_terms(m1, m2)
        print(f"{name}: {label} = {cov_term + mean_term:.4f}  "
              f"(covariance terms {cov_term:.4f}, mean term {mean_term:.4f})")
```

```
Example 1: h_KL(f, g) = 0.1392  (covariance terms 0.0689, mean term 0.0703)
Example 1: h_KL(g, f) = 0.2079  (covariance terms 0.1012, mean term 0.1067)
Example 2: h_KL(f, g) = 0.3443  (covariance terms 0.3181, mean term 0.0261)
Example 2: h_KL(g, f) = 0.9614  (covariance terms 0.8069, mean term 0.1546)
```

For Example 2, $h_{KL}(g, f) = 0.961$ is almost three times $h_{KL}(f, g) = 0.344$.

That is why $\log L_t$ falls faster when g generates the data than it rises when f generates the data.

The covariance terms account for most of both rates.

Both models assign variance 0.16 to the shock to $(x_{1t} + x_{2t})/\sqrt{2}$.

Model g assigns variance 0.16 to the shock to $(x_{1t} - x_{2t})/\sqrt{2}$; model f assigns it variance 0.04.

Let r be the variance of the shock to $(x_{1t} - x_{2t})/\sqrt{2}$ under the model that generates the data divided by its variance under the other model.

Because the two models agree about the other direction, the covariance terms equal $\frac{1}{2}(r - 1 - \log r)$.

This expression equals 0.807 for $r = 4$ (nature $= g$) and 0.318 for $r = 1/4$ (nature $= f$).

Kullback–Leibler divergence penalizes a model that understates a variance more heavily than a model that overstates it.

In Example 1, the two parts contribute about equally, and $h_{KL}(g, f) = 0.208$ exceeds $h_{KL}(f, g) = 0.139$.

Let's compare the theoretical rates for Example 2 with sample averages of $\frac{1}{T} \log L_T$ across the paths simulated above

```
T2 = L_ratios_ff.shape[1] - 1

print(f"nature = f: mean of log L_T / T = {L_ratios_ff[:, -1].mean() / T2:.4f}, "
      f"h_KL(f, g) = {kl_rate_var(model2_f, model2_g):.4f}")
print(f"nature = g: mean of log L_T / T = {L_ratios_gf[:, -1].mean() / T2:.4f}, "
      f"-h_KL(g, f) = {-kl_rate_var(model2_g, model2_f):.4f}")
```

```
nature = f: mean of log L_T / T = 0.3472, h_KL(f, g) = 0.3443
nature = g: mean of log L_T / T = -0.9924, -h_KL(g, f) = -0.9614
```

The sample averages include the initial-condition term $\log L_0$ divided by $T = 50$, so they need not equal the rates exactly.

The KL rates describe the means of the increments ℓ_t.

Error probabilities for small T depend on the entire distribution of $\log L_T$.

```
for nature, L_ratios in [('f', L_ratios_ff), ('g', L_ratios_gf)]:
    ℓ = np.diff(L_ratios, axis=1).ravel()
    print(f"nature = {nature}: increments ℓ_t have mean {ℓ.mean():.2f}, "
          f"median {np.median(ℓ):.2f}, standard deviation {ℓ.std():.2f}")
```

```
nature = f: increments ℓ_t have mean 0.34, median 0.53, standard deviation 0.54
nature = g: increments ℓ_t have mean -0.98, median -0.07, standard deviation 2.35
```

Under g, the increments ℓ_t have a mean near -1, a median near 0, and a large standard deviation.

Under f, their median exceeds their mean and their standard deviation is small.

That is why β_T exceeds α_T for small T in the error-probability figure above, although $\log L_t$ falls faster under g than it rises under f.

24.7 Application: Samuelson multiplier-accelerator

Now let's connect to the Samuelson multiplier-accelerator model.

The model consists of:

- Consumption: $C_t = \gamma + aY_{t-1}$ where $a \in (0, 1)$ is the marginal propensity to consume
- Investment: $I_t = b(Y_{t-1} - Y_{t-2}) + \sigma\epsilon_t$ where $b > 0$ is the accelerator coefficient and $\{\epsilon_t\}$ is an IID sequence of standard normal random variables
- Government spending: $G_t = G$ (constant)

We have the national income identity

$$Y_t = C_t + I_t + G_t$$

Samuelson Multiplier-Accelerator writes α and β for a and b.

That lecture adds the shock $\sigma\epsilon_t$ directly to the second-order difference equation for Y_t.

We put the shock in the investment equation.

This leads to the same difference equation for Y_t and also determines how C_t and I_t respond to ϵ_t.

Substituting the consumption and investment equations into the national income identity yields the second-order difference equation:

$$Y_t = (\gamma + G) + (a + b)Y_{t-1} - bY_{t-2} + \sigma\epsilon_t$$

With $\rho_1 = a + b$ and $\rho_2 = -b$, we have:

$$Y_t = (\gamma + G) + \rho_1 Y_{t-1} + \rho_2 Y_{t-2} + \sigma\epsilon_t$$

When the roots of $z^2 - \rho_1 z - \rho_2$ lie inside the unit circle, Y_t has a stationary distribution with mean

$$Y^* = \frac{\gamma + G}{1 - \rho_1 - \rho_2} = \frac{\gamma + G}{1 - a}$$

When $\sigma = 0$, Y_t converges to the steady state Y^*, where investment is zero and $Y^* = \gamma + aY^* + G$.

To fit into our discussion, we write it into state-space representation.

To handle the constant term properly, we use an augmented state vector $x_t = [1, Y_t, Y_{t-1}]^\top$:

$$x_{t+1} = \begin{bmatrix} 1 \\ Y_{t+1} \\ Y_t \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ \gamma + G & \rho_1 & \rho_2 \\ 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} 1 \\ Y_t \\ Y_{t-1} \end{bmatrix} + \begin{bmatrix} 0 \\ \sigma \\ 0 \end{bmatrix} \epsilon_{t+1}$$

The observation equation extracts the economic variables:

$$y_t = \begin{bmatrix} Y_t \\ C_t \\ I_t \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 \\ \gamma & 0 & a \\ -(\gamma + G) & 1 & -a \end{bmatrix} \begin{bmatrix} 1 \\ Y_t \\ Y_{t-1} \end{bmatrix}$$

This gives us:

- Y_t (total output)
- $C_t = \gamma \cdot 1 + aY_{t-1}$ (consumption)
- $I_t = Y_t - C_t - G = b(Y_{t-1} - Y_{t-2}) + \sigma\epsilon_t$ (investment)

The third row uses the national income identity to recover I_t from Y_t and Y_{t-1}, so the state vector need not include Y_{t-2}.

The matrix $CC^\top$ has rank one: given x_t, the first and third components of x_{t+1} are known and only Y_{t+1} is random.

Consequently (24.1) is not a density with respect to Lebesgue measure on $\mathbb{R}^3$.

`create_var_model` replaces $(CC^\top)^{-1}$ with a pseudo-inverse and adds $10^{-10}I$ to $CC^\top$ before taking the log determinant.

The regularization terms cancel in ℓ_{t+1}, which equals the log ratio of the conditional densities of Y_{t+1} given x_t under the two models.

The same device handles the singular covariance matrix Σ_0 of x_0, whose first component is always 1.

An econometrician who observes Y_t and Y_{t-1} observes the state x_t.

When an econometrician observes only some components of a state vector, or observes them with error, a Kalman filter produces innovations from which to compute the likelihood, as in *A First Look at the Kalman Filter* and *The Kalman Filter and Vector Autoregressions*.

```
def samuelson_to_var(a, b, γ, G, σ):

We define functions in the code cell below to get the initial conditions and check stability

With `stationary_init=True`, the initial state $[1, Y_0, Y_{-1}]^\top$ has the stationary distribution: (Y_0, Y_{-1}) has mean (Y^*, Y^*) and a covariance matrix that solves a discrete Lyapunov equation.

Let's implement it and inspect the likelihood ratio processes induced by two Samuelson models with different parameters.

```
def create_samuelson_var_model(a, b, γ, G, σ, stationary_init=False,

In the figure on the left, data are generated by f and the log likelihood ratio diverges to plus infinity.

In the figure on the right, data are generated by g and the log likelihood ratio diverges to negative infinity.

In both cases, the likelihood ratio processes eventually lead us to select the correct model.

Almost all of the information that discriminates between the two models comes from the transient that carries Y_t from $Y_0 \approx 100$ toward $Y^* = 1000$.

The two models share a, γ, G, σ, and Y^*; they differ only in the accelerator coefficient b.

Their forecasts of Y_{t+1} differ by $(b_f - b_g)(Y_t - Y_{t-1}) = 0.05\,\Delta Y_t$.

Because the two models share σ, the expected increment of $\log L_t$ under f is

$$E_f[\ell_{t+1} | x_t] = \frac{(b_f - b_g)^2 (\Delta Y_t)^2}{2\sigma^2}$$

and $E_g[-\ell_{t+1} | x_t]$ is given by the same formula.

Along the transient, $|\Delta Y_t|$ is large relative to $\sigma = 0.5$.

In the stationary distribution, ΔY_t is small, and the KL divergence rate is $h_{KL}(f, g) = (b_f - b_g)^2 E_f[(\Delta Y_t)^2]/(2\sigma^2)$.

The function below computes this rate from the stationary distribution of x_t for a model created with `stationary_init=True`.

```
def samuelson_kl_rate(model_f, model_g):
    """
    KL divergence rate h_KL(f, g) for two Samuelson models created with
    stationary_init=True; only the Y component of x_{t+1} is random
    """
    σ2_f, σ2_g = model_f.CC[1, 1], model_g.CC[1, 1]
```

(continues on next page)

(continued from previous page)

```

ax.legend()
plt.show()
```

```
median log L_50: nature = f: 413.5, nature = g: -279.2
stationary sd of ΔY_t under f: 1.15
h_KL(f, g) = 0.0066, h_KL(g, f) = 0.0045
50 × h_KL(f, g) = 0.33, 50 × h_KL(g, f) = 0.23
largest mean expected increment: nature = f: 33.8 at t = 10, nature = g: 23.9 at t␣
↪= 9
```

The expected increments reach about 34 under f and 24 under g near $t = 10$, when Y_t rises fastest.

They approach the stationary rates $h_{KL}(f, g)$ and $h_{KL}(g, f)$ only near the turning points of the oscillation, where ΔY_t is close to zero.

The stationary standard deviation of ΔY_t under f is 1.15.

From the stationary distribution, 50 periods raise $E_f[\log L_t]$ by only about 0.33, while the transient raises the median of $\log L_{50}$ to about 400.

Exercise Exercise 24.8.2 starts both models from their stationary distributions and studies how much harder the two models are to tell apart.

24.8 Exercises

Exercise 24.8.1

Derive formula (24.4) for the KL divergence rate $h_{KL}(f, g)$.

Use the formula for the Kullback–Leibler divergence of two multivariate normal distributions:

$$KL(\mathcal{N}(\mu_1, \Sigma_1), \mathcal{N}(\mu_2, \Sigma_2)) = \frac{1}{2}\left[\text{tr}(\Sigma_2^{-1}\Sigma_1) - n + (\mu_1 - \mu_2)^\top \Sigma_2^{-1}(\mu_1 - \mu_2) + \log\frac{\det\Sigma_2}{\det\Sigma_1}\right]$$

Then verify by simulation that $\frac{1}{t}\log L_t \to h_{KL}(f, g)$ when f generates the data and $\frac{1}{t}\log L_t \to -h_{KL}(g, f)$ when g generates the data.

Do this for Examples 1 and 2 with $T = 2000$.

Solution

Under model f, $x_t|x_{t-1} \sim \mathcal{N}(A_f x_{t-1}, \Sigma_f)$; under model g, $x_t|x_{t-1} \sim \mathcal{N}(A_g x_{t-1}, \Sigma_g)$.

So $E_f[\ell_t|x_{t-1}] = KL(\mathcal{N}(A_f x_{t-1}, \Sigma_f), \mathcal{N}(A_g x_{t-1}, \Sigma_g))$.

Setting $\mu_1 - \mu_2 = (A_f - A_g)x_{t-1}$ in the formula above gives

$$E_f[\ell_t|x_{t-1}] = \frac{1}{2}\left[\text{tr}(\Sigma_g^{-1}\Sigma_f) - n + \log\frac{\det\Sigma_g}{\det\Sigma_f} + x_{t-1}^\top (A_f - A_g)^\top \Sigma_g^{-1}(A_f - A_g)x_{t-1}\right]$$

Under f, $x_{t-1} \sim \mathcal{N}(0, V_f)$.

For any matrix M, $E[x_{t-1}^\top M x_{t-1}] = \text{tr}(MV_f)$.

With $M = (A_f - A_g)^\top \Sigma_g^{-1}(A_f - A_g)$ and the cyclic property of the trace,

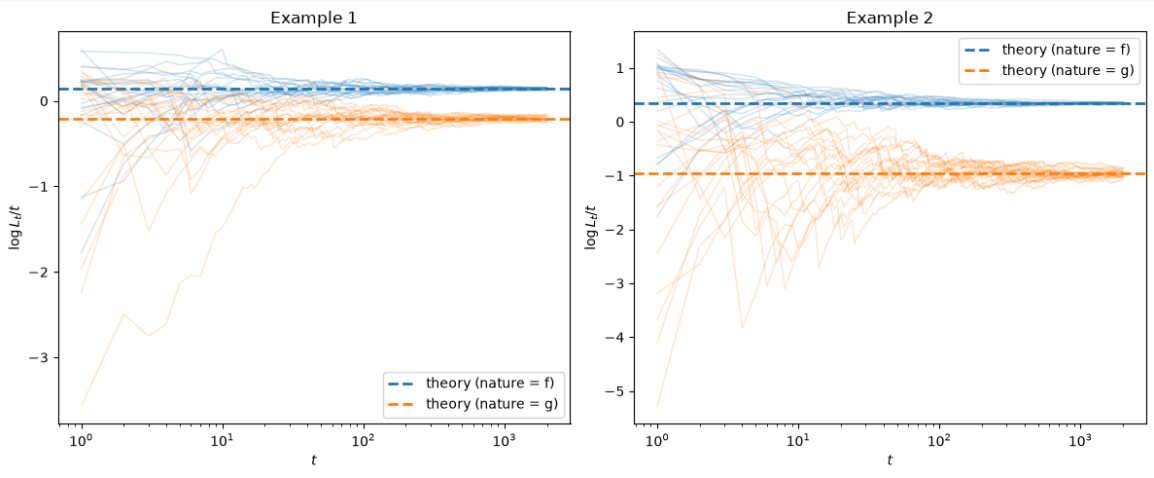
$$E_f[x_{t-1}^\top M x_{t-1}] = \text{tr}\left(\Sigma_g^{-1}(A_f - A_g)V_f(A_f - A_g)^\top\right)$$

Taking expectations of $E_f[\ell_t|x_{t-1}]$ over x_{t-1} gives (24.4).

Because x_{t-1} has the same distribution $\mathcal{N}(0, V_f)$ for every t, every increment ℓ_t has mean $h_{KL}(f, g)$ and

$$E_f[\log L_t] = E_f\left[\log\frac{p_f(x_0)}{p_g(x_0)}\right] + t\, h_{KL}(f, g)$$

The ergodic theorem implies $\frac{1}{t}\sum_{s=1}^t \ell_s \to h_{KL}(f, g)$ almost surely, and $\frac{1}{t}\log\frac{p_f(x_0)}{p_g(x_0)} \to 0$.



Here is the simulation.

```
T_long = 2000
N_long = 20
t_grid = np.arange(1, T_long + 1)

fig, axes = plt.subplots(1, 2, figsize=(12, 5))

for ax, (name, m_f, m_g) in zip(axes, examples):
    for nature, m_true, rate, color in [
            ('f', m_f, kl_rate_var(m_f, m_g), 'C0'),
            ('g', m_g, -kl_rate_var(m_g, m_f), 'C1')]:
        paths = simulate_var(m_true, T_long, rng, N_long)
        log_L = compute_likelihood_ratio_var(paths, m_f, m_g)
        avg = log_L[:, 1:] / t_grid
        ax.plot(t_grid, avg.T, color=color, alpha=0.2, lw=1)
        ax.axhline(rate, color=color, ls='--', lw=2,
                   label=f'theory (nature = {nature})')
        print(f"{name}, nature = {nature}: mean of log L_T / T = "
              f"{avg[:, -1].mean():.4f}, theory = {rate:.4f}")
    ax.set_xscale('log')
    ax.set_xlabel('$t$')
    ax.set_ylabel(r'$\log L_t / t$')
    ax.set_title(name)
    ax.legend()
```

```
Example 1, nature = f: mean of log L_T / T = 0.1420, theory = 0.1392
Example 1, nature = g: mean of log L_T / T = -0.2068, theory = -0.2079
Example 2, nature = f: mean of log L_T / T = 0.3423, theory = 0.3443
Example 2, nature = g: mean of log L_T / T = -0.9629, theory = -0.9614
```

In all four cases, $\frac{1}{t}\log L_t$ settles down near the theoretical rate.

Exercise 24.8.2

In the Samuelson example, both models start from $Y_0 \approx 100$, far below the common steady state $Y^* = 1000$.

Start both models from their stationary distributions instead by using the models `model_stat_f` and `model_stat_g` created with `stationary_init=True`.

1. Simulate 500 paths of length $T = 50$ from each model. Report the median of $\log L_{50}$ and the error probabilities α_{50}, β_{50}, and $\frac{1}{2}(\alpha_{50} + \beta_{50})$. Compare them with those for the paths that start from $Y_0 \approx 100$.
2. Use `samuelson_kl_rate` and the Kullback–Leibler divergence of the two stationary distributions of (Y_0, Y_{-1}) to compute the number of periods t at which $E_f[\log L_t] = 5$.
3. Simulate paths of that length and plot α_t and β_t.

Solution

Here are the error probabilities at $T = 50$ for the two initial conditions.

```
T_s, N_s = 50, 500

paths_stat_f = simulate_var(model_stat_f, T_s, rng, N_s)
paths_stat_g = simulate_var(model_stat_g, T_s, rng, N_s)
log_L_stat_f = compute_likelihood_ratio_var(paths_stat_f,
                                            model_stat_f, model_stat_g)
log_L_stat_g = compute_likelihood_ratio_var(paths_stat_g,
                                            model_stat_f, model_stat_g)

for label, log_L_f, log_L_g in [
        ("stationary start", log_L_stat_f, log_L_stat_g),
        ("Y_0 ≈ 100", L_ratios_ff, L_ratios_gf)]:
```

```
    α = np.mean(log_L_f[:, -1] < 0)
    β = np.mean(log_L_g[:, -1] >= 0)
    print(f"{label}:")
    print(f"  median log L_50: nature = f: {np.median(log_L_f[:, -1]):.3f}, "
          f"nature = g: {np.median(log_L_g[:, -1]):.3f}")
    print(f"  α_50 = {α:.3f}, β_50 = {β:.3f}, "
          f"average error = {0.5 * (α + β):.3f}")
```

```
stationary start:
  median log L_50: nature = f: 0.132, nature = g: -0.452
  α_50 = 0.426, β_50 = 0.244, average error = 0.335
Y_0 ≈ 100:
  median log L_50: nature = f: 413.526, nature = g: -279.175
  α_50 = 0.000, β_50 = 0.000, average error = 0.000
```

From the stationary distributions, the medians of $\log L_{50}$ are within 0.5 of zero, α_{50} is about 0.4, and the likelihood ratio test selects the wrong model in about a third of the samples.

From $Y_0 \approx 100$, it selects the correct model in all 50 samples from each model.

Under f, $E_f[\log L_t] = KL_0 + t\, h_{KL}(f,g)$, where KL_0 is the Kullback–Leibler divergence of the stationary distribution of (Y_0, Y_{-1}) under g from that under f.

```
def kl_gauss(μ_1, Σ_1, μ_2, Σ_2):
    """
    KL divergence of N(μ_2, Σ_2) from N(μ_1, Σ_1)
    """
    n = len(μ_1)
    Σ_2_inv = np.linalg.inv(Σ_2)
    d = μ_1 - μ_2
    return 0.5 * (np.trace(Σ_2_inv @ Σ_1) - n + d @ Σ_2_inv @ d
                  + np.log(np.linalg.det(Σ_2) / np.linalg.det(Σ_1)))

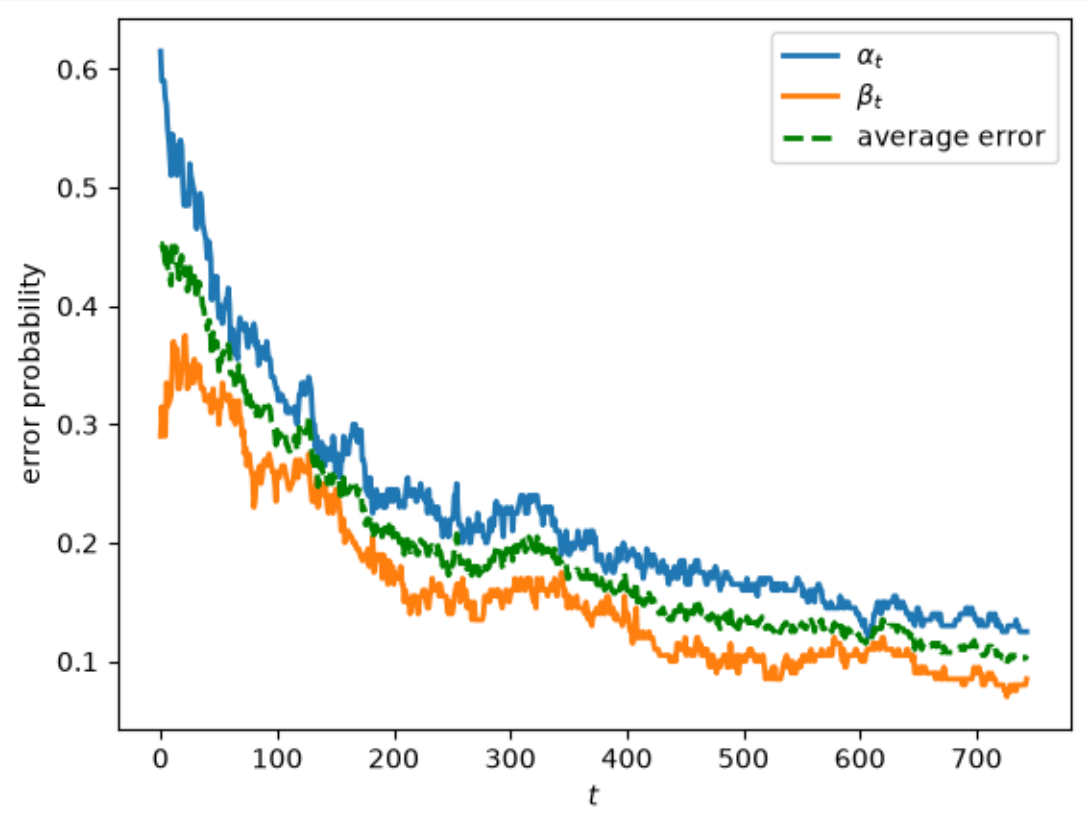
KL_0 = kl_gauss(model_stat_f.μ_0[1:], model_stat_f.Σ_0[1:, 1:],
                model_stat_g.μ_0[1:], model_stat_g.Σ_0[1:, 1:])
t_star = int(np.ceil((5 - KL_0) / h_fg))

print(f"KL_0 = {KL_0:.4f}, h_KL(f, g) = {h_fg:.5f}")
print(f"E_f[log L_50]: theory = {KL_0 + 50 * h_fg:.3f}, "
      f"simulation = {log_L_stat_f[:, -1].mean():.3f}")
print(f"stationary start: E_f[log L_t] = 5 at t = {t_star}")

# Transient from Y_0 ≈ 100: cumulative mean expected increments
t_transient = np.argmax(np.cumsum(inc_f) >= 5) + 1
print(f"Y_0 ≈ 100: cumulative expected increments reach 5 at t = {t_transient}")
```

```
KL_0 = 0.0881, h_KL(f, g) = 0.00661
E_f[log L_50]: theory = 0.419, simulation = 0.391
stationary start: E_f[log L_t] = 5 at t = 743
Y_0 ≈ 100: cumulative expected increments reach 5 at t = 3
```

About 750 periods of stationary data contain as much information about b, on average, as the first three periods of the transient from $Y_0 \approx 100$.



```
N_star = 200

paths_f = simulate_var(model_stat_f, t_star, rng, N_star)
paths_g = simulate_var(model_stat_g, t_star, rng, N_star)
log_L_f = compute_likelihood_ratio_var(paths_f, model_stat_f, model_stat_g)
log_L_g = compute_likelihood_ratio_var(paths_g, model_stat_f, model_stat_g)
```

```
α_t = np.mean(log_L_f < 0, axis=0)
β_t = np.mean(log_L_g >= 0, axis=0)

fig, ax = plt.subplots()
ax.plot(α_t, color='C0', lw=2, label=r'$\alpha_t$')
ax.plot(β_t, color='C1', lw=2, label=r'$\beta_t$')
ax.plot(0.5 * (α_t + β_t), 'g--', lw=2, label='average error')
ax.set_xlabel('$t$')
ax.set_ylabel('error probability')
ax.legend()
plt.show()

print(f"at t = {t_star}: α = {α_t[-1]:.3f}, β = {β_t[-1]:.3f}")
```

```
at t = 743: α = 0.125, β = 0.085
```

Even after about 750 periods, both error probabilities remain roughly 0.1.

Exercise 24.8.3

Suppose that neither f nor g of Example 2 generates the data.

Instead a third VAR h with matrices (A_h, C_h) generates the data.

Show that

$$\frac{1}{t}\log L_t \to h_{KL}(h,g) - h_{KL}(h,f)$$

almost surely, where $h_{KL}(h, \cdot)$ is (24.4) with h in place of f.

This is the VAR counterpart of the formula in *A helpful formula* of *Likelihood Ratio Processes*.

Verify the limit by simulation for $(A_h, C_h) = (A_f, C_g)$ and for $(A_h, C_h) = (A_g, C_f)$.

Which model does the likelihood ratio select in each case?

Solution

Write

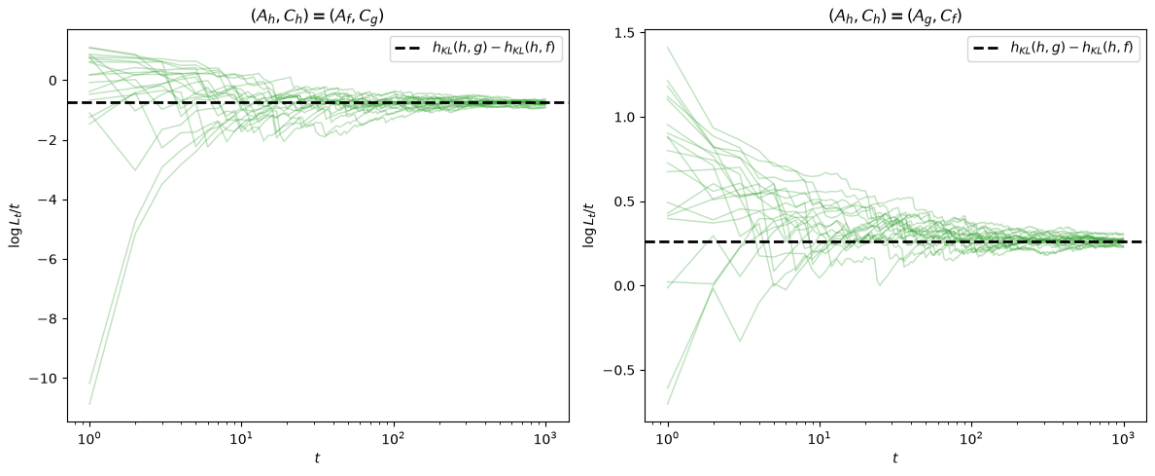
$$\ell_t = \log \frac{p_h(x_t|x_{t-1})}{p_g(x_t|x_{t-1})} - \log \frac{p_h(x_t|x_{t-1})}{p_f(x_t|x_{t-1})}$$

Taking expectations under h, with x_{t-1} drawn from the stationary distribution of h, gives $E_h[\ell_t] = h_{KL}(h, g) - h_{KL}(h, f)$.

The ergodic theorem under h then gives the almost sure limit.

```
model_h1 = create_var_model(model2_f.A, model2_g.C)
model_h2 = create_var_model(model2_g.A, model2_f.C)

T_h, N_h = 1000, 20
t_grid = np.arange(1, T_h + 1)



fig, axes = plt.subplots(1, 2, figsize=(12, 5))

cases = [("(A_f, C_g)", r'$(A_h, C_h) = (A_f, C_g)$', model_h1),
         ("(A_g, C_f)", r'$(A_h, C_h) = (A_g, C_f)$', model_h2)]

for ax, (name, title, m_h) in zip(axes, cases):
    K_f = kl_rate_var(m_h, model2_f)
    K_g = kl_rate_var(m_h, model2_g)
    paths = simulate_var(m_h, T_h, rng, N_h)
    log_L = compute_likelihood_ratio_var(paths, model2_f, model2_g)
    avg = log_L[:, 1:] / t_grid
    ax.plot(t_grid, avg.T, color='C2', alpha=0.3, lw=1)
    ax.axhline(K_g - K_f, color='k', ls='--', lw=2,
               label=r'$h_{KL}(h, g) - h_{KL}(h, f)$')
    ax.set_xscale('log')
    ax.set_xlabel('$t$')
    ax.set_ylabel(r'$\log L_t / t$')
    ax.set_title(title)
    ax.legend()
    print(f"(A_h, C_h) = {name}: h_KL(h, f) = {K_f:.4f}, "
          f"h_KL(h, g) = {K_g:.4f}, difference = {K_g - K_f:.4f}, "
          f"mean of log L_T / T = {avg[:, -1].mean():.4f}")

plt.tight_layout()
plt.show()
```

```
(A_h, C_h) = (A_f, C_g): h_KL(h, f) = 0.8069, h_KL(h, g) = 0.0586, difference =␣
↪-0.7482, mean of log L_T / T = -0.7711
(A_h, C_h) = (A_g, C_f): h_KL(h, f) = 0.0542, h_KL(h, g) = 0.3181, difference =␣
↪0.2639, mean of log L_T / T = 0.2643
```

When $(A_h, C_h) = (A_f, C_g)$, $\log L_t \to -\infty$ and the likelihood ratio selects g, although f has the correct transition matrix.

When $(A_h, C_h) = (A_g, C_f)$, $\log L_t \to +\infty$ and the likelihood ratio selects f, although g has the correct transition matrix.

In both cases the likelihood ratio selects the model with the correct shock covariance matrix.

When $(A_h, C_h) = (A_f, C_g)$, $h_{KL}(h, f)$ consists only of covariance terms and $h_{KL}(h, g)$ only of a conditional-mean term.

When $(A_h, C_h) = (A_g, C_f)$, the roles of f and g are reversed.

In both cases the covariance terms are larger, as in the decomposition for Example 2 above.

TWENTYFIVE

MEAN OF A LIKELIHOOD RATIO PROCESS

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

25.1 Overview

In *Likelihood Ratio Processes* we described a peculiar property of a likelihood ratio process, namely, that its mean equals one for all $t \geq 0$ despite its converging to zero almost surely.

While it is easy to verify that peculiar property analytically (i.e., in population), it is challenging to use a computer simulation to verify it via an application of a law of large numbers that entails studying sample averages of repeated simulations.

To confront this challenge, this lecture puts **importance sampling** to work to accelerate convergence of sample averages to population means.

We use importance sampling to estimate the mean of a cumulative likelihood ratio $L\left(\omega^t\right) = \prod_{i=1}^t \ell\left(\omega_i\right)$.

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install jax
```

We start by importing some Python packages.

```
import jax
import jax.numpy as jnp
import numpy as np
import matplotlib.pyplot as plt
from jax.scipy.stats import beta
from typing import NamedTuple
from functools import partial

# Set JAX to use 64-bit floats
jax.config.update("jax_enable_x64", True)
```

25.2 Mathematical expectation of likelihood ratio

In *Likelihood Ratio Processes*, we studied a likelihood ratio $\ell\left(\omega_t\right)$

$$\ell\left(\omega_t\right) = \frac{f\left(\omega_t\right)}{g\left(\omega_t\right)}$$

where f is the Beta$(F_a, F_b) =$ Beta$(1, 1)$ density, the uniform density on $[0, 1]$, and g is the Beta$(G_a, G_b) =$ Beta$(3, 1.2)$ density.

Assume that an i.i.d. random variable $\omega_t \in \Omega$ is generated by g.

The **cumulative likelihood ratio** $L\left(\omega^t\right)$ is

$$L\left(\omega^t\right) = \prod_{i=1}^t \ell\left(\omega_i\right)$$

Our goal is to approximate the mathematical expectation $E\left[L\left(\omega^t\right)\right]$ well.

In *this section* of *Likelihood Ratio Processes*, we showed that $E\left[L\left(\omega^t\right)\right]$ equals 1 for all t.

We want to check out how well this holds if we replace E with sample averages from simulations.

This turns out to be easier said than done because for Beta distributions assumed above, $L\left(\omega^t\right)$ has a very skewed distribution with a very long tail as $t \to \infty$.

This property makes it difficult efficiently and accurately to estimate the mean by standard Monte Carlo simulation methods.

In this lecture we explore how a standard Monte Carlo method fails.

We also show how **importance sampling** provides a more computationally efficient way to approximate the mean of the cumulative likelihood ratio.

We first take a look at the density functions `f` and `g` .

```
# Parameters for the model
class ImpSampleParams(NamedTuple):
    F_a: float = 1.0    # Beta parameters for f
```

(continues on next page)

(continued from previous page)

```
    F_b: float = 1.0
    G_a: float = 3.0    # Beta parameters for g
    G_b: float = 1.2

params = ImpSampleParams()

def f(w):
    return beta.pdf(w, params.F_a, params.F_b)

def g(w):
    return beta.pdf(w, params.G_a, params.G_b)
```

```
w_range = np.linspace(1e-2, 1-1e-5, 1000)

plt.plot(w_range, g(w_range), lw=2, label='g')
plt.plot(w_range, f(w_range), lw=2, label='f')
plt.xlabel(r'$\omega$')
plt.legend()
plt.show()
```

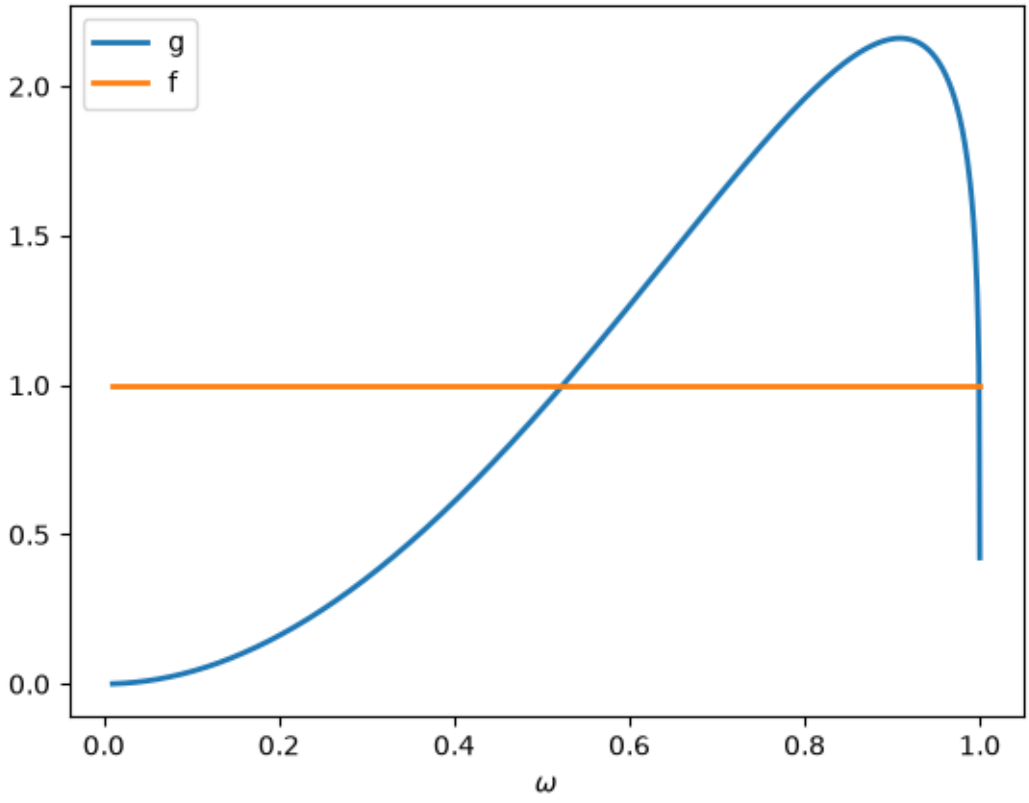

Fig. 25.1: Beta density functions f and g

The likelihood ratio is `l(w)=f(w)/g(w)`.

```
def l(w):
    return f(w) / g(w)
```

```
plt.plot(w_range, l(w_range), lw=2)
plt.yscale('log')
plt.xlabel(r'$\omega$')
plt.ylabel(r'$\ell(\omega)$')
plt.show()
```

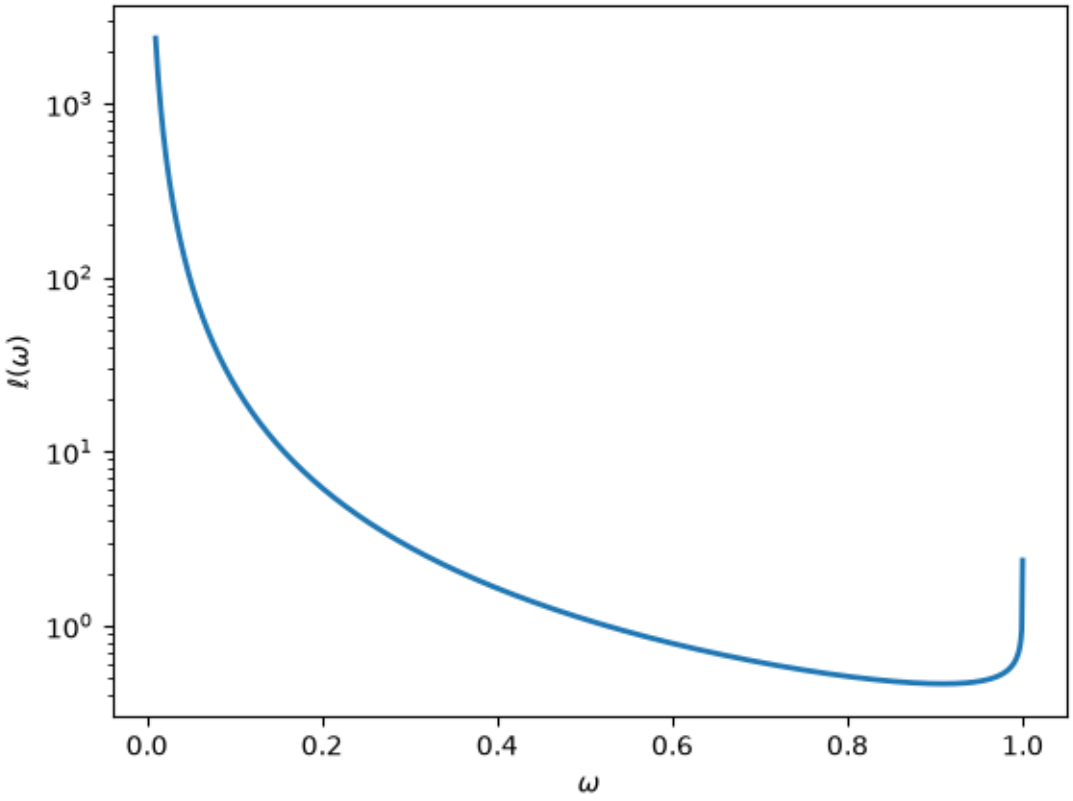

Fig. 25.2: Likelihood ratio $\ell(\omega)$, log scale

Note the log scale on the vertical axis: on a linear scale the entire curve would be flattened against zero by the spike at the left-hand edge.

Fig. 25.1 shows that as $\omega \to 0$, $f(\omega)$ is unchanged while $g(\omega) \to 0$.

Hence the likelihood ratio in Fig. 25.2 diverges to infinity, at rate ω^{-2}.

The same thing happens as $\omega \to 1$, since $G_b > 1$ also forces $g(\omega) \to 0$ there, which explains the upturn at the right-hand edge.

But that divergence is far slower — at rate $(1-\omega)^{-1/5}$ — and it is the behavior near $\omega = 0$ that causes the trouble below.

A Monte Carlo approximation of $E[L(\omega^t)]$ would repeatedly draw a sequence $\omega^t = (\omega_1, \ldots, \omega_t)$ of t independent observations from g, form the product $L(\omega^t) = \prod_{i=1}^{t} \ell(\omega_i)$ for each such sequence, then average these products across independently drawn sequences.

Because $g(\omega) \to 0$ as $\omega \to 0$, such a simulation procedure undersamples a part of the sample space $[0, 1]$ that it is important to visit often in order to do a good job of approximating the mathematical expectation of $\ell(\omega)$.

Every one of the t factors in $L(\omega^t)$ is distorted in the same way, so the problem compounds as t grows.

We illustrate this numerically below.

25.3 Importance sampling

We circumvent the issue by using a *change of distribution* called **importance sampling**.

Instead of drawing from g to generate data during the simulation, we use an alternative distribution h to generate draws of ω.

In *Likelihood Ratio Processes*, h denotes a third density that generates the data; here h denotes an importance distribution that we choose.

The idea is to design h so that it oversamples the region of Ω where $\ell(\omega_t)$ has large values but low density under g.

After we construct a sample in this way, we must then weight each realization by the likelihood ratio of g and h when we compute the empirical mean of the likelihood ratio.

By doing this, we properly account for the fact that we are using h and not g to simulate data.

To illustrate, suppose we were interested in $E[\ell(\omega)]$.

We could simply compute:

$$\hat{E}^g[\ell(\omega)] = \frac{1}{N}\sum_{i=1}^{N} \ell(\omega_i^g)$$

where ω_i^g indicates that ω_i is drawn from g.

But using our insight from importance sampling, we could instead calculate the object:

$$\hat{E}^h\left[\ell(\omega)\frac{g(\omega)}{h(\omega)}\right] = \frac{1}{N}\sum_{i=1}^{N} \ell(\omega_i^h)\frac{g(\omega_i^h)}{h(\omega_i^h)}$$

where ω_i is now drawn from importance distribution h.

Notice that the above two are exactly the same population objects:

$$E^g[\ell(\omega)] = \int_\Omega \ell(\omega)g(\omega)d\omega = \int_\Omega \ell(\omega)\frac{g(\omega)}{h(\omega)}h(\omega)d\omega = E^h\left[\ell(\omega)\frac{g(\omega)}{h(\omega)}\right]$$

The second equality requires $h(\omega) > 0$ wherever $\ell(\omega)g(\omega) = f(\omega) > 0$.

Since we must use an h that has larger mass in parts of the distribution to which g puts low mass, we use $h = Beta(0.5, 0.5)$ as our importance distribution.

The plots compare g and h.

```
g_a, g_b = params.G_a, params.G_b
h_a, h_b = 0.5, 0.5
```

```
w_range = np.linspace(1e-5, 1-1e-5, 1000)

plt.plot(w_range, g(w_range),
         lw=2, label=f'g=Beta({g_a}, {g_b})')
```

(continues on next page)

(continued from previous page)

```
plt.plot(w_range, beta.pdf(w_range, 0.5, 0.5),
         lw=2, label=f'h=Beta({h_a}, {h_b})')
plt.legend()
plt.ylim([0., 3.])
plt.show()
```

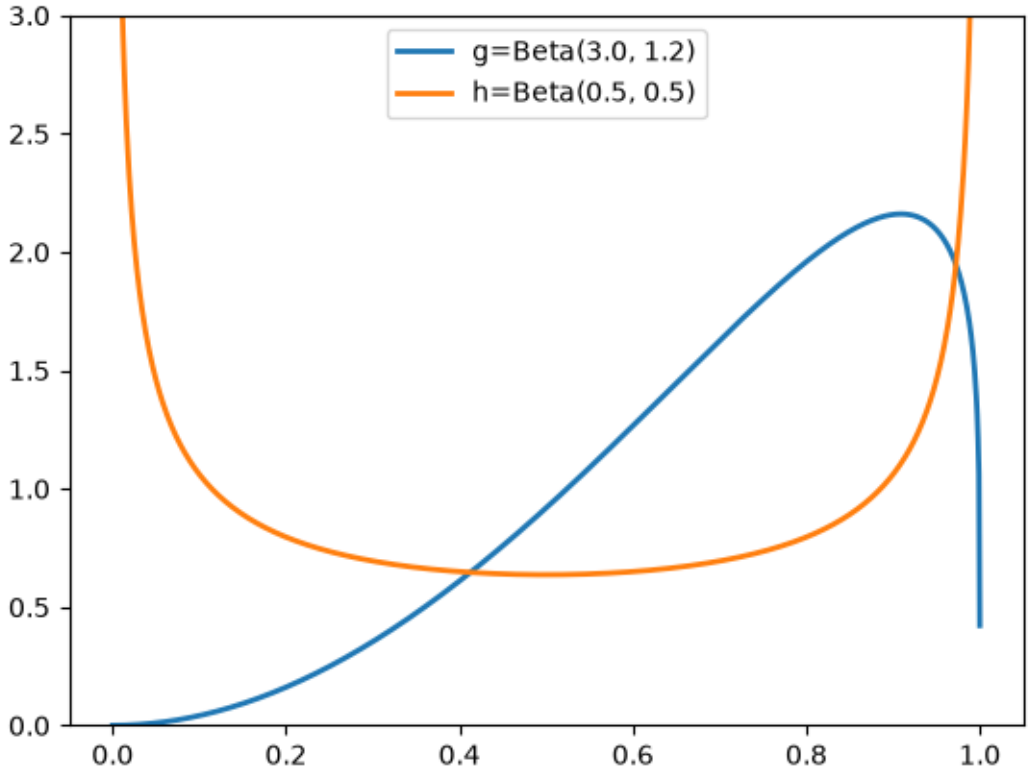

Fig. 25.3: Data and importance sampling distributions

25.4 Approximating a cumulative likelihood ratio

We now study how to use importance sampling to approximate $E\left[L\left(\omega^t\right)\right] = E\left[\prod_{i=1}^t \ell\left(\omega_i\right)\right]$.

To write code for general Beta densities, we let p denote the density under which we want the expectation and q the density from which we draw.

In our application $p = g$ and q is an importance distribution such as h.

In *Likelihood Ratio Processes*, q denotes the density that nature chose; here q denotes the importance distribution.

As above, our plan is to draw sequences ω^t from q and then re-weight the likelihood ratio appropriately.

The change of distribution holds in population, exactly as it did for a single draw:

$$E^p\left[L\left(\omega^t\right)\right] = E^p\left[\prod_{i=1}^t \ell\left(\omega_i\right)\right] = E^q\left[\prod_{i=1}^t \ell\left(\omega_i\right)\frac{p\left(\omega_i\right)}{q\left(\omega_i\right)}\right]$$

This suggests the estimator

$$\hat{E}^q\left[L\left(\omega^t\right)\right] = \frac{1}{N}\sum_{n=1}^{N}\left(\prod_{i=1}^{t}\ell\left(\omega_{n,i}^q\right)\frac{p\left(\omega_{n,i}^q\right)}{q\left(\omega_{n,i}^q\right)}\right)$$

where $\omega_{n,i}^q$ is the i-th observation of the n-th sequence, drawn from the importance distribution q.

Here $\frac{p\left(\omega_{n,i}^q\right)}{q\left(\omega_{n,i}^q\right)}$ is the weight we assign to each data point $\omega_{n,i}^q$.

Below we prepare a Python function for computing the importance sampling estimates given any beta distributions p, q.

```
def estimate_single_path(key, p_a, p_b, q_a, q_b, T):
    """
    Estimation for a single sample path.
    """

    def loop_body(i, carry):
        L, weight, key_state = carry
        key_state, subkey = jax.random.split(key_state)
        w = jax.random.beta(subkey, q_a, q_b)

        # Keep draws off the boundary, where the log densities
        # below produce the undefined form 0 * inf
        w = jnp.clip(w, 1e-12, 1 - 1e-12)

        # Compute likelihood ratio using f/g functions
        likelihood_ratio = f(w) / g(w)
        L = L * likelihood_ratio

        # Importance sampling weight
        p_w = beta.pdf(w, p_a, p_b)
        q_w = beta.pdf(w, q_a, q_b)
        weight = weight * (p_w / q_w)

        return (L, weight, key_state)

    # Use fori_loop for dynamic T values
    final_L, final_weight, _ = jax.lax.fori_loop(
        0, T, loop_body, (1.0, 1.0, key)
    )
    return final_L * final_weight

@partial(jax.jit, static_argnames=['N'])
def estimate(key, p_a, p_b, q_a, q_b, T=1, N=10000):
    """Estimation of a batch of sample paths."""
    keys = jax.random.split(key, N)

    # Vectorize over keys, holding the parameters fixed
    estimates = jax.vmap(
        estimate_single_path,
        in_axes=(0, None, None, None, None, None)
    )(keys, p_a, p_b, q_a, q_b, T)

    return jnp.mean(estimates)
```

Consider the case when $T = 1$, which amounts to approximating $E\left[\ell\left(\omega\right)\right]$.

For the standard Monte Carlo estimate, we can set $p = g$ and $q = g$.

```
estimate(jax.random.key(0), g_a, g_b, g_a, g_b,
         T=1, N=10000)
```

```
Array(0.98300826, dtype=float64)
```

For our importance sampling estimate, we set $q = h$.

```
estimate(jax.random.key(1), g_a, g_b, h_a, h_b,
         T=1, N=10000)
```

```
Array(1.00722995, dtype=float64)
```

Evidently, even at $T = 1$, our importance sampling estimate is closer to 1 than is the Monte Carlo estimate.

Bigger differences arise when computing expectations over longer sequences, $E\left[L\left(\omega^t\right)\right]$.

Setting $T = 10$, we find that the Monte Carlo method severely underestimates the mean while importance sampling still produces an estimate close to its theoretical value of unity.

```
estimate(jax.random.key(2), g_a, g_b, g_a, g_b,
         T=10, N=10000)
```

```
Array(0.60388316, dtype=float64)
```

```
estimate(jax.random.key(3), g_a, g_b, h_a, h_b,
         T=10, N=10000)
```

```
Array(0.99185478, dtype=float64)
```

The Monte Carlo method underestimates because the likelihood ratio $L(\omega^T) = \prod_{t=1}^{T} \frac{f(\omega_t)}{g(\omega_t)}$ has a highly skewed distribution under g.

Most samples from g produce small likelihood ratios, while the true mean requires occasional very large values that are rarely sampled.

In our case, since $g(\omega) \to 0$ as $\omega \to 0$ while $f(\omega)$ remains constant, the Monte Carlo procedure undersamples precisely where the likelihood ratio $\frac{f(\omega)}{g(\omega)}$ is largest.

In fact the situation is worse than skewness — the Monte Carlo estimator has **infinite variance**.

To see this, note that the second moment of a single likelihood ratio is

$$E^g\left[\ell\left(\omega\right)^2\right] = \int_0^1 \left(\frac{f\left(\omega\right)}{g\left(\omega\right)}\right)^2 g\left(\omega\right) d\omega = \int_0^1 \frac{f\left(\omega\right)^2}{g\left(\omega\right)} d\omega$$

Here f is the uniform density, while $g\left(\omega\right)$ vanishes like $\omega^{G_a - 1} = \omega^2$ as $\omega \to 0$.

The integrand therefore behaves like ω^{-2} near the origin, and the integral diverges.

So $\ell\left(\omega\right)$ has no finite variance, and since the draws are independent, neither does $L\left(\omega^t\right)$ for any t.

Likelihood Ratio Processes meets the same divergent integral as the mean of $\ell(\omega)$ under f, since $E^g\left[\ell(\omega)^2\right] = E^f\left[\ell(\omega)\right]$.

The mean $E^g\left[\ell(\omega)\right] = 1$ is finite, so the strong law of large numbers still applies: the Monte Carlo average converges to 1 almost surely as the number of draws N grows.

The ordinary central limit theorem does not apply, and its $N^{-1/2}$ rate of convergence fails.

Near the origin, $g(\omega) \approx k\omega^2$ with $k = 1/B(3, 1.2)$, where B is the Beta function.

For large x, the event $\ell(\omega) > x$ occurs mainly when $\omega < (kx)^{-1/2}$, an event with probability about $\frac{1}{3}k^{-1/2}x^{-3/2}$ under g.

A tail that decays like $x^{-3/2}$ puts $\ell(\omega)$ in the domain of attraction of a stable law with index $3/2$.

By the generalized central limit theorem, the error of a sample mean of N draws shrinks like $N^{-1/3}$, and its limiting distribution is skewed, with a long right tail.

Exercise 25.7.2 confirms the tail index and the $N^{-1/3}$ rate numerically.

As T increases, the problem worsens, making standard Monte Carlo increasingly unreliable.

Importance sampling with $q = h$ fixes the infinite variance by sampling more often near $\omega = 0$, where ℓ is large.

25.5 Distribution of sample mean

We next study the bias and efficiency of the Monte Carlo and importance sampling approaches.

The code below repeats the estimate `N_simu` times, so that we can look at the distribution of the estimates that each method produces.

```
@partial(jax.jit, static_argnames=['N_simu', 'N_samples'])
def simulate(key, p_a, p_b, q_a, q_b, N_simu, T=1,
             N_samples=10000):
    """Repeat the estimate N_simu times, drawing from q."""
    keys = jax.random.split(key, N_simu)
    return jax.vmap(
        lambda k: estimate(k, p_a, p_b, q_a, q_b, T,
                           N_samples)
    )(keys)
```

Setting $q = p$ recovers standard Monte Carlo, since every importance weight is then identically one.

Again, we first consider estimating $E[\ell(\omega)]$ by setting T=1.

We simulate 1000 times for each method.

```
N_simu = 1000
μ_L_g = simulate(jax.random.key(4), g_a, g_b,
                 g_a, g_b, N_simu)
μ_L_h = simulate(jax.random.key(5), g_a, g_b,
                 h_a, h_b, N_simu)
```

```
# standard Monte Carlo (mean and variance)
jnp.mean(μ_L_g), jnp.var(μ_L_g)
```

```
(Array(0.99558545, dtype=float64), Array(0.00448641, dtype=float64))
```

```
# importance sampling (mean and variance)
jnp.mean(μ_L_h), jnp.var(μ_L_h)
```

```
(Array(0.99985196, dtype=float64), Array(2.46227759e-05, dtype=float64))
```

Although both methods tend to provide a mean estimate of $E[\ell(\omega)]$ close to 1, the importance sampling estimates have smaller variance.

Next, we present distributions of estimates for $\hat{E}[L(\omega^t)]$, in cases for $T = 1, 5, 10, 20$.

```
def simulate_multiple_T(key, p_a, p_b, q_a, q_b, T_values,
                        N_simu, N_samples=10000):

                    s=r'$\hat{μ}$=' + f'{np.mean(μ_L):.3g}' +
                      '\n' + 'med=' + f'{np.median(μ_L):.3g}' +
                      '\n' + r'$\hat{σ}^2$=' + f'{np.var(μ_L):.3g}')

    plt.show()
```

The Monte Carlo estimates do not depend on the importance distribution, so we compute them once and reuse them in each of the figures below.

```
T_values = [1, 5, 10, 20]

mc = simulate_multiple_T(jax.random.key(6), g_a, g_b,
                         g_a, g_b, T_values, N_simu)
```

```
imp_h1 = simulate_multiple_T(jax.random.key(7), g_a, g_b,
                             h_a, h_b, T_values, N_simu)

plot_estimates(T_values, mc, imp_h1, '$h$ generating',
               n_rows=2)
```

The simulation exercises above show that the importance sampling estimates stay centered on 1 for every T, while the distribution of the standard Monte Carlo estimates drifts steadily to the left as T increases.

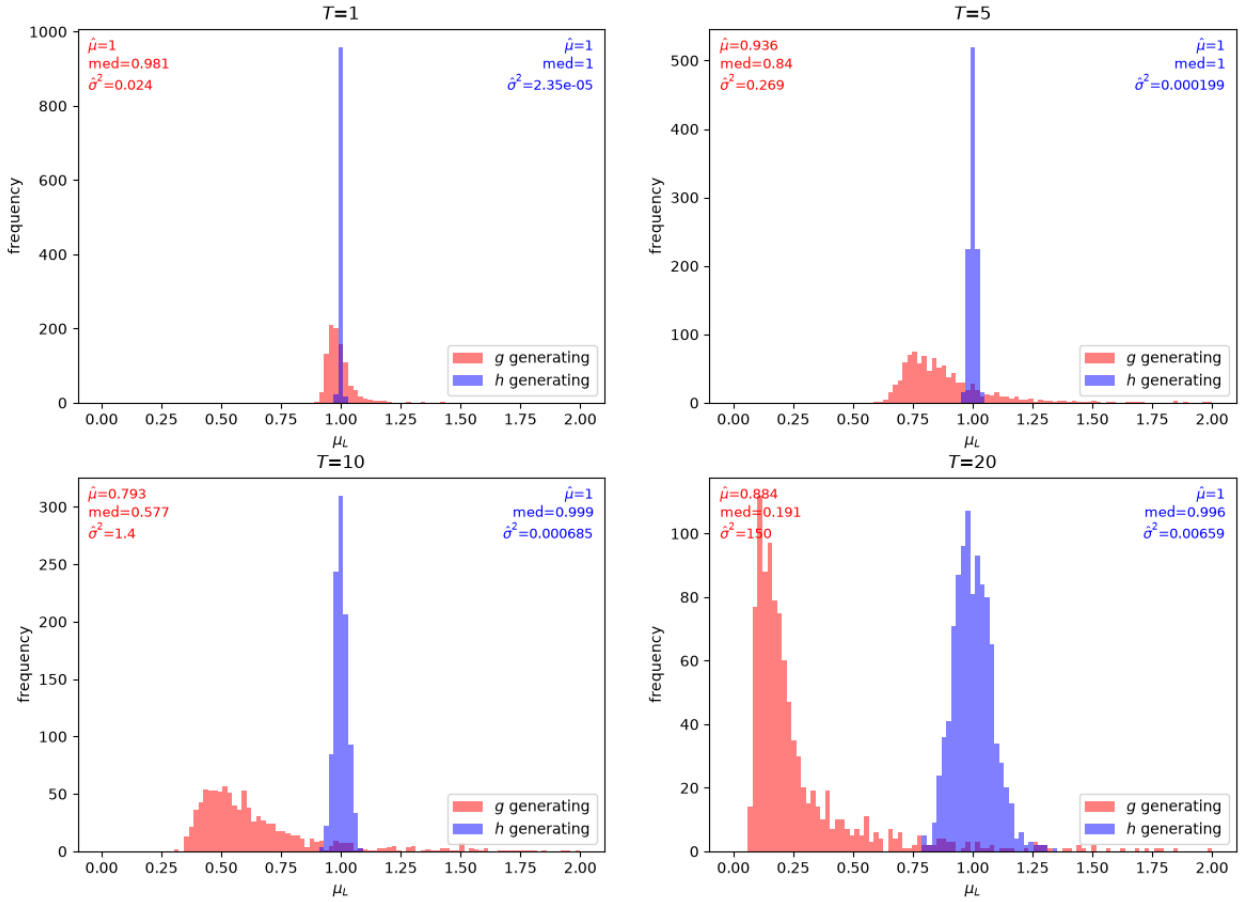

Fig. 25.4: Monte Carlo and importance sampling estimates

It is worth being careful about what is going wrong here.

The Monte Carlo estimator is unbiased in population — its expectation is exactly 1 for every T.

What deteriorates as T grows is the *shape* of its sampling distribution: almost all of the mass collapses towards zero, while the expectation is sustained by rare, very large outliers.

This is why each panel reports a median alongside the mean.

The median falls steadily in T, whereas the reported mean $\hat{\mu}$ is an unreliable statistic — recall that the underlying variance is infinite, so the $\hat{\sigma}^2$ printed in each panel estimates a quantity that does not exist, and a different seed can move $\hat{\mu}$ a long way.

Importance sampling with h removes the infinite variance, but it does not stop the variance from growing with T.

Drawing a path from h and reweighting gives the path the value $\prod_{i=1}^{T} \ell(\omega_i) g(\omega_i)/h(\omega_i) = \prod_{i=1}^{T} f(\omega_i)/h(\omega_i)$.

Its second moment is $\left(\int_0^1 f^2/h \, d\omega\right)^T = \left(1 + \chi^2(f\|h)\right)^T$, where $\chi^2(f\|h) = \int_0^1 (f-h)^2/h \, d\omega$ is the χ^2 divergence of f from h (see *Statistical Divergence Measures*).

For $h = \text{Beta}(0.5, 0.5)$, each weight $f(\omega)/h(\omega) = \pi\sqrt{\omega(1-\omega)}$ is at most $\pi/2$, and $\int_0^1 f^2/h \, d\omega = \pi^2/8 \approx 1.234$.

The variance of a single path's contribution, $(\pi^2/8)^T - 1$, is finite but grows geometrically: it equals 66 at $T = 20$ and about 3.6×10^4 at $T = 50$.

25.6 Choosing a sampling distribution

Above, we arbitrarily chose $h = Beta(0.5, 0.5)$ as the importance distribution.

Is there an optimal importance distribution?

An importance sampling estimator has zero variance when the importance density is proportional to the integrand, here ℓg.

Since $\ell g = f$, the zero-variance importance density for a single draw is f itself; for a path of length T it is the product density $f(\omega_1) f(\omega_2) \cdots f(\omega_T)$.

To use it we need only be able to draw from f; we do not need to know in advance that $E\left[L\left(\omega^t\right)\right] = 1$.

Thus, suppose that we simply use $h = f$.

When estimating the mean of the likelihood ratio (T=1), we get:

$$\hat{E}^f\left[\ell(\omega)\frac{g(\omega)}{f(\omega)}\right] = \hat{E}^f\left[\frac{f(\omega)}{g(\omega)}\frac{g(\omega)}{f(\omega)}\right] = \frac{1}{N}\sum_{i=1}^{N} \ell\left(\omega_i^f\right)\frac{g\left(\omega_i^f\right)}{f\left(\omega_i^f\right)} = 1$$

```
μ_L_f = simulate(jax.random.key(8), g_a, g_b,
                 params.F_a, params.F_b, N_simu)
```

```
# importance sampling (mean and variance)
jnp.mean(μ_L_f), jnp.var(μ_L_f)
```

```
(Array(1., dtype=float64), Array(0., dtype=float64))
```

We could also use other distributions as our importance distribution.

Below we choose just a few and compare their sampling properties.

```
a_list = [0.5, 1., 2.]
b_list = [0.5, 1.2, 5.]
```

```
w_range = np.linspace(1e-5, 1-1e-5, 1000)

plt.plot(w_range, g(w_range),
         lw=2, label=f'g=Beta({g_a}, {g_b})')
plt.plot(w_range, beta.pdf(w_range, a_list[0], b_list[0]),
         lw=2, label=f'$h_1$=Beta({a_list[0]},{b_list[0]})')
plt.plot(w_range, beta.pdf(w_range, a_list[1], b_list[1]),
         lw=2, label=f'$h_2$=Beta({a_list[1]},{b_list[1]})')
plt.plot(w_range, beta.pdf(w_range, a_list[2], b_list[2]),
         lw=2, label=f'$h_3$=Beta({a_list[2]},{b_list[2]})')
plt.legend()
plt.ylim([0., 3.])
plt.show()
```

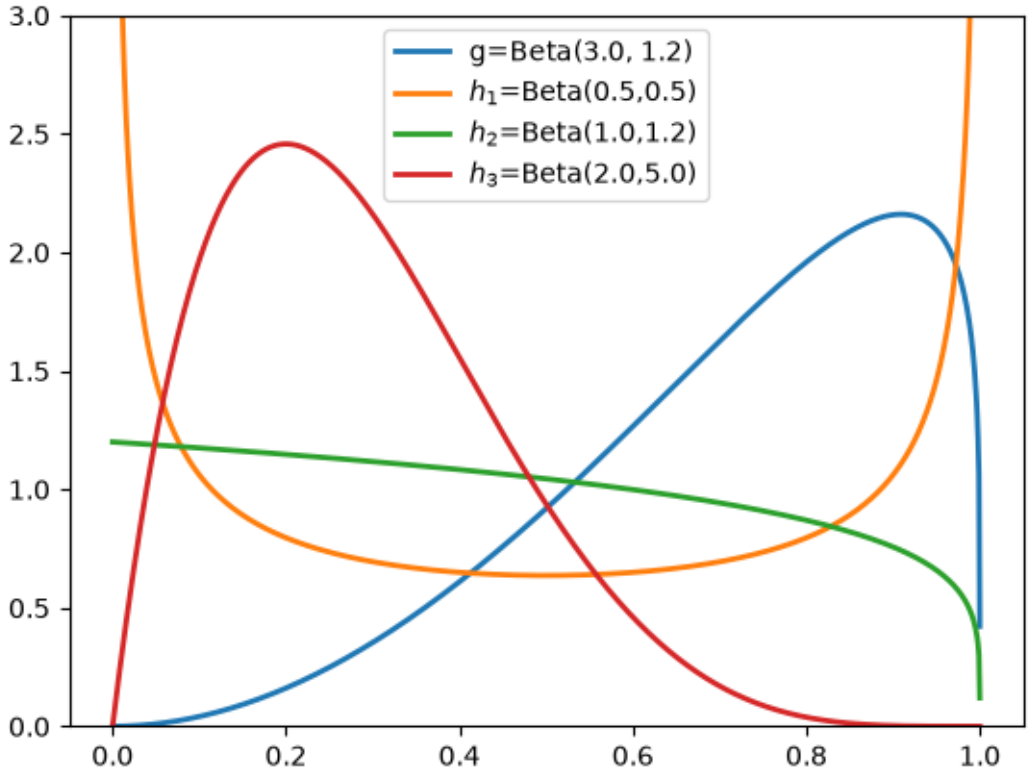

Fig. 25.5: Comparison of importance sampling distributions

We consider two additional distributions.

As a reminder h_1 is the original $Beta(0.5, 0.5)$ distribution that we used above.

h_2 is the $Beta(1, 1.2)$ distribution.

Note how h_2 has a similar shape to g at higher values of ω but more mass at lower values.

Our hunch is that h_2 should be a good importance sampling distribution.

h_3 is the $Beta(2,5)$ distribution.

Note how h_3 has almost no mass at values very close to 0 and at values close to 1.

Our hunch is that h_3 will be a poor importance sampling distribution.

The variance calculation above lets us make these hunches precise.

Drawing from h and reweighting gives each observation the value $\ell(\omega) g(\omega) / h(\omega) = f(\omega) / h(\omega)$, so the estimator has finite variance exactly when

$$\int_0^1 \frac{f(\omega)^2}{h(\omega)} d\omega < \infty$$

For a Beta(a,b) importance density h and the uniform f,

$$\int_0^1 \frac{f(\omega)^2}{h(\omega)} d\omega = B(a,b) \int_0^1 \omega^{1-a}(1-\omega)^{1-b} d\omega = B(a,b)\, B(2-a, 2-b)$$

when $a < 2$ and $b < 2$, and the integral is infinite otherwise.

The integral equals $\pi^2/8 \approx 1.234$ for h_1, $1/0.96 \approx 1.042$ for h_2, and 1 for $h = f$.

The proposal h_2 is good because it is close to f.

For h_3 it diverges at **both** endpoints, since h_3 vanishes like ω at the origin and like $(1-\omega)^4$ at one.

So importance sampling with h_3 has infinite variance, just as standard Monte Carlo does — which is what makes it a poor choice.

We first simulate and plot the distribution of estimates for $\hat{E}[L(\omega^t)]$ using h_2 as the importance sampling distribution.

```
T_values_h2 = [1, 20]
imp_h2 = simulate_multiple_T(jax.random.key(9), g_a, g_b,
                             a_list[1], b_list[1],
                             T_values_h2, N_simu)

plot_estimates(T_values_h2, mc, imp_h2, '$h_2$ generating')
```

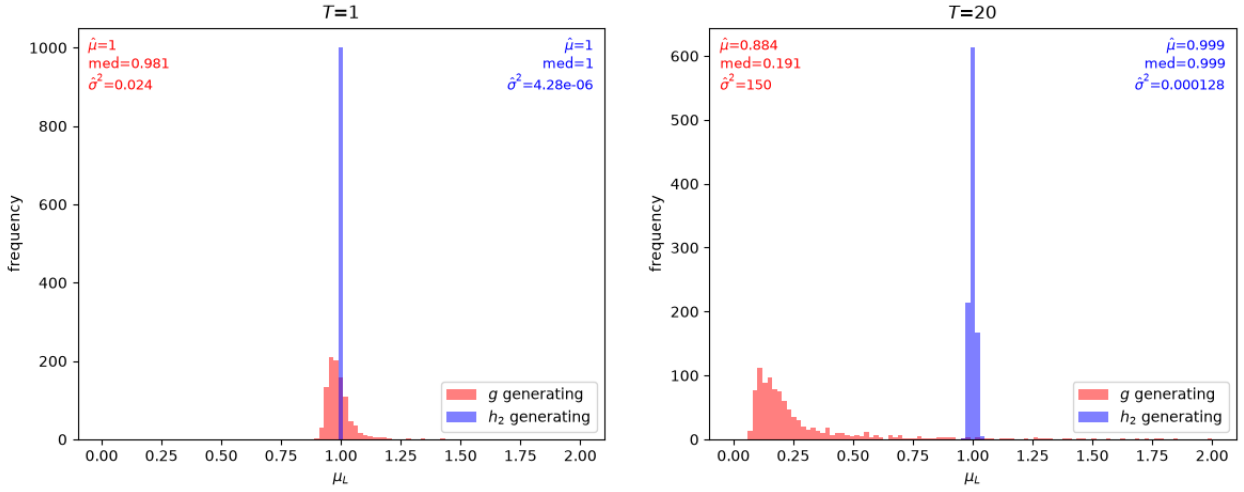

Fig. 25.6: Estimates using importance distribution h_2

Our simulations suggest that indeed h_2 is a quite good importance sampling distribution for our problem.

Even at $T = 20$, the mean is very close to 1 and the variance is small.

```
T_values_h3 = [1, 20]
imp_h3 = simulate_multiple_T(jax.random.key(10), g_a, g_b,
                             a_list[2], b_list[2],
                             T_values_h3, N_simu)

plot_estimates(T_values_h3, mc, imp_h3, '$h_3$ generating')
```

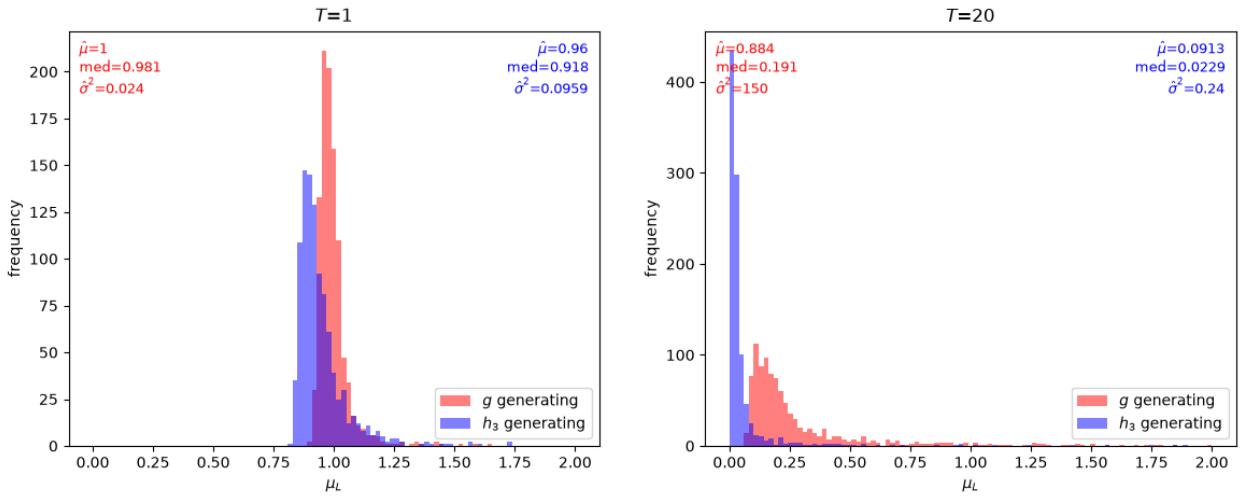

Fig. 25.7: Estimates using importance distribution h_3

However, h_3 is evidently a poor importance sampling distribution for our problem, with a mean estimate far away from 1 for $T = 20$.

Because $h_3 > 0$ on $(0, 1)$, the importance sampling estimator with h_3 is unbiased for every T, just as the Monte Carlo estimator under g is.

The trouble lies in the shape of its sampling distribution.

Even at $T = 1$, the estimates under h_3 are more dispersed than the Monte Carlo estimates under g, and the median estimate lies farther below 1.

Near $\omega = 1$, h_3 vanishes like $(1 - \omega)^4$ while $f = 1$, so the weight f/h_3 has tail index $5/4$ under h_3, smaller than the tail index $3/2$ of f/g under g.

The error of a sample mean of N draws therefore shrinks like $N^{-1/5}$ under h_3 and like $N^{-1/3}$ under g (Exercise 25.7.2).

Thus, our simulations suggest that for our problem we would be better off simply using Monte Carlo approximations under g than using h_3 as an importance sampling distribution.

25.7 Exercises

Exercise 25.7.1

Consider estimating $E^g\left[L\left(\omega^T\right)\right] = 1$ by drawing paths of length T from a Beta(a, b) importance density q.

1. Show that each path contributes $\prod_{i=1}^T f(\omega_i)/q(\omega_i)$ to the estimator and that the second moment of this contribution is $M(a,b)^T$, where $M(a,b) = \int_0^1 f^2/q\, d\omega = B(a,b)B(2-a, 2-b)$ when $a, b < 2$ and $M(a,b) = +\infty$ otherwise.
2. Use the Cauchy–Schwarz inequality to show that $M(a,b) \geq 1$, with equality only at $(a,b) = (1,1)$. Plot contours of $\log M(a,b)$ on $(0,2) \times (0,2)$.
3. The effective sample size of N weighted paths is approximately $N/M(a,b)^T$. Plot the ratio of the effective sample size to N against T for h_1 and h_2. How many paths does h_1 need for an effective sample size of 1000 at $T = 20$ and at $T = 50$?

Solution

Part 1. Each path contributes $\prod_{i=1}^T \ell(\omega_i)g(\omega_i)/q(\omega_i) = \prod_{i=1}^T f(\omega_i)/q(\omega_i)$.

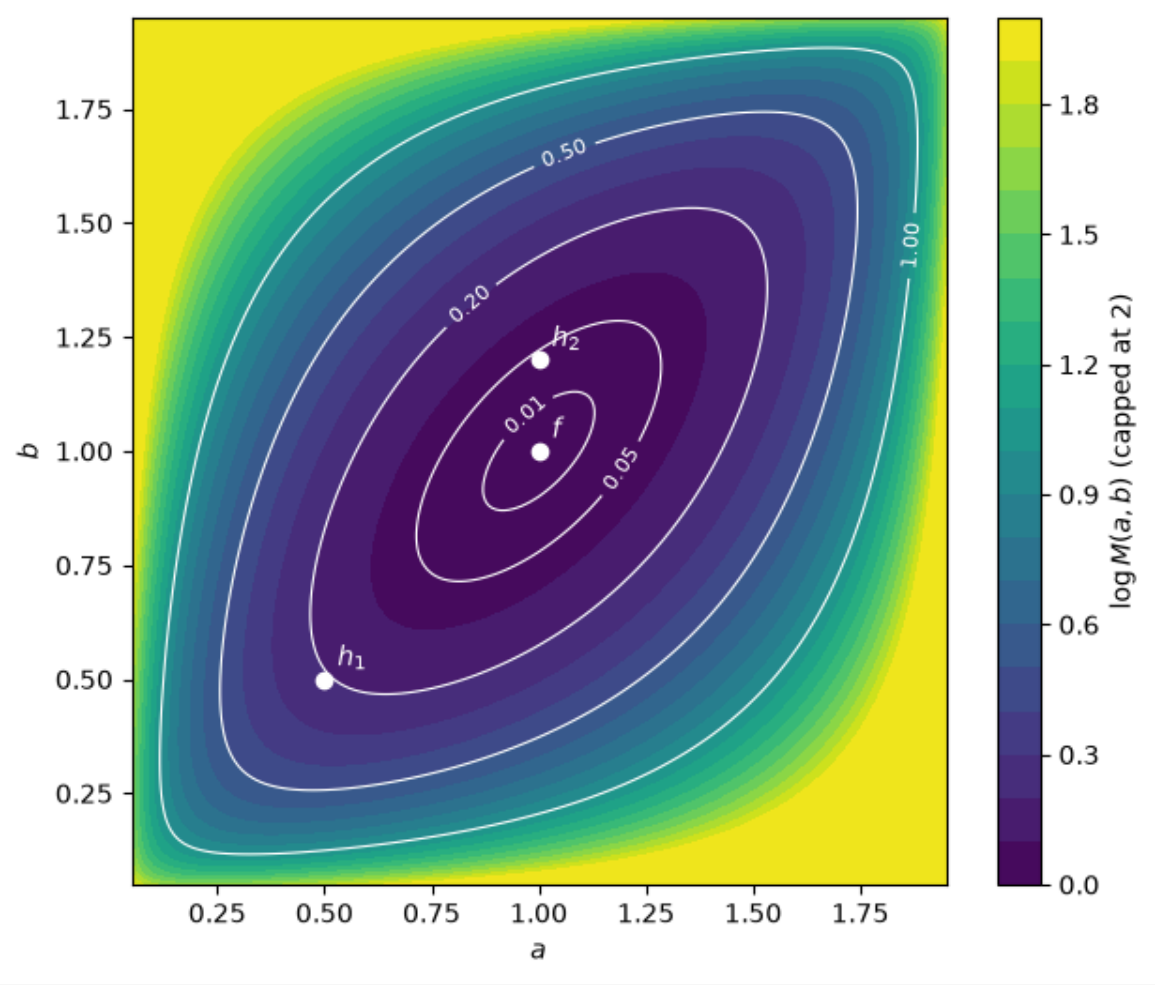
Because the ω_i's are IID draws from q, the second moment is $\left(E^q\left[(f/q)^2\right]\right)^T = M(a,b)^T$ with $M(a,b) = \int_0^1 f^2/q\, d\omega$.

Since $f = 1$, $M(a,b) = B(a,b)\int_0^1 \omega^{1-a}(1-\omega)^{1-b}d\omega$, which equals $B(a,b)B(2-a,2-b)$ when $a < 2$ and $b < 2$ and is infinite otherwise.

Part 2. By the Cauchy–Schwarz inequality,

$$1 = \left(\int_0^1 f\, d\omega\right)^2 = \left(\int_0^1 \frac{f}{\sqrt{q}}\sqrt{q}\, d\omega\right)^2 \leq \int_0^1 \frac{f^2}{q} d\omega \int_0^1 q\, d\omega = M(a,b),$$

with equality if and only if $f/\sqrt{q}$ is proportional to $\sqrt{q}$, that is, $q = f$.



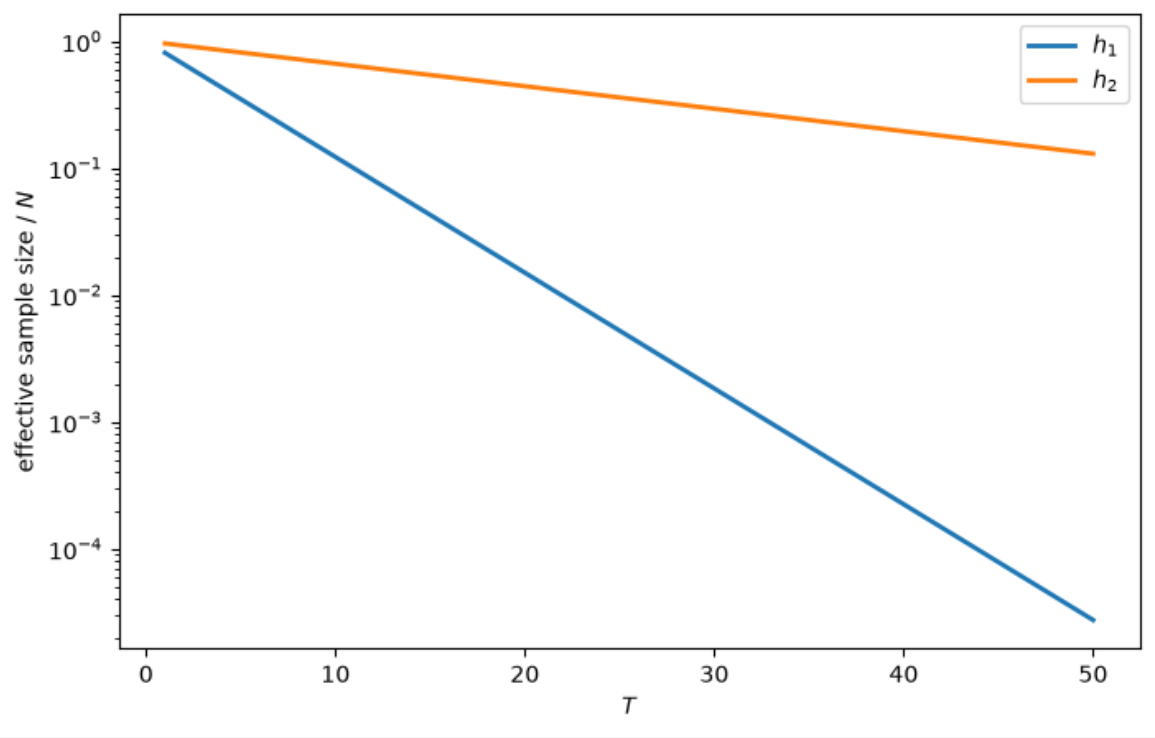
The variance of a single weight is $M(a,b) - 1 = \chi^2(f\|q)$.

```
from scipy.special import betaln

def M(a, b):
    """Second moment of the importance weight f/q for q = Beta(a, b)."""
    if a < 2 and b < 2:
        return np.exp(betaln(a, b) + betaln(2 - a, 2 - b))
    return np.inf

grid = np.linspace(0.05, 1.95, 191)
log_M = np.array([[np.log(M(a, b)) for a in grid] for b in grid])

fig, ax = plt.subplots(figsize=(7, 6))
cs = ax.contourf(grid, grid, np.minimum(log_M, 2),
                 levels=np.linspace(0, 2, 21), cmap='viridis')
fig.colorbar(cs, label=r'$\log M(a, b)$ (capped at 2)')
lines = ax.contour(grid, grid, log_M, levels=[0.01, 0.05, 0.2, 0.5, 1],
                   colors='w', linewidths=0.8)
ax.clabel(lines, fmt='%.2f', fontsize=8)
for (a, b), name in zip([(0.5, 0.5), (1.0, 1.2), (1.0, 1.0)],
                        ['$h_1$', '$h_2$', '$f$']):
    ax.plot(a, b, 'wo')
    ax.annotate(name, (a, b), xytext=(5, 5), textcoords='offset points',
                color='w')
ax.set_xlabel('$a$')
ax.set_ylabel('$b$')
plt.show()
```



```
Minimum of M on the grid at (a, b) = (1.00, 1.00)
M(h_1) = 1.2337, M(h_2) = 1.0417
```

Part 3.

```
T_grid = np.arange(1, 51)
plt.figure(figsize=(8, 5))
for (a, b), name in zip([(0.5, 0.5), (1.0, 1.2)], ['$h_1$', '$h_2$']):
    plt.semilogy(T_grid, M(a, b)**(-T_grid), lw=2, label=name)
plt.xlabel('$T$')
plt.ylabel('effective sample size / $N$')
plt.legend()
plt.show()

for T in [20, 50]:
    print(f"T = {T}: h_1 needs N = {1000 * M(0.5, 0.5)**T:,.0f} paths, "
          f"h_2 needs N = {1000 * M(1, 1.2)**T:,.0f} paths")
```

```
T = 20: h_1 needs N = 66,711 paths, h_2 needs N = 2,262 paths
T = 50: h_1 needs N = 36,348,619 paths, h_2 needs N = 7,699 paths
```

The effective sample size under h_1 shrinks by the factor $8/\pi^2$ with each additional period.

Exercise 25.7.2

1. Let $\omega \sim g$. Show that $\Pr\{\ell(\omega) > x\}$ is approximately proportional to $x^{-3/2}$ for large x, so that $\ell(\omega)$ has tail index $3/2$ under g.
2. Let $\omega \sim h_3 = \text{Beta}(2, 5)$. Show that the weight $f(\omega)/h_3(\omega)$ has tail index $5/4$ under h_3. Which endpoint of $(0, 1)$ determines the tail index?
3. Confirm both tail indices with the Hill estimator [Hill, 1975], which uses the k largest of n draws $X_{(1)} \geq X_{(2)} \geq \cdots \geq X_{(k+1)}$ to estimate the tail index by

$$\hat{\alpha}_k = \left(\frac{1}{k} \sum_{i=1}^{k} \log \frac{X_{(i)}}{X_{(k+1)}} \right)^{-1}.$$

4. Set $T = 1$. For $N = 10^2, 10^3, 10^4, 10^5$, compute 500 replicate sample means of f/q for N draws from q when q is g (standard Monte Carlo), h_2, and h_3. Plot the interquartile range of the replicate means against N on log-log scales, and compare the slopes with $-1/3$, $-1/2$, and $-1/5$.

Solution

Part 1. Near the origin, $g(\omega) \approx k\omega^2$ with $k = 1/B(3, 1.2)$.

For large x, $\ell(\omega) = 1/g(\omega) > x$ occurs mainly when $\omega < (kx)^{-1/2}$.

Since $\Pr_g\{\omega < u\} \approx ku^3/3$ for small u,

$$\Pr_g\{\ell(\omega) > x\} \approx \frac{k}{3}(kx)^{-3/2} = \frac{1}{3}k^{-1/2}x^{-3/2}.$$

Near $\omega = 1$, g vanishes like $(1-\omega)^{0.2}$, which contributes a tail proportional to x^{-6}, too thin to matter.

Part 2. The density $h_3(\omega) = 30\,\omega(1-\omega)^4$ vanishes at both endpoints.

Near $\omega = 0$, $1/h_3 > x$ occurs when $\omega < 1/(30x)$, which has probability about $15/(30x)^2$, proportional to x^{-2}.

Near $\omega = 1$, $1/h_3 > x$ occurs when $1 - \omega < (30x)^{-1/4}$, which has probability about $6(30x)^{-5/4}$, proportional to $x^{-5/4}$.

The heavier tail, with index $5/4$, comes from the right endpoint.

By the generalized central limit theorem, a tail index $\alpha \in (1, 2)$ makes the error of a sample mean shrink like $N^{1/\alpha - 1}$: $N^{-1/3}$ for $\alpha = 3/2$ and $N^{-1/5}$ for $\alpha = 5/4$.

Part 3.

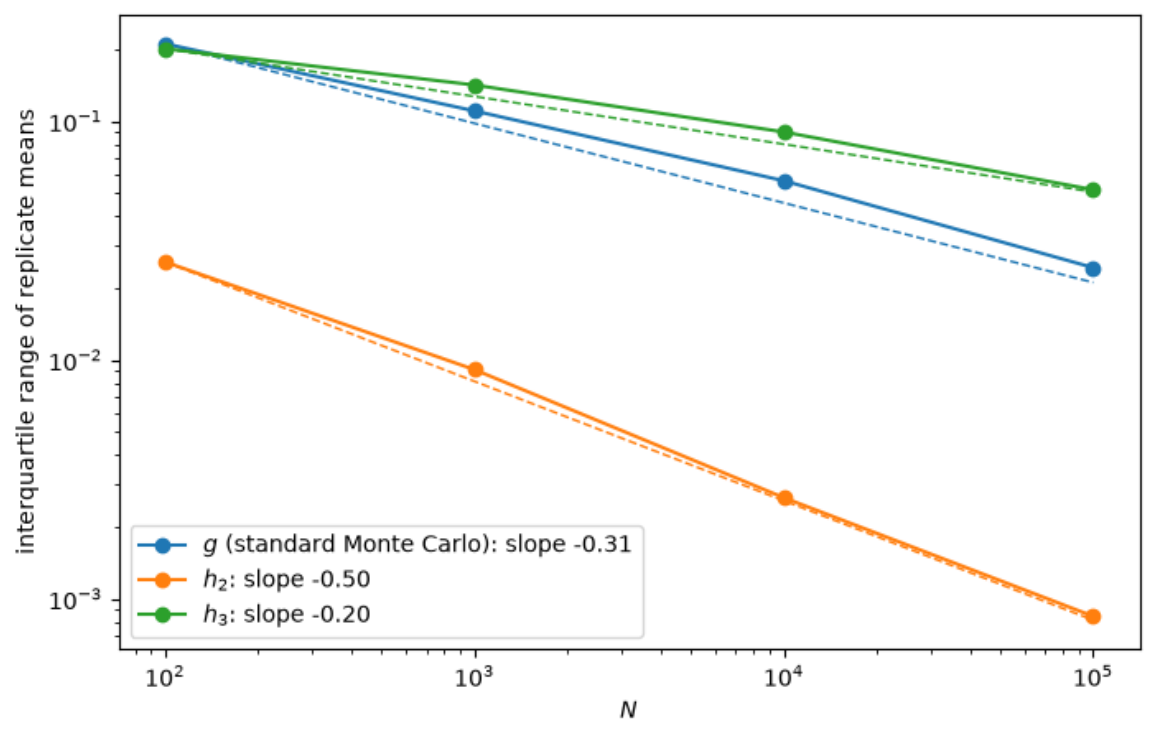
```
def log_beta_pdf(w, a, b):
    """Log density of Beta(a, b)."""
    return (a - 1) * np.log(w) + (b - 1) * np.log1p(-w) - betaln(a, b)

def hill(x, k):
    """Hill estimator of the tail index from the k largest values of x."""
    x_sorted = np.sort(x)[::-1]
    return 1 / np.mean(np.log(x_sorted[:k] / x_sorted[k]))

rng = np.random.default_rng(0)
n = 1_000_000
w_g = rng.beta(g_a, g_b, n)
w_h3 = rng.beta(2, 5, n)
weights = {'f/g under g': np.exp(-log_beta_pdf(w_g, g_a, g_b)),
           'f/h_3 under h_3': np.exp(-log_beta_pdf(w_h3, 2, 5))}

for name, x in weights.items():
    estimates = [f"{hill(x, k):.3f}" for k in (500, 1000, 2000, 5000)]
    print(f"{name}: Hill estimates for k = 500, 1000, 2000, 5000: {estimates}")
```

```
f/g under g: Hill estimates for k = 500, 1000, 2000, 5000: ['1.483', '1.476',
 ↪'1.497', '1.514']
f/h_3 under h_3: Hill estimates for k = 500, 1000, 2000, 5000: ['1.248', '1.265
 ↪', '1.267', '1.271']
```



The Hill estimates are close to $3/2$ and $5/4$.

Part 4.

```
N_values = np.array([10**2, 10**3, 10**4, 10**5])
R = 500
proposals = {'$g$ (standard Monte Carlo)': (g_a, g_b, 1/3),
             '$h_2$': (1.0, 1.2, 1/2),
             '$h_3$': (2.0, 5.0, 1/5)}

plt.figure(figsize=(8, 5))
for name, (a, b, rate) in proposals.items():
    iqr = []
    for N in N_values:
        means = np.empty(R)
```

```
        for r in range(R):
            w = np.clip(rng.beta(a, b, N), 1e-16, 1 - 1e-16)
            means[r] = np.mean(np.exp(-log_beta_pdf(w, a, b)))
        q75, q25 = np.quantile(means, [0.75, 0.25])
        iqr.append(q75 - q25)
    slope = np.polyfit(np.log(N_values), np.log(iqr), 1)[0]
    line, = plt.loglog(N_values, iqr, 'o-',
                       label=f'{name}: slope {slope:.2f}')
    plt.loglog(N_values, iqr[0] * (N_values / N_values[0])**(-rate),
               '--', color=line.get_color(), lw=1)
plt.xlabel('$N$')
plt.ylabel('interquartile range of replicate means')
plt.legend()
plt.show()
```

The dashed lines have slopes $-1/3$, $-1/2$, and $-1/5$.

The fitted slopes are close to them.

Exercise 25.7.3

In *this section* of *Likelihood Ratio Processes*, the probability $\alpha_T = \Pr_f\{L(\omega^T) < 1\}$ of a type I error decays exponentially in T, so standard Monte Carlo cannot estimate it for large T.

Let ϕ^* minimize the Chernoff coefficient $\rho(\phi) = \int_0^1 f^\phi g^{1-\phi} d\omega$, and let $q = f^{\phi^*} g^{1-\phi^*}/\rho(\phi^*)$ be the tilted density.

1. Show that q is the Beta$(\phi^* F_a + (1-\phi^*)G_a,\ \phi^* F_b + (1-\phi^*)G_b)$ density, and compute ϕ^* and the parameters of q.

2. Show that

$$\alpha_T = \rho(\phi^*)^T \, E^q \left[\mathbf{1}\{L(\omega^T) < 1\} \, L(\omega^T)^{1-\phi^*} \right].$$

3. For $T = 30, 60, 100$, estimate α_T by standard Monte Carlo with $N = 20{,}000$ paths drawn from f and by importance sampling with $N = 20{,}000$ paths drawn from q. Report the relative standard error of the importance sampling estimate.

Solution

Part 1. For Beta densities,

$$f(\omega)^\phi g(\omega)^{1-\phi} \propto \omega^{\phi F_a + (1-\phi) G_a - 1} (1-\omega)^{\phi F_b + (1-\phi) G_b - 1},$$

which is proportional to the stated Beta density.

Part 2. Since $f/q = \rho(\phi^*)(f/g)^{1-\phi^*}$,

$$\alpha_T = E^q \left[\mathbf{1}\{L(\omega^T) < 1\} \prod_{i=1}^T \frac{f(\omega_i)}{q(\omega_i)} \right] = \rho(\phi^*)^T \, E^q \left[\mathbf{1}\{L(\omega^T) < 1\} \, L(\omega^T)^{1-\phi^*} \right].$$

On the event $L(\omega^T) < 1$, the weight $\rho(\phi^*)^T L(\omega^T)^{1-\phi^*}$ is at most $\rho(\phi^*)^T = e^{-C(f,g)T}$, so the estimator has a small variance.

At ϕ^*, the derivative of $\log \rho(\phi)$, which equals $E^q \log \ell(\omega)$, is zero.

Thus $\log L(\omega^T)$ has mean zero under q, and the rare event $L(\omega^T) < 1$ under f occurs about half the time under q.

Choosing q in this way is called exponential tilting [Bucklew, 2004].

Part 3.

```
from scipy.optimize import minimize_scalar

F_a, F_b = params.F_a, params.F_b

def log_ρ(ϕ):
    """Log Chernoff coefficient for f = Beta(F_a, F_b) and g = Beta(g_a, g_b)."""
    return (betaln(ϕ * F_a + (1 - ϕ) * g_a, ϕ * F_b + (1 - ϕ) * g_b)
            - ϕ * betaln(F_a, F_b) - (1 - ϕ) * betaln(g_a, g_b))

res = minimize_scalar(log_ρ, bounds=(0, 1), method='bounded')
ϕ_star, log_ρ_star = res.x, res.fun
q_a = ϕ_star * F_a + (1 - ϕ_star) * g_a
q_b = ϕ_star * F_b + (1 - ϕ_star) * g_b
print(f"ϕ* = {ϕ_star:.4f}, C(f, g) = {-log_ρ_star:.4f}, "
      f"q = Beta({q_a:.4f}, {q_b:.4f})")

rng = np.random.default_rng(1)
N = 20_000

for T in [30, 60, 100]:
    # Standard Monte Carlo under f
    w = rng.uniform(size=(N, T))
    log_L = np.sum(log_beta_pdf(w, F_a, F_b) - log_beta_pdf(w, g_a, g_b), axis=1)
    α_mc = np.mean(log_L < 0)

    # Importance sampling under the tilted density q
    w = np.clip(rng.beta(q_a, q_b, (N, T)), 1e-300, 1 - 1e-16)
    log_L = np.sum(log_beta_pdf(w, F_a, F_b) - log_beta_pdf(w, g_a, g_b), axis=1)
    X = np.where(log_L < 0, np.exp(T * log_ρ_star + (1 - ϕ_star) * log_L), 0.0)
    α_is = np.mean(X)
    rel_se = np.std(X) / np.sqrt(N) / α_is

    print(f"T = {T:>3}: standard MC = {α_mc:.2e}, "
```

```
ϕ* = 0.5969, C(f, g) = 0.1212, q = Beta(1.8063, 1.0806)
T =  30: standard MC = 4.15e-03, importance sampling = 4.401e-03 (relative s.e.␣
↪0.011)
T =  60: standard MC = 1.00e-04, importance sampling = 8.448e-05 (relative s.e.␣
↪0.013)
T = 100: standard MC = 0.00e+00, importance sampling = 5.143e-07 (relative s.e.␣
↪0.015)
```

At $T = 30$ the two estimates agree.

At $T = 60$, standard Monte Carlo rests on a handful of paths with $L(\omega^T) < 1$, while importance sampling has a relative standard error near 1 percent.

At $T = 100$, standard Monte Carlo records no paths with $L(\omega^T) < 1$, while importance sampling still delivers an estimate with a relative standard error near 1.5 percent.

26.1 Overview

This is the first of three lectures about a statistical decision problem that a US Navy Captain presented to Milton Friedman and W. Allen Wallis during World War II when they were analysts at the U.S. Government's Statistical Research Group at Columbia University.

This problem led Abraham Wald [Wald, 1947] to formulate **sequential analysis**, an approach to statistical decision problems that is intimately related to dynamic programming.

In the spirit of *this earlier lecture*, the present lecture and its *sequel* approach the problem from two distinct points of view, one frequentist, the other Bayesian.

In this lecture, we describe Wald's formulation of the problem from the perspective of a frequentist statistician working within the Neyman-Pearson tradition who thinks about testing hypotheses and consequently uses laws of large numbers to investigate limiting properties of particular statistics under a given **hypothesis**, i.e., a vector of **parameters** that pins down a particular member of a manifold of statistical models that interest the statistician.

- From *this lecture on frequentist and bayesian statistics*, please remember that a frequentist statistician routinely calculates functions of sequences of random variables, conditioning on a vector of parameters.

In *this related lecture* we'll discuss another formulation that adopts the perspective of a **Bayesian statistician** who views parameters as random variables that are jointly distributed with observable variables that he is concerned about.

Because we are taking a frequentist perspective that is concerned about relative frequencies conditioned on alternative parameter values, i.e., alternative **hypotheses**, key ideas in this lecture

- Type I and type II statistical errors
  - a type I error occurs when you reject a null hypothesis that is true
  - a type II error occurs when you accept a null hypothesis that is false
- The **power** of a frequentist statistical test
- The **size** of a frequentist statistical test
- The **critical region** of a statistical test
- A **most powerful test**
- The role of a Law of Large Numbers (LLN) in interpreting **power** and **size** of a frequentist statistical test
- Abraham Wald's **sequential probability ratio test**

We'll begin with some imports:

```
import numpy as np
import matplotlib.pyplot as plt
from numba import njit, prange, vectorize, jit
from numba.experimental import jitclass
from math import gamma
from scipy.special import betaln, digamma
from scipy.stats import beta
from collections import namedtuple
import pandas as pd
import scipy as sp
```

This lecture uses ideas studied in *the lecture on likelihood ratio processes* and *the lecture on Bayesian learning*.

26.2 Source of the Problem

On pages 137-139 of his 1998 book *Two Lucky People* with Rose Friedman [Friedman and Friedman, 1998], Milton Friedman described a problem presented to him and Allen Wallis during World War II, when they worked at the US Government's Statistical Research Group at Columbia University.

Note

See pages 25 and 26 of Allen Wallis's 1980 article [Wallis, 1980] about the Statistical Research Group at Columbia University during World War II for his account of the episode and for important contributions that Harold Hotelling made to formulating the problem. Also see chapter 5 of Jennifer Burns' book about Milton Friedman [Burns, 2023].

Let's listen to Milton Friedman tell us what happened

> In order to understand the story, it is necessary to have an idea of a simple statistical problem, and of the standard procedure for dealing with it. The actual problem out of which sequential analysis grew will serve. The Navy has two alternative designs (say A and B) for a projectile. It wants to determine which is superior. To do so it undertakes a series of paired firings. On each round, it assigns the value 1 or 0 to A accordingly as

> its performance is superior or inferior to that of B and conversely 0 or 1 to B. The Navy asks the statistician how to conduct the test and how to analyze the results.
>
> The standard statistical answer was to specify a number of firings (say 1,000) and a pair of percentages (e.g., 53% and 47%) and tell the client that if A receives a 1 in more than 53% of the firings, it can be regarded as superior; if it receives a 1 in fewer than 47%, B can be regarded as superior; if the percentage is between 47% and 53%, neither can be so regarded.
>
> When Allen Wallis was discussing such a problem with (Navy) Captain Garret L. Schuyler, the captain objected that such a test, to quote from Allen's account, may prove wasteful. If a wise and seasoned ordnance officer like Schuyler were on the premises, he would see after the first few thousand or even few hundred [rounds] that the experiment need not be completed either because the new method is obviously inferior or because it is obviously superior beyond what was hoped for ….

Friedman and Wallis worked on the problem for a while but didn't completely solve it.

Realizing that, they told Abraham Wald about the problem.

That set Wald on a path that led him to create *Sequential Analysis* [Wald, 1947].

26.3 Neyman-Pearson formulation

It is useful to begin by describing the theory underlying the test that the U.S. Navy told Captain Garret L. Schuyler to use.

Captain Schuyler's doubts motivated him to tell Milton Friedman and Allen Wallis his conjecture that superior practical procedures existed.

Evidently, the Navy had told Captain Schuyler to use what was then a state-of-the-art Neyman-Pearson hypothesis test.

We'll rely on Abraham Wald's [Wald, 1947] elegant summary of Neyman-Pearson theory.

Watch for these features of the setup:

- the assumption of a *fixed* sample size n
- the application of laws of large numbers, conditioned on alternative probability models, to interpret probabilities α and β of the type I and type II errors defined in the Neyman-Pearson theory

In chapter 1 of **Sequential Analysis** [Wald, 1947] Abraham Wald summarizes the Neyman-Pearson approach to hypothesis testing.

Wald frames the problem as making a decision about a probability distribution that is partially known.

(You have to assume that *something* is already known in order to state a well-posed problem – usually, *something* means *a lot*)

By limiting what is unknown, Wald uses the following simple structure to illustrate the main ideas:

- A decision-maker wants to decide which of two distributions f_0, f_1 govern an IID random variable z.
- The null hypothesis H_0 is the statement that f_0 governs the data.
- The alternative hypothesis H_1 is the statement that f_1 governs the data.
- The problem is to devise and analyze a test of hypothesis H_0 against the alternative hypothesis H_1 on the basis of a sample of a fixed number n independent observations $z_1, z_2, \ldots, z_n$ of the random variable z.

To quote Abraham Wald,

> A test procedure leading to the acceptance or rejection of the [null] hypothesis in question is simply a rule specifying, for each possible sample of size n, whether the [null] hypothesis should be accepted or rejected on the basis of the sample. This may also be expressed as follows: A test procedure is simply a subdivision of the totality of all possible samples of size n into two mutually exclusive parts, say part 1 and part 2, together

> with the application of the rule that the [null] hypothesis be accepted if the observed sample is contained in part 2. Part 1 is also called the critical region. Since part 2 is the totality of all samples of size n which are not included in part 1, part 2 is uniquely determined by part 1. Thus, choosing a test procedure is equivalent to determining a critical region.

Let's listen to Wald longer:

> As a basis for choosing among critical regions the following considerations have been advanced by Neyman and Pearson: In accepting or rejecting H_0 we may commit errors of two kinds. We commit an error of the first kind if we reject H_0 when it is true; we commit an error of the second kind if we accept H_0 when H_1 is true. After a particular critical region W has been chosen, the probability of committing an error of the first kind, as well as the probability of committing an error of the second kind is uniquely determined. The probability of committing an error of the first kind is equal to the probability, determined by the assumption that H_0 is true, that the observed sample will be included in the critical region W. The probability of committing an error of the second kind is equal to the probability, determined on the assumption that H_1 is true, that the observed sample will fall outside the critical region W. For any given critical region W we shall denote the probability of an error of the first kind by α and the probability of an error of the second kind by β.

Let's listen carefully to how Wald applies law of large numbers to interpret α and β:

> The probabilities α and β have the following important practical interpretation: Suppose that we draw a large number of samples of size n. Let M be the number of such samples drawn. Suppose that for each of these M samples we reject H_0 if the sample is included in W and accept H_0 if the sample lies outside W. In this way we make M statements of rejection or acceptance. Some of these statements will in general be wrong. If H_0 is true and if M is large, the probability is nearly 1 (i.e., it is practically certain) that the proportion of wrong statements (i.e., the number of wrong statements divided by M) will be approximately α. If H_1 is true, the probability is nearly 1 that the proportion of wrong statements will be approximately β. Thus, we can say that in the long run [here Wald applies law of large numbers by driving $M \to \infty$ (our comment, not Wald's)] the proportion of wrong statements will be α if H_0 is true and β if H_1 is true.

The quantity α is called the *size* of the critical region, and the quantity $1 - \beta$ is called the *power* of the critical region.

Wald notes that

> one critical region W is more desirable than another if it has smaller values of α and β. Although either α or β can be made arbitrarily small by a proper choice of the critical region W, it is impossible to make both α and β arbitrarily small for a fixed value of n, i.e., a fixed sample size.

Wald summarizes Neyman and Pearson's setup as follows:

> Neyman and Pearson show that a region consisting of all samples $(z_1, z_2, \ldots, z_n)$ which satisfy the inequality
>
> $$\frac{f_1(z_1) \cdots f_1(z_n)}{f_0(z_1) \cdots f_0(z_n)} \geq k$$
>
> is a most powerful critical region for testing the hypothesis H_0 against the alternative hypothesis H_1. The term k on the right side is a constant chosen so that the region will have the required size α.

Wald goes on to discuss Neyman and Pearson's concept of *uniformly most powerful* test.

Our H_0 and H_1 each specify a single distribution, so the most powerful test above is all that we need.

Here is how Wald introduces the notion of a sequential test

> A rule is given for making one of the following three decisions at any stage of the experiment (at the m th trial for each integral value of m): (1) to accept the hypothesis H, (2) to reject the hypothesis H, (3) to continue the experiment by making an additional observation. Thus, such a test procedure is carried out sequentially. On the basis of the first observation, one of the aforementioned decision is made. If the first or second decision is made, the process is terminated. If the third decision is made, a second trial is performed. Again, on the basis of the first two observations, one of the three decision is made. If the third decision

is made, a third trial is performed, and so on. The process is continued until either the first or the second decisions is made. The number n of observations required by such a test procedure is a random variable, since the value of n depends on the outcome of the observations.

26.4 Wald's sequential formulation

By way of contrast to Neyman and Pearson's formulation of the problem, in Wald's formulation

- The sample size n is not fixed but rather a random variable.
- Two parameters A and B that are related to but distinct from Neyman and Pearson's α and β; A and B characterize cut-off rules that Wald uses to determine the random variable n as a function of random outcomes.

Here is how Wald sets up the problem.

A decision-maker can observe a sequence of draws of a random variable z.

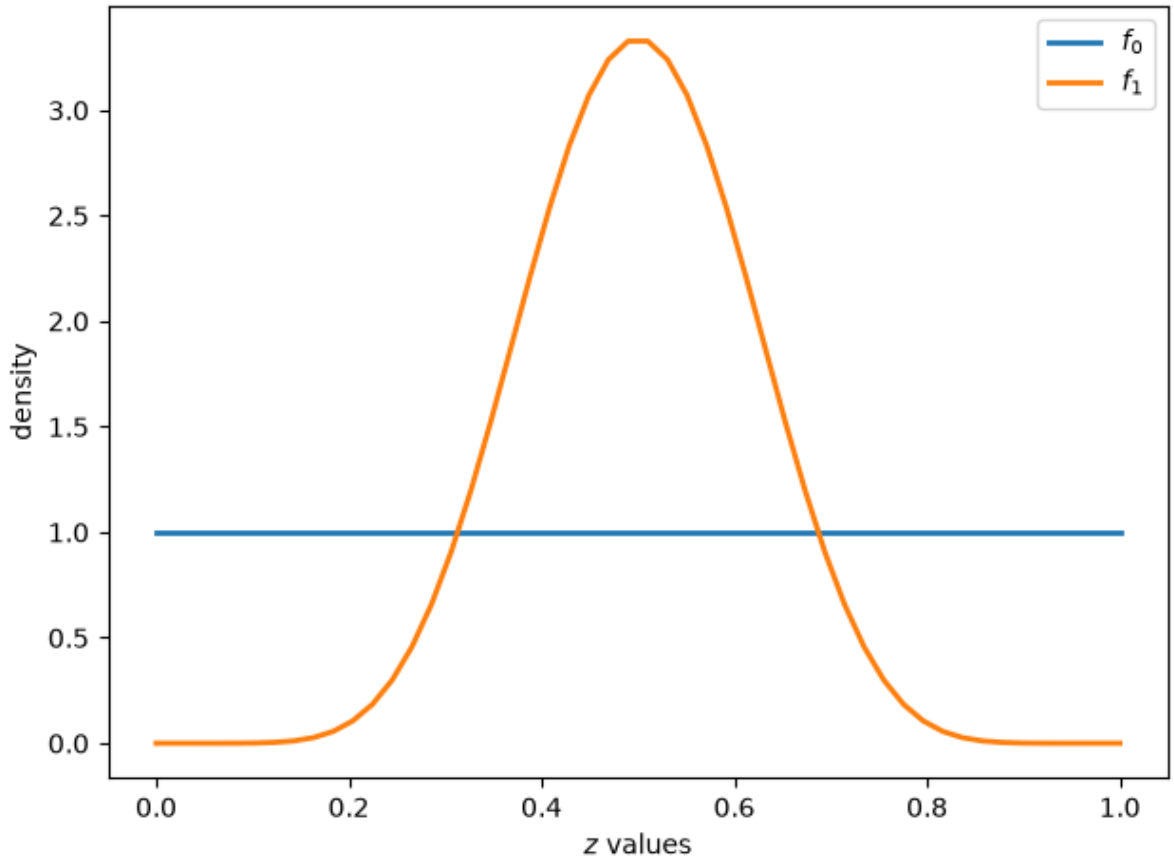
He (or she) wants to know which of two probability distributions f_0 or f_1 governs z.

We use beta distributions as examples.

We will also work with the Kullback–Leibler divergence introduced in *Statistical Divergence Measures*.

For two beta densities, Kullback–Leibler divergence has a closed form.

```
@vectorize
def p(x, a, b):
    """Beta distribution density function."""
    r = gamma(a + b) / (gamma(a) * gamma(b))
    return r * x** (a-1) * (1 - x) ** (b-1)



def create_beta_density(a, b):
    """Create a beta density function with specified parameters."""
    return jit(lambda x: p(x, a, b))

def compute_KL(a1, b1, a2, b2):
    """KL divergence KL(f, g) for f = Beta(a1, b1) and g = Beta(a2, b2)."""
    return (betaln(a2, b2) - betaln(a1, b1)
            + (a1 - a2) * digamma(a1) + (b1 - b2) * digamma(b1)
            + (a2 - a1 + b2 - b1) * digamma(a1 + b1))
```

The next figure shows two beta distributions

```
f0 = create_beta_density(1, 1)
f1 = create_beta_density(9, 9)
grid = np.linspace(0, 1, 50)

fig, ax = plt.subplots()
ax.plot(grid, f0(grid), lw=2, label="$f_0$")
ax.plot(grid, f1(grid), lw=2, label="$f_1$")
ax.legend()
ax.set(xlabel="$z$ values", ylabel="density")
plt.tight_layout()
plt.show()
```

Conditional on knowing that successive observations are drawn from distribution f_0, the sequence of random variables is independently and identically distributed (IID).

Conditional on knowing that successive observations are drawn from distribution f_1, the sequence of random variables is also independently and identically distributed (IID).

But the observer does not know which of the two distributions generated the sequence.

For reasons explained in *Exchangeability and Bayesian Updating*, this means that the observer thinks that the sequence is not IID.

Consequently, the observer has something to learn, namely, whether the observations are drawn from f_0 or from f_1.

The decision maker wants to decide which of the two distributions is generating outcomes.

26.4.1 Type I and type II errors

If we regard $f = f_0$ as a null hypothesis and $f = f_1$ as an alternative hypothesis, then

- a type I error is an incorrect rejection of a true null hypothesis (a "false positive")
- a type II error is a failure to reject a false null hypothesis (a "false negative")

To repeat ourselves

- α is the probability of a type I error
- β is the probability of a type II error

26.4.2 Choices

After observing $z_k, z_{k-1}, \ldots, z_1$, the decision-maker chooses among three distinct actions:

- He decides that $f = f_0$ and draws no more z's
- He decides that $f = f_1$ and draws no more z's
- He postpones deciding and instead chooses to draw z_{k+1}

Wald defines

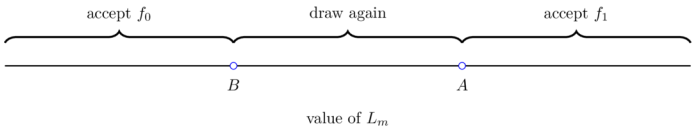
- $p_{0m} = f_0(z_1) \cdots f_0(z_m)$
- $p_{1m} = f_1(z_1) \cdots f_1(z_m)$
- $L_m = \frac{p_{1m}}{p_{0m}}$

for $m \geq 1$ and sets $L_0 = 1$.

Here $\{L_m\}_{m=0}^{\infty}$ is a **likelihood ratio process**.

Wald's sequential decision rule is parameterized by real numbers $0 < B < 1 < A$.

For a given pair A, B, the decision rule is



$$\begin{aligned} \text{accept } f = f_1 \text{ if } L_m &\geq A \\ \text{accept } f = f_0 \text{ if } L_m &\leq B \\ \text{draw another } z \text{ if } B < L_m &< A \end{aligned}$$

Note

The sequel *A Bayesian Formulation of Friedman and Wald's Problem* uses A and B for thresholds on the posterior probability π_k that $f = f_1$, and L_0 and L_1 for losses from wrong decisions.

There we write Λ_k for the likelihood ratio and A_Λ, B_Λ for the thresholds on it that correspond to Wald's A and B here.

The following figure illustrates aspects of Wald's procedure.

26.5 Links between A, B and α, β

In chapter 3 of **Sequential Analysis** [Wald, 1947] Wald establishes the inequalities

$$\begin{aligned} \frac{\alpha}{1-\beta} &\leq \frac{1}{A} \\ \frac{\beta}{1-\alpha} &\leq B \end{aligned}$$

These inequalities follow from a change of measure.

Let P_i and E_i denote probabilities and mathematical expectations computed under the assumption that f_i generates the data.

Let N be the random number of draws at which the test stops, and assume that $P_0\{N < \infty\} = P_1\{N < \infty\} = 1$.

On the event $\{N = n\}$, the factor $L_n^{-1} = p_{0n}/p_{1n}$ converts the joint density p_{1n} of $z_1, \ldots, z_n$ into the joint density p_{0n}.

The test rejects H_0 when $L_N \geq A$, so

$$\alpha = P_0\{L_N \geq A\} = E_1\left[L_N^{-1}\mathbf{1}\{L_N \geq A\}\right] \leq \frac{1}{A}P_1\{L_N \geq A\} = \frac{1-\beta}{A}$$

The test accepts H_0 when $L_N \leq B$, so

$$\beta = P_1\{L_N \leq B\} = E_0\left[L_N\mathbf{1}\{L_N \leq B\}\right] \leq B\,P_0\{L_N \leq B\} = B(1-\alpha)$$

The same change of measure underlies importance sampling in *Mean of a Likelihood Ratio Process*.

Both inequalities hold with equality when L_N lands exactly on A or on B.

They are strict when L_N can jump past A or B at the stopping time.

His analysis of these inequalities leads Wald to recommend the following approximations as rules for setting A and B that come close to attaining a decision maker's target values for probabilities α of a type I and β of a type II error:

$$\begin{aligned} A &\approx a(\alpha,\beta) \equiv \frac{1-\beta}{\alpha} \\ B &\approx b(\alpha,\beta) \equiv \frac{\beta}{1-\alpha} \end{aligned} \tag{26.1}$$

For small values of α and β, Wald shows that approximation (26.1) provides a good way to set A and B.

In particular, Wald constructs a mathematical argument that leads him to conclude that the use of approximation (26.1) rather than the true functions $A(\alpha,\beta), B(\alpha,\beta)$ for setting A and B

> ... cannot result in any appreciable increase in the value of either α or β. In other words, for all practical purposes the test corresponding to $A = a(\alpha,\beta), B = b(\alpha,\beta)$ provides at least the same protection against wrong decisions as the test corresponding to $A = A(\alpha,\beta)$ and $B = B(\alpha,\beta)$.
>
> Thus, the only disadvantage that may arise from using $a(\alpha,\beta), b(\alpha,\beta)$ instead of $A(\alpha,\beta), B(\alpha,\beta)$, respectively, is that it may result in an appreciable increase in the number of observations required by the test.

Wald's argument runs as follows.

Let α' and β' be the error probabilities of the test that sets $A = a(\alpha,\beta)$ and $B = b(\alpha,\beta)$.

Applying the inequalities above to that test gives

$$\frac{\alpha'}{1-\beta'} \leq \frac{\alpha}{1-\beta}, \quad \frac{\beta'}{1-\alpha'} \leq \frac{\beta}{1-\alpha}$$

These imply

$$\alpha' \leq \frac{\alpha}{1-\beta}, \quad \beta' \leq \frac{\beta}{1-\alpha}, \quad \alpha'+\beta' \leq \alpha+\beta \tag{26.2}$$

The third inequality comes from cross-multiplying the two inequalities above and adding them.

When α and β are small, $\alpha/(1-\beta)$ and $\beta/(1-\alpha)$ are close to α and β.

The test attains $\alpha' = \alpha$ and $\beta' = \beta$ only when L_N never jumps past A or B.

We'll write some Python code to help us illustrate Wald's claims about how α and β are related to the parameters A and B that characterize his sequential probability ratio test.

26.6 Simulations

We experiment with different distributions f_0 and f_1 to examine how Wald's test performs under various conditions.

Our goal in conducting these simulations is to understand trade-offs between decision speed and accuracy associated with Wald's **sequential probability ratio test**.

Specifically, we will watch how:

- The decision thresholds A and B (or equivalently the target error rates α and β) affect the average stopping time
- The discrepancy between distributions f_0 and f_1 affects average stopping times

We will focus on the case where f_0 and f_1 are beta distributions since it is easy to control the overlapping regions of the two densities by adjusting their shape parameters.

First, we define a namedtuple to store all the parameters we need for our simulation studies.

We also compute Wald's recommended thresholds A and B based on the target type I and type II errors α and β

```
SPRTParams = namedtuple('SPRTParams',
                ['α', 'β',  # Target type I and type II errors
                'a0', 'b0', # Shape parameters for f_0
                'a1', 'b1', # Shape parameters for f_1
                'N',        # Number of simulations
                'seed'])

@njit
def compute_wald_thresholds(α, β):
    """Compute Wald's recommended thresholds."""
    A = (1 - β) / α
    B = β / (1 - α)
    return A, B, np.log(A), np.log(B)
```

Now we can run the simulation following Wald's recommendation.

We'll compare the log-likelihood ratio to logarithms of the thresholds $\log(A)$ and $\log(B)$.

The following algorithm underlies our simulations.

1. Compute thresholds $A = \frac{1-\beta}{\alpha}$, $B = \frac{\beta}{1-\alpha}$ and work with $\log A$, $\log B$.
2. Given true distribution (either f_0 or f_1):
    - Initialize log-likelihood ratio $\log L_0 = 0$
    - Repeat:
        - Draw observation z from the true distribution
        - Update: $\log L_{n+1} \leftarrow \log L_n + (\log f_1(z) - \log f_0(z))$
        - If $\log L_{n+1} \geq \log A$: stop, reject H_0
        - If $\log L_{n+1} \leq \log B$: stop, accept H_0
3. Repeat step 2 for N replications with $N/2$ replications for each distribution, compute the empirical type I error $\hat{\alpha}$ and type II error $\hat{\beta}$ with

$$\hat{\alpha} = \frac{\#\text{ of times reject } H_0 \text{ when } f_0 \text{ is true}}{\#\text{ of replications with } f_0 \text{ true}}$$

$$\hat{\beta} = \frac{\#\text{ of times accept } H_0 \text{ when } f_1 \text{ is true}}{\#\text{ of replications with } f_1 \text{ true}}$$

```
@njit
def sprt_single_run(a0, b0, a1, b1, logA, logB, true_f0, seed):
    """Run a single SPRT until a decision is reached."""
    log_L = 0.0
    n = 0
    np.random.seed(seed)

    while True:
        z = np.random.beta(a0, b0) if true_f0 else np.random.beta(a1, b1)
        n += 1

        # Update log-likelihood ratio
        log_L += np.log(p(z, a1, b1)) - np.log(p(z, a0, b0))

        # Check stopping conditions
        if log_L >= logA:
            return n, False  # Reject H0
        elif log_L <= logB:
            return n, True   # Accept H0

```
    return {
        'stopping_times': stopping_times,
        'decisions_h0': decisions_h0_bool,
        'truth_h0': truth_h0_bool,
        'type_I': type_I,
        'type_II': type_II
    }

# Run simulation
params = SPRTParams(α=0.05, β=0.10, a0=2, b0=5, a1=5, b1=2, N=20000, seed=1)
results = run_sprt(params)

print(f"Average stopping time: {results['stopping_times'].mean():.2f}")
print(f"Empirical type I  error: {results['type_I']:.3f} (target = {params.α})")
print(f"Empirical type II error: {results['type_II']:.3f} (target = {params.β})")
```

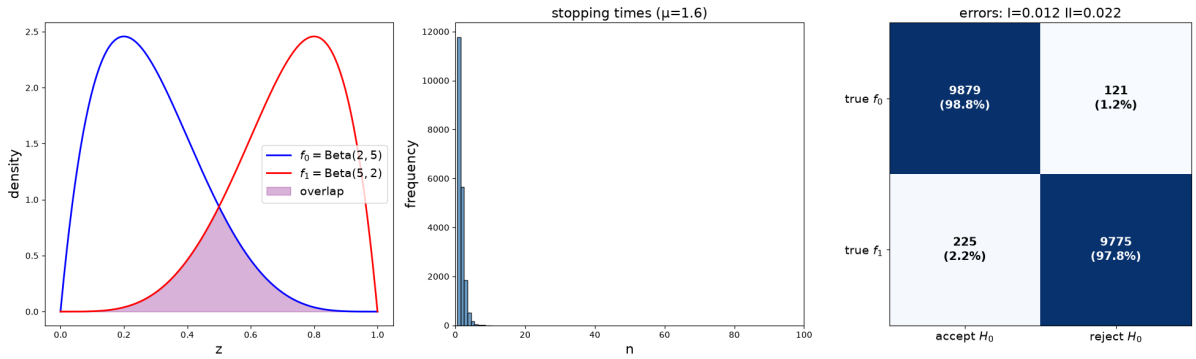
```
Average stopping time: 1.59
Empirical type I  error: 0.012 (target = 0.05)
Empirical type II error: 0.022 (target = 0.1)
```

As anticipated in the passage above in which Wald discussed the quality of $a(\alpha, \beta), b(\alpha, \beta)$ given in approximation (26.1), we find that the algorithm actually gives **lower** type I and type II error rates than the target values.

The empirical error rates satisfy Wald's bounds (26.2), which here are $\alpha' \leq 0.05/0.90 \approx 0.056$, $\beta' \leq 0.10/0.95 \approx 0.105$, and $\alpha' + \beta' \leq 0.15$.

The bounds are far from tight because $f_0 = \text{Beta}(2, 5)$ and $f_1 = \text{Beta}(5, 2)$ are far apart.

A single draw often carries $\log L_m$ far past $\log A$ or $\log B$, and that overshoot pushes α' and β' below α and β.



Note

For recent work on the quality of approximation (26.1), see, e.g., [Fischer and Ramdas, 2024].

The following code creates a few graphs that illustrate the results of our simulation.

Let's plot the results of our simulation

```
plot_sprt_results(results, params)
```

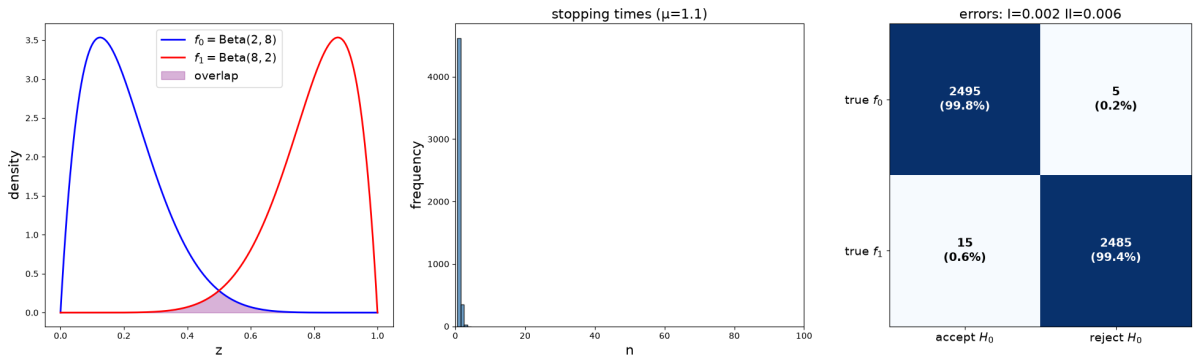
In this example, the stopping time never exceeds 10, and the mean stopping time is 1.59.

We can construct a 2×2 "confusion matrix" whose diagonal elements count the number of times that Wald's decision rule correctly accepts and rejects the null hypothesis.

```
print("Confusion Matrix data:")
print(f"Type I error: {results['type_I']:.3f}")
print(f"Type II error: {results['type_II']:.3f}")
```

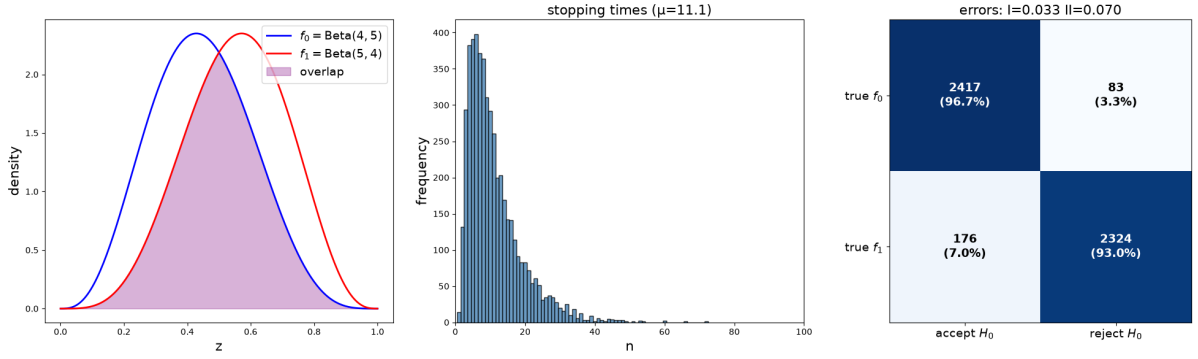
```
Confusion Matrix data:
Type I error: 0.012
Type II error: 0.022
```

Next we use our code to study three different f_0, f_1 pairs having different discrepancies between distributions.



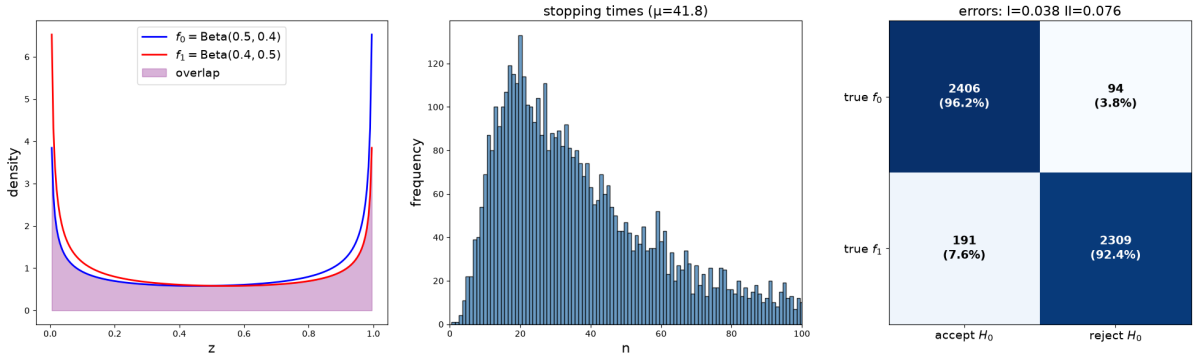
We plot the same three graphs we used above for each pair of distributions

```
params_1 = SPRTParams(α=0.05, β=0.10, a0=2, b0=8, a1=8, b1=2, N=5000, seed=42)
results_1 = run_sprt(params_1)



params_2 = SPRTParams(α=0.05, β=0.10, a0=4, b0=5, a1=5, b1=4, N=5000, seed=42)
results_2 = run_sprt(params_2)

params_3 = SPRTParams(α=0.05, β=0.10, a0=0.5, b0=0.4, a1=0.4,
                      b1=0.5, N=5000, seed=42)
results_3 = run_sprt(params_3)
```



```
plot_sprt_results(results_1, params_1)
```

```
plot_sprt_results(results_2, params_2)
```

```
plot_sprt_results(results_3, params_3)
```

Notice that the stopping times are less when the two distributions are farther apart.

This makes sense.

When two distributions are "far apart", it should not take too long to decide which one is generating the data.

When two distributions are "close", it should take longer to decide which one is generating the data.

The *Kullback–Leibler divergence* described in *Statistical Divergence Measures* measures how far apart two distributions are.

Wald linked it to the expected number of draws that his test requires.

Under H_0, $\log L_N = \sum_{i=1}^{N} \log \frac{f_1(z_i)}{f_0(z_i)}$ is a sum of a random number N of IID terms, each with mean $E_0 \log \frac{f_1(z)}{f_0(z)} = -KL(f_0, f_1)$.

Under H_1, each term has mean $E_1 \log \frac{f_1(z)}{f_0(z)} = KL(f_1, f_0)$.

Because N is a stopping time with finite mean, **Wald's identity** gives

$$E_0[\log L_N] = -E_0[N]\, KL(f_0, f_1), \qquad E_1[\log L_N] = E_1[N]\, KL(f_1, f_0) \tag{26.3}$$

This section of *Likelihood Ratio Processes* describes the link between KL divergence and the expected log likelihood ratio for a fixed number of draws.

Wald ignored overshoot: he approximated $\log L_N$ by $\log A$ when the test rejects H_0 and by $\log B$ when it accepts H_0.

Setting $P_0\{L_N \geq A\} \approx \alpha$ and $P_1\{L_N \leq B\} \approx \beta$ in (26.3) then gives Wald's approximations to the **average sample numbers**

$$E_0[N] \approx \frac{(1-\alpha)\log(1/B) - \alpha \log A}{KL(f_0, f_1)}, \qquad E_1[N] \approx \frac{(1-\beta)\log A - \beta \log(1/B)}{KL(f_1, f_0)} \tag{26.4}$$

KL divergence is not symmetric, so (26.4) divides by $KL(f_0, f_1)$ under H_0 and by $KL(f_1, f_0)$ under H_1.

In the experiments below, $f_0 = \text{Beta}(a, b)$ and $f_1 = \text{Beta}(b, a)$, so $f_1(z) = f_0(1-z)$ and $KL(f_0, f_1) = KL(f_1, f_0)$.

Half of our replications draw from f_0 and half from f_1, so (26.4) makes the mean stopping time proportional to $1/KL(f_0, f_1)$.

We compute $KL(f_0, f_1)$ and the mean stopping time for 100 such pairs and compare the mean stopping time with (26.4).

      f"{ratio.min():.2f} (closest pair) to {ratio.max():.1f} (farthest pair)")
```

```
corr(mean stopping time, 1/KL) = 0.9999
simulated / approximate mean stopping time: 1.14 (closest pair) to 28.1 (farthest␣
↪pair)
```

On log scales, Wald's approximation is a straight line with slope -1.

Across the 100 pairs, the correlation between the mean stopping time and $1/KL(f_0, f_1)$ is 0.9999.

The mean stopping time is close to a linear function of $1/KL(f_0, f_1)$.

The simulated mean stopping times lie above Wald's approximation for two reasons.

Overshoot makes $|\log L_N|$ larger than $\log A$ or $\log(1/B)$, so by (26.3) it makes $E_0[N]$ and $E_1[N]$ larger than (26.4).

The test always takes at least one draw, so the mean stopping time cannot fall below 1, while (26.4) goes to zero as $KL(f_0, f_1)$ grows.

Exercise 26.8.4 asks you to study these two sources of discrepancy.

Below are sampled examples from the experiments we have above

```

```

Let's pause and think about the table more carefully by referring back to (26.1).

Recall that $A = \frac{1-\beta}{\alpha}$ and $B = \frac{\beta}{1-\alpha}$.

When we multiply A by a factor less than 1 (making A smaller), we are effectively making it easier to reject the null hypothesis H_0.

This increases the probability of Type I errors.

When we multiply B by a factor greater than 1 (making B larger), we are making it easier to accept the null hypothesis H_0.

This increases the probability of Type II errors.

The table confirms this intuition: as A decreases and B increases from Wald's approximate values (26.1), both Type I and Type II error rates increase, while the mean stopping time decreases.

26.7 Related lectures

We'll dig deeper into some of the ideas used here in the following earlier and later lectures:

- In *this sequel*, we reformulate the problem from the perspective of a **Bayesian statistician** who views parameters as vectors of random variables that are jointly distributed with the observables they are concerned about.
- The concept of **exchangeability**, which underlies much of statistical learning, is explored in depth in our *lecture on exchangeable random variables*.
- For a deeper understanding of likelihood ratio processes and their role in frequentist and Bayesian statistical theories, see *Likelihood Ratio Processes*.
- Building on that foundation, *Likelihood Ratio Processes and Bayesian Learning* examines the role of likelihood ratio processes in **Bayesian learning**.
- Finally, *this later lecture* revisits the subject discussed here and examines whether the frequentist decision rule that the Navy ordered the captain to use would perform better or worse than Abraham Wald's sequential decision rule.

26.8 Exercises

In the first two exercises below, please try to rewrite the entire SPRT suite in this lecture.

Exercise 26.8.1

In the first exercise, we apply the sequential probability ratio test to distinguish two models generated by 3-state Markov chains

(For a review on likelihood ratio processes for Markov chains, see *this section*.)

Consider distinguishing between two 3-state Markov chain models using Wald's sequential probability ratio test.

You have competing hypotheses about the transition probabilities:

- H_0: The chain follows transition matrix $P^{(0)}$

- H_1: The chain follows transition matrix $P^{(1)}$

Given transition matrices:

$$P^{(0)} = \begin{bmatrix} 0.7 & 0.2 & 0.1 \\ 0.3 & 0.5 & 0.2 \\ 0.1 & 0.3 & 0.6 \end{bmatrix}, \quad P^{(1)} = \begin{bmatrix} 0.5 & 0.3 & 0.2 \\ 0.2 & 0.6 & 0.2 \\ 0.2 & 0.2 & 0.6 \end{bmatrix}$$

For a sequence of observations $(x_0, x_1, \ldots, x_t)$, the likelihood ratio is:

$$\Lambda_t = \frac{\pi^{(1)}_{x_0}}{\pi^{(0)}_{x_0}} \prod_{s=1}^{t} \frac{P^{(1)}_{x_{s-1},x_s}}{P^{(0)}_{x_{s-1},x_s}}$$

where $\pi^{(i)}$ is the stationary distribution under hypothesis i.

Tasks:

1. Implement the likelihood ratio computation for Markov chains
2. Implement Wald's sequential test with Type I error $\alpha = 0.05$ and Type II error $\beta = 0.10$
3. Run 1000 simulations under each hypothesis and compute empirical error rates
4. Analyze the distribution of stopping times

The test stops when:

- $\Lambda_t \geq A = \frac{1-\beta}{\alpha} = 18$: Reject H_0
- $\Lambda_t \leq B = \frac{\beta}{1-\alpha} = 0.105$: Accept H_0

Solution

Below is one solution to the exercise.

In the lecture, we write the code more verbosely to illustrate the concepts clearly.

In the code below, we simplified some of the code structure for a shorter presentation.

First we define the parameters for the Markov chain SPRT

```
MarkovSPRTParams = namedtuple('MarkovSPRTParams',
            ['α', 'β', 'P_0', 'P_1', 'N', 'seed'])

def compute_stationary_distribution(P):
    """Compute stationary distribution of transition matrix P."""
    eigenvalues, eigenvectors = np.linalg.eig(P.T)
    idx = np.argmin(np.abs(eigenvalues - 1))
    pi = np.real(eigenvectors[:, idx])
    return pi / pi.sum()

@njit
def simulate_markov_chain(P, pi_0, T, seed):
    """Simulate a Markov chain path."""
    np.random.seed(seed)
    path = np.zeros(T, dtype=np.int32)

    cumsum_pi = np.cumsum(pi_0)
    path[0] = np.searchsorted(cumsum_pi, np.random.uniform())

    for t in range(1, T):
        cumsum_row = np.cumsum(P[path[t-1]])
        path[t] = np.searchsorted(cumsum_row, np.random.uniform())

    return path
```

Here we define the function that runs SPRT for Markov chains

```
@njit
def markov_sprt_single_run(P_0, P_1, π_0, π_1,
                           logA, logB, true_P, true_π, seed):
    """Run single SPRT for Markov chains."""
    max_n = 10000
    path = simulate_markov_chain(true_P, true_π, max_n, seed)

    log_L = np.log(π_1[path[0]] / π_0[path[0]])
    if log_L >= logA: return 1, False
    if log_L <= logB: return 1, True

    for t in range(1, max_n):
        prev_state, curr_state = path[t-1], path[t]
        p_1, p_0 = P_1[prev_state, curr_state], P_0[prev_state, curr_state]

        if p_0 > 0:
            log_L += np.log(p_1 / p_0)
        elif p_1 > 0:
            log_L = np.inf

        if log_L >= logA: return t+1, False
        if log_L <= logB: return t+1, True

    return max_n, log_L < 0

def run_markov_sprt(params):
    """Run SPRT for Markov chains."""
    π_0 = compute_stationary_distribution(params.P_0)
    π_1 = compute_stationary_distribution(params.P_1)
    A, B, logA, logB = compute_wald_thresholds(params.α, params.β)

    stopping_times = np.zeros(params.N, dtype=np.int64)
    decisions_h0 = np.zeros(params.N, dtype=bool)
    truth_h0 = np.zeros(params.N, dtype=bool)

    for i in range(params.N):
        true_P, true_π = (params.P_0, π_0) if i % 2 == 0 else (params.P_1, π_1)
        truth_h0[i] = i % 2 == 0

        n, accept_h0 = markov_sprt_single_run(
            params.P_0, params.P_1, π_0, π_1, logA, logB,
            true_P, true_π, params.seed + i)

        stopping_times[i] = n
        decisions_h0[i] = accept_h0

    type_I = np.sum(truth_h0 & ~decisions_h0) / np.sum(truth_h0)
    type_II = np.sum(~truth_h0 & decisions_h0) / np.sum(~truth_h0)

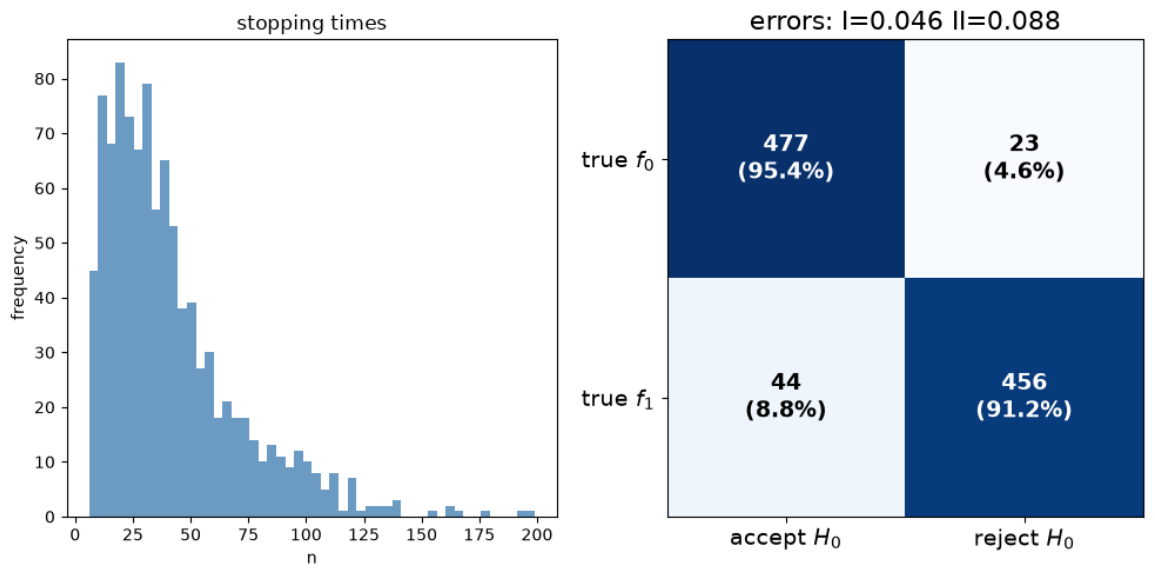
    return {
        'stopping_times': stopping_times, 'decisions_h0': decisions_h0,
        'truth_h0': truth_h0, 'type_I': type_I, 'type_II': type_II
    }
```

Now we can run the SPRT for the Markov chain models and visualize the results

```
# Run Markov chain SPRT
P_0 = np.array([[0.7, 0.2, 0.1],
```

```
                [0.3, 0.5, 0.2],
                [0.1, 0.3, 0.6]])

P_1 = np.array([[0.5, 0.3, 0.2],
                [0.2, 0.6, 0.2],
                [0.2, 0.2, 0.6]])



params_markov = MarkovSPRTParams(α=0.05, β=0.10,
                         P_0=P_0, P_1=P_1, N=1000, seed=42)
results_markov = run_markov_sprt(params_markov)

fig, (ax1, ax2) = plt.subplots(1, 2, figsize=(10, 5))

ax1.hist(results_markov['stopping_times'],
            bins=50, color="steelblue", alpha=0.8)
ax1.set_title("stopping times")
ax1.set_xlabel("n")
ax1.set_ylabel("frequency")

plot_confusion_matrix(results_markov, ax2)

plt.tight_layout()
plt.show()
```

Exercise 26.8.2

In this exercise, apply Wald's sequential test to distinguish between two VAR(1) models with different dynamics and noise structures.

For a review of the likelihood ratio process with VAR models, see *Likelihood Processes For VAR Models*.

Given VAR models under each hypothesis:

- H_0: $x_{t+1} = A^{(0)} x_t + C^{(0)} w_{t+1}$

- H_1: $x_{t+1} = A^{(1)} x_t + C^{(1)} w_{t+1}$

where $w_t \sim \mathcal{N}(0, I)$ and:

$$A^{(0)} = \begin{bmatrix} 0.8 & 0.1 \\ 0.2 & 0.7 \end{bmatrix}, \quad C^{(0)} = \begin{bmatrix} 0.3 & 0.1 \\ 0.1 & 0.3 \end{bmatrix}$$

$$A^{(1)} = \begin{bmatrix} 0.6 & 0.2 \\ 0.3 & 0.5 \end{bmatrix}, \quad C^{(1)} = \begin{bmatrix} 0.4 & 0 \\ 0 & 0.4 \end{bmatrix}$$

Tasks:

1. Implement the VAR likelihood ratio using the functions from the VAR lecture
2. Implement Wald's sequential test with $\alpha = 0.05$ and $\beta = 0.10$
3. Analyze performance under both hypotheses and with model misspecification, when a third VAR(1) model generates the data
4. Compare with the Markov chain case in terms of stopping times and accuracy

Solution

Below is one solution to the exercise.

First we define the parameters for the VAR models and simulator

```
VARSPRTParams = namedtuple('VARSPRTParams',
            ['α', 'β', 'A_0', 'C_0', 'A_1', 'C_1', 'N', 'seed'])

def create_var_model(A, C):
    """Create VAR model."""
    μ_0 = np.zeros(A.shape[0])
    CC = C @ C.T
    Σ_0 = sp.linalg.solve_discrete_lyapunov(A, CC)

    CC_inv = np.linalg.inv(CC + 1e-10 * np.eye(CC.shape[0]))
    Σ_0_inv = np.linalg.inv(Σ_0 + 1e-10 * np.eye(Σ_0.shape[0]))

    return {
        'A': A, 'C': C, 'μ_0': μ_0, 'Σ_0': Σ_0,
        'CC_inv': CC_inv, 'Σ_0_inv': Σ_0_inv,
        'log_det_CC': np.log(
            np.linalg.det(CC + 1e-10 * np.eye(CC.shape[0]))),
        'log_det_Σ_0': np.log(
            np.linalg.det(Σ_0 + 1e-10 * np.eye(Σ_0.shape[0])))
    }
```

Now we define the likelihood ratio for the VAR models and the SPRT function similar to the Markov chain case

```
def var_log_likelihood(x_curr, x_prev, model, initial=False):
    """Compute VAR log-likelihood."""
    n = len(x_curr)
    if initial:
        diff = x_curr - model['μ_0']
        return -0.5 * (n * np.log(2 * np.pi) + model['log_det_Σ_0'] +
                       diff @ model['Σ_0_inv'] @ diff)
    else:
        diff = x_curr - model['A'] @ x_prev
```

```
        return -0.5 * (n * np.log(2 * np.pi) + model['log_det_CC'] +
                       diff @ model['CC_inv'] @ diff)

def var_sprt_single_run(model_0, model_1, model_true,
                        logA, logB, seed):
    """Single VAR SPRT run."""
    np.random.seed(seed)
    max_T = 500

    # Generate VAR path
    Σ_chol = np.linalg.cholesky(model_true['Σ_0'])
    x = model_true['μ_0'] + Σ_chol @ np.random.randn(
                len(model_true['μ_0']))

    # Initial likelihood ratio
    log_L = (var_log_likelihood(x, None, model_1, True) -
             var_log_likelihood(x, None, model_0, True))

    if log_L >= logA: return 1, False
    if log_L <= logB: return 1, True

    # Sequential updates
    for t in range(1, max_T):
        x_prev = x.copy()
        w = np.random.randn(model_true['C'].shape[1])
        x = model_true['A'] @ x + model_true['C'] @ w

        log_L += (var_log_likelihood(x, x_prev, model_1) -
                  var_log_likelihood(x, x_prev, model_0))

        if log_L >= logA: return t+1, False
        if log_L <= logB: return t+1, True

    return max_T, log_L < 0

def run_var_sprt(params):
    """Run VAR SPRT."""

    model_0 = create_var_model(params.A_0, params.C_0)
    model_1 = create_var_model(params.A_1, params.C_1)
    A, B, logA, logB = compute_wald_thresholds(params.α, params.β)

    stopping_times = np.zeros(params.N)
    decisions_h0 = np.zeros(params.N, dtype=bool)
    truth_h0 = np.zeros(params.N, dtype=bool)

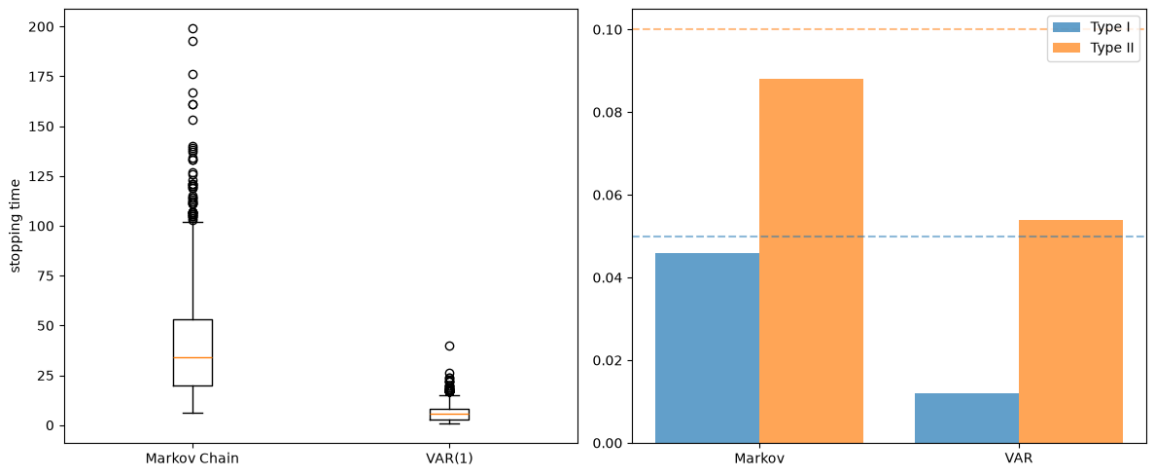
    for i in range(params.N):
        model_true = model_0 if i % 2 == 0 else model_1
        truth_h0[i] = i % 2 == 0

        n, accept_h0 = var_sprt_single_run(model_0, model_1, model_true,
                                           logA, logB, params.seed + i)
        stopping_times[i] = n
        decisions_h0[i] = accept_h0

    type_I = np.sum(truth_h0 & ~decisions_h0) / np.sum(truth_h0)
    type_II = np.sum(~truth_h0 & decisions_h0) / np.sum(~truth_h0)
```

```
    return {'stopping_times': stopping_times,
            'decisions_h0': decisions_h0,
            'truth_h0': truth_h0,
            'type_I': type_I, 'type_II': type_II}
```

Let's run SPRT and visualize the results



```
# Run VAR SPRT
A_0 = np.array([[0.8, 0.1],
                [0.2, 0.7]])
C_0 = np.array([[0.3, 0.1],
                [0.1, 0.3]])
A_1 = np.array([[0.6, 0.2],
                [0.3, 0.5]])
C_1 = np.array([[0.4, 0.0],
                [0.0, 0.4]])

params_var = VARSPRTParams(α=0.05, β=0.10,
                A_0=A_0, C_0=C_0, A_1=A_1, C_1=C_1,
                N=1000, seed=42)
results_var = run_var_sprt(params_var)

fig, (ax1, ax2) = plt.subplots(1, 2, figsize=(12, 5))

ax1.boxplot([results_markov['stopping_times'],
             results_var['stopping_times']],
            tick_labels=['Markov Chain', 'VAR(1)'])
ax1.set_ylabel('stopping time')

x = np.arange(2)
ax2.bar(x - 0.2, [results_markov['type_I'], results_var['type_I']],
        0.4, label='Type I', alpha=0.7)
ax2.bar(x + 0.2, [results_markov['type_II'], results_var['type_II']],
        0.4, label='Type II', alpha=0.7)
ax2.axhline(y=0.05, linestyle='--', alpha=0.5, color='C0')
ax2.axhline(y=0.10, linestyle='--', alpha=0.5, color='C1')
ax2.set_xticks(x), ax2.set_xticklabels(['Markov', 'VAR'])
ax2.legend()
plt.tight_layout()
plt.show()
```

Both tests keep their empirical error rates below the targets, and the VAR test stops much sooner than the Markov chain test.

Now we turn to misspecification.

Suppose that a third VAR(1) model h with

$$A^{(h)} = (1-\lambda)A^{(0)} + \lambda A^{(1)}, \quad C^{(h)} = (1-\lambda)C^{(0)} + \lambda C^{(1)}, \quad \lambda \in [0,1]$$

generates the data.

Let $f_i(x_{t+1}|x_t)$ be the conditional density of model i.

Under h, the expected increment of $\log L_t$ per period is

$$E_h\left[\log \frac{f_1(x_{t+1}|x_t)}{f_0(x_{t+1}|x_t)}\right] = KL(h, f_0) - KL(h, f_1)$$

where $KL(h, f_i)$ is the KL divergence of $f_i(\cdot|x_t)$ from the conditional density of h, averaged over the stationary distribution of x_t under h.

This is the formula in *this section* of *Likelihood Ratio Processes*, applied to conditional densities.

When $KL(h, f_0) > KL(h, f_1)$, $\log L_t$ drifts up and the test tends to reject H_0.

When $KL(h, f_0) < KL(h, f_1)$, $\log L_t$ drifts down and the test tends to accept H_0.

Either way, the test tends to select the model that is closer to h in KL divergence.

Let $\Sigma_i = C^{(i)}C^{(i)\top}$ and let V_h be the stationary covariance matrix of x_t under h.

For our Gaussian models,

$$E_h[\log f_i(x_{t+1}|x_t)] = -\frac{1}{2}\left[2\log 2\pi + \log\det\Sigma_i + \operatorname{tr}(\Sigma_i^{-1}\Sigma_h) + \operatorname{tr}\left((A^{(h)} - A^{(i)})^\top \Sigma_i^{-1}(A^{(h)} - A^{(i)})V_h\right)\right]$$

The code below computes $KL(h, f_0) - KL(h, f_1)$ with this formula and runs the test on 1000 paths from h for several values of λ.

```
def var_drift(A_h, C_h, model_0, model_1):
    """KL(h, f_0) - KL(h, f_1) per period under the stationary law of h."""
    n = A_h.shape[0]
    Σ_h = C_h @ C_h.T
    V_h = sp.linalg.solve_discrete_lyapunov(A_h, Σ_h)

    def expected_loglik(model):
        D = A_h - model['A']
        quad_form = (np.trace(model['CC_inv'] @ Σ_h)
                     + np.trace(D.T @ model['CC_inv'] @ D @ V_h))
        return -0.5 * (n * np.log(2 * np.pi) + model['log_det_CC']
                       + quad_form)

    return expected_loglik(model_1) - expected_loglik(model_0)

model_0 = create_var_model(A_0, C_0)
model_1 = create_var_model(A_1, C_1)
_, _, logA, logB = compute_wald_thresholds(0.05, 0.10)

rows = []
for λ in [0.0, 0.25, 0.4, 0.5, 0.75, 1.0]:
    A_h = (1 - λ) * A_0 + λ * A_1
    C_h = (1 - λ) * C_0 + λ * C_1
```

```
    model_h = create_var_model(A_h, C_h)
    runs = [var_sprt_single_run(model_0, model_1, model_h,
                                logA, logB, 42 + i)
            for i in range(1000)]
    n_stop = np.array([run[0] for run in runs])
    accept_h0 = np.array([run[1] for run in runs])
    rows.append([λ, var_drift(A_h, C_h, model_0, model_1),
                 1 - accept_h0.mean(), n_stop.mean()])

df_misspec = pd.DataFrame(rows, columns=['λ', 'KL(h,f0) - KL(h,f1)',
                                         'share rejecting H0',
                                         'mean stop time'])
df_misspec.set_index('λ').round(3)
```

λ	KL(h,f0) - KL(h,f1)	share rejecting H0	mean stop time
0.00	-0.362	0.015	7.210
0.25	-0.126	0.216	10.084
0.40	0.046	0.444	10.522
0.50	0.174	0.599	9.609
0.75	0.551	0.842	7.579
1.00	1.019	0.940	5.507

At $\lambda = 0$ and $\lambda = 1$, h coincides with one of the two models.

As λ rises, $KL(h, f_0) - KL(h, f_1)$ rises and changes sign between $\lambda = 0.25$ and $\lambda = 0.4$; the share of runs that reject H_0 rises with it.

Near the sign change, $\log L_t$ has little drift, and the test takes the most draws.

A driftless random walk with small steps hits $\log A$ before $\log B$ with probability close to $\log(1/B)/(\log A - \log B) = 0.44$, close to the share of runs that reject H_0 at $\lambda = 0.4$.

Exercise 26.8.3

Wald and Wolfowitz [1948] proved that among all tests, sequential or not, whose type I and type II error probabilities do not exceed those of an SPRT, the SPRT minimizes both $E_0[N]$ and $E_1[N]$.

This exercise compares the SPRT with the fixed-sample Neyman–Pearson test that the Navy told Captain Schuyler to use.

Use `results_2`, which we computed above for $f_0 = \text{Beta}(4, 5)$ and $f_1 = \text{Beta}(5, 4)$.

1. Compute the empirical error probabilities $\hat{\alpha}$ and $\hat{\beta}$ of the SPRT and its mean stopping times under f_0 and under f_1.
2. For each $n = 1, \ldots, 40$, construct the most powerful test of size $\hat{\alpha}$ based on a fixed sample of n draws, and compute its type II error probability $\beta(n)$.
3. Find the smallest n with $\beta(n) \leq \hat{\beta}$ and compare it with the SPRT's mean stopping times.

Hint: for these two densities, $\log\left(f_1(z)/f_0(z)\right) = \log\left(z/(1-z)\right)$.

Solution

By the Neyman–Pearson lemma, the most powerful test based on n draws rejects H_0 when $S_n = \sum_{i=1}^{n} \log\left(f_1(z_i)/f_0(z_i)\right) \geq k_n$, where k_n sets $P_0\{S_n \geq k_n\} = \hat{\alpha}$.

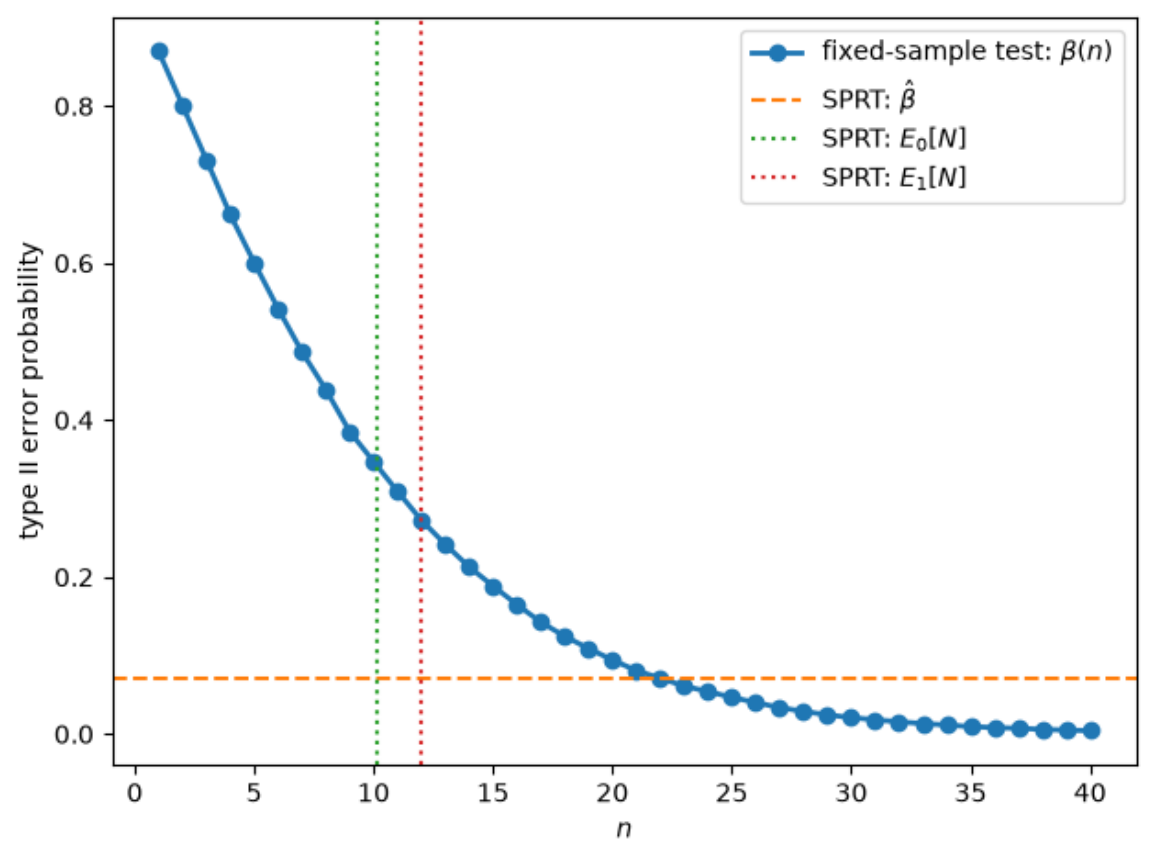
We compute the distributions of S_n under f_0 and f_1 by Monte Carlo.

```
truth_h0 = results_2['truth_h0']
stops = results_2['stopping_times']
α_hat, β_hat = results_2['type_I'], results_2['type_II']
E0_N_sprt = stops[truth_h0].mean()
E1_N_sprt = stops[~truth_h0].mean()

print(f"SPRT: α̂ = {α_hat:.3f}, β = {β_hat:.3f}, "
      f"E_0[N] = {E0_N_sprt:.1f}, E_1[N] = {E1_N_sprt:.1f}")

rng = np.random.default_rng(1234)
M, n_max = 100_000, 40

def llr_partial_sums(a, b):
    """Paths of S_n = sum of log(f_1/f_0), n = 1, ..., n_max."""
    z = rng.beta(a, b, size=(M, n_max))
    return np.cumsum(np.log(z / (1 - z)), axis=1)



S0 = llr_partial_sums(params_2.a0, params_2.b0)
S1 = llr_partial_sums(params_2.a1, params_2.b1)

ns = np.arange(1, n_max + 1)
k_n = np.quantile(S0, 1 - α_hat, axis=0)   # critical values
β_n = (S1 < k_n).mean(axis=0)              # type II error probabilities
n_star = ns[np.argmax(β_n <= β_hat)]

print(f"smallest fixed n with β(n) <= β: {n_star}")

fig, ax = plt.subplots()
ax.plot(ns, β_n, 'o-', lw=2, label=r'fixed-sample test: $\beta(n)$')
ax.axhline(β_hat, color='C1', linestyle='--', label=r'SPRT: $\hat\beta$')
ax.axvline(E0_N_sprt, color='C2', linestyle=':', label='SPRT: $E_0[N]$')
ax.axvline(E1_N_sprt, color='C3', linestyle=':', label='SPRT: $E_1[N]$')
ax.set_xlabel('$n$')
ax.set_ylabel('type II error probability')
ax.legend()
plt.tight_layout()
plt.show()
```

```
SPRT: α̂ = 0.033, β = 0.070, E_0[N] = 10.1, E_1[N] = 12.0
smallest fixed n with β(n) <= β: 23
```

To match the SPRT's error probabilities, the fixed-sample test needs 23 draws.

The SPRT needs 10.1 draws on average under f_0 and 12.0 under f_1.

On average, the SPRT uses 44 percent as many draws as the fixed-sample test under f_0 and 52 percent as many under f_1.

The theorem of Wald and Wolfowitz implies that no test with error probabilities at most $\hat{\alpha}$ and $\hat{\beta}$ does better on either count.

Exercise 26.8.4

Wald's approximation (26.4) ignores overshoot and the fact that $N \geq 1$.

1. Modify `sprt_single_run` so that it also returns $\log L_N$.
2. For every fifth beta pair generated by `generate_β_pairs`, simulate 50,000 replications under f_0 and 50,000 under f_1 and estimate $E_0[N]$, $E_1[N]$, $E_0[\log L_N]$, and $E_1[\log L_N]$.
3. Verify Wald's identity (26.3).
4. Plot the ratios of simulated $E_0[N]$ and $E_1[N]$ to Wald's approximations (26.4) against $KL(f_0, f_1)$ and explain the pattern.

Solution

We work with log densities to avoid underflow when a shape parameter is small.

```
from math import lgamma

@njit
def log_p(z, a, b):
    """Log of the beta density."""
    return (lgamma(a + b) - lgamma(a) - lgamma(b)
            + (a - 1) * np.log(z) + (b - 1) * np.log(1 - z))

@njit
def sprt_single_run_log_L(a0, b0, a1, b1, logA, logB, true_f0, seed):
    """Run a single SPRT and return N and log L_N."""
    log_L = 0.0
    n = 0
    np.random.seed(seed)

    while True:

5	1.757	2.158	2.163	1.135	2.437	2.437	1.352
10	6.347	1.162	1.160	0.314	1.206	1.210	0.374
15	16.272	1.015	1.015	0.123	1.022	1.023	0.146
19	41.573	1.001	1.000	0.048	1.001	1.002	0.057

The columns `E0_N_identity` and `E1_N_identity` compute $E_0[N]$ and $E_1[N]$ from simulated $E_i[\log L_N]$ and (26.3).

They agree with the direct estimates up to Monte Carlo error: the largest of the 40 t-statistics is 1.61 in absolute value.

All of the gap between the simulated $E_i[N]$ and (26.4) therefore comes from Wald's approximation of $E_i[\log L_N]$, which ignores overshoot.

At the stopping time, $\log L_N$ lies beyond the threshold that it crosses.

Overshoot also pushes the error probabilities below α and β.

Both effects make $|E_i[\log L_N]|$ larger than the value that Wald's approximation assigns to it, so (26.4) understates $E_i[N]$.

For the closest pair, each draw moves $\log L_m$ by a small amount, the overshoot is small relative to $\log A$ and $\log(1/B)$, and the ratio is about 1.1.

As $KL(f_0, f_1)$ grows, a single draw often moves $\log L_m$ by more than the distance between $\log B$ and $\log A$.

Then the test stops after one or two draws, the overshoot dominates, and the ratio grows because (26.4) goes to zero while $N \geq 1$.

27.1 Overview

This lecture revisits the statistical decision problem presented to Milton Friedman and W. Allen Wallis during World War II when they were analysts at the U.S. Government's Statistical Research Group at Columbia University.

In *an earlier lecture*, we described how Abraham Wald [Wald, 1947] solved the problem by extending frequentist hypothesis testing techniques and formulating the problem sequentially.

Note

Wald's idea of formulating the problem sequentially created links to the **dynamic programming** that Richard Bellman developed in the 1950s.

Arrow *et al.* [1949] computed Bayes solutions of sequential decision problems by backward induction, anticipating Bellman's methods.

Wald and Wolfowitz [1948] used Bayes solutions to prove that Wald's sequential probability ratio test is optimal.

A section below shows that the Bayesian decision rule studied in this lecture is a sequential probability ratio test.

As we learned in *Elementary Probability with Matrices* and *Two Meanings of Probability*, a frequentist statistician views a probability distribution as measuring relative frequencies of a statistic that he anticipates constructing from a very long sequence of i.i.d. draws from a known probability distribution.

That known probability distribution is his 'hypothesis'.

A frequentist statistician studies the distribution of that statistic under that known probability distribution

- when the distribution is a member of a set of parameterized probability distributions, his hypothesis takes the form of a particular parameter vector.
- this is what we mean when we say that the frequentist statistician 'conditions on the parameters'
- he regards the parameters as fixed numbers that are known to nature, but not to him.
- the statistician copes with his ignorance of those parameters by constructing type I and type II errors associated with frequentist hypothesis testing.

In this lecture, we reformulate Friedman and Wald's problem by transforming our point of view from the 'objective' frequentist perspective of *the lecture on Wald's sequential analysis* to an explicitly 'subjective' perspective taken by a Bayesian decision maker who regards parameters not as fixed numbers but as (hidden) random variables that are jointly distributed with the random variables that he can observe by sampling from that joint distribution.

To form that joint distribution, the Bayesian statistician supplements the conditional distributions used by the frequentist statistician with a prior probability distribution over the parameters that represents his personal, subjective opinion about them.

That lets the Bayesian statistician calculate the joint distribution that he requires to calculate the conditional distributions that he wants.

To proceed in this way, we endow our decision maker with

- an initial prior subjective probability $\pi_{-1} \in (0, 1)$ that nature uses to generate $\{z_k\}$ as a sequence of i.i.d. draws from f_1 rather than f_0.
- faith in Bayes' law as a way to revise his subjective beliefs as observations on $\{z_k\}$ sequence arrive.
- a loss function that tells how the decision maker values type I and type II errors.

In our *previous frequentist version*, key ideas in play were:

- Type I and type II statistical errors
  - a type I error occurs when you reject a null hypothesis that is true
  - a type II error occurs when you accept a null hypothesis that is false
- Abraham Wald's **sequential probability ratio test**
- The **power** of a statistical test
- The **critical region** of a statistical test
- A **most powerful test**

In this lecture about a Bayesian reformulation of the problem, additional ideas at work are

- an initial prior probability π_{-1} that model f_1 generates the data
- Bayes' Law
- a sequence of posterior probabilities that model f_1 is generating the data
- dynamic programming

This lecture uses ideas studied in the lectures on *likelihood ratio processes*, *their roles in Bayesian learning*, and *this lecture on exchangeability*.

Blackwell's Theorem on Comparing Experiments studies a complementary question: how to rank experiments by their informativeness.

Here the experiment is fixed, and the decision maker chooses when to stop sampling from it.

We'll begin with some imports:

```
import numpy as np
import matplotlib.pyplot as plt
from numba import jit, prange, float64, int64
from numba.experimental import jitclass
from math import gamma
```

27.2 A Dynamic Programming Approach

The following presentation of the problem closely follows Dimitri Bertsekas's treatment in **Dynamic Programming and Stochastic Control** [Bertsekas, 1976].

A decision-maker can observe a sequence of draws of a random variable z.

He (or she) wants to know which of two probability distributions f_0 or f_1 governs z.

Conditional on knowing that successive observations are drawn from distribution f_0, the sequence of random variables is independently and identically distributed (IID).

Conditional on knowing that successive observations are drawn from distribution f_1, the sequence of random variables is also independently and identically distributed (IID).

But the observer does not know which of the two distributions generated the sequence.

For reasons explained in *Exchangeability and Bayesian Updating*, this means that the sequence is not IID.

The observer has something to learn, namely, whether the observations are drawn from f_0 or from f_1.

The decision maker wants to decide which of the two distributions is generating outcomes.

We adopt a Bayesian formulation.

The decision maker begins with a prior probability

$$\pi_{-1} = \mathbb{P}\{f = f_1 \mid \text{ no observations}\} \in (0, 1)$$

Note

In Bertsekas [1976], the belief is associated with the distribution f_0, but here we associate the belief with the distribution f_1 to match the discussions in *the lecture on Wald's sequential analysis*.

After observing $k+1$ observations $z_k, z_{k-1}, \ldots, z_0$, he updates his personal probability that the observations are described by distribution f_1 to

$$\pi_k = \mathbb{P}\{f = f_1 \mid z_k, z_{k-1}, \ldots, z_0\}$$

which is calculated recursively by applying Bayes' law:

$$\pi_{k+1} = \frac{\pi_k f_1(z_{k+1})}{(1-\pi_k) f_0(z_{k+1}) + \pi_k f_1(z_{k+1})}, \quad k = -1, 0, 1, \ldots$$

After observing $z_k, z_{k-1}, \ldots, z_0$, the decision-maker believes that z_{k+1} has probability distribution

$$f_{\pi_k}(v) = (1-\pi_k) f_0(v) + \pi_k f_1(v),$$

which is a mixture of distributions f_0 and f_1, with the weight on f_1 being the posterior probability that $f = f_1$[1].

[1] The decision maker acts as if he believes that the sequence of random variables $[z_0, z_1, \ldots]$ is *exchangeable*. See *Exchangeability and Bayesian Updating* and [Kreps, 1988] chapter 11, for discussions of exchangeability.

To illustrate such a distribution, let's inspect some mixtures of beta distributions.

The density of a beta probability distribution with parameters a and b is

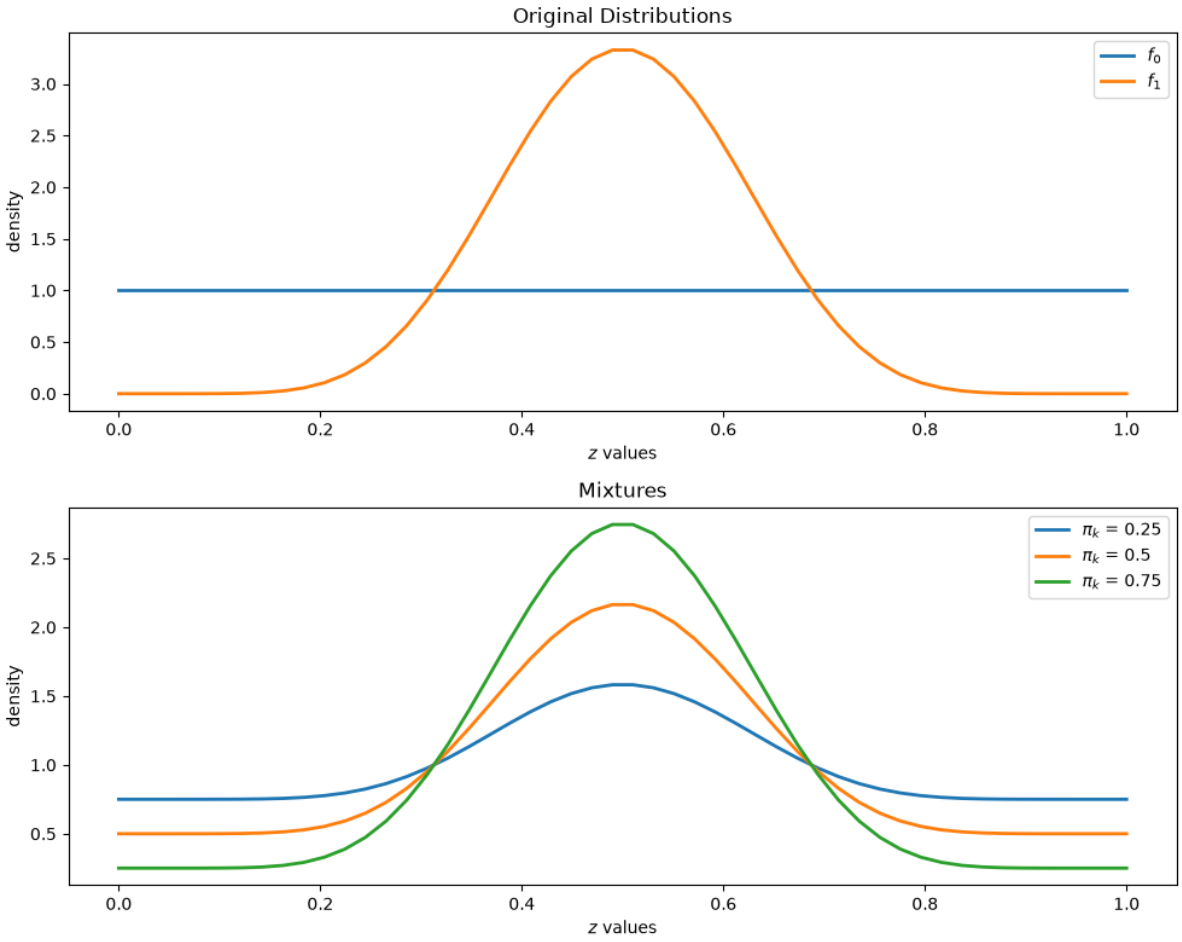
$$f(z;a,b) = \frac{\Gamma(a+b)z^{a-1}(1-z)^{b-1}}{\Gamma(a)\Gamma(b)} \quad \text{where} \quad \Gamma(t) := \int_0^\infty x^{t-1}e^{-x}dx$$

The next figure shows two beta distributions in the top panel.

The bottom panel presents mixtures of these distributions, with various mixing probabilities π_k

```
@jit
def p(x, a, b):
    r = gamma(a + b) / (gamma(a) * gamma(b))
    return r * x**(a-1) * (1 - x)**(b-1)

f0 = lambda x: p(x, 1, 1)
f1 = lambda x: p(x, 9, 9)
grid = np.linspace(0, 1, 50)



fig, axes = plt.subplots(2, figsize=(10, 8))

axes[0].set_title("Original Distributions")
axes[0].plot(grid, f0(grid), lw=2, label="$f_0$")
axes[0].plot(grid, f1(grid), lw=2, label="$f_1$")

axes[1].set_title("Mixtures")
for π in 0.25, 0.5, 0.75:
    y = (1 - π) * f0(grid) + π * f1(grid)
    axes[1].plot(grid, y, lw=2, label=fr"$\pi_k$ = {π}")

for ax in axes:
    ax.legend()
    ax.set(xlabel="$z$ values", ylabel="density")

plt.tight_layout()
plt.show()
```

27.2.1 Losses and Costs

After observing $z_k, z_{k-1}, \ldots, z_0$, the decision-maker chooses among three distinct actions:

- He decides that $f = f_0$ and draws no more z's
- He decides that $f = f_1$ and draws no more z's
- He postpones deciding now and instead chooses to draw a z_{k+1}

Associated with these three actions, the decision-maker can suffer three kinds of losses:

- A loss L_0 if he decides $f = f_0$ when actually $f = f_1$
- A loss L_1 if he decides $f = f_1$ when actually $f = f_0$
- A cost c if he postpones deciding and chooses instead to draw another z

27.2.2 Digression on Type I and Type II Errors

If we regard $f = f_0$ as a null hypothesis and $f = f_1$ as an alternative hypothesis, then L_1 and L_0 are losses associated with two types of statistical errors

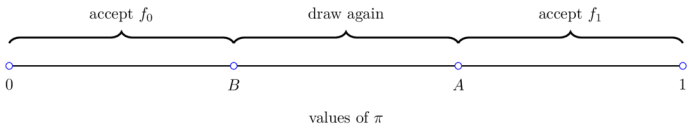
- a type I error is an incorrect rejection of a true null hypothesis (a "false positive")
- a type II error is a failure to reject a false null hypothesis (a "false negative")

So when we treat $f = f_0$ as the null hypothesis

- We can think of L_1 as the loss associated with a type I error.
- We can think of L_0 as the loss associated with a type II error.

27.2.3 Intuition

Before proceeding, let's try to guess what an optimal decision rule might look like.



Suppose at some given point in time that π is close to 1.

Then our prior beliefs and the evidence so far point strongly to $f = f_1$.

If, on the other hand, π is close to 0, then $f = f_0$ is strongly favored.

Finally, if π is in the middle of the interval $[0, 1]$, then we are confronted with more uncertainty.

This reasoning suggests a sequential decision rule that we illustrate in the following figure:

As we'll see, this is indeed the correct form of the decision rule.

Our problem is to determine threshold values A, B that somehow depend on the parameters described above.

You might like to pause at this point and try to predict the impact of a parameter such as c or L_0 on A or B.

27.2.4 A Bellman Equation

Let $J(\pi)$ be the total loss for a decision-maker with current belief π who chooses optimally.

Principles of **dynamic programming** teach us that an optimal loss function J satisfies the following Bellman functional equation

$$J(\pi) = \min \left\{ \underbrace{\pi L_0}_{\text{accept } f_0} , \underbrace{(1-\pi) L_1}_{\text{accept } f_1} , \underbrace{c + \mathbb{E}[J(\pi')]}_{\text{draw again}} \right\} \tag{27.1}$$

where π' is the random variable defined by Bayes' Law

$$\pi' = \kappa(z', \pi) = \frac{\pi f_1(z')}{(1-\pi) f_0(z') + \pi f_1(z')}$$

when π is fixed and z' is drawn from the current best guess, which is the distribution f defined by

$$f_\pi(v) = (1-\pi) f_0(v) + \pi f_1(v)$$

In the Bellman equation, minimization is over three actions:

1. Accept the hypothesis that $f = f_0$
2. Accept the hypothesis that $f = f_1$
3. Postpone deciding and draw again

We can represent the Bellman equation as

$$J(\pi) = \min\{\pi L_0,\ (1-\pi)L_1,\ h(\pi)\} \tag{27.2}$$

where $\pi \in [0, 1]$ and

- πL_0 is the expected loss associated with accepting f_0 (i.e., the cost of making a type II error).
- $(1-\pi)L_1$ is the expected loss associated with accepting f_1 (i.e., the cost of making a type I error).
- $h(\pi) := c + \mathbb{E}[J(\pi')]$; this is the continuation value; i.e., the expected cost associated with drawing one more z.

The optimal decision rule is characterized by two numbers $0 < B \leq A < 1$ that satisfy

$$\pi L_0 \leq \min\{(1-\pi)L_1, c + \mathbb{E}[J(\pi')]\} \text{ if } \pi \leq B$$

and

$$(1-\pi)L_1 \leq \min\{\pi L_0, c + \mathbb{E}[J(\pi')]\} \text{ if } \pi \geq A$$

The optimal decision rule is then

$$\begin{aligned} \text{accept } f = f_1 \text{ if } \pi \geq A \\ \text{accept } f = f_0 \text{ if } \pi \leq B \\ \text{draw another } z \text{ if } B < \pi < A \end{aligned}$$

The two-threshold form of this rule follows from three properties of h and of the stopping loss $S(\pi) = \min\{\pi L_0, (1-\pi)L_1\}$.

First, $h(0) = h(1) = c$.

When $\pi \in \{0, 1\}$, Bayes' law sets $\pi' = \pi$, and $J(0) = J(1) = 0$.

Second, h is concave.

Write $\mathbb{E}[J(\pi')] = \int f_\pi(z') J\left(\pi f_1(z')/f_\pi(z')\right) dz'$.

For each z', the integrand is the perspective $tJ(x/t)$ of J evaluated at $x = \pi f_1(z')$ and $t = f_\pi(z')$, both linear in π.

The perspective of a concave function is concave, so $\mathbb{E}[J(\pi')]$ is concave in π whenever J is.

J is the minimum of h and two linear functions, so J is concave whenever h is.

Therefore the operator Q defined below maps concave functions into concave functions, and its fixed point h, a limit of iterates that start from $h = 0$, is concave.

Third, S is linear on each side of $\hat{\pi} = L_1/(L_0 + L_1)$.

On $[0, \hat{\pi}]$, accepting f_0 is optimal where $\pi L_0 - h(\pi) \leq 0$.

The function $\pi L_0 - h(\pi)$ is convex and equals $-c < 0$ at $\pi = 0$, so this set is an interval $[0, B]$ with $B > 0$.

On $[\hat{\pi}, 1]$, the same argument applied to $(1-\pi)L_1 - h(\pi)$ gives an interval $[A, 1]$ with $A < 1$ on which accepting f_1 is optimal.

The decision maker draws again on the interval (B, A) between them.

That interval is empty, and $B = A = \hat{\pi}$, when $h(\hat{\pi}) \geq S(\hat{\pi})$.

Because $h \geq c$, this happens whenever $c \geq L_0 L_1/(L_0 + L_1)$.

Our aim is to compute the cost function J as well as the associated cutoffs A and B.

To help make our computations more manageable, we can use (27.2) to write the continuation cost $h(\pi)$ as

$$\begin{aligned} h(\pi) &= c + \mathbb{E}[J(\pi')] \\ &= c + \mathbb{E}_{\pi'} \min\{\pi' L_0, (1-\pi') L_1, h(\pi')\} \\ &= c + \int \min\{\kappa(z', \pi) L_0, (1 - \kappa(z', \pi)) L_1, h(\kappa(z', \pi))\} f_\pi(z') dz' \end{aligned} \tag{27.3}$$

The equality

$$h(\pi) = c + \int \min\{\kappa(z', \pi) L_0, (1 - \kappa(z', \pi)) L_1, h(\kappa(z', \pi))\} f_\pi(z') dz' \tag{27.4}$$

is an equation in an unknown function h.

Note

Such an equation is called a **functional equation**.

Using the functional equation, (27.4), for the continuation cost, we can back out optimal choices using the right side of (27.2).

This functional equation can be solved by taking an initial guess and iterating to find a fixed point.

Thus, we iterate with an operator Q, where

$$Qh(\pi) = c + \int \min\{\kappa(z', \pi) L_0, (1 - \kappa(z', \pi)) L_1, h(\kappa(z', \pi))\} f_\pi(z') dz'$$

The operator Q is monotone: $h \leq g$ implies $Qh \leq Qg$.

The decision maker does not discount future losses, so Q is not a contraction in the sup norm.

We start from $h = 0$.

Then $Qh \geq h$, and monotonicity makes the iterates $Q^n h$ increase with n.

The iterates are bounded above by $c + L_0 L_1 / (L_0 + L_1)$, so they converge, and the limit solves (27.4).

27.3 Implementation

First, we will construct a `jitclass` to store the parameters of the model

```
wf_data = [('a0', float64),          # Parameters of beta distributions
           ('b0', float64),
           ('a1', float64),
           ('b1', float64),
           ('c', float64),           # Cost of another draw
           ('π_grid_size', int64),
           ('L0', float64),          # Cost of selecting f0 when f1 is true
           ('L1', float64),          # Cost of selecting f1 when f0 is true
           ('π_grid', float64[:]),
           ('mc_size', int64),
           ('z0', float64[:]),
           ('z1', float64[:])]
```

```
@jitclass(wf_data)
class WaldFriedman:

    def __init__(self,
                 c=1.25,
                 a0=1,
                 b0=1,
                 a1=3,
                 b1=1.2,
                 L0=25,
                 L1=25,
                 π_grid_size=200,
                 mc_size=1000,
                 seed=1234):

        self.a0, self.b0 = a0, b0
        self.a1, self.b1 = a1, b1
        self.c, self.π_grid_size = c, π_grid_size
        self.L0, self.L1 = L0, L1
        self.π_grid = np.linspace(0, 1, π_grid_size)
        self.mc_size = mc_size

        np.random.seed(seed)   # Monte Carlo draws used to compute E[J(π')]
        self.z0 = np.random.beta(a0, b0, mc_size)
        self.z1 = np.random.beta(a1, b1, mc_size)

    def f0(self, x):

        return p(x, self.a0, self.b0)

    def f1(self, x):

        return p(x, self.a1, self.b1)

    def f0_rvs(self):
        return np.random.beta(self.a0, self.b0)

    def f1_rvs(self):
        return np.random.beta(self.a1, self.b1)

    def κ(self, z, π):
        """
        Updates π using Bayes' rule and the current observation z
        """

        f0, f1 = self.f0, self.f1

        π_f0, π_f1 = (1 - π) * f0(z), π * f1(z)
        π_new = π_f1 / (π_f0 + π_f1)

        return π_new
```

As in *Optimal Savings III: Stochastic Returns*, to approximate a continuous value function

- We iterate at a finite grid of possible values of π.
- When we evaluate $\mathbb{E}[J(\pi')]$ between grid points, we use linear interpolation.

We define the operator function `Q` below.

```
@jit(nopython=True, parallel=True)
def Q(h, wf):

    c, π_grid = wf.c, wf.π_grid
    L0, L1 = wf.L0, wf.L1
    z0, z1 = wf.z0, wf.z1
    mc_size = wf.mc_size

    κ = wf.κ

    h_new = np.empty_like(π_grid)
    h_func = lambda p: np.interp(p, π_grid, h)

    for i in prange(len(π_grid)):
        π = π_grid[i]

        # Find the expected value of J by integrating over z
        integral_f0, integral_f1 = 0, 0
        for m in range(mc_size):
            π_0 = κ(z0[m], π)  # Draw z from f0 and update π
            integral_f0 += min(π_0 * L0, (1 - π_0) * L1, h_func(π_0))

            π_1 = κ(z1[m], π)  # Draw z from f1 and update π
            integral_f1 += min(π_1 * L0, (1 - π_1) * L1, h_func(π_1))

        integral = ((1 - π) * integral_f0 + π * integral_f1) / mc_size

        h_new[i] = c + integral

    return h_new
```

To solve the key functional equation, we will iterate using `Q` to find the fixed point

```
@jit
def solve_model(wf, tol=1e-4, max_iter=1000):
    """
    Compute the continuation cost function

    * wf is an instance of WaldFriedman
    """

    # Set up loop
    h = np.zeros(len(wf.π_grid))
    i = 0
    error = tol + 1

    while i < max_iter and error > tol:
        h_new = Q(h, wf)

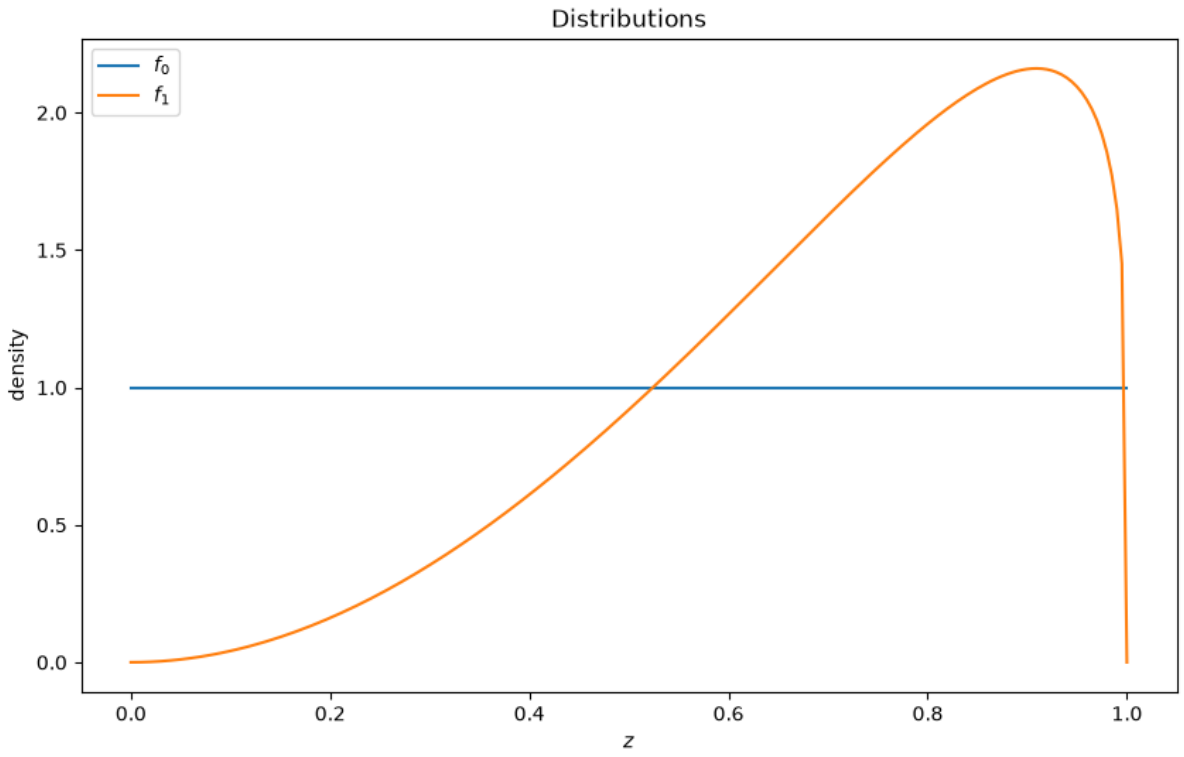
        h = h_new

    if error > tol:
        print("Failed to converge!")

    return h_new
```

27.4 Analysis



Let's inspect outcomes.

We will be using the default parameterization with distributions like so

```
wf = WaldFriedman()

z_grid = np.linspace(0, 1, 200)
fig, ax = plt.subplots(figsize=(10, 6))
ax.plot(z_grid, wf.f0(z_grid), label="$f_0$")
ax.plot(z_grid, wf.f1(z_grid), label="$f_1$")
ax.set(ylabel="density", xlabel="$z$", title="Distributions")
ax.legend()

plt.show()
```

27.4.1 Cost Function

To solve the model, we will call our `solve_model` function

```
h_star = solve_model(wf)     # Solve the model
```

We will also set up a function to compute the cutoffs A and B and plot these on our cost function plot

```
@jit
def find_cutoff_rule(wf, h):

    """
```

(continues on next page)

(continued from previous page)

```
    This function takes a continuation cost function and returns the
    corresponding cutoffs of where you transition between continuing and
    choosing a specific model
    """

    π_grid = wf.π_grid

       xlabel=r"$\pi$", title=r"Cost function $J(\pi)$")

plt.legend(borderpad=1.1)
plt.show()
```

The cost function J equals πL_0 for $\pi \leq B$, and $(1-\pi)L_1$ for $\pi \geq A$.

The slopes of the two linear pieces of the cost function $J(\pi)$ are determined by L_0 and $-L_1$.

The cost function J is smooth in the interior region, where the posterior probability assigned to f_1 is in the indecisive region $\pi \in (B, A)$.

The decision-maker continues to sample until the probability that he attaches to model f_1 falls below B or above A.

27.4.2 The Bayesian rule is a sequential probability ratio test

Let

$$\Lambda_k = \prod_{j=0}^{k} \frac{f_1(z_j)}{f_0(z_j)}$$

be the likelihood ratio after the $k+1$ observations $z_0, \ldots, z_k$.

We write Λ_k rather than L_k because L_0 and L_1 denote losses in this lecture.

Iterating on Bayes' law, as in *Likelihood Ratio Processes and Bayesian Learning*, gives

$$\pi_k = \frac{\pi_{-1}\Lambda_k}{\pi_{-1}\Lambda_k + 1 - \pi_{-1}}$$

The posterior π_k is a strictly increasing function of Λ_k.

Therefore $\pi_k \geq A$ if and only if $\Lambda_k \geq A_\Lambda$, and $\pi_k \leq B$ if and only if $\Lambda_k \leq B_\Lambda$, where

$$A_\Lambda = \frac{1-\pi_{-1}}{\pi_{-1}} \frac{A}{1-A}, \qquad B_\Lambda = \frac{1-\pi_{-1}}{\pi_{-1}} \frac{B}{1-B} \tag{27.5}$$

The Bayesian decision rule is Wald's sequential probability ratio test from *A Problem that Stumped Milton Friedman* with thresholds A_Λ and B_Λ on the likelihood ratio.

The thresholds do not depend on k because J and h do not depend on time.

Wald and Wolfowitz [1948] used this connection in the other direction.

They showed that every sequential probability ratio test is a Bayes rule for a problem of this kind with suitably chosen losses and cost per draw.

They used that fact to prove that no other test with the same or smaller error probabilities has a smaller expected number of draws under f_0 or under f_1.

Arrow *et al.* [1949] characterized Bayes and minimax solutions of more general sequential decision problems.

For our default parameters and $\pi_{-1} = 0.5$, the thresholds are

```
def LR_thresholds(B, A, π_minus_1=0.5):
    """Map thresholds on π into thresholds on the likelihood ratio."""
    prior_odds = (1 - π_minus_1) / π_minus_1
    return prior_odds * B / (1 - B), prior_odds * A / (1 - A)

B_Λ, A_Λ = LR_thresholds(B, A)
print(f"B = {B:.3f}, A = {A:.3f}")
print(f"B_Λ = {B_Λ:.2f}, A_Λ = {A_Λ:.2f}")
```

```
B = 0.256, A = 0.794
B_Λ = 0.34, A_Λ = 3.85
```

Exercise 27.5.1 compares the error probabilities of this test with the ones that Wald's formulas in *A Problem that Stumped Milton Friedman* imply.

27.4.3 Simulations

The next figure shows the outcomes of 500 simulations of the decision process.

In all 500 simulations, f_0 generates the data, and the decision maker starts from the prior $\pi_{-1} = 0.5$.

On the left is a histogram of **stopping times**, i.e., the number of draws of z_k required to make a decision.

The average number of draws is 2.82.

On the right is the fraction of correct decisions at the stopping time.

In this case, the decision-maker is correct 80% of the time.

```
@jit

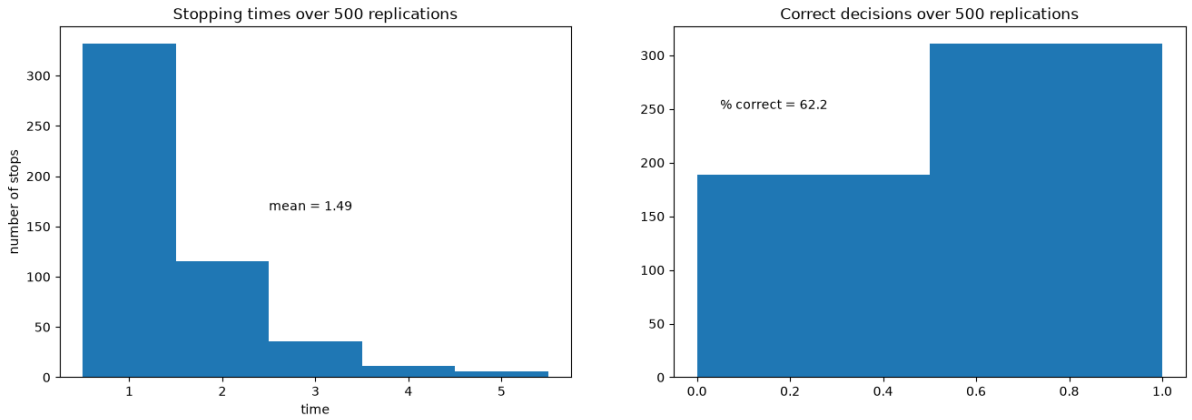
    plt.show()

simulation_plot(wf)
```

27.4.4 Comparative Statics



Now let's consider the following exercise.

We double the cost of drawing an additional observation.

Before you look, think about what will happen:

- Will the decision-maker be correct more or less often?
- Will he make decisions sooner or later?

```
wf = WaldFriedman(c=2.5)
simulation_plot(wf)
```

Increased cost per draw has induced the decision-maker to take fewer draws before deciding.

Because he decides with fewer draws, the percentage of time he is correct drops.

This leads to him having a higher expected loss when he puts equal weight on both models.

The code below computes $J(0.5)$ and the mean number of draws $\mathbb{E}[N]$ when $\pi_{-1} = 0.5$ for both values of c.

Because the prior puts equal weight on f_0 and f_1, $\mathbb{E}[N]$ averages simulated mean stopping times under f_0 and under f_1.

```
def J_and_mean_N(c, ndraws=5000):
    """J(0.5) and the mean number of draws when π_{-1} = 0.5."""
    wf_c = WaldFriedman(c=c)
    h_c = solve_model(wf_c)
    S = np.minimum(wf_c.π_grid * wf_c.L0, (1 - wf_c.π_grid) * wf_c.L1)
    J_half = np.interp(0.5, wf_c.π_grid, np.minimum(S, h_c))
    _, t0 = stopping_dist(wf_c, h_c, ndraws, "f0", seed=1)
    _, t1 = stopping_dist(wf_c, h_c, ndraws, "f1", seed=2)
    return J_half, 0.5 * (t0.mean() + t1.mean())

for c in (1.25, 2.5):
    J_half, mean_N = J_and_mean_N(c)
    print(f"c = {c}: J(0.5) = {J_half:.2f}, E[N] = {mean_N:.2f}")
```

```
c = 1.25: J(0.5) = 7.56, E[N] = 3.34
c = 2.5: J(0.5) = 10.42, E[N] = 1.49
```

Doubling c raises $J(0.5)$ from 7.56 to 10.42.

The envelope theorem accounts for the size of the increase.

For a fixed decision rule, the expected loss equals $c\,\mathbb{E}[N]$ plus the expected loss from wrong decisions, a linear function of c with slope $\mathbb{E}[N]$.

J is the minimum of these linear functions over decision rules, so $dJ/dc = \mathbb{E}[N^*]$ at every c where J is differentiable; N^* is the number of draws under the optimal rule.

$\mathbb{E}[N^*]$ falls from 3.34 to 1.49 as c rises from 1.25 to 2.5, so the increase in $J(0.5)$ lies between $1.25 \times 1.49 = 1.86$ and $1.25 \times 3.34 = 4.17$.

The exercises below study how c, L_0, and L_1 shape the thresholds B and A and the error probabilities of the Bayesian decision rule.

27.5 Exercises

Exercise 27.5.1

Use the default parameters, $\pi_{-1} = 0.5$, and the thresholds B_Λ and A_Λ that we computed *above*.

1. Simulate the Bayesian decision rule 20,000 times under f_0 and 20,000 times under f_1, and estimate its type I error probability α (accepting f_1 when f_0 generates the data) and its type II error probability β (accepting f_0 when f_1 generates the data).
2. In *A Problem that Stumped Milton Friedman*, Wald's inequalities $\alpha \leq (1-\beta)/A$ and $\beta \leq B(1-\alpha)$ hold with equality when the likelihood ratio never jumps past its thresholds. Use those equalities with $A = A_\Lambda$ and $B = B_\Lambda$ to compute the error probabilities that the test would have without overshoot, and compare them with your estimates.
3. Record $\log \Lambda_N$ at the stopping time N and plot its distribution under f_0 and under f_1. Use the plot to explain the comparison in step 2.

Solution

Without overshoot, $\alpha = (1-\beta)/A_\Lambda$ and $\beta = B_\Lambda(1-\alpha)$.

Solving these two equations gives

$$\alpha = \frac{1 - B_\Lambda}{A_\Lambda - B_\Lambda}, \qquad \beta = \frac{B_\Lambda(A_\Lambda - 1)}{A_\Lambda - B_\Lambda}$$

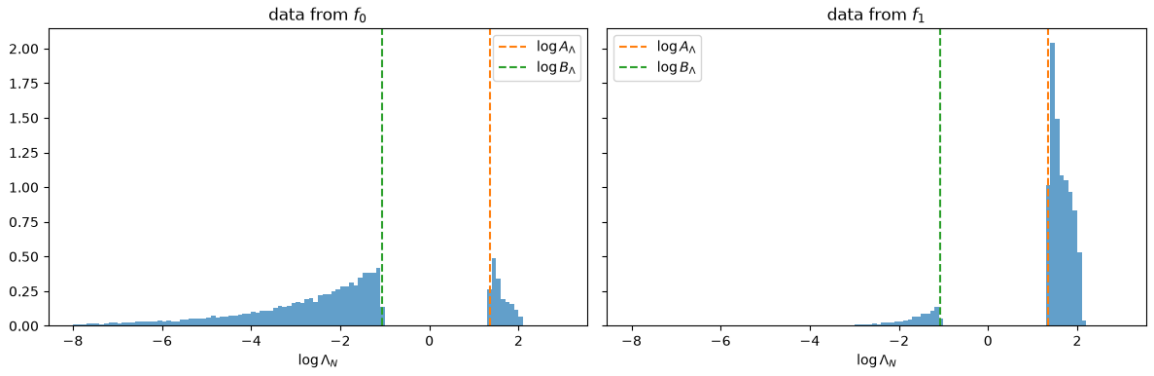
With $\pi_{-1} = 0.5$, Λ_N equals the posterior odds $\pi_N/(1-\pi_N)$ at the stopping time.

```
def simulate_many(wf, h_star, ndraws, true_dist, seed):
    """Correctness, terminal posterior, and stopping time of ndraws runs."""
    seed_numba(seed)
    correct = np.empty(ndraws, bool)
    π_N = np.empty(ndraws)
    N = np.empty(ndraws, int)
    for i in range(ndraws):
        correct[i], π_N[i], N[i] = simulate(wf, true_dist, h_star)
    return correct, π_N, N

wf = WaldFriedman()
h_star = solve_model(wf)
B, A = find_cutoff_rule(wf, h_star)
B_Λ, A_Λ = LR_thresholds(B, A)

correct_0, π_N0, N0 = simulate_many(wf, h_star, 20_000, "f0", seed=1)
correct_1, π_N1, N1 = simulate_many(wf, h_star, 20_000, "f1", seed=2)
α_hat, β_hat = 1 - correct_0.mean(), 1 - correct_1.mean()

α_wald = (1 - B_Λ) / (A_Λ - B_Λ)
β_wald = B_Λ * (A_Λ - 1) / (A_Λ - B_Λ)



print(f"simulated:           α = {α_hat:.3f}, β = {β_hat:.3f}")
print(f"without overshoot:   α = {α_wald:.3f}, β = {β_wald:.3f}")

log_Λ0 = np.log(π_N0 / (1 - π_N0))
log_Λ1 = np.log(π_N1 / (1 - π_N1))
```

```
log_Λ = np.concatenate((log_Λ0, log_Λ1))
above = log_Λ >= np.log(A_Λ)
print(f"mean of log Λ_N - log A_Λ when the test accepts f1: "
      f"{np.mean(log_Λ[above] - np.log(A_Λ)):.2f}")
print(f"mean of log B_Λ - log Λ_N when the test accepts f0: "
      f"{np.mean(np.log(B_Λ) - log_Λ[~above]):.2f}")
print(f"runs with log Λ_N < -8: {np.sum(log_Λ0 < -8)} under f0, "
      f"{np.sum(log_Λ1 < -8)} under f1")

fig, axes = plt.subplots(1, 2, figsize=(12, 4), sharey=True)
for ax, x, title in zip(axes, (log_Λ0, log_Λ1),
                        ("data from $f_0$", "data from $f_1$")):
    ax.hist(x, bins=np.linspace(-8, 3, 111), density=True, alpha=0.7)
    ax.axvline(np.log(A_Λ), color='C1', linestyle='--',
               label=r'$\log A_\Lambda$')
    ax.axvline(np.log(B_Λ), color='C2', linestyle='--',
               label=r'$\log B_\Lambda$')
    ax.set_title(title)
    ax.set_xlabel(r'$\log \Lambda_N$')
    ax.legend()
plt.tight_layout()
plt.show()
```

```
simulated:           α = 0.176, β = 0.095
without overshoot:   α = 0.187, β = 0.280
mean of log Λ_N - log A_Λ when the test accepts f1: 0.29
mean of log B_Λ - log Λ_N when the test accepts f0: 1.83
runs with log Λ_N < -8: 494 under f0, 0 under f1
```

The histograms omit the 494 runs under f_0 in which $\log \Lambda_N < -8$.

The simulated β is far below the value without overshoot, and the simulated α is somewhat below it.

On average, $\log \Lambda_N$ exceeds $\log A_\Lambda$ by 0.29 when the test accepts f_1 and falls short of $\log B_\Lambda$ by 1.83 when the test accepts f_0.

Because f_0 is uniform, the likelihood ratio of a single draw is $f_1(z)$.

The density $f_1(z)$ never exceeds 2.16, so one draw raises $\log \Lambda$ by at most $\log 2.16 = 0.77$, and $\log \Lambda_N$ lands only a little above $\log A_\Lambda$.

The density $f_1(z)$ goes to zero as $z \to 0$, so one draw can lower $\log \Lambda$ by an arbitrarily large amount, and $\log \Lambda_N$ often lands far below $\log B_\Lambda$.

The change of measure in *A Problem that Stumped Milton Friedman* gives $\beta = E_0[\Lambda_N \mathbf{1}\{\Lambda_N \leq B_\Lambda\}]$, so the further Λ_N falls below B_Λ, the smaller β is relative to $B_\Lambda(1-\alpha)$.

Exercise 27.5.2

Let $S(\pi) = \min\{\pi L_0, (1-\pi)L_1\}$ be the stopping loss.

1. Holding the other parameters at their defaults, solve the model for values of c between 0.5 and 5, and plot $B(c)$ and $A(c)$.
2. Show that the continuation region is empty if and only if $c \geq \bar{c} = \max_\pi\{S(\pi) - \mathbb{E}[S(\pi')]\}$, the largest expected reduction in the stopping loss that one more draw delivers.
3. Compute $\bar{c}$ and compare it with the values of c at which your solutions in step 1 have an empty continuation region.

Solution

Suppose that $c < S(\pi) - \mathbb{E}[S(\pi')]$ for some π.

Since $J \leq S$, $h(\pi) = c + \mathbb{E}[J(\pi')] \leq c + \mathbb{E}[S(\pi')] < S(\pi)$, so drawing again is optimal at π.

Suppose instead that $c \geq S(\pi) - \mathbb{E}[S(\pi')]$ for every π.

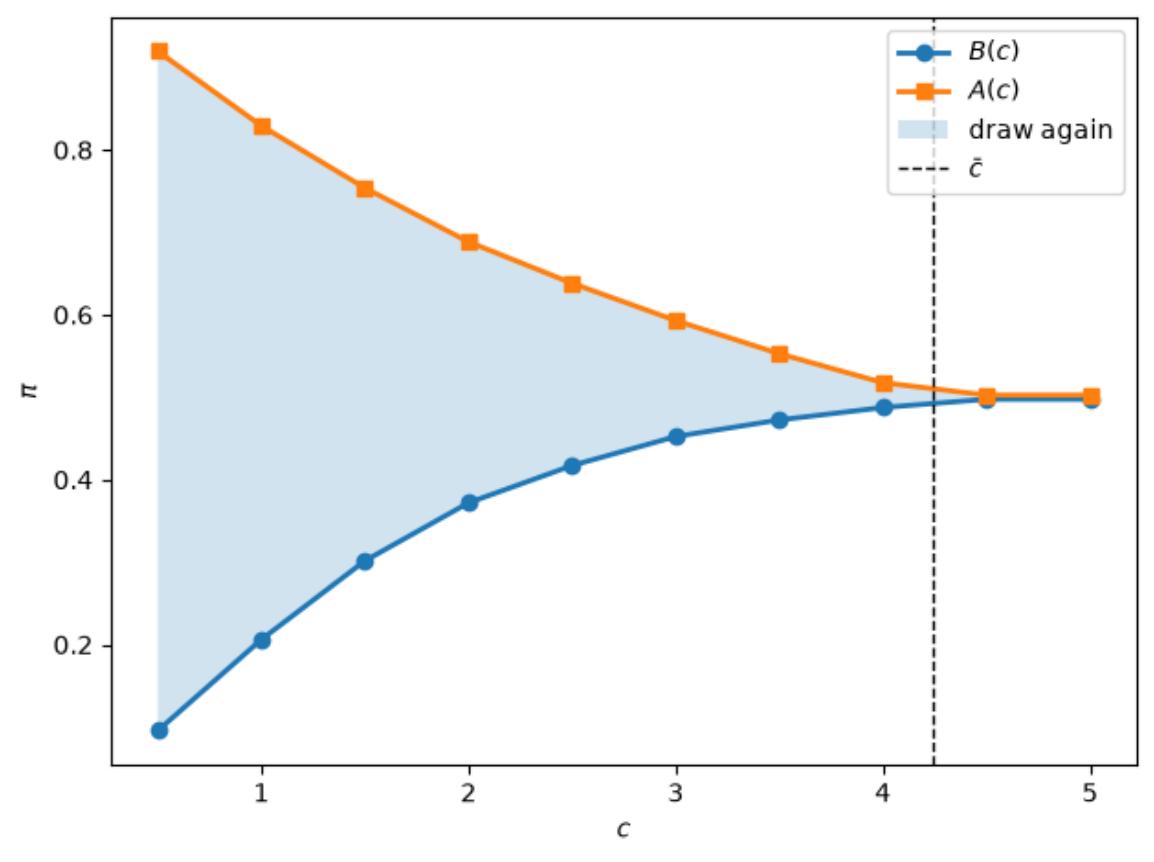
Let p_n be the posterior probability of f_1 after n draws, with $p_0 = \pi_{-1}$.

Then $\mathbb{E}[c(n+1) + S(p_{n+1})|p_n] \geq cn + S(p_n)$, so $cn + S(p_n)$ is a submartingale under the decision maker's beliefs.

By the optional stopping theorem, $\mathbb{E}[cN + S(p_N)] \geq S(p_0)$ for every stopping rule N with finite mean.

No rule improves on stopping immediately, so the continuation region is empty.

```
def one_draw_value(wf):
    """S(π) - E[S(π')] on the grid, using the Monte Carlo draws in wf."""
    S = lambda π: np.minimum(π * wf.L0, (1 - π) * wf.L1)
    values = np.empty(len(wf.π_grid))
    for i, π in enumerate(wf.π_grid):
        ES = ((1 - π) * S(wf.κ(wf.z0, π)).mean()
              + π * S(wf.κ(wf.z1, π)).mean())
        values[i] = S(π) - ES
    return values



c_bar = one_draw_value(WaldFriedman()).max()
print(f"c̄ = {c_bar:.2f}")

c_grid = np.linspace(0.5, 5, 10)
B_c, A_c, empty = [], [], []
for c in c_grid:
    wf_c = WaldFriedman(c=c)
    h_c = solve_model(wf_c)
    B_val, A_val = find_cutoff_rule(wf_c, h_c)
    S_grid = np.minimum(wf_c.π_grid * wf_c.L0, (1 - wf_c.π_grid) * wf_c.L1)
    B_c.append(B_val)
    A_c.append(A_val)
    empty.append(not np.any(h_c < S_grid))

print("c values with an empty continuation region:",
      np.round(c_grid[np.array(empty)], 2))

fig, ax = plt.subplots()
ax.plot(c_grid, B_c, 'o-', lw=2, label='$B(c)$')
ax.plot(c_grid, A_c, 's-', lw=2, label='$A(c)$')
ax.fill_between(c_grid, B_c, A_c, alpha=0.2, label='draw again')
ax.axvline(c_bar, color='black', linestyle='--', lw=1, label=r'$\bar c$')
ax.set_xlabel('$c$')
ax.set_ylabel(r'$\pi$')
ax.legend(loc='upper right')
plt.tight_layout()
plt.show()
```

```
c̄ = 4.24
c values with an empty continuation region: [4.5 5. ]
```

As c rises, $B(c)$ rises and $A(c)$ falls, and the continuation region shrinks.

The region vanishes at $\bar{c} = 4.24$, far below the bound $L_0 L_1/(L_0 + L_1) = 12.5$ that we derived from $h \geq c$.

When the region is empty, `find_cutoff_rule` returns the two grid points next to $\hat{\pi} = 0.5$.

Exercise 27.5.3

Set (L_0, L_1) to $(50, 25)$, $(25, 25)$, and $(25, 50)$ in turn, holding the other parameters at their defaults.

For each setting, compute B, A, B_Λ, and A_Λ with $\pi_{-1} = 0.5$, and estimate α, β, and the mean stopping times under f_0 and under f_1 by simulation.

Explain how the thresholds and the error probabilities respond to L_0 and L_1.

Solution

We reuse `simulate_many` from the solution to Exercise 27.5.1.

```
for L0, L1 in [(50, 25), (25, 25), (25, 50)]:
    wf_L = WaldFriedman(L0=L0, L1=L1)
    h_L = solve_model(wf_L)
```

```
    B_val, A_val = find_cutoff_rule(wf_L, h_L)
    B_Λ_val, A_Λ_val = LR_thresholds(B_val, A_val)
    correct_0, _, N0 = simulate_many(wf_L, h_L, 20_000, "f0", seed=1)
    correct_1, _, N1 = simulate_many(wf_L, h_L, 20_000, "f1", seed=2)
    print(f"L0 = {L0}, L1 = {L1}: B = {B_val:.3f}, A = {A_val:.3f}, "
          f"B_Λ = {B_Λ_val:.2f}, A_Λ = {A_Λ_val:.2f}, "
          f"α = {1 - correct_0.mean():.3f}, β = {1 - correct_1.mean():.3f}, "
          f"E_0[N] = {N0.mean():.2f}, E_1[N] = {N1.mean():.2f}")
```

```
L0 = 50, L1 = 25: B = 0.116, A = 0.774, B_Λ = 0.13, A_Λ = 3.42, α = 0.214, β =␣
↪0.035, E_0[N] = 3.68, E_1[N] = 3.99
L0 = 25, L1 = 25: B = 0.256, A = 0.794, B_Λ = 0.34, A_Λ = 3.85, α = 0.176, β =␣
↪0.095, E_0[N] = 2.88, E_1[N] = 3.84
L0 = 25, L1 = 50: B = 0.302, A = 0.899, B_Λ = 0.43, A_Λ = 8.95, α = 0.070, β =␣
↪0.136, E_0[N] = 3.16, E_1[N] = 5.73
```

Raising L_1 from 25 to 50 makes accepting f_1 when f_0 is true costlier.

The decision maker requires more evidence before accepting f_1: A rises from 0.794 to 0.899, and A_Λ rises from 3.85 to 8.95.

He also accepts f_0 on weaker evidence: B rises from 0.256 to 0.302, and B_Λ rises from 0.34 to 0.43.

The type I error probability α falls from 0.176 to 0.070, and the type II error probability β rises from 0.095 to 0.136.

Raising L_0 from 25 to 50 works in the opposite direction.

B falls from 0.256 to 0.116 and A falls from 0.794 to 0.774, so β falls to 0.035 and α rises to 0.214.

In both cases the mean stopping times rise because a larger loss from one kind of error makes evidence more valuable.

28.1 Overview

This lecture studies learning via Bayes' Law.

We touch foundations of Bayesian statistical inference invented by de Finetti [1937].

The relevance of de Finetti's work for economists is presented forcefully by David Kreps in chapter 11 of [Kreps, 1988].

An example that we study below is a key component of *Job Search IX: Search with Learning*.

That lecture augments the classic job search model of McCall [McCall, 1970], studied in *Job Search I: The McCall Search Model*, by presenting an unemployed worker with a statistical inference problem.

Here we create graphs that illustrate the role that a likelihood ratio plays in Bayes' Law.

We'll use such graphs to provide insights into the mechanics driving outcomes in *Job Search IX: Search with Learning*.

Among other things, this lecture discusses connections between the statistical concepts of sequences of random variables that are

- independently and identically distributed

- exchangeable

Understanding these concepts is essential for appreciating how Bayesian updating works.

You can read about exchangeability here.

De Finetti's theorem states that an infinite exchangeable sequence is **conditionally independently and identically distributed**: it is IID conditional on a random variable whose value the observer does not know.[1]

We want to convey an answer to the question *conditional on what?*

We also tell why an assumption of independence precludes learning while an assumption that a sequence is conditionally IID makes learning possible.

Below, we'll often use

- W to denote a random variable
- w to denote a particular realization of a random variable W

Let's start with some imports:

```
from math import gamma

import matplotlib.pyplot as plt
import numpy as np
import scipy.optimize as op
from scipy.integrate import quad
from scipy.special import expit
```

28.2 Independently and identically distributed

We begin by looking at the notion of an **independently and identically distributed sequence** of random variables.

An independently and identically distributed sequence is often abbreviated as IID.

Two notions are involved

- **independence**
- **identically distributed**

A sequence $W_0, W_1, \ldots$ is **independently distributed** if, for every $n \geq 0$, the joint probability density of $W_0, W_1, \ldots, W_n$ is the **product** of the marginal densities of $W_0, W_1, \ldots, W_n$.

The sequence $W_0, W_1, \ldots$ is **independently and identically distributed** (IID) if in addition the marginal density of W_t is the same for all $t = 0, 1, \ldots$.

For example, let $p(W_0, W_1, \ldots, W_n)$ be the **joint density** of $W_0, W_1, \ldots, W_n$ and let $p(W_t)$ be the common **marginal density** of each W_t.

Then the sequence $W_0, W_1, \ldots$ is IID if

$$p(W_0, W_1, \ldots, W_n) = p(W_0)p(W_1)\cdots p(W_n) \quad \text{for every } n \geq 0$$

so that each joint density is the product of identical marginal densities.

[1] Conditional independence alone does not imply exchangeability. Let $W_t = t\theta + \varepsilon_t$, where θ is a random variable and $\{\varepsilon_t\}$ is an IID $N(0,1)$ sequence independent of θ. Conditional on θ, the W_t are independent, but they are not identically distributed, and the sequence $\{W_t\}$ is not exchangeable.

28.2.1 IID means past observations don't tell us anything about future observations

If a sequence of random variables is IID, past information provides no information about future realizations.

Therefore, there is **nothing to learn** from the past about the future.

To understand these statements, let the joint distribution of a sequence of random variables $\{W_t\}_{t=0}^T$ that is not necessarily IID be

$$p(W_T, W_{T-1}, \dots, W_1, W_0)$$

Using the laws of probability, we can always factor such a joint density into a product of conditional densities:

$$\begin{aligned} p(W_T, W_{T-1}, \dots, W_1, W_0) =& p(W_T|W_{T-1}, \dots, W_0)p(W_{T-1}|W_{T-2}, \dots, W_0)\cdots \\ & \cdots p(W_1|W_0)p(W_0) \end{aligned}$$

In general,

$$p(W_t|W_{t-1}, \dots, W_0) \neq p(W_t)$$

which states that the **conditional density** on the left side does not equal the **marginal density** on the right side.

But in the special IID case,

$$p(W_t|W_{t-1}, \dots, W_0) = p(W_t),$$

so that the partial history $W_{t-1}, \dots, W_0$ contains no information about the probability of W_t.

So in the IID case, there is **nothing to learn** about the densities of future random variables from past random variables.

But when the sequence is not IID, there is something to learn about the future from observations of past random variables.

We turn next to an instance of the general case in which the sequence is not IID.

Please watch for what can be learned from the past and when.

28.3 A setting in which past observations are informative

Let $\{W_t\}_{t=0}^\infty$ be a sequence of nonnegative scalar random variables with a joint probability distribution constructed as follows.

There are two distinct cumulative distribution functions F and G that have densities f and g, respectively, for a nonnegative scalar random variable W.

Before the start of time, say at time $t = -1$, "nature" once and for all selects **either** f **or** g.

Thereafter at each time $t \geq 0$, nature draws a random variable W_t from the selected distribution.

So the data are permanently generated as independently and identically distributed (IID) draws from **either** F **or** G.

We could say that *objectively*, meaning *after* nature has chosen either F or G, the probability that the data are generated as draws from F is either 0 or 1.

We now drop into this setting a partially informed decision maker who

- knows both F and G, but
- does not know whether at $t = -1$ nature had drawn F or whether nature had drawn G once-and-for-all

Thus, although our decision maker knows F and knows G, he does not know which of these two known distributions nature had selected to draw from.

The decision maker describes his ignorance with a **subjective probability** $\tilde{\pi}$ and reasons as if nature had selected F with probability $\tilde{\pi} \in (0,1)$ and G with probability $1-\tilde{\pi}$.

Thus, we assume that the decision maker

- **knows** both F and G
- **doesn't know** which of these two distributions that nature has drawn
- expresses his ignorance by **acting as if** or **thinking that** nature chose distribution F with probability $\tilde{\pi} \in (0,1)$ and distribution G with probability $1-\tilde{\pi}$
- at date $t \geq 0$ knows the partial history $w_t, w_{t-1}, \ldots, w_0$

To proceed, we want to know the decision maker's belief about the joint distribution of the partial history.

We'll discuss that next and in the process describe the concept of **exchangeability**.

28.4 Relationship between IID and exchangeable

Conditional on nature selecting F, the joint density of $W_0, W_1, \ldots, W_n$ is

$$f(W_0)f(W_1)\cdots f(W_n)$$

for every $n \geq 0$.

Conditional on nature selecting G, the joint density of $W_0, W_1, \ldots, W_n$ is

$$g(W_0)g(W_1)\cdots g(W_n)$$

Thus, **conditional on nature having selected** F, the sequence $W_0, W_1, \ldots$ is independently and identically distributed.

Furthermore, **conditional on nature having selected** G, the sequence $W_0, W_1, \ldots$ is also independently and identically distributed.

But what about the **unconditional distribution** of a partial history?

The unconditional joint density of $W_0, W_1, \ldots, W_n$ is evidently

$$h(W_0, W_1, \ldots, W_n) \equiv \tilde{\pi}[f(W_0)f(W_1)\cdots f(W_n)] + (1-\tilde{\pi})[g(W_0)g(W_1)\cdots g(W_n)], \quad n \geq 0 \tag{28.1}$$

Under the unconditional distribution (28.1), the sequence $W_0, W_1, \ldots$ is **not** independently and identically distributed.

To verify this claim, let $h(W_t) = \tilde{\pi}f(W_t) + (1-\tilde{\pi})g(W_t)$ be the marginal density of W_t.

Then

$$h(W_0, W_1) - h(W_0)h(W_1) = \tilde{\pi}(1-\tilde{\pi})(f(W_0) - g(W_0))(f(W_1) - g(W_1)) \tag{28.2}$$

The right side is not zero when $f(W_0) \neq g(W_0)$ and $f(W_1) \neq g(W_1)$, so the joint density $h(W_0, W_1)$ is not the product of the marginal densities $h(W_0)$ and $h(W_1)$.

Thus, the conditional distribution

$$h(W_1|W_0) \equiv \frac{h(W_0, W_1)}{(\tilde{\pi}f(W_0) + (1-\tilde{\pi})g(W_0))} \neq (\tilde{\pi}f(W_1) + (1-\tilde{\pi})g(W_1))$$

This means that random variable W_0 contains information about random variable W_1.

So there is something to learn from the past about the future.

Exercise Exercise 28.10.1 uses (28.2) to show that W_0 and W_1 are positively correlated.

28.5 Exchangeability

While the sequence $W_0, W_1, \ldots$ is not IID, it can be verified that it is **exchangeable**, which means that the joint distributions $h(W_0, W_1)$ and $h(W_1, W_0)$ of the "re-ordered" sequences satisfy

$$h(W_0, W_1) = h(W_1, W_0)$$

and so on.

More generally, a sequence of random variables is said to be **exchangeable** if the joint probability distribution for a sequence does not change when the positions in the sequence in which finitely many of random variables appear are altered.

Equation (28.1) represents our instance of an exchangeable joint density over a sequence of random variables as a **mixture** of two IID joint densities over a sequence of random variables.

A Bayesian statistician interprets the mixing parameter $\tilde{\pi} \in (0, 1)$ as a decision maker's subjective belief – the decision maker's **prior probability** – that nature had selected probability distribution F.

28.5.1 De Finetti's theorem

As de Finetti [1937] proved, every infinite exchangeable sequence is a mixture of IID sequences.

For binary random variables $W_t \in \{0, 1\}$, de Finetti's theorem states that the infinite sequence $W_0, W_1, \ldots$ is exchangeable if and only if there is a probability measure μ on $[0, 1]$ such that

$$\text{Prob}(W_0 = w_0, \ldots, W_{n-1} = w_{n-1}) = \int_0^1 \theta^k (1-\theta)^{n-k} \mu(d\theta), \quad k = \sum_{t=0}^{n-1} w_t \tag{28.3}$$

for every $n \geq 1$ and every $(w_0, \ldots, w_{n-1}) \in \{0, 1\}^n$.

The mixing measure μ is unique.

It is the probability distribution of the limiting relative frequency

$$\theta = \lim_{n \to \infty} \frac{1}{n} \sum_{t=0}^{n-1} W_t,$$

a limit that exists with probability one.

Conditional on θ, the W_t are IID Bernoulli random variables with success probability θ.

This answers the question *conditional on what?*: conditional on the limiting relative frequency θ.

A Bayesian statistician interprets μ as a prior probability distribution over the unknown Bernoulli parameter $\theta \in [0, 1]$.

The measure μ need not have a density; it can put positive probability on finitely many points.

Hewitt and Savage [1955] extended de Finetti's theorem to sequences that take values in more general spaces.

In their version the mixing measure is a probability distribution over probability distributions of W, and the conditioning variable is the limiting empirical distribution of $W_0, W_1, \ldots$.

Equation (28.1) is an instance with a two-point mixing measure that puts probability $\tilde{\pi}$ on F and probability $1 - \tilde{\pi}$ on G.

In that instance the limiting empirical distribution of $W_0, W_1, \ldots$ is F when nature has drawn F and G when nature has drawn G.

De Finetti's theorem requires an infinite sequence.

Exercise Exercise 28.10.1 describes a finite exchangeable sequence that is not a mixture of IID sequences.

The Beta–Bernoulli model in *Merging of Opinions: The Blackwell–Dubins Theorem* is the instance of (28.3) in which μ is a Beta distribution.

Exercise Exercise 28.10.3 describes an urn scheme that generates it.

28.6 Bayes' Law

We noted above that in our example model there is something to learn about the future from past data drawn from our particular instance of a process that is exchangeable but not IID.

But how can we learn?

And about what?

The answer to the *about what* question is: about which distribution, F or G, nature selected at time -1.

The decision maker knows his prior probability $\tilde{\pi}$.

What he learns is expressed in a posterior probability that moves away from $\tilde{\pi}$ as data arrive.

The answer to the *how* question is to use Bayes' Law.

Another way to say *use Bayes' Law* is to say *from a (subjective) joint distribution, compute an appropriate conditional distribution*.

Let's dive into Bayes' Law in this context.

Let q represent the distribution that nature actually draws w from and let

$$\pi = \mathbb{P}\{q = f\}$$

where we regard π as a decision maker's **subjective probability** (also called a **personal probability**).

Suppose that at $t \geq 0$, the decision maker has observed a history $w^t \equiv [w_t, w_{t-1}, \ldots, w_0]$.

We let

$$\pi_t = \mathbb{P}\{q = f | w^t\}$$

where we adopt the convention

$$\pi_{-1} = \tilde{\pi}$$

Conditional on q, the draw w_{t+1} is independent of the history w^t.

The density of w_{t+1} conditional on w^t is then

$$\pi_t f + (1 - \pi_t) g.$$

Bayes' rule for updating π_{t+1} is

$$\pi_{t+1} = \frac{\pi_t f(w_{t+1})}{\pi_t f(w_{t+1}) + (1 - \pi_t) g(w_{t+1})} \tag{28.4}$$

Equation (28.4) follows from Bayes' rule, which tells us that

$$\mathbb{P}\{q = f \,|\, w^{t+1}\} = \frac{p(w_{t+1} \,|\, q = f, w^t)\, \mathbb{P}\{q = f \,|\, w^t\}}{p(w_{t+1} \,|\, w^t)}$$

where p denotes a density and

$$p(w_{t+1} \,|\, w^t) = \sum_{a \in \{f, g\}} p(w_{t+1} \,|\, q = a, w^t)\, \mathbb{P}\{q = a \,|\, w^t\}.$$

Because w_{t+1} is independent of w^t conditional on q, $p(w_{t+1} \,|\, q = f, w^t) = f(w_{t+1})$ and $p(w_{t+1} \,|\, q = g, w^t) = g(w_{t+1})$.

28.7 More details about Bayesian updating

Let's stare at and rearrange Bayes' Law as represented in equation (28.4) with the aim of understanding how the **posterior** probability π_{t+1} is influenced by the **prior** probability π_t and the **likelihood ratio**

$$\ell(w) = \frac{f(w)}{g(w)}$$

It is convenient for us to rewrite the updating rule (28.4) as

$$\pi_{t+1} = \frac{\pi_t f\left(w_{t+1}\right)}{\pi_t f\left(w_{t+1}\right) + \left(1-\pi_t\right) g\left(w_{t+1}\right)} = \frac{\pi_t \frac{f(w_{t+1})}{g(w_{t+1})}}{\pi_t \frac{f(w_{t+1})}{g(w_{t+1})} + \left(1-\pi_t\right)} = \frac{\pi_t \ell\left(w_{t+1}\right)}{\pi_t \ell\left(w_{t+1}\right) + \left(1-\pi_t\right)}$$

This implies that

$$\frac{\pi_{t+1}}{\pi_t} = \frac{\ell\left(w_{t+1}\right)}{\pi_t \ell\left(w_{t+1}\right) + \left(1-\pi_t\right)} \begin{cases} > 1 & \text{if } \ell\left(w_{t+1}\right) > 1 \\ \leq 1 & \text{if } \ell\left(w_{t+1}\right) \leq 1 \end{cases} \tag{28.5}$$

The likelihood ratio alone determines whether an observation w_{t+1} leads the decision maker to increase or decrease the subjective probability he/she attaches to distribution F.

When the likelihood ratio $\ell(w_{t+1})$ exceeds one, the observation w_{t+1} nudges the probability π put on distribution F upward, and when the likelihood ratio $\ell(w_{t+1})$ is less than one, the observation w_{t+1} nudges π downward.

The prior π_t affects the size of the move:

$$\pi_{t+1} - \pi_t = \frac{\pi_t(1-\pi_t)(\ell(w_{t+1}) - 1)}{\pi_t \ell(w_{t+1}) + 1 - \pi_t}$$

The move shrinks to zero as π_t approaches 0 or 1.

Representation (28.5) is the foundation of some graphs that we'll use to display the dynamics of $\{\pi_t\}_{t=0}^{\infty}$ that are induced by Bayes' Law.

We'll plot $\ell\left(w\right)$ as a way to enlighten us about how learning – i.e., Bayesian updating of the probability π that nature has chosen distribution f – works.

We build up the picture in three steps, each of which produces one graph.

All three are built from the same ingredients: the densities f and g, and the values of w at which the likelihood ratio $\ell(w) = f(w)/g(w)$ crosses one.

Both f and g are Beta densities, so we start with the general Beta density.

```
def p(w, a, b):
    "The Beta density with parameters a and b."
    r = gamma(a + b) / (gamma(a) * gamma(b))
    return r * w**(a - 1) * (1 - w)**(b - 1)
```

The next function assembles the ingredients for a given pair of Beta distributions.

```
def create_model(F_a=1, F_b=1, G_a=3, G_b=1.2):
    """
    Build the densities f and g, along with the two values of w at which
    the likelihood ratio ℓ(w) = f(w) / g(w) equals one.

    The root finder assumes that f is uniform (F_a = F_b = 1) and that
    G_a > 1 and G_b > 1.  Then g vanishes at 0 and 1 and has a single
```

(continues on next page)

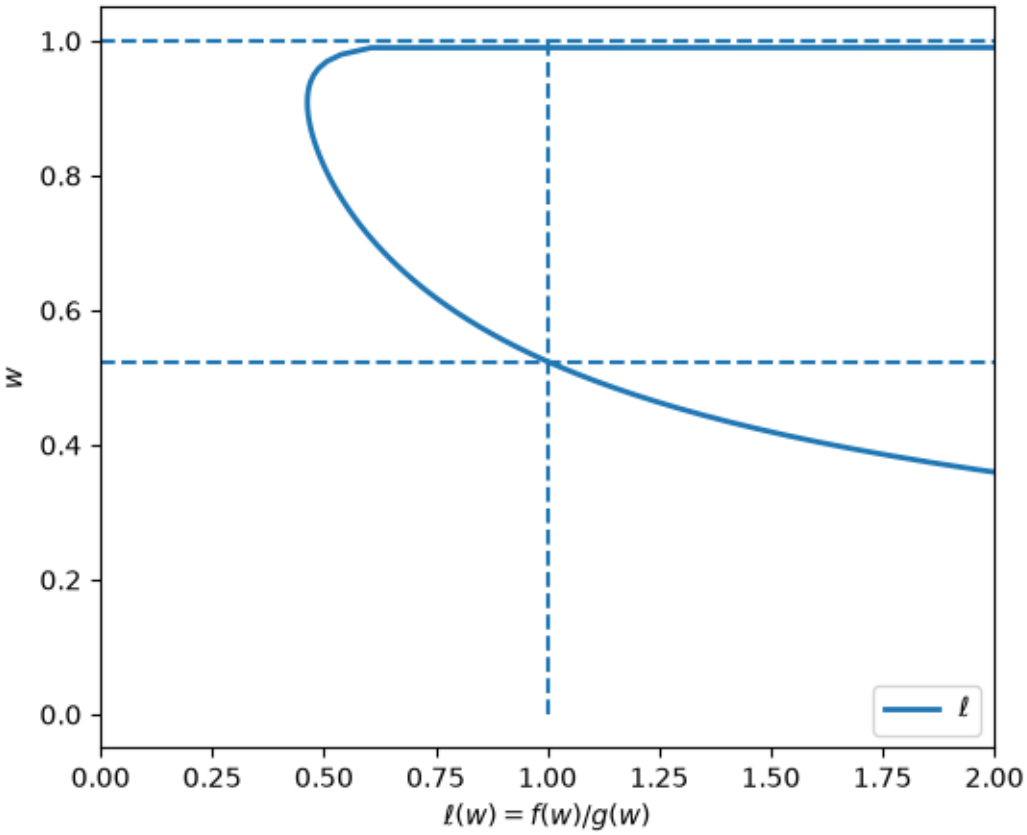
(continued from previous page)

```
    interior mode at which g exceeds one, so ℓ(w) = 1 / g(w) equals one
    exactly once on each side of the mode of g.
    """
    f = lambda w: p(w, F_a, F_b)
    g = lambda w: p(w, G_a, G_b)

    # The mode of g divides [0, 1] into two intervals, each holding one root
    G_mode = (G_a - 1) / (G_a + G_b - 2)
    obj = lambda w: f(w) / g(w) - 1
    roots = np.array([op.root_scalar(obj, bracket=[1e-10, G_mode]).root,
                      op.root_scalar(obj, bracket=[G_mode, 1 - 1e-10]).root])
    return f, g, roots
```

28.7.1 The likelihood ratio

Our first graph plots the likelihood ratio $\ell(w)$ on the abscissa axis against w on the ordinate axis.



We orient it this way so that w shares an axis with the two graphs that follow.

```
def plot_likelihood_ratio(F_a=1, F_b=1, G_a=3, G_b=1.2):
    f, g, roots = create_model(F_a, F_b, G_a, G_b)
    w_grid = np.linspace(1e-12, 1 - 1e-12, 100)

    fig, ax = plt.subplots(figsize=(6, 5))
    ax.plot(f(w_grid) / g(w_grid), w_grid, label=r'$\ell$', lw=2)
    ax.vlines(1, 0, 1, linestyle='--')
    ax.hlines(roots, 0, 2, linestyle='--')
    ax.set_xlim(0, 2)
    ax.legend(loc=4)
    ax.set(xlabel=r'$\ell(w) = f(w) / g(w)$', ylabel='$w$')
    plt.show()
```

We begin with f uniform on $[0, 1]$ — that is, Beta with $F_a = 1, F_b = 1$ — and g Beta with $G_a = 3, G_b = 1.2$.

```
plot_likelihood_ratio()
```

The two horizontal dashed lines mark the values of w at which $\ell(w) = 1$.

Between them the likelihood ratio is below one, so by (28.5) a draw in that region pushes π down.

Outside them it exceeds one, so a draw there pushes π up.

28.7.2 The densities and the probabilities of moving in each direction

Our second graph plots $f(w)$ and $g(w)$ against w, and shades the regions delineated by those same two values of w.

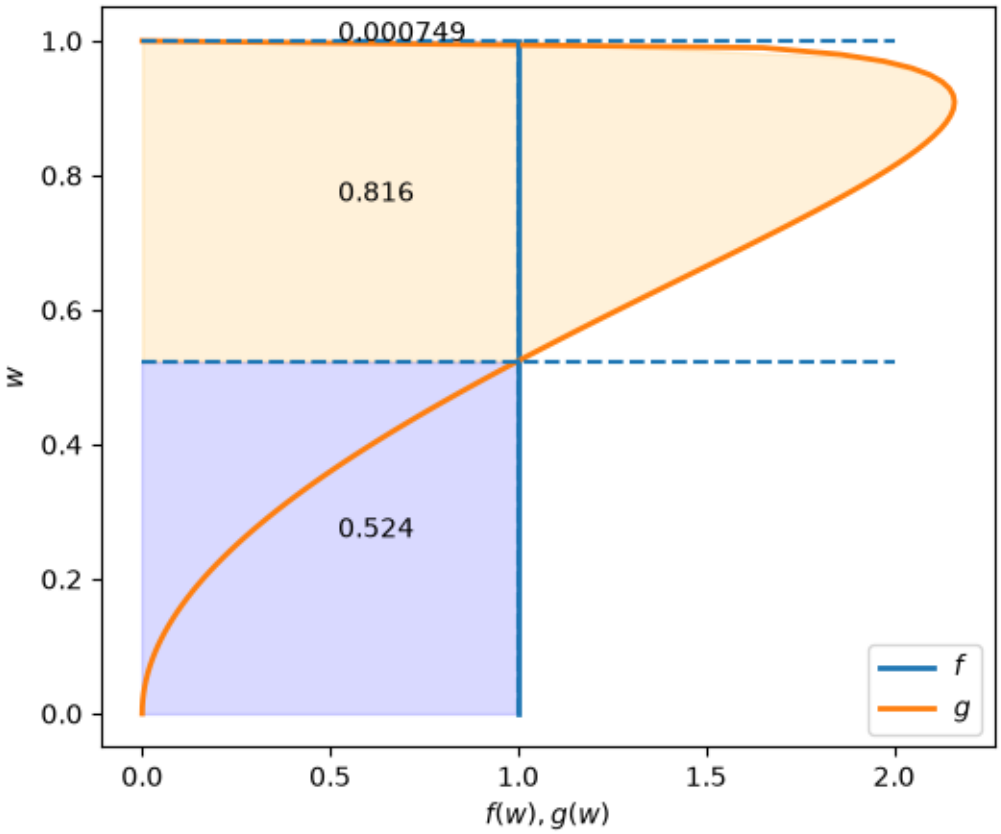
Shading them lets us attach a probability to each direction of movement, which we compute by integrating the relevant density over the region.

```
def plot_densities(F_a=1, F_b=1, G_a=3, G_b=1.2):
    f, g, roots = create_model(F_a, F_b, G_a, G_b)
    w_grid = np.linspace(0, 1, 100)

    fig, ax = plt.subplots(figsize=(6, 5))
    ax.plot(f(w_grid), w_grid, label='$f$', lw=2)
    ax.plot(g(w_grid), w_grid, label='$g$', lw=2)
    ax.vlines(1, 0, 1, linestyle='--')
    ax.hlines(roots, 0, 2, linestyle='--')
    ax.legend(loc=4)
    ax.set(xlabel='$f(w), g(w)$', ylabel='$w$')

    # Probability of landing in each region, under whichever density is shaded
    area_lower = quad(f, 0, roots[0])[0]
```

(continues on next page)



(continued from previous page)

```
    area_middle = quad(g, roots[0], roots[1])[0]
    area_upper = quad(f, roots[1], 1)[0]

    ax.fill_between([0, 1], 0, roots[0], color='blue', alpha=0.15)
    ax.text((f(0) + f(roots[0])) / 4, roots[0] / 2, f"{area_lower: .3g}")
    w_middle = np.linspace(roots[0], roots[1], 20)
    ax.fill_betweenx(w_middle, 0, g(w_middle), color='orange', alpha=0.15)
    ax.text(np.mean(g(roots)) / 2, np.mean(roots), f"{area_middle: .3g}")
    ax.fill_between([0, 1], roots[1], 1, color='blue', alpha=0.15)
    ax.text((f(roots[1]) + f(1)) / 4, (roots[1] + 1) / 2, f"{area_upper: .3g}")
    plt.show()
```

Let's look at the same pair of distributions as before.

```
plot_densities()
```

The fractions in the colored areas are probabilities that a realization of w falls into the region beside them.

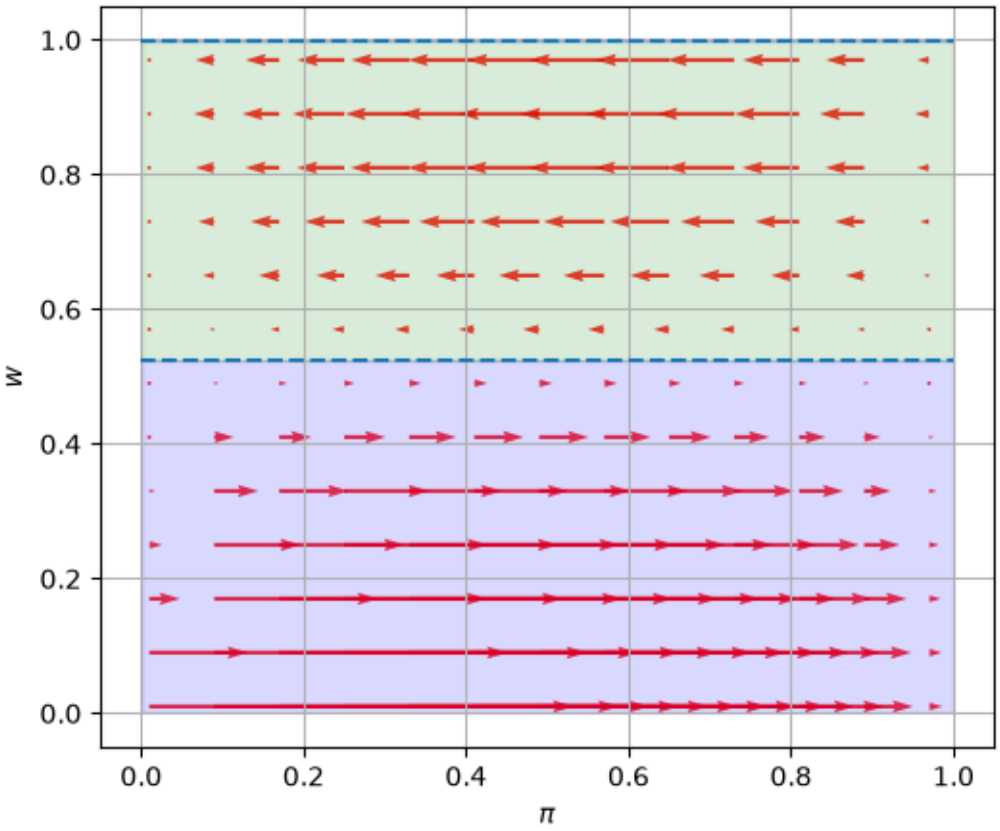
The blue regions are integrals of f and the orange region is an integral of g.

For example, under true distribution F, π will be updated toward 0 if w falls into the interval $[0.524, 0.999]$, which occurs with probability $0.999 - 0.524 \approx 0.475$ under F.

But this would occur with probability 0.816 if G were the true distribution.

28.7.3 Dynamics of the belief

Our third graph attaches an arrow to each point in the (π, w) plane showing the change in π that Bayes' Law induces when the current belief is π and the new draw is w.



```
def plot_belief_dynamics(F_a=1, F_b=1, G_a=3, G_b=1.2):
    f, g, roots = create_model(F_a, F_b, G_a, G_b)
    π_grid = np.linspace(1e-3, 1 - 1e-3, 100)

    # Change in π at each point of a coarse grid over (π, w)
    W = np.arange(0.01, 0.99, 0.08)
    Π = np.arange(0.01, 0.99, 0.08)
    lw = (f(W) / g(W))[:, None]      # likelihood ratio at each w, as a column
    ΔΠ = Π * (lw / (Π * lw + 1 - Π) - 1)
    ΔW = np.zeros_like(ΔΠ)

    fig, ax = plt.subplots(figsize=(6, 5))
    ax.quiver(Π, W, ΔΠ, ΔW, scale=2, color='r', alpha=0.8)
    ax.fill_between(π_grid, 0, roots[0], color='blue', alpha=0.15)
    ax.fill_between(π_grid, roots[0], roots[1], color='green', alpha=0.15)
    ax.fill_between(π_grid, roots[1], 1, color='blue', alpha=0.15)
    ax.hlines(roots, 0, 1, linestyle='--')
    ax.set(xlabel=r'$\pi$', ylabel='$w$')
    ax.grid()
    plt.show()
```

Again we use the same pair of distributions.

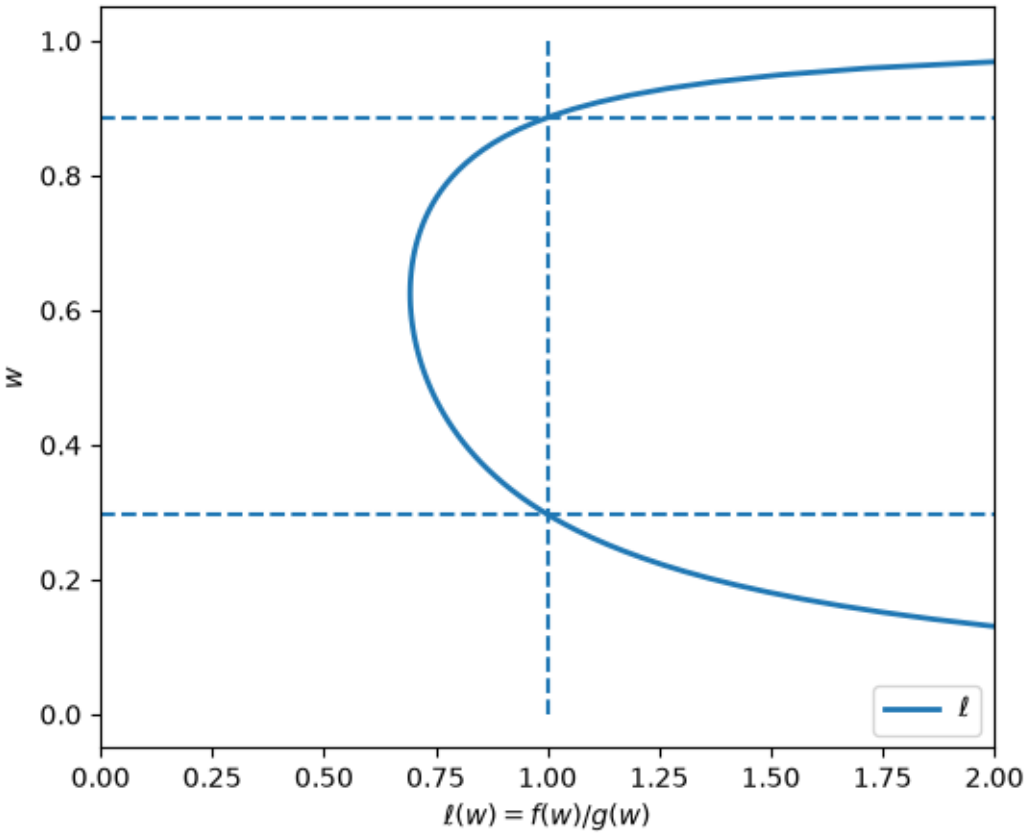
```
plot_belief_dynamics()
```

Arrows pointing right show when Bayes' Law makes π increase and arrows pointing left show when it makes π decrease.

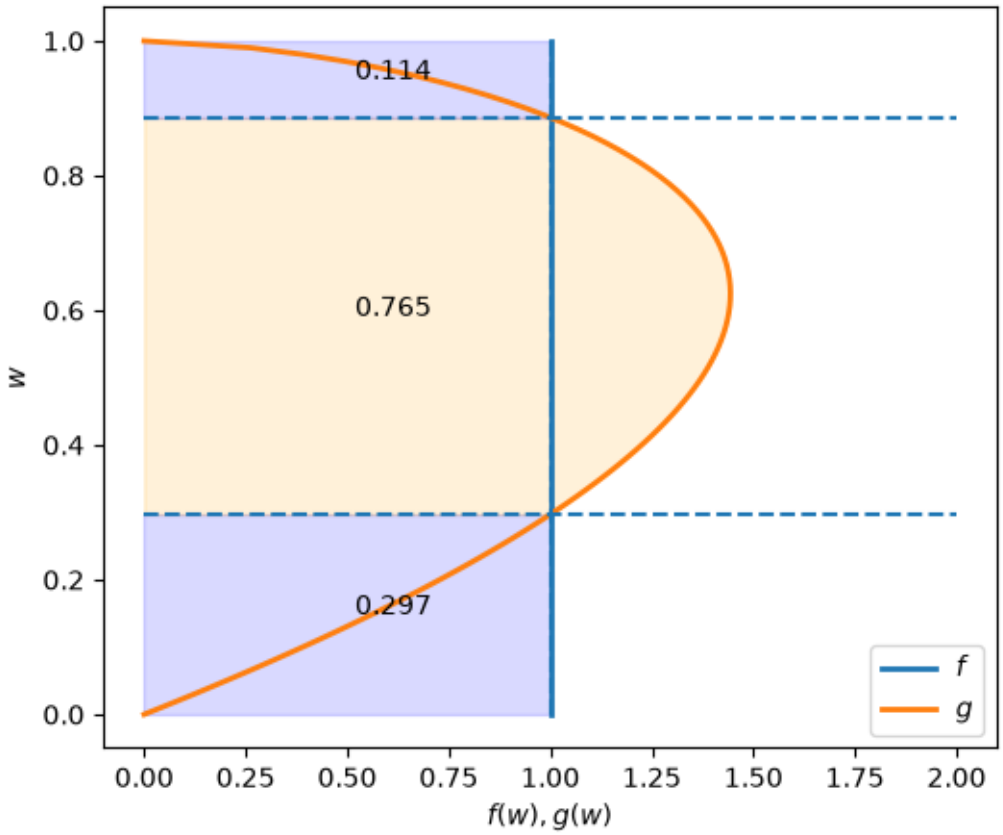
Lengths of the arrows show magnitudes of the force from Bayes' Law impelling π to change.

These lengths depend on both the prior probability π on the abscissa axis and the evidence in the form of the current draw of w on the ordinate axis.

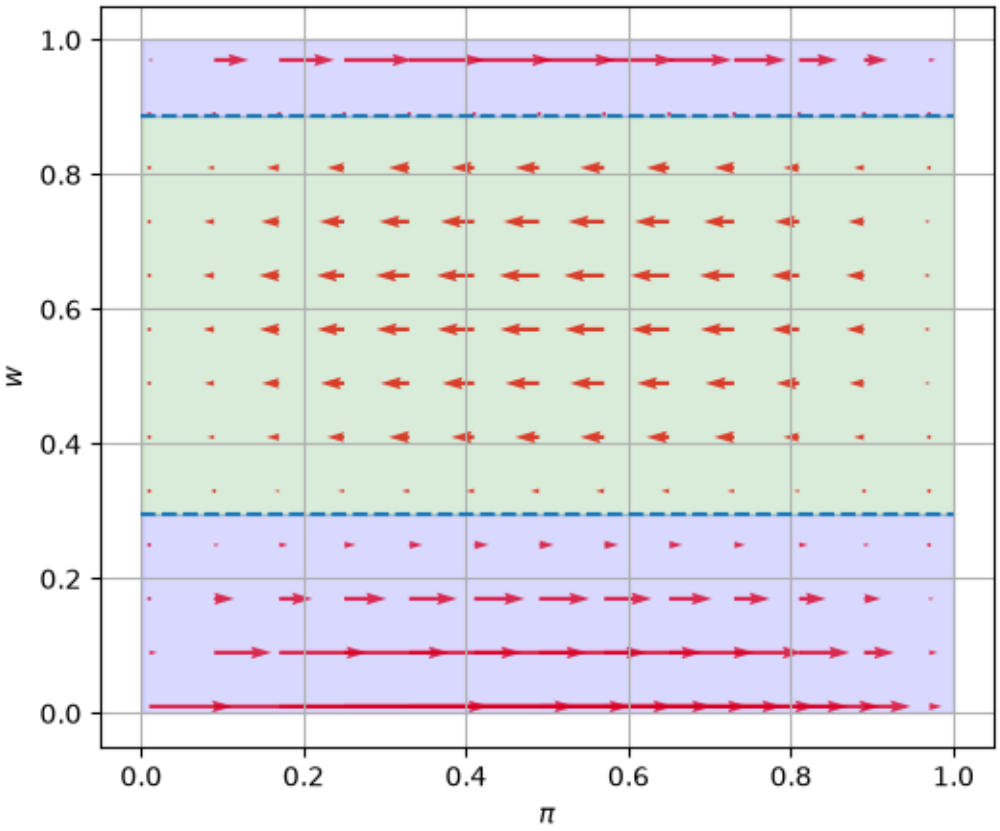
Arrows point right in the blue regions, where $\ell(w) > 1$, and left in the green region between the dashed lines, where $\ell(w) < 1$.



For these parameters the upper blue region is a thin sliver just below $w = 1$, since $\ell(w)$ returns above one only for draws very close to the upper limit.



28.7.4 Another instance



Next we use our code to create graphs for another instance of our model.

We keep F the same as in the preceding instance, namely a uniform distribution, but now assume that G is a Beta distribution with parameters $G_a = 2, G_b = 1.6$.

```
plot_likelihood_ratio(G_a=2, G_b=1.6)
plot_densities(G_a=2, G_b=1.6)
plot_belief_dynamics(G_a=2, G_b=1.6)
```

28.8 Appendix

28.8.1 Sample paths of π_t

Now we'll have some fun by plotting multiple realizations of sample paths of π_t under two possible assumptions about nature's choice of distribution, namely

- that nature permanently draws from F
- that nature permanently draws from G

Outcomes depend on a peculiar property of likelihood ratio processes discussed in *this section* of *Likelihood Ratio Processes*.

Before simulating, it pays to rewrite Bayes' Law in terms of **odds** rather than probabilities.

In terms of the odds $\pi/(1-\pi)$, the updating rule (28.4) becomes

$$\frac{\pi_{t+1}}{1-\pi_{t+1}} = \ell(w_{t+1})\frac{\pi_t}{1-\pi_t} \tag{28.6}$$

So Bayes' Law is *multiplicative* in the odds, and iterating (28.6) back to the prior π_{-1} yields

$$\frac{\pi_t}{1-\pi_t} = \frac{\pi_{-1}}{1-\pi_{-1}}\prod_{s=0}^{t}\ell(w_s) \tag{28.7}$$

The belief path is thus a running product of likelihood ratios, which is why properties of likelihood ratio processes govern its behavior.

Taking logarithms turns the product into a sum:

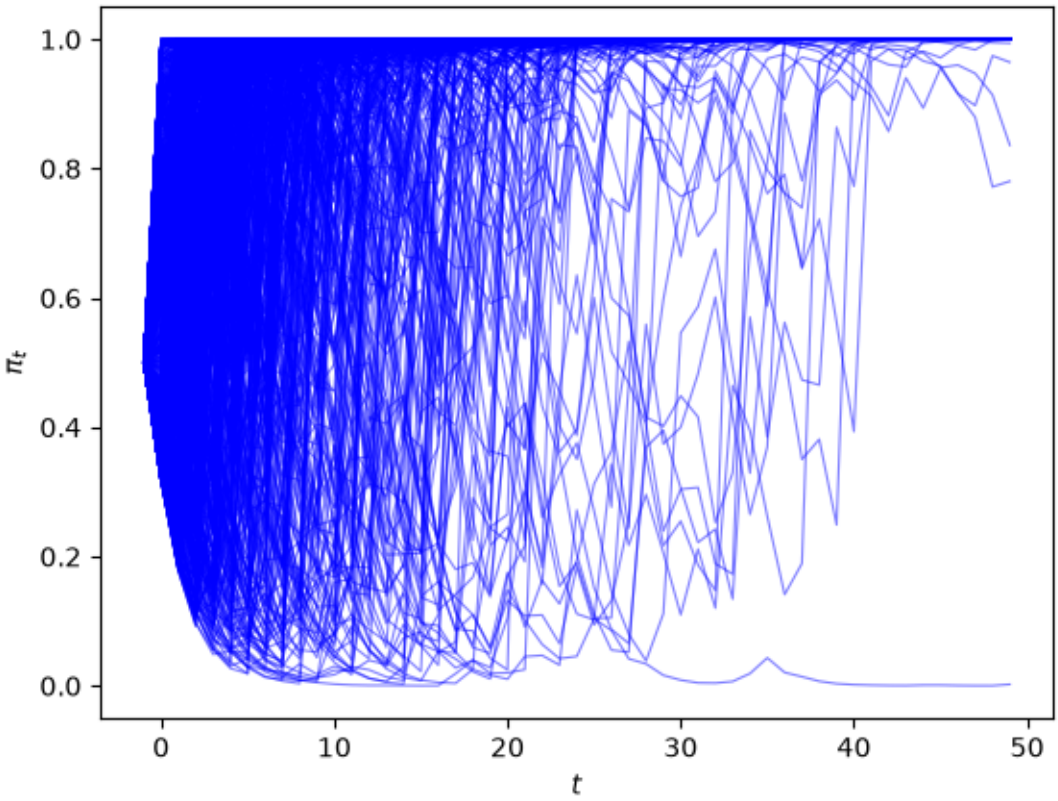
$$\log \frac{\pi_t}{1-\pi_t} = \log \frac{\pi_{-1}}{1-\pi_{-1}} + \sum_{s=0}^{t} \log \ell(w_s)$$

We simulate with this sum.

It avoids overflow in the product and loss of precision when π_t is close to 0 or 1.

It also means that we can simulate an entire ensemble of paths with a cumulative sum, with no iteration over dates.

```
def simulate(rng, a, b, T=50, N=1000, π_init=0.5,
             F_a=1, F_b=1, G_a=3, G_b=1.2):
    """
    Simulate N paths of the belief π when nature draws w_0, ..., w_{T-1}
    IID from Beta(a, b).  Returns an array of shape (N, T+1) whose column 0
    holds the prior π_{-1} = π_init and whose column t+1 holds π_t.
    """
    w = rng.beta(a, b, size=(N, T))
    log_l = np.log(p(w, F_a, F_b)) - np.log(p(w, G_a, G_b))
    log_odds = np.log(π_init / (1 - π_init)) + np.cumsum(log_l, axis=1)
    return np.column_stack([np.full(N, π_init), expit(log_odds)])
```



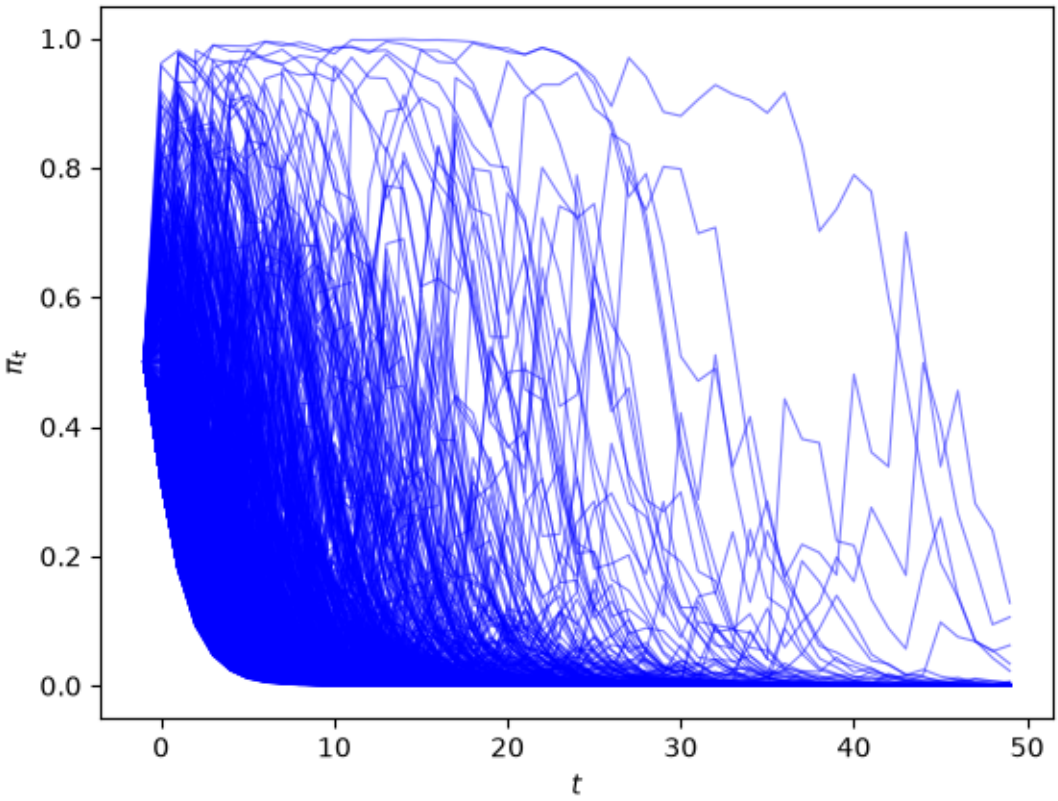
The paths are plotted by the next function.

```
def plot_paths(π_paths):
    "Plot belief paths against the dates t = -1, 0, ..., T-1."
    t = np.arange(π_paths.shape[1]) - 1
    fig, ax = plt.subplots()
    ax.plot(t, π_paths.T, color='b', lw=0.8, alpha=0.5)
    ax.set(xlabel='$t$', ylabel=r'$\pi_t$')
    plt.show()
```

We begin by generating N simulated $\{\pi_t\}$ paths with T periods when the sequence is truly IID draws from F. We set an initial prior $\pi_{-1} = .5$.

```
rng = np.random.default_rng(42)
T = 50
```

```
# when nature selects F
π_paths_F = simulate(rng, a=1, b=1, T=T, N=1000)
plot_paths(π_paths_F)
```



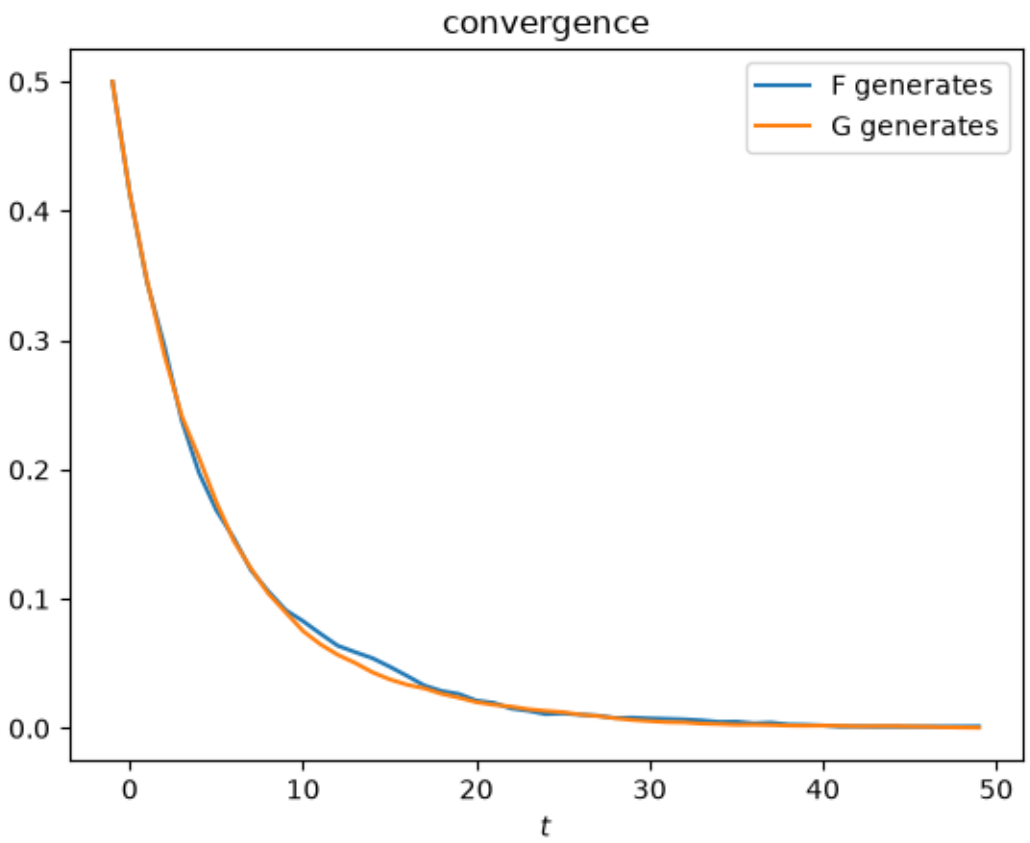
In the above example, for most paths $\pi_t \to 1$.

So Bayes' Law evidently eventually discovers the truth for most of our paths.

Next, we generate paths with T periods when the sequence is truly IID draws from G. Again, we set the initial prior $\pi_{-1} = .5$.

```
# when nature selects G
π_paths_G = simulate(rng, a=3, b=1.2, T=T, N=1000)
plot_paths(π_paths_G)
```

In the above graph we observe that now most paths $\pi_t \to 0$.



28.8.2 Rates of convergence

We study rates of convergence of π_t to 1 when nature generates the data as IID draws from F and of convergence of π_t to 0 when nature generates IID draws from G.

We do this by averaging across simulated paths of $\{\pi_t\}_{t=-1}^{T-1}$.

Using N simulated π_t paths, we compute $1 - \frac{1}{N}\sum_{i=1}^{N} \pi_{i,t}$ at each t when the data are generated as draws from F and compute $\frac{1}{N}\sum_{i=1}^{N} \pi_{i,t}$ when the data are generated as draws from G.

```
t_grid = np.arange(-1, T)
fig, ax = plt.subplots()
ax.plot(t_grid, 1 - np.mean(π_paths_F, axis=0), label='F generates')
ax.plot(t_grid, np.mean(π_paths_G, axis=0), label='G generates')
ax.set(xlabel='$t$', title='convergence')
ax.legend()
plt.show()
```

The two curves nearly coincide.

An exact identity explains why:

$$\pi_{-1} E_f[1 - \pi_t] = (1 - \pi_{-1}) E_g[\pi_t] = E[\pi_t (1 - \pi_t)] \tag{28.8}$$

Here E_f and E_g denote expectations under IID draws from F and from G, and E denotes the expectation under the decision maker's subjective joint distribution (28.1).

To prove (28.8), let ϕ be a bounded function of the history w^t.

Because $\pi_t = \mathbb{P}\{q = f \mid w^t\}$, the law of iterated expectations implies

$$E[\pi_t \phi(w^t)] = E[\mathbf{1}\{q = f\} \phi(w^t)] = \pi_{-1} E_f[\phi(w^t)].$$

Setting $\phi = 1 - \pi_t$ equates the first and third terms of (28.8).

The same argument applied to $1 - \pi_t = \mathbb{P}\{q = g \mid w^t\}$ with $\phi = \pi_t$ equates the second and third terms.

With $\pi_{-1} = 0.5$, the identity says that $E_f[1 - \pi_t] = E_g[\pi_t]$ for every t, so the two simulated curves differ only by sampling error.

With another prior, the two curves differ by the constant factor $(1 - \pi_{-1})/\pi_{-1}$.

The identity does not say that typical paths converge at the same rate under F and under G.

By (28.7) and the law of large numbers, $\frac{1}{t+1} \log \frac{\pi_t}{1 - \pi_t}$ converges to $E_f[\log \ell(w)] = KL(f, g) = 0.759$ when F generates the data and to $E_g[\log \ell(w)] = -KL(g, f) = -0.344$ when G generates the data, where $KL(f, g) = \int f(w) \log \frac{f(w)}{g(w)} dw$ is the Kullback–Leibler divergence of g from f.

So a typical path approaches 1 under F faster than it approaches 0 under G.

The averages plotted above are dominated by rare paths along which π_t leans the wrong way for a long time.

Both averages decay at the exponential rate

$$C(f,g) = -\log \min_{s\in[0,1]} \int f(w)^s g(w)^{1-s} dw = 0.121,$$

the Chernoff entropy of f and g described in *Statistical Divergence Measures*.

Exercise Exercise 28.10.2 verifies these claims.

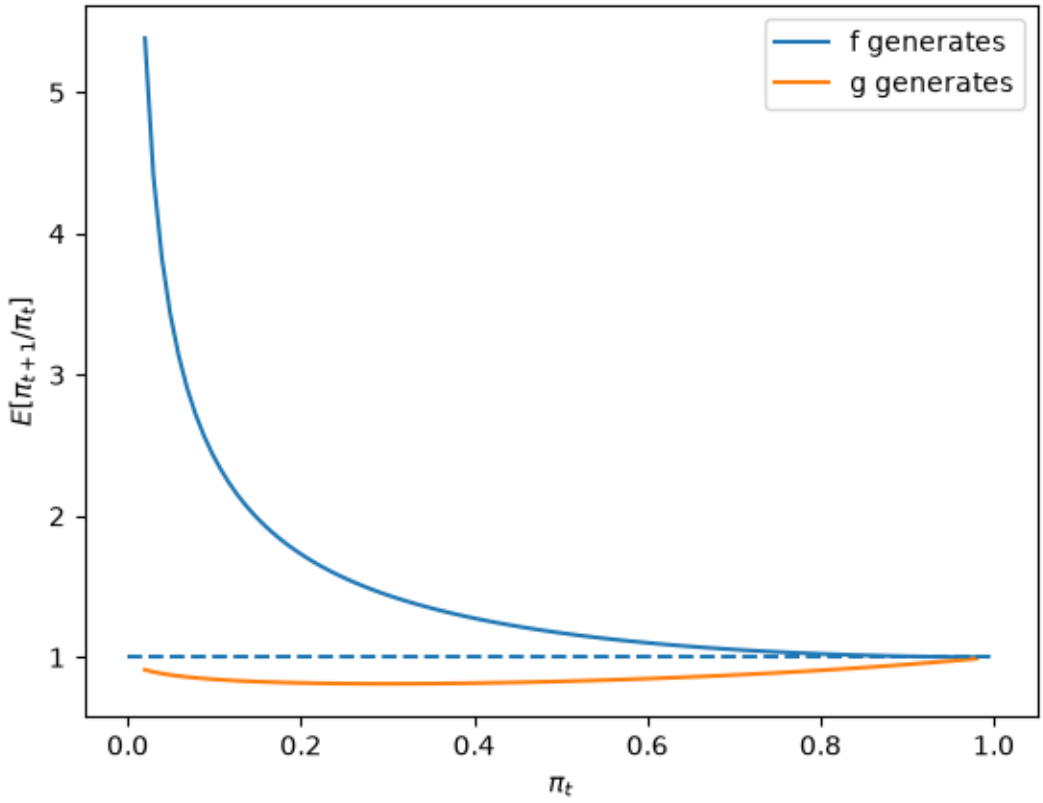
28.8.3 Graph of ensemble dynamics of π_t

More insights about the dynamics of $\{\pi_t\}$ can be gleaned by computing conditional expectations of $\frac{\pi_{t+1}}{\pi_t}$ as functions of π_t via integration with respect to the pertinent probability distribution:

$$\begin{aligned} E\left[\frac{\pi_{t+1}}{\pi_t}\,\middle|\, q=a,\pi_t\right] &= E\left[\frac{\ell\left(w_{t+1}\right)}{\pi_t\ell\left(w_{t+1}\right)+\left(1-\pi_t\right)}\,\middle|\, q=a,\pi_t\right], \\ &= \int_0^1 \frac{\ell\left(w_{t+1}\right)}{\pi_t\ell\left(w_{t+1}\right)+\left(1-\pi_t\right)} a\left(w_{t+1}\right) dw_{t+1} \end{aligned}$$

where $a = f, g$.

The following code approximates the integral above:



```
def plot_expected_ratio(F_a=1, F_b=1, G_a=3, G_b=1.2):
    # Build f and g directly: here they can coincide, so ℓ(w) = 1 has no root
    f = lambda w: p(w, F_a, F_b)
    g = lambda w: p(w, G_a, G_b)
    l = lambda w: f(w) / g(w)
    π_grid = np.linspace(0.02, 0.98, 100)

    fig, ax = plt.subplots()
    for label, a in [('f', f), ('g', g)]:
        integrand = lambda w, π: a(w) * l(w) / (π * l(w) + 1 - π)
        ratios = [quad(integrand, 0, 1, args=(π,))[0] for π in π_grid]
        ax.plot(π_grid, ratios, label=f'{label} generates')

    ax.hlines(1, 0, 1, linestyle='--')
    ax.set(xlabel=r'$\pi_t$', ylabel=r'$E[\pi_{t+1} / \pi_t]$')
    ax.legend()
    plt.show()
```

First, consider the case where $F_a = F_b = 1$ and $G_a = 3, G_b = 1.2$.

```
plot_expected_ratio()
```

The above graph shows that when F generates the data, π_t on average always heads north, while when G generates the data, π_t heads south.

Two inequalities hold for every pair $f \neq g$ and every $\pi_t = \pi \in (0, 1)$.

Let $r(\ell) = \ell/(\pi\ell + 1 - \pi)$ be the ratio π_{t+1}/π_t as a function of $\ell = \ell(w_{t+1})$.

The function r is strictly concave and $E_g[\ell(w)] = \int f(w)dw = 1$, so Jensen's inequality implies

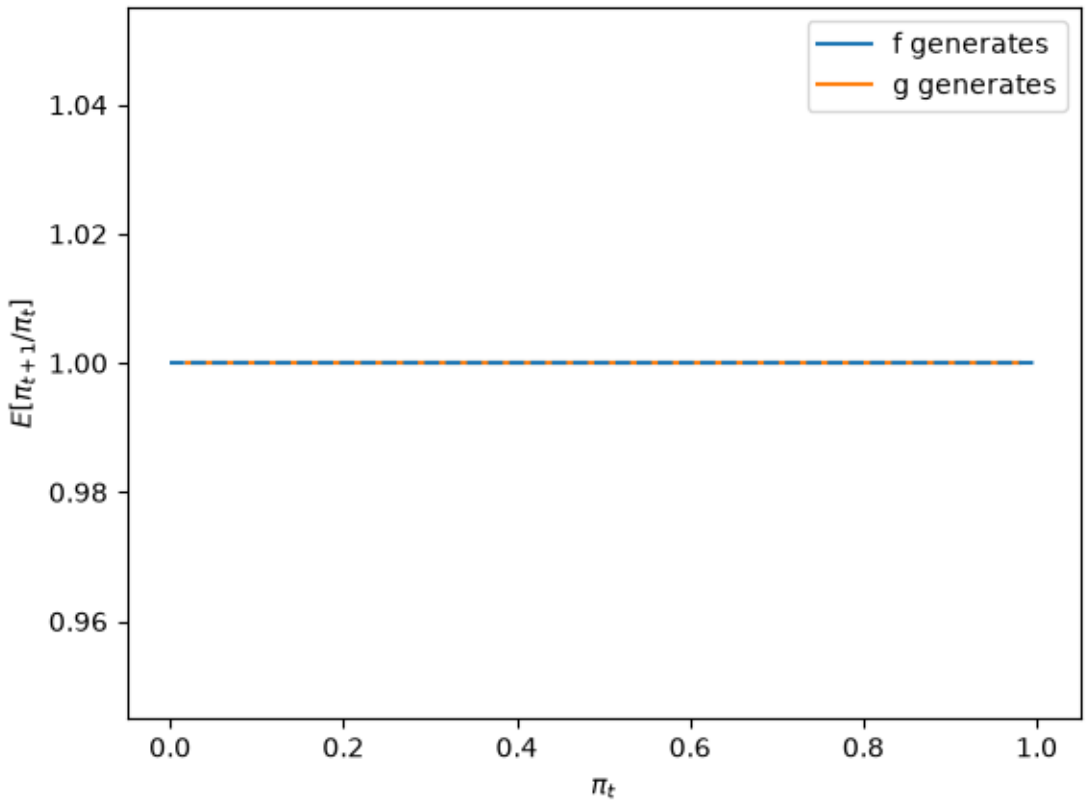
$$E_g[r(\ell(w))] < r(1) = 1.$$

The π-weighted average of the two expectations equals one:

$$\pi E_f[r(\ell(w))] + (1-\pi)E_g[r(\ell(w))] = \int \frac{f(w)}{\pi f(w) + (1-\pi)g(w)}(\pi f(w) + (1-\pi)g(w))dw = 1.$$

This equality is the martingale property of π_t under the decision maker's subjective distribution, studied in *Likelihood Ratio Processes and Bayesian Learning*.

It and the first inequality imply

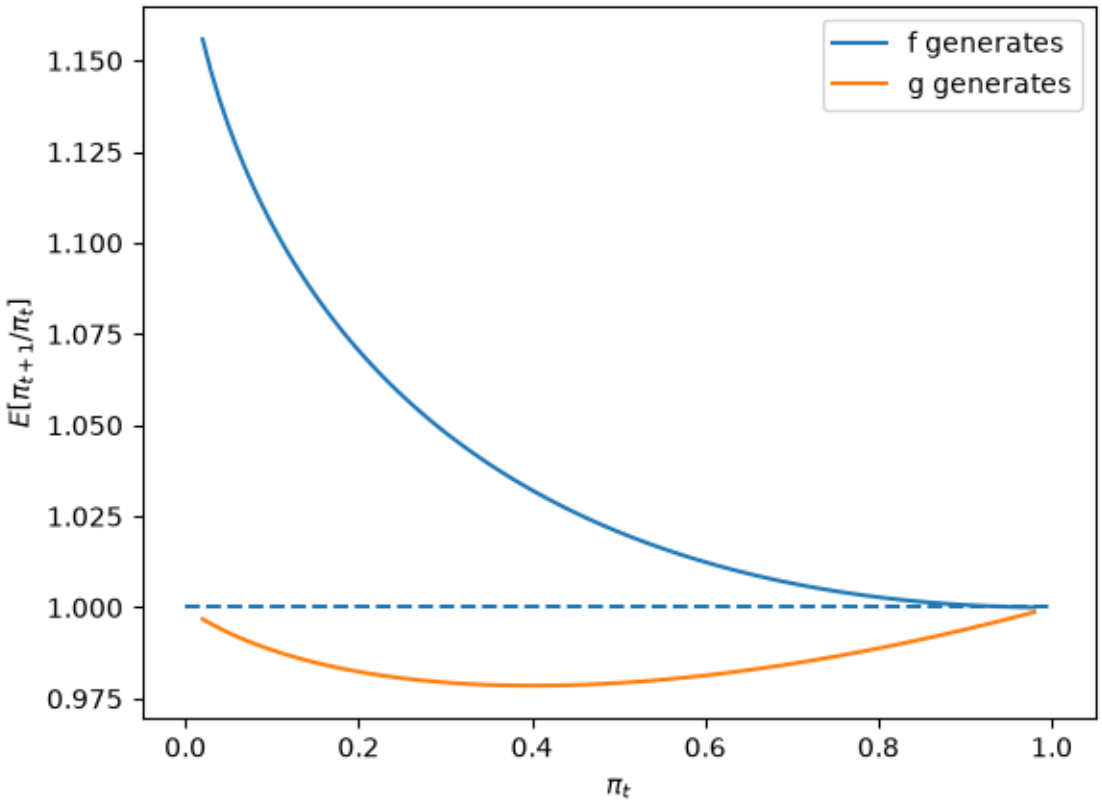


$$E_f[r(\ell(w))] > 1.$$

Thus π_t is a submartingale when F generates the data and a supermartingale when G generates the data.

Next, we'll look at a degenerate case in which f and g are identical beta distributions, and $F_a = G_a = 3, F_b = G_b = 1.2$.

In a sense, here there is nothing to learn.



```
plot_expected_ratio(F_a=3, F_b=1.2)
```

The above graph says that π_t is inert and remains at its initial value.

Finally, let's look at a case in which f and g are neither very different nor identical, in particular one in which $F_a = 2, F_b = 1$ and $G_a = 3, G_b = 1.2$.

```
plot_expected_ratio(F_a=2, F_b=1, G_a=3, G_b=1.2)
```

The two inequalities still hold, but both curves now stay close to one.

On the plotted grid, $E_f[\pi_{t+1}/\pi_t]$ never exceeds 1.16 and $E_g[\pi_{t+1}/\pi_t]$ never falls below 0.978.

In the first case the corresponding numbers are 5.38 and 0.811.

The densities Beta$(2, 1)$ and Beta$(3, 1.2)$ are close to each other: $KL(f, g) = 0.052$ and $KL(g, f) = 0.039$, compared with 0.759 and 0.344 in the first case.

A draw moves π_t only a little on average, so learning is slow.

28.9 Sequels

We'll apply and dig deeper into some of the ideas presented in this lecture:

- *Likelihood Ratio Processes* describes **likelihood ratio processes** and their role in frequentist and Bayesian statistical theories
- *Likelihood Ratio Processes and Bayesian Learning* studies how a likelihood ratio process drives the posterior probability π_t and shows that π_t is a martingale under the decision maker's subjective distribution (28.1)
- *Incorrect Models* studies a decision maker who uses this lecture's statistical model when nature actually mixes F and G anew each period
- *Merging of Opinions: The Blackwell–Dubins Theorem* studies the Beta–Bernoulli model, an instance of de Finetti's representation (28.3), and asks when the opinions of two Bayesians with different priors merge
- *Statistical Divergence Measures* describes the Kullback–Leibler divergence and the Chernoff entropy that govern rates of learning

- *A Bayesian Formulation of Friedman and Wald's Problem* studies a decision maker with this lecture's beliefs who decides sequentially when to stop sampling
- *Bayesian versus Frequentist Decision Rules* studies a World War II US Navy Captain's hunch that a (frequentist) decision rule that the Navy had told him to use was inferior to a sequential rule that Abraham Wald had not yet designed

28.10 Exercises

Exercise 28.10.1

This exercise shows that a mixture of IID sequences has nonnegative serial covariances and that a finite exchangeable sequence need not be a mixture of IID sequences.

1. Prove identity (28.2).
2. Let ϕ be a function for which $E_f[\phi(W)]$ and $E_g[\phi(W)]$ are finite. Use (28.2) to show that under the joint density (28.1)

$$\text{Cov}(\phi(W_0), \phi(W_1)) = \tilde{\pi}(1-\tilde{\pi})(E_f[\phi(W)] - E_g[\phi(W)])^2 \geq 0.$$

3. For this lecture's densities $f = \text{Beta}(1,1)$ and $g = \text{Beta}(3, 1.2)$ and $\tilde{\pi} = 0.5$, compute $\text{Cov}(W_0, W_1)$ from the formula in part 2 and compare it with a simulation.
4. An urn contains one red ball and one black ball. We draw both balls without replacement. Let $W_t = 1$ if draw $t \in \{0, 1\}$ is red and $W_t = 0$ if it is black. Show that (W_0, W_1) is exchangeable and that $\text{Cov}(W_0, W_1) < 0$. Explain why (W_0, W_1) is not a mixture of IID pairs and why de Finetti's theorem requires an infinite sequence.

Solution

Part 1.

With $h(W_t) = \tilde{\pi} f(W_t) + (1-\tilde{\pi}) g(W_t)$,

$$h(W_0)h(W_1) = \tilde{\pi}^2 f(W_0)f(W_1) + \tilde{\pi}(1-\tilde{\pi})(f(W_0)g(W_1) + g(W_0)f(W_1)) + (1-\tilde{\pi})^2 g(W_0)g(W_1).$$

Subtracting this from $h(W_0, W_1) = \tilde{\pi} f(W_0)f(W_1) + (1-\tilde{\pi}) g(W_0)g(W_1)$ and using $\tilde{\pi} - \tilde{\pi}^2 = (1-\tilde{\pi}) - (1-\tilde{\pi})^2 = \tilde{\pi}(1-\tilde{\pi})$ gives

$$h(W_0, W_1) - h(W_0)h(W_1) = \tilde{\pi}(1-\tilde{\pi})(f(W_0)f(W_1) + g(W_0)g(W_1) - f(W_0)g(W_1) - g(W_0)f(W_1)),$$

which factors into the right side of (28.2).

Part 2.

Multiply (28.2) by $\phi(W_0)\phi(W_1)$ and integrate over W_0 and W_1:

$$\text{Cov}(\phi(W_0), \phi(W_1)) = \tilde{\pi}(1-\tilde{\pi}) \int \phi(w)(f(w) - g(w))dw \int \phi(w)(f(w) - g(w))dw = \tilde{\pi}(1-\tilde{\pi})(E_f[\phi(W)] - E_g[\phi(W)])^2.$$

The same conclusion holds for a mixture of IID sequences with any mixing measure.

Let Q be the distribution, drawn from the mixing measure, from which the W_t are IID draws.

The law of total covariance gives

$$\text{Cov}(\phi(W_0), \phi(W_1)) = E[\text{Cov}(\phi(W_0), \phi(W_1) \mid Q)] + \text{Cov}(E[\phi(W_0)|Q], E[\phi(W_1)|Q]) = 0 + \text{Var}(E[\phi(W)|Q]) \geq 0.$$

Part 3.

The means of Beta$(1,1)$ and Beta$(3,1.2)$ are $1/2$ and $3/4.2$.

```
π_tilde = 0.5
μ_f, μ_g = 1 / (1 + 1), 3 / (3 + 1.2)
cov_theory = π_tilde * (1 - π_tilde) * (μ_f - μ_g)**2

rng = np.random.default_rng(1234)
N = 1_000_000
nature_draws_f = rng.random(N) < π_tilde
W = np.where(nature_draws_f[:, None],
             rng.beta(1, 1, size=(N, 2)),
             rng.beta(3, 1.2, size=(N, 2)))
cov_sim = np.cov(W[:, 0], W[:, 1])[0, 1]

print(f"Cov(W_0, W_1): formula {cov_theory:.5f}, simulation {cov_sim:.5f}")
```

```
Cov(W_0, W_1): formula 0.01148, simulation 0.01147
```

Part 4.

The first draw is red with probability $1/2$, and then the second draw is black with probability one.

So Prob$(W_0 = 1, W_1 = 0)$ = Prob$(W_0 = 0, W_1 = 1) = 1/2$ and Prob$(W_0 = W_1) = 0$.

The joint distribution is invariant to exchanging W_0 and W_1, so (W_0, W_1) is exchangeable.

$E[W_0] = E[W_1] = 1/2$ and $E[W_0 W_1] = 0$, so Cov$(W_0, W_1) = -1/4$.

By part 2, every mixture of IID pairs has Cov$(W_0, W_1) \geq 0$.

So (W_0, W_1) is not a mixture of IID pairs.

If (W_0, W_1) were the first two members of an infinite exchangeable sequence, de Finetti's theorem would make the pair a mixture of IID pairs.

So the urn sequence cannot be extended to an infinite exchangeable sequence.

More generally, let $W_0, \ldots, W_{n-1}$ be exchangeable with common variance $\sigma^2 > 0$ and common pairwise correlation ρ.

Then $0 \leq$ Var$(\sum_t W_t) = n\sigma^2(1 + (n-1)\rho)$, so $\rho \geq -1/(n-1)$.

The urn attains this bound with $n = 2$ and $\rho = -1$.

The bound approaches 0 as $n \to \infty$.

Exercise 28.10.2

This exercise studies identity (28.8) and rates of convergence of π_t.

1. Prove (28.8) by a second route. Use $\pi_t = \pi_{-1} L_t / (\pi_{-1} L_t + 1 - \pi_{-1})$, where $L_t = \prod_{s=0}^{t} \ell(w_s)$, and $E_f[\phi(w^t)] = E_g[L_t \phi(w^t)]$ for every bounded function ϕ of w^t.
2. Set $\pi_{-1} = 0.3$. Plot $1 - E_f[\pi_t]$ and $E_g[\pi_t]$ against t, then plot $\pi_{-1}(1 - E_f[\pi_t])$ and $(1 - \pi_{-1}) E_g[\pi_t]$ against t.
3. Compute the slopes over t of the medians across paths of $\log(\pi_t/(1-\pi_t))$ under F and under G. Compare them with $KL(f,g)$ and $-KL(g,f)$.
4. Compute the slope over t of $\log(1 - E_f[\pi_t])$ and compare it with $-C(f,g)$, where $C(f,g)$ is the Chernoff

entropy.

Hint for part 4: rare paths dominate $1 - E_f[\pi_t]$, so plain Monte Carlo estimates of it are imprecise for large t.

Let $A(s) = \int f(w)^s g(w)^{1-s} dw$, let s^* minimize $A(s)$ on $[0, 1]$, and let $m(w) = f(w)^{s^*} g(w)^{1-s^*} / A(s^*)$.

Then $f(w)/m(w) = A(s^*)\ell(w)^{1-s^*}$, so

$$E_f[\phi(w^t)] = A(s^*)^{t+1} E_m[\phi(w^t) L_t^{1-s^*}].$$

Draw from m to estimate the expectation on the right.

With f uniform, m is the Beta$(3 - 2s^*, 1.2 - 0.2s^*)$ density.

Solution

Part 1.

Under F, the density of w^t is $f(w_0) \cdots f(w_t) = L_t \, g(w_0) \cdots g(w_t)$, which gives $E_f[\phi(w^t)] = E_g[L_t \phi(w^t)]$.

Since $1 - \pi_t = (1 - \pi_{-1})/(\pi_{-1} L_t + 1 - \pi_{-1})$,

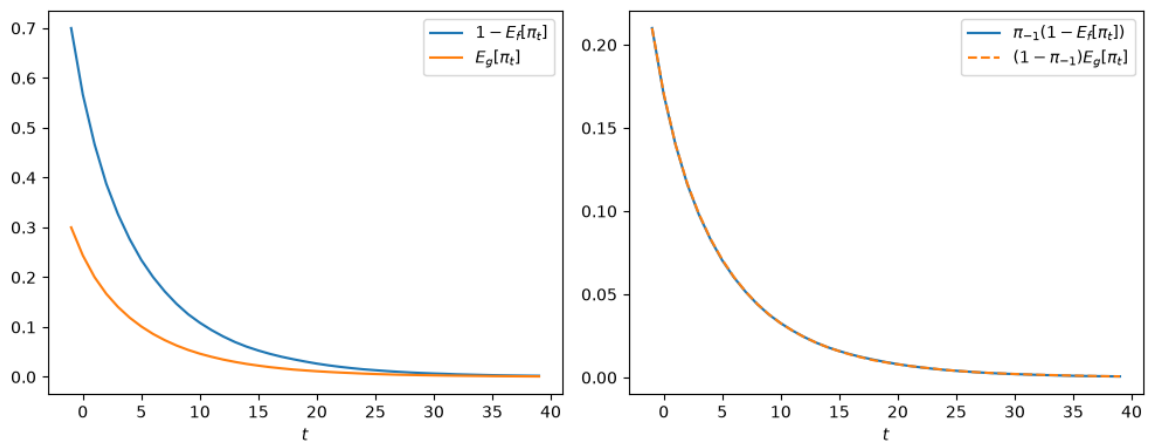
$$\pi_{-1} E_f[1 - \pi_t] = E_g\left[\frac{\pi_{-1} L_t (1 - \pi_{-1})}{\pi_{-1} L_t + 1 - \pi_{-1}}\right] = (1 - \pi_{-1}) E_g[\pi_t].$$

The subjective distribution (28.1) has density $\pi_{-1} f(w^t) + (1 - \pi_{-1}) g(w^t) = (\pi_{-1} L_t + 1 - \pi_{-1}) g(w^t)$, so

$$E[\pi_t(1 - \pi_t)] = E_g[(\pi_{-1} L_t + 1 - \pi_{-1}) \pi_t (1 - \pi_t)] = E_g[\pi_{-1} L_t (1 - \pi_t)] = \pi_{-1} E_f[1 - \pi_t].$$

Part 2.

We write a version of `simulate` that returns log odds, because π_t rounds to exactly 1 once its log odds exceed about 37.



```
def simulate_log_odds(rng, a, b, T, N, π_init):
    "Log odds of π_t for t = -1, 0, ..., T-1 along N paths of IID Beta(a, b) draws.
 ↪"
    w = rng.beta(a, b, size=(N, T))
    log_l = np.log(p(w, 1, 1)) - np.log(p(w, 3, 1.2))
    log_odds_init = np.log(π_init / (1 - π_init))
    log_odds = log_odds_init + np.cumsum(log_l, axis=1)
    return np.column_stack([np.full(N, log_odds_init), log_odds])

π_init, T_ex, N_ex = 0.3, 40, 100_000
rng = np.random.default_rng(2024)
lo_F = simulate_log_odds(rng, 1, 1, T_ex, N_ex, π_init)
lo_G = simulate_log_odds(rng, 3, 1.2, T_ex, N_ex, π_init)
t_ex = np.arange(-1, T_ex)

err_F = np.mean(expit(-lo_F), axis=0)       # 1 - E_f[π_t]
err_G = np.mean(expit(lo_G), axis=0)        # E_g[π_t]

fig, axes = plt.subplots(1, 2, figsize=(10, 4))
axes[0].plot(t_ex, err_F, label=r'$1 - E_f[\pi_t]$')
axes[0].plot(t_ex, err_G, label=r'$E_g[\pi_t]$')
axes[1].plot(t_ex, π_init * err_F, label=r'$\pi_{-1}(1 - E_f[\pi_t])$')
axes[1].plot(t_ex, (1 - π_init) * err_G, '--',
             label=r'$(1 - \pi_{-1}) E_g[\pi_t]$')
for ax in axes:
    ax.set_xlabel('$t$')
    ax.legend()
plt.tight_layout()
plt.show()
```

```
for t in [0, 5, 10, 20]:
    print(f"t = {t:2d}: (1 - E_f[π_t]) / E_g[π_t] = {err_F[t+1] / err_G[t+1]:.3f}")
print(f"(1 - π_init) / π_init = {(1 - π_init) / π_init:.3f}")
```

```
t =  0: (1 - E_f[π_t]) / E_g[π_t] = 2.325
t =  5: (1 - E_f[π_t]) / E_g[π_t] = 2.320
t = 10: (1 - E_f[π_t]) / E_g[π_t] = 2.335
t = 20: (1 - E_f[π_t]) / E_g[π_t] = 2.354
(1 - π_init) / π_init = 2.333
```

The two curves in the left panel differ by the factor $7/3$; the two curves in the right panel coincide up to sampling error.

Part 3.

```
f = lambda w: p(w, 1, 1)
g = lambda w: p(w, 3, 1.2)
KL_fg = quad(lambda w: f(w) * np.log(f(w) / g(w)), 0, 1)[0]
KL_gf = quad(lambda w: g(w) * np.log(g(w) / f(w)), 0, 1)[0]

slope_F = np.polyfit(t_ex, np.median(lo_F, axis=0), 1)[0]
slope_G = np.polyfit(t_ex, np.median(lo_G, axis=0), 1)[0]
print(f"slope of median log odds under F: {slope_F:.3f},  KL(f, g) = {KL_fg:.3f}")
print(f"slope of median log odds under G: {slope_G:.3f}, -KL(g, f) = {-KL_gf:.3f}")
```

```
slope of median log odds under F: 0.754,  KL(f, g) = 0.759
slope of median log odds under G: -0.345, -KL(g, f) = -0.344
```

Typical paths converge faster under F than under G.

Part 4.

We compute the Chernoff entropy and the minimizer s^*.

```
A = lambda s: quad(lambda w: f(w)**s * g(w)**(1 - s), 0, 1)[0]
res = op.minimize_scalar(A, bounds=(0, 1), method='bounded')
s_star, C = res.x, -np.log(res.fun)
print(f"s* = {s_star:.3f}, C(f, g) = {C:.4f}")
```

```
s* = 0.597, C(f, g) = 0.1212
```

Next we estimate $\log(1 - E_f[\pi_t])$ by importance sampling from m for t up to 199.

```
T_is, N_is = 200, 100_000
rng = np.random.default_rng(2025)
w = rng.beta(3 - 2 * s_star, 1.2 - 0.2 * s_star, size=(N_is, T_is))
log_L = np.cumsum(np.log(f(w)) - np.log(g(w)), axis=1)     # log L_t, t = 0, ...,␣
↪199
t_is = np.arange(T_is)

log_odds = np.log(π_init / (1 - π_init)) + log_L
weights = np.exp((1 - s_star) * log_L)                      # L_t^(1 - s*)
log_err_F = (t_is + 1) * np.log(A(s_star)) \
            + np.log(np.mean(expit(-log_odds) * weights, axis=0))

for t in [10, 20, 30]:
    print(f"t = {t}: log(1 - E_f[π_t]) importance sampling {log_err_F[t]:.3f}, "
          f"plain Monte Carlo {np.log(err_F[t+1]):.3f}")

late = t_is >= 100
slope = np.polyfit(t_is[late], log_err_F[late], 1)[0]
slope_adj = np.polyfit(t_is[late], log_err_F[late] + 0.5 * np.log(t_is[late] + 1),␣
↪1)[0]
print(f"slope of log(1 - E_f[π_t]) for t in [100, 199]: {slope:.4f}")
print(f"slope after adding log(t+1)/2:                  {slope_adj:.4f}")
print(f"-C(f, g):                                       {-C:.4f}")
```

```
t = 10: log(1 - E_f[π_t]) importance sampling -2.215, plain Monte Carlo -2.219
t = 20: log(1 - E_f[π_t]) importance sampling -3.638, plain Monte Carlo -3.626
t = 30: log(1 - E_f[π_t]) importance sampling -4.994, plain Monte Carlo -5.000
slope of log(1 - E_f[π_t]) for t in [100, 199]: -0.1243
slope after adding log(t+1)/2:                  -0.1209
-C(f, g):                                       -0.1212
```

The two estimates agree at small t.

Under m, $E_m[\log \ell(w)] = A'(s^*)/A(s^*) = 0$, so $\log L_t$ is a random walk without drift.

The expectation $E_m[(1-\pi_t)L_t^{1-s^*}]$ therefore decays only like $t^{-1/2}$, and

$$1 - E_f[\pi_t] \approx K\, t^{-1/2} e^{-C(f,g)t}$$

for a constant K.

The fitted slope is close to $-C(f,g)$, and adding $\frac{1}{2}\log(t+1)$ to remove the factor $t^{-1/2}$ brings it closer.

By (28.8), $E_g[\pi_t]$ decays at the same rate.

Exercise 28.10.3

A Pólya urn starts with a red balls and b black balls.

At each date $t = 0, 1, \ldots$ we draw a ball at random, set $W_t = 1$ if it is red and $W_t = 0$ if it is black, and return it to the urn together with one more ball of the same color.

1. Show that $\text{Prob}(W_0 = 1, W_1 = 0) = \text{Prob}(W_0 = 0, W_1 = 1)$. More generally, show that the probability of a sequence $(w_0, \ldots, w_{n-1})$ depends only on the number k of red draws, so that $W_0, W_1, \ldots$ is exchangeable. Find the mixing measure μ in de Finetti's representation (28.3).
2. Simulate many urns with $a = 2$ and $b = 3$ for $n = 2000$ draws. Compare the distribution across urns of the

fraction of red draws with the Beta(a, b) density.

3. Show that the fraction of red balls in the urn after n draws, k of them red, equals the probability Prob$(W_n = 1 \,|\, w_0, \ldots, w_{n-1})$ that a Bayesian with a Beta(a, b) prior over the success probability θ of IID Bernoulli draws attaches to the next draw being red.

Solution

Part 1.

Prob$(W_0 = 1, W_1 = 0) = \frac{a}{a+b}\frac{b}{a+b+1}$ and Prob$(W_0 = 0, W_1 = 1) = \frac{b}{a+b}\frac{a}{a+b+1}$.

The two are equal.

For a sequence of n draws with k red draws, the denominators of the successive conditional probabilities are $a + b, a + b + 1, \ldots, a + b + n - 1$ in every order.

The numerators for the red draws are $a, a + 1, \ldots, a + k - 1$, and the numerators for the black draws are $b, b + 1, \ldots, b + n - k - 1$, in every order.

So

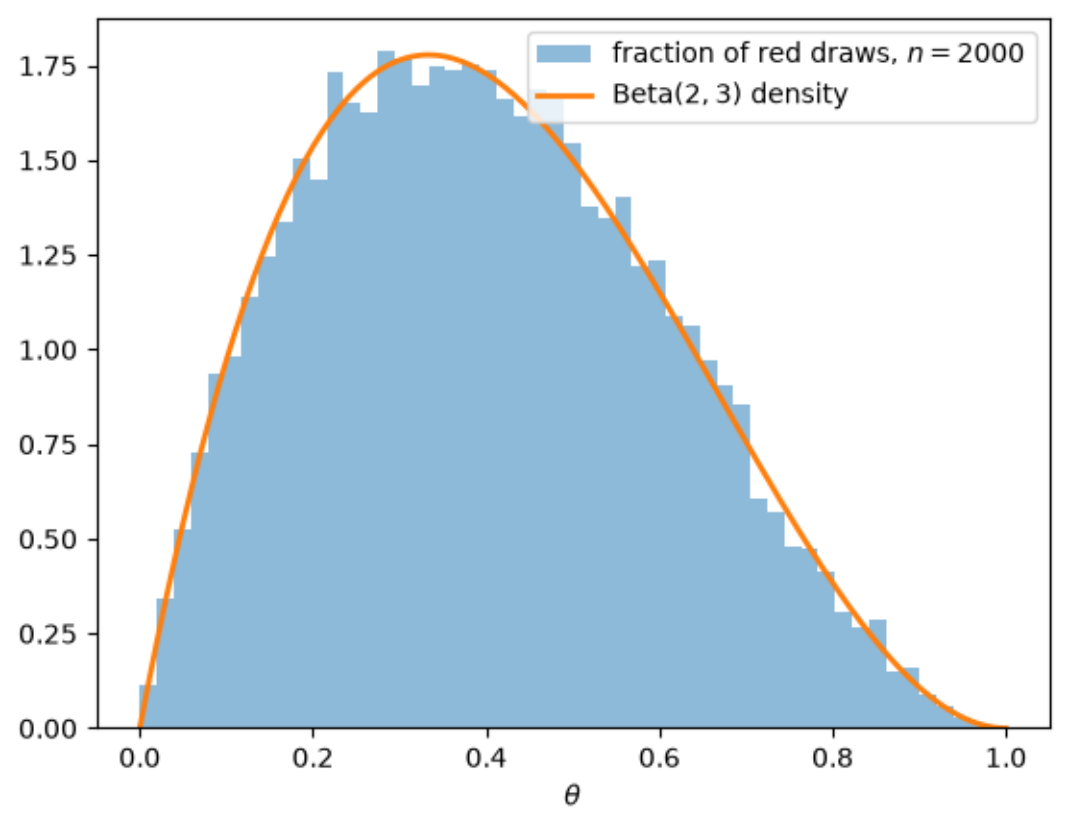
$$\text{Prob}(W_0 = w_0, \ldots, W_{n-1} = w_{n-1}) = \frac{\prod_{j=0}^{k-1}(a+j)\prod_{j=0}^{n-k-1}(b+j)}{\prod_{j=0}^{n-1}(a+b+j)} = \frac{B(a+k, b+n-k)}{B(a,b)},$$

where B is the Beta function.

The right side equals $\int_0^1 \theta^k (1-\theta)^{n-k} \mu(d\theta)$ with μ the Beta(a, b) distribution.

That is de Finetti's representation (28.3).

Part 2.



```
from scipy.stats import beta as beta_dist, kstest

def polya_urn(rng, a, b, n, N):
    "Simulate N Pólya urns for n draws; return the N x n array of draws."
    red = np.full(N, float(a))
    total = float(a + b)
    W = np.empty((N, n), dtype=np.int8)
    for t in range(n):
        W[:, t] = rng.random(N) < red / total
        red += W[:, t]
        total += 1
    return W

a, b, n, N = 2, 3, 2000, 20_000
rng = np.random.default_rng(7)
W = polya_urn(rng, a, b, n, N)
freq = W.mean(axis=1)

grid = np.linspace(0, 1, 200)
fig, ax = plt.subplots()
ax.hist(freq, bins=50, density=True, alpha=0.5,
        label=f'fraction of red draws, $n = {n}$')
ax.plot(grid, beta_dist.pdf(grid, a, b), lw=2, label=f'Beta$({a}, {b})$ density')
ax.set_xlabel(r'$\theta$')
ax.legend()
plt.show()

print(f"Prob(W_0=1, W_1=0) = {np.mean((W[:, 0] == 1) & (W[:, 1] == 0)):.4f}, "
      f"Prob(W_0=0, W_1=1) = {np.mean((W[:, 0] == 0) & (W[:, 1] == 1)):.4f}, "
      f"a * b / ((a + b) * (a + b + 1)) = {a * b / ((a + b) * (a + b + 1)):.4f}")
print(f"Kolmogorov-Smirnov test against Beta({a}, {b}): "
      f"p-value = {kstest(freq, beta_dist(a, b).cdf).pvalue:.3f}")
```

```
Prob(W_0=1, W_1=0) = 0.2033, Prob(W_0=0, W_1=1) = 0.2003, exact = 0.2000
Kolmogorov-Smirnov test against Beta(2, 3): p-value = 0.209
```

The fraction of red draws is distributed approximately Beta$(2, 3)$ across urns, and the Kolmogorov–Smirnov test does not reject that distribution.

Part 3.

After n draws with k red draws, the urn holds $a + k$ red balls out of $a + b + n$ balls, so the next draw is red with probability $(a + k)/(a + b + n)$.

A Bayesian with a Beta(a, b) prior over θ has the Beta$(a + k, b + n - k)$ posterior after observing k successes in n IID Bernoulli trials.

His probability that the next draw is a success is the posterior mean of θ, namely $(a + k)/(a + b + n)$.

The urn and the Bayesian agree.

The next cell checks this by grouping the simulated urns according to the number of red balls among the first 10 draws.

Frequencies computed from few urns are less precise.

```
n0 = 10
k = W[:, :n0].sum(axis=1)
for k_val in range(0, n0 + 1, 2):
    sel = k == k_val
    print(f"k = {k_val:2d} ({sel.sum():4d} urns): "
          f"frequency of red at draw {n0} = {W[sel, n0].mean():.3f}, "
          f"(a + k) / (a + b + n) = {(a + k_val) / (a + b + n0):.3f}")
```

```
k =  0 (1378 urns): frequency of red at draw 10 = 0.129, (a + k) / (a + b + n)␣
↪= 0.133
k =  2 (2686 urns): frequency of red at draw 10 = 0.265, (a + k) / (a + b + n)␣
↪= 0.267
k =  4 (2850 urns): frequency of red at draw 10 = 0.403, (a + k) / (a + b + n)␣
↪= 0.400
k =  6 (2077 urns): frequency of red at draw 10 = 0.535, (a + k) / (a + b + n)␣
↪= 0.533
k =  8 (1118 urns): frequency of red at draw 10 = 0.684, (a + k) / (a + b + n)␣
↪= 0.667
k = 10 ( 218 urns): frequency of red at draw 10 = 0.839, (a + k) / (a + b + n)␣
↪= 0.800
```

CHAPTER

TWENTYNINE

LIKELIHOOD RATIO PROCESSES AND BAYESIAN LEARNING

29.1 Overview

This lecture describes the role that *likelihood ratio processes* play in *Bayesian learning*.

As in *Likelihood Ratio Processes*, we'll use a simple statistical setting from *Exchangeability and Bayesian Updating*.

We'll focus on how a likelihood ratio process and a *prior* probability determine a *posterior* probability.

We'll derive a convenient recursion for today's posterior as a function of yesterday's posterior and today's multiplicative increment to a likelihood process.

We'll also present a useful generalization of that formula that represents today's posterior in terms of an initial prior and today's realization of the likelihood ratio process.

We'll study how, at least in our setting, a Bayesian eventually learns the probability distribution that generates the data, an outcome that rests on the asymptotic behavior of likelihood ratio processes studied in *Likelihood Ratio Processes*.

We'll also drill down into the psychology of our Bayesian learner and study dynamics under his subjective beliefs.

This lecture provides technical results that underlie outcomes to be studied in *Job Search IX: Search with Learning*, *A Problem that Stumped Milton Friedman*, and *Bayesian versus Frequentist Decision Rules*.

We'll begin by loading some Python modules.

```
import matplotlib.pyplot as plt
import numpy as np
from numba import vectorize, jit
from math import gamma
import pandas as pd
from scipy.integrate import quad
from scipy.special import expit, logit
from scipy.stats import ks_2samp

import seaborn as sns
colors = sns.color_palette()

rng = np.random.default_rng(142857)
```

29.2 The setting

We begin by reviewing the setting in *Likelihood Ratio Processes*, which we adopt here too.

A nonnegative random variable W has one of two probability density functions, either f or g.

Before the beginning of time, nature once and for all decides whether she will draw a sequence of IID draws from f or from g.

We let q be the density that nature chose once and for all, so that q is either f or g, permanently.

Nature knows which density it permanently draws from, but we the observers do not.

We do know both f and g, but we don't know which density nature chose.

But we want to know.

To do that, we use observations.

We observe a sequence $w_0, w_1, \ldots$ of IID draws from either f or g.

We date the first draw $t = 0$ and the prior $t = -1$, as in *Exchangeability and Bayesian Updating*.

Likelihood Ratio Processes dates the first draw $t = 1$.

We want to use these observations to infer whether nature chose f or g.

A likelihood ratio process is a useful tool for this task.

To begin, we define the key component of a likelihood ratio process, namely, the time t likelihood ratio as the random variable

$$\ell(w_t) = \frac{f(w_t)}{g(w_t)}, \quad t \geq 0.$$

We assume that f and g both put positive probabilities on the same intervals of possible realizations of the random variable W.

That means that under the g density, $\ell(w_t) = \frac{f(w_t)}{g(w_t)}$ is evidently a nonnegative random variable with mean 1.

A **likelihood ratio process** for sequence $\{w_t\}_{t=0}^{\infty}$ is defined as

$$L(w^t) = \prod_{s=0}^{t} \ell(w_s),$$

where $w^t = \{w_0, \ldots, w_t\}$ is a history of observations up to and including time t.

Sometimes for shorthand we'll write

$$L_t = L(w^t) = \frac{f(w^t)}{g(w^t)}$$

where we use the conventions that $f(w^t) = f(w_0)f(w_1)\ldots f(w_t)$ and $g(w^t) = g(w_0)g(w_1)\ldots g(w_t)$.

Notice that the likelihood process satisfies the **recursion** or **multiplicative decomposition**

$$L(w^t) = \ell(w_t)L(w^{t-1}),$$

with $L(w^{-1}) \equiv 1$.

The likelihood ratio and its logarithm are key tools for making inferences using a classic frequentist approach due to Neyman and Pearson [Neyman and Pearson, 1933].

We'll again deploy the following Python code from *Likelihood Ratio Processes* that evaluates f and g as two different beta distributions, then computes and simulates an associated likelihood ratio process by generating a sequence w^t from *some* probability distribution, for example, a sequence of IID draws from g.

```
# Parameters in the two beta distributions.
F_a, F_b = 1, 1
G_a, G_b = 3, 1.2

@vectorize
def p(x, a, b):
    r = gamma(a + b) / (gamma(a) * gamma(b))
    return r * x**(a-1) * (1 - x)**(b-1)

# The two density functions.
f = jit(lambda x: p(x, F_a, F_b))
g = jit(lambda x: p(x, G_a, G_b))
```

```
@jit
def simulate(a, b, rng, T=50, N=500):
    '''
    Generate N sets of T observations of the likelihood ratio,
    return as N x T matrix.  Column s holds ℓ(w_s), s = 0, ..., T-1.
    '''

    l_arr = np.empty((N, T))

    for i in range(N):

        for j in range(T):
            w = rng.beta(a, b)
            l_arr[i, j] = f(w) / g(w)

    return l_arr
```

We'll also use the following Python code to prepare some informative simulations.

Column t of `l_seq_g` and `l_seq_f` holds $L(w^t)$.

```
l_arr_g = simulate(G_a, G_b, rng, N=50000)
l_seq_g = np.cumprod(l_arr_g, axis=1)
```

```
l_arr_f = simulate(F_a, F_b, rng, N=50000)
l_seq_f = np.cumprod(l_arr_f, axis=1)
```

29.3 Likelihood ratio processes and Bayes' law

Let $\pi_{-1} \in [0, 1]$ be a Bayesian statistician's prior probability that nature generates w^t as a sequence of IID draws from distribution f.

- here "probability" is to be interpreted as a way to summarize or express a subjective opinion
- it does *not* mean an anticipated relative frequency as sample size grows without limit

Let π_t be a Bayesian posterior probability defined as

$$\pi_t = \text{Prob}(q = f | w^t) \tag{29.1}$$

The likelihood ratio process is a principal actor in the formula that governs the evolution of the posterior probability π_t, an instance of *Bayes' law*.

Let's derive a couple of formulas for π_t, one in terms of the likelihood ratio $\ell(w_t)$, the other in terms of $L(w^t)$.

To begin, we use the notational conventions

- $f(w^t) \equiv f(w_0)f(w_1)\cdots f(w_t)$
- $g(w^t) \equiv g(w_0)g(w_1)\cdots g(w_t)$
- $\pi_{-1} = \text{Prob}(q = f|\emptyset)$
- $\pi_t = \text{Prob}(q = f|w^t)$

Here the symbol $\emptyset$ means "empty set" or "no data".

With no data in hand, our Bayesian statistician thinks that the probability density of the sequence w^t is

$$\text{Prob}(w^t|\emptyset) = \pi_{-1}f(w^t) + (1-\pi_{-1})g(w^t)$$

Laws of probability say that the joint distribution $\text{Prob}(AB)$ of events A and B are connected to the conditional distributions $\text{Prob}(A|B)$ and $\text{Prob}(B|A)$ by

$$\text{Prob}(AB) = \text{Prob}(A|B)\text{Prob}(B) = \text{Prob}(B|A)\text{Prob}(A). \tag{29.2}$$

We are interested in events

$$A = \{q = f\}, \quad B = \{w^t\},$$

where braces $\{\cdot\}$ are our shorthand for "event".

So in our setting, probability laws (29.2) imply that

$$\text{Prob}(q = f|w^t)\text{Prob}(w^t|\emptyset) = \text{Prob}(w^t|q = f)\text{Prob}(q = f|\emptyset)$$

or

$$\pi_t\left[\pi_{-1}f(w^t) + (1-\pi_{-1})g(w^t)\right] = f(w^t)\pi_{-1}$$

or

$$\pi_t = \frac{f(w^t)\pi_{-1}}{\pi_{-1}f(w^t) + (1-\pi_{-1})g(w^t)}$$

Dividing both the numerator and the denominator on the right side of the above equation by $g(w^t)$ implies

$$\pi_t = \frac{\pi_{-1}L\left(w^t\right)}{\pi_{-1}L\left(w^t\right) + 1 - \pi_{-1}}. \tag{29.3}$$

Formula (29.3) can be regarded as a one step revision of prior probability π_{-1} after seeing the batch of data $\{w_s\}_{s=0}^t$.

Formula (29.3) shows the key role that the likelihood ratio process $L\left(w^t\right)$ plays in determining the posterior probability π_t.

Formula (29.3) is the foundation for the insight that, because of how the likelihood ratio process behaves as $t \to +\infty$, the likelihood ratio process dominates the initial prior π_{-1} in determining the limiting behavior of π_t.

29.3.1 A recursive formula

We can use a similar line of argument to get a recursive version of formula (29.3).

The laws of probability imply

$$\text{Prob}(q = f|w^{t+1}) = \frac{\text{Prob}(q = f|w^t)f(w_{t+1})}{\text{Prob}(q = f|w^t)f(w_{t+1}) + (1 - \text{Prob}(q = f|w^t))g(w_{t+1})}$$

or

$$\pi_{t+1} = \frac{\pi_t f(w_{t+1})}{\pi_t f(w_{t+1}) + (1 - \pi_t)g(w_{t+1})} \tag{29.4}$$

Evidently, the above equation asserts that

$$\text{Prob}(q = f|w^{t+1}) = \frac{\text{Prob}(q = f|w^t)f(w_{t+1})}{\text{Prob}(w_{t+1}|w^t)}$$

where

$$\text{Prob}(w_{t+1}|w^t) = \pi_t f(w_{t+1}) + (1 - \pi_t)g(w_{t+1})$$

is the density of w_{t+1} conditional on the history w^t.

Conditional on q, the draw w_{t+1} is independent of w^t, so $f(w_{t+1})$ is the density of w_{t+1} conditional on $q = f$ and w^t.

Dividing both the numerator and the denominator on the right side of the equation (29.4) by $g(w_{t+1})$ implies the recursion

$$\pi_{t+1} = \frac{\pi_t \ell(w_{t+1})}{\pi_t \ell(w_{t+1}) + 1 - \pi_t} \tag{29.5}$$

with π_{-1} being a Bayesian prior probability that $q = f$, i.e., a personal or subjective belief about q based on our having seen no data.

Formula (29.3) can be deduced by iterating on equation (29.5).

In terms of log odds, recursion (29.5) is

$$\log \frac{\pi_{t+1}}{1 - \pi_{t+1}} = \log \frac{\pi_t}{1 - \pi_t} + \log \ell(w_{t+1}) \tag{29.6}$$

and formula (29.3) is

$$\log \frac{\pi_t}{1 - \pi_t} = \log \frac{\pi_{-1}}{1 - \pi_{-1}} + \log L(w^t).$$

Our code iterates on log odds.

Iterating on (29.5) itself accumulates rounding errors that push π_t slightly above 1 or below 0 once π_t is close to 1 or 0.

Below we define a Python function that updates the log odds of $q = f$ using likelihood ratio ℓ according to recursion (29.6)

```
@jit
def update(log_odds, l):
    "Update the log odds of q = f using likelihood ratio l"
    return log_odds + np.log(l)
```

To illustrate how the likelihood ratio process dominates the initial prior, below we will plot graphs showing *one* simulated path of the likelihood ratio process L_t along with two paths of π_t that are associated with the *same* realization of the likelihood ratio process but *different* initial prior probabilities π_{-1}.

First, we tell Python two values of π_{-1}.

```
π1, π2 = 0.2, 0.8
```

Next we generate paths of the likelihood ratio process L_t and the posterior π_t for a history of IID draws from density f.

Column 0 of `π_seq_f` holds the prior π_{-1} and column $t+1$ holds π_t.

```
T = l_arr_f.shape[1]
log_odds_f = np.empty((2, T+1))
log_odds_f[:, 0] = logit([π1, π2])

for t in range(T):
    for i in range(2):
        log_odds_f[i, t+1] = update(log_odds_f[i, t], l_arr_f[0, t])

π_seq_f = expit(log_odds_f)
```

```
fig, ax1 = plt.subplots()

for i in range(2):
    ax1.plot(range(-1, T), π_seq_f[i, :],
    label=fr"$\pi_{{-1}}$={π_seq_f[i, 0]:.1f}", lw=2)

ax1.set_ylabel(r"$\pi_t$")
ax1.set_xlabel(r"$t$")
ax1.legend()

ax2 = ax1.twinx()
ax2.plot(range(T), np.log(l_seq_f[0, :]), '--', color='b', lw=2)
ax2.set_ylabel(r"$\log(L(w^{t}))$")

plt.show()
```

The dashed line in the graph above records the logarithm of the likelihood ratio process $\log L(w^t)$.

Please note that there are two different scales on the y axis.

Now let's study what happens when the history consists of IID draws from density g

```
T = l_arr_g.shape[1]
log_odds_g = np.empty((2, T+1))
log_odds_g[:, 0] = logit([π1, π2])

for t in range(T):
    for i in range(2):
        log_odds_g[i, t+1] = update(log_odds_g[i, t], l_arr_g[0, t])

π_seq_g = expit(log_odds_g)
```

```
fig, ax1 = plt.subplots()

for i in range(2):
    ax1.plot(range(-1, T), π_seq_g[i, :],
        label=fr"$\pi_{{-1}}$={π_seq_g[i, 0]:.1f}", lw=2)

ax1.set_ylabel(r"$\pi_t$")
ax1.set_xlabel(r"$t$")
```

(continues on next page)

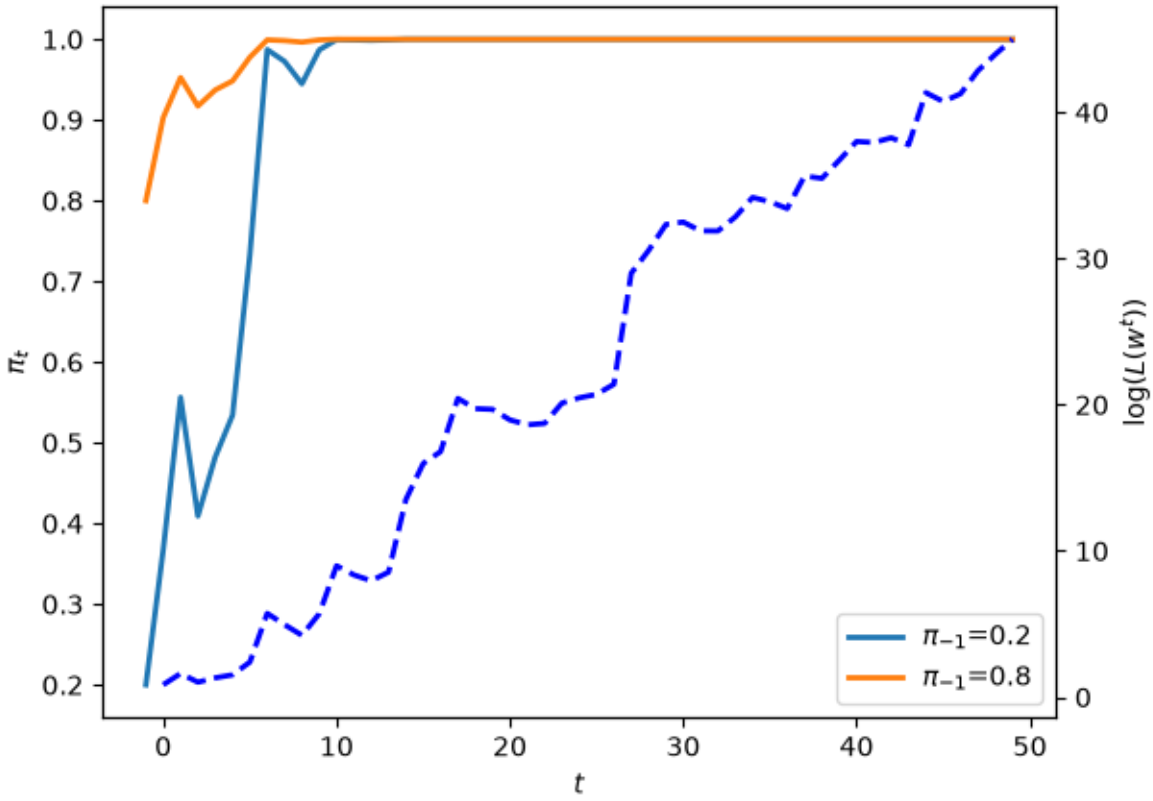


Fig. 29.1: Posterior paths and log likelihood ratio

(continued from previous page)

```
ax1.legend()

ax2 = ax1.twinx()
ax2.plot(range(T), np.log(l_seq_g[0, :]), '--', color='b', lw=2)
ax2.set_ylabel(r"$\log(L(w^{t}))$")

plt.show()
```

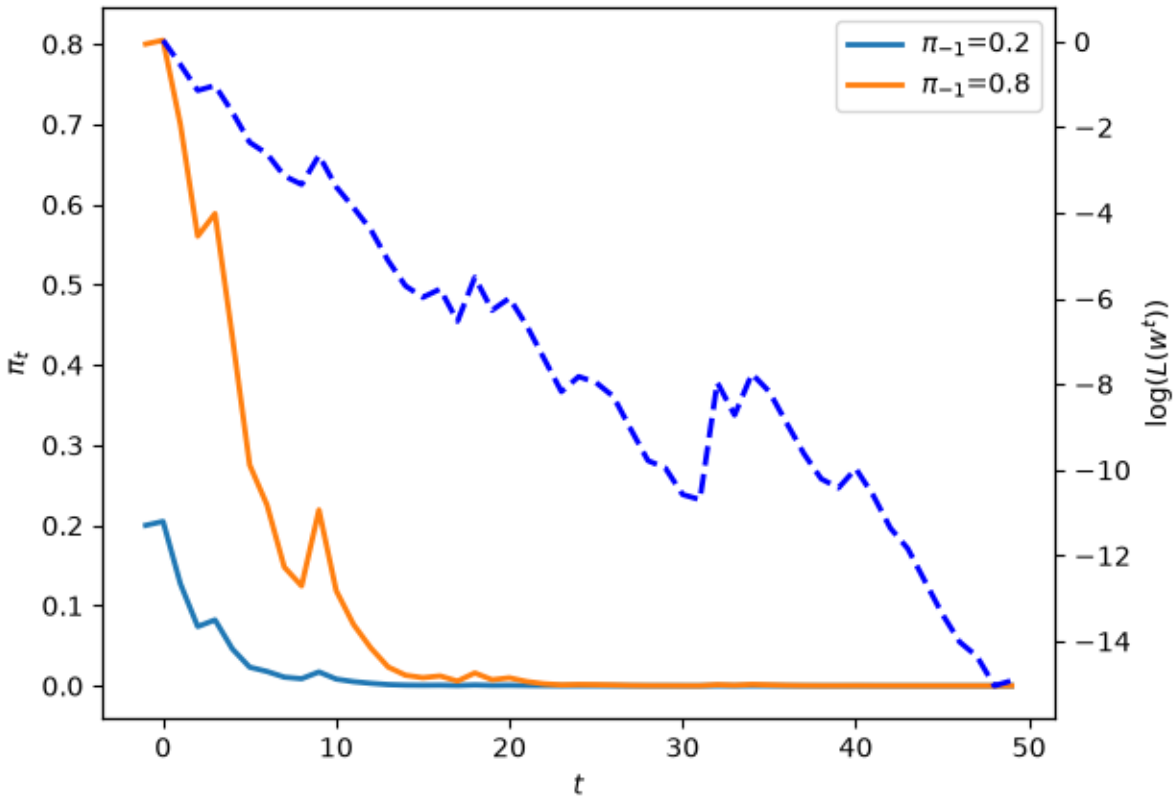

Fig. 29.2: Posterior paths and log likelihood ratio

The next cell checks that the batch formula (29.3) reproduces the paths of π_t that recursion (29.6) generated from the draws from density f.

```
π_seq = np.empty((2, T+1))
π_seq[:, 0] = π1, π2

for i in range(2):
    πL = π_seq[i, 0] * l_seq_f[0, :]
    π_seq[i, 1:] = πL / (πL + 1 - π_seq[i, 0])
```

```
np.abs(π_seq - π_seq_f).max() < 1e-10
```

```
np.True_
```

We thus conclude that the likelihood ratio process is a key ingredient of the formula (29.3) for a Bayesian's posterior

probability that nature has drawn history w^t as repeated draws from density f.

29.4 Another timing protocol

Let's study how the posterior probability $\pi_t = \text{Prob}(q = f|w^t)$ behaves when nature generates the history $w^t = \{w_0, w_1, \ldots, w_t\}$ under a different timing protocol.

Until now we assumed that before time 0 nature somehow chose to draw w^t as an IID sequence from either f or g.

Nature's decision about whether to draw from f or g was thus *permanent*.

We now assume a different timing protocol in which before *each period* $t = 0, 1, \ldots$ nature

- flips an α-weighted coin, then
- draws from f if it has drawn a "head"
- draws from g if it has drawn a "tail".

Under this timing protocol, nature draws permanently from *neither* f *nor* g, so a statistician who thinks that nature is drawing IID draws *permanently* from one of them is mistaken.

- in truth, nature draws IID from the mixture $h(w|\alpha) = \alpha f(w) + (1-\alpha)g(w)$, a density that is neither f nor g when $\alpha \in (0, 1)$

The statistician's posterior π_t remains his probability that $q = f$, as defined in (29.1).

It is not an estimate of the mixing parameter α.

The statistician's model is misspecified, and Kullback–Leibler divergences of f and g from h determine the limit of π_t.

By the law of large numbers, $\frac{1}{t+1} \log L(w^t)$ converges with probability one to

$$E_h[\log \ell(w)] = E_h\left[\log \frac{h(w|\alpha)}{g(w)}\right] - E_h\left[\log \frac{h(w|\alpha)}{f(w)}\right] = KL(h,g) - KL(h,f),$$

where E_h denotes the expectation under $h(\cdot|\alpha)$ and $KL(h,f) = \int h(w|\alpha) \log \frac{h(w|\alpha)}{f(w)} dw$; see *A helpful formula* in *Likelihood Ratio Processes*.

So $\log L(w^t) \to +\infty$ and $\pi_t \to 1$ when $KL(h,f) < KL(h,g)$.

And $\log L(w^t) \to -\infty$ and $\pi_t \to 0$ when $KL(h,f) > KL(h,g)$.

The statistician comes to believe the member of $\{f, g\}$ that is closer to h in Kullback–Leibler divergence.

Let's write some Python code to check this when $\alpha = 0.5$.

```
@jit
def simulate_mixture_path(α, T, rng):
    """
    Simulate draws w_0, ..., w_{T-1} under the mixture timing protocol.
    """
    w = np.empty(T)
    for t in range(T):
        if rng.random() < α:
            w[t] = rng.beta(F_a, F_b)
        else:
            w[t] = rng.beta(G_a, G_b)
    return w
```

(continues on next page)

(continued from previous page)

```
α = 0.5
T_mix = 200
rng = np.random.default_rng(142857)
w_mix = simulate_mixture_path(α, T_mix, rng)
```

We compute paths of π_t for three priors π_{-1}.

```
log_L_mix = np.cumsum(np.log(f(w_mix) / g(w_mix)))

fig, ax = plt.subplots(figsize=(10, 6))
for i, π_init in enumerate([0.25, 0.5, 0.75]):
    π_path = expit(logit(π_init) + log_L_mix)
    ax.plot(range(-1, T_mix), np.concatenate(([π_init], π_path)),
            label=fr'$\pi_{{-1}} = ${π_init:.2f}', color=colors[i], linewidth=2)

ax.set_xlabel('$t$')
ax.set_ylabel(r'$\pi_t$')
ax.legend()
plt.show()
```

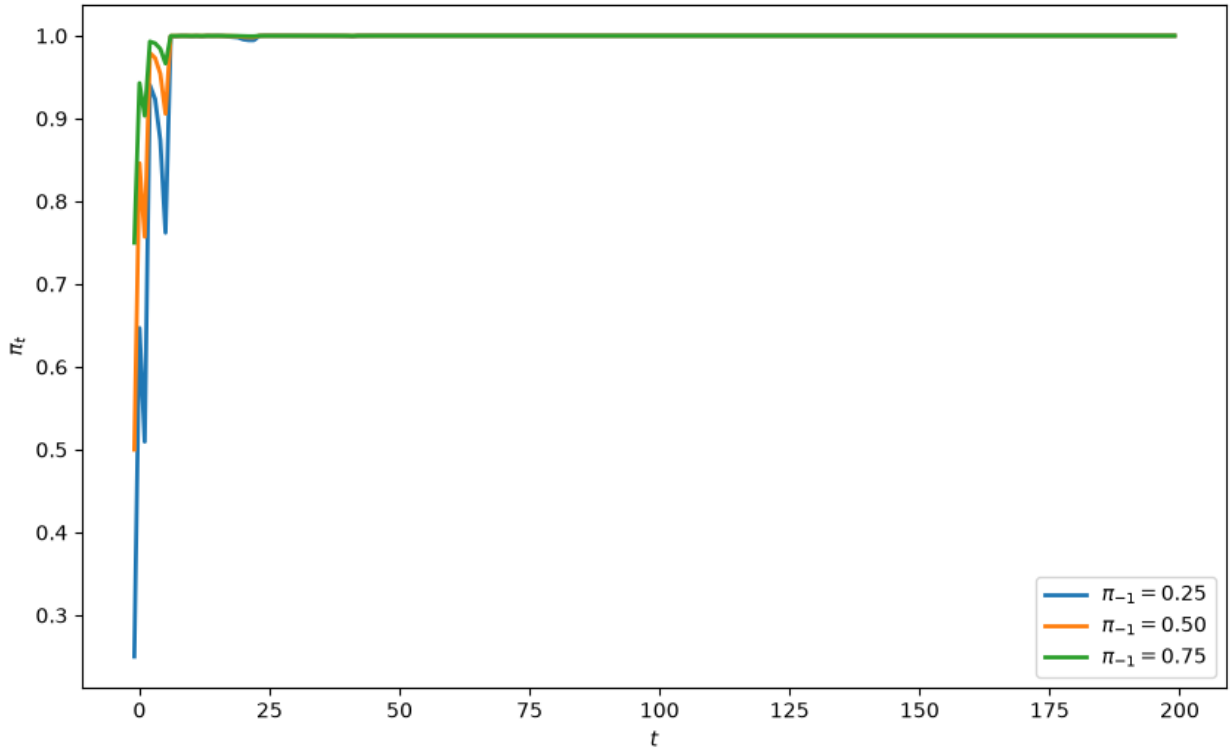

Fig. 29.3: Posterior under mixture model

Evidently, π_t converges to 1.

Let's check the *KL divergences* of f and g from h.

```
def compute_KL(f, g):
    """
    Compute KL divergence KL(f, g)
    """
    integrand = lambda w: f(w) * np.log(f(w) / g(w))
    val, _ = quad(integrand, 1e-5, 1-1e-5)
    return val

h = lambda w: α * f(w) + (1 - α) * g(w)
KL_hf, KL_hg = compute_KL(h, f), compute_KL(h, g)

print(f'KL(h, f) = {KL_hf:.3f}\nKL(h, g) = {KL_hg:.3f}')
```

```
KL(h, f) = 0.073
KL(h, g) = 0.281
```

Since $KL(h,f) < KL(h,g)$, f is closer to h, $\log L(w^t) \to +\infty$, and $\pi_t \to 1$ for every $\pi_{-1} \in (0,1)$.

Incorrect Models studies this misspecified statistician further, including the value of α at which $KL(h,f) = KL(h,g)$ and π_t does not converge.

It also studies a statistician who knows that nature mixes each period and uses Bayes' law to learn α.

29.5 Behavior of posterior probability $\{\pi_t\}$ under subjective probability distribution

We'll end this lecture by briefly studying what our Bayesian learner expects to learn under the subjective beliefs π_t cranked out by Bayes' law.

This will provide us with some perspective on our application of Bayes' law as a theory of learning.

As we shall see, at each time t, the Bayesian learner knows that he will be surprised.

But he expects that new information will not lead him to change his beliefs.

And it won't on average under his subjective beliefs.

We'll continue with our setting in which a McCall worker knows that successive draws of his wage are drawn from either F or G, but does not know which of these two distributions nature has drawn once-and-for-all before time 0.

We'll review and reiterate and rearrange some formulas that we have encountered above and in associated lectures.

The worker's initial beliefs induce a joint probability distribution over a potentially infinite sequence of draws $w_0, w_1, \ldots$.

Bayes' law is simply an application of laws of probability to compute the conditional distribution of the tth draw w_t conditional on $[w_0, \ldots, w_{t-1}]$.

After our worker puts a subjective probability π_{-1} on nature having selected distribution F, we have in effect assumed from the start that the decision maker *knows* the joint distribution for the process $\{w_t\}_{t=0}^{\infty}$.

We assume that the worker also knows the laws of probability theory.

A respectable view is that Bayes' law is less a theory of learning than a statement about the consequences of information inflows for a decision maker who thinks he knows the truth (i.e., a joint probability distribution) from the beginning.

29.5.1 Mechanical details again

At time 0 *before* drawing a wage offer, the worker attaches probability $\pi_{-1} \in (0,1)$ to the distribution being F.

Before drawing a wage at time 0, the worker thus believes that the density of w_0 is

$$h(w_0|\pi_{-1}) = \pi_{-1} f(w_0) + (1-\pi_{-1}) g(w_0).$$

Here and below $h(w|\pi) \equiv \pi f(w) + (1-\pi) g(w)$ denotes the mixture of f and g with weight π on f.

Recall that $q \in \{f, g\}$ indicates whether nature chose permanently to draw from distribution f or from distribution g.

After drawing w_0, the worker uses Bayes' law to deduce that the posterior probability $\pi_0 = \text{Prob}(q = f|w_0)$ that the density is $f(w)$ is

$$\pi_0 = \frac{\pi_{-1} f(w_0)}{\pi_{-1} f(w_0) + (1-\pi_{-1}) g(w_0)}.$$

More generally, after making the tth draw and having observed $w_t, w_{t-1}, \ldots, w_0$, the worker believes that the probability that w_{t+1} is being drawn from distribution F is

$$\pi_t = \pi_t(w_t|\pi_{t-1}) \equiv \frac{\pi_{t-1} f(w_t)/g(w_t)}{\pi_{t-1} f(w_t)/g(w_t) + (1-\pi_{t-1})} \tag{29.7}$$

or

$$\pi_t = \frac{\pi_{t-1} \ell(w_t)}{\pi_{t-1} \ell(w_t) + 1 - \pi_{t-1}}$$

and that the density of w_{t+1} conditional on $w_t, w_{t-1}, \ldots, w_0$ is

$$h(w_{t+1}|\pi_t) = \pi_t f(w_{t+1}) + (1-\pi_t) g(w_{t+1}).$$

Notice that

$$\begin{aligned} E(\pi_t|\pi_{t-1}) &= \int \Big[\frac{\pi_{t-1} f(w)}{\pi_{t-1} f(w) + (1-\pi_{t-1}) g(w)}\Big] \Big[\pi_{t-1} f(w) + (1-\pi_{t-1}) g(w)\Big] dw \\ &= \pi_{t-1} \int f(w) dw \\ &= \pi_{t-1}, \end{aligned}$$

so that the process π_t is a *martingale*.

Indeed, it is a *bounded martingale* because each π_t, being a probability, is between 0 and 1.

In the first line in the above string of equalities, the term in the first set of brackets is just π_t as a function of w_t, while the term in the second set of brackets is the density of w_t conditional on $w_{t-1}, \ldots, w_0$ or equivalently conditional on the *sufficient statistic* π_{t-1} for $w_{t-1}, \ldots, w_0$.

Notice that here we are computing $E(\pi_t|\pi_{t-1})$ under the *subjective* density described in the second term in brackets.

Because $\{\pi_t\}$ is a bounded martingale sequence, it follows from the *martingale convergence theorem* that π_t converges almost surely to a random variable in $[0,1]$.

Practically, this means that probability one is attached to sample paths $\{\pi_t\}_{t=0}^{\infty}$ that converge.

According to the theorem, different sample paths can converge to different limiting values.

Thus, let $\{\pi_t(\omega)\}_{t=0}^{\infty}$ denote a particular sample path indexed by a particular $\omega \in \Omega$.

We can think of nature as drawing an $\omega \in \Omega$ from a probability distribution $\text{Prob}(\Omega)$ and then generating a single realization (or *simulation*) $\{\pi_t(\omega)\}_{t=0}^{\infty}$ of the process.

The limit points of $\{\pi_t(\omega)\}_{t=0}^{\infty}$ as $t \to +\infty$ are realizations of a random variable that is swept out as we sample ω from Ω and construct repeated draws of $\{\pi_t(\omega)\}_{t=0}^{\infty}$.

Let

$$\pi_\infty(\omega) = \lim_{t \to +\infty} \pi_t(\omega).$$

The martingale convergence theorem does not say where $\pi_t(\omega)$ goes.

Two facts settle that.

First, π_t is the conditional expectation $E[\mathbf{1}\{q = f\} \mid w^t]$ of the indicator of the event $q = f$.

Second, an observer of the infinite history $w_0, w_1, \ldots$ can determine q.

By the strong law of large numbers, $\frac{1}{t+1} \log L(w^t)$ converges to $E_f[\log \ell(w)] = KL(f,g) > 0$ when $q = f$ and to $E_g[\log \ell(w)] = -KL(g,f) < 0$ when $q = g$.

Doob's martingale convergence theorem [Doob, 1953] then implies that π_t converges with probability one to $E[\mathbf{1}\{q = f\} \mid w_0, w_1, \ldots] = \mathbf{1}\{q = f\}$.

Thus, for realizations along which nature drew f, $\lim_{t \to +\infty} \pi_t(\omega) = 1$, while for realizations along which nature drew g, $\lim_{t \to +\infty} \pi_t(\omega) = 0$.

The section *Drilling down a little bit* and Exercise Exercise 29.9.2 give a second proof that $\pi_\infty(\omega) \in \{0, 1\}$.

Now let's remember that $\{\pi_t\}_{t=0}^{\infty}$ is a martingale and apply the law of iterated expectations.

The law of iterated expectations implies

$$E_t \pi_{t+j} = \pi_t$$

and in particular

$$E_{-1} \pi_{t+j} = \pi_{-1}.$$

Applying the above formula to π_∞, we obtain

$$E_{-1} \pi_\infty(\omega) = \pi_{-1} \tag{29.8}$$

where the mathematical expectation E_{-1} here is taken with respect to the probability measure $\text{Prob}(\Omega)$.

Since the only two values that $\pi_\infty(\omega)$ can take are 1 and 0, we know that for some $\lambda \in [0, 1]$

$$\text{Prob}\Big(\pi_\infty(\omega) = 1\Big) = \lambda, \quad \text{Prob}\Big(\pi_\infty(\omega) = 0\Big) = 1 - \lambda$$

and consequently that

$$E_{-1} \pi_\infty(\omega) = \lambda \cdot 1 + (1 - \lambda) \cdot 0 = \lambda$$

Combining this equation with equation (29.8), we deduce that the probability that $\text{Prob}(\Omega)$ attaches to $\pi_\infty(\omega)$ being 1 must be π_{-1}.

The same answer follows from $\pi_\infty = \mathbf{1}\{q = f\}$ and $\text{Prob}(q = f) = \pi_{-1}$.

Thus, under the worker's subjective distribution, π_{-1} of the sample paths of $\{\pi_t\}$ will converge pointwise to 1 and $1 - \pi_{-1}$ of the sample paths will converge pointwise to 0.

29.5.2 Some simulations

Let's watch the martingale convergence theorem at work in some simulations of our learning model under the worker's subjective distribution.

Let us simulate $\{\pi_t\}_{t=-1}^{T-1}$, $\{w_t\}_{t=0}^{T-1}$ paths where for each $t \geq 0$, w_t is drawn from the subjective distribution

$$h(w_t|\pi_{t-1}) = \pi_{t-1} f(w_t) + (1 - \pi_{t-1}) g(w_t)$$

This sampling scheme gives the history w^t the same joint distribution as drawing q once and for all with Prob$(q = f) = \pi_{-1}$ and then drawing $w_0, w_1, \ldots$ IID from q:

$$\prod_{s=0}^{t} h(w_s|\pi_{s-1}) = \pi_{-1} f(w^t) + (1 - \pi_{-1}) g(w^t).$$

Exercise Exercise 29.9.1 asks you to prove and check this.

Per-period mixing with a *fixed* weight α gives a different joint density, $\prod_{s=0}^{t} h(w_s|\alpha)$; that is the timing protocol of *Incorrect Models*.

We'll plot a large sample of paths.

Our code tracks log odds of $q = f$ and converts them to probabilities.

```
@jit
def martingale_simulate(π_prior, rng, N=5000, T=200):
    """
    Simulate N paths of w_0, ..., w_{T-1} from the subjective distribution.
    Column 0 of π_path holds the prior π_{-1}; column t+1 holds π_t.
    """
    π_path = np.empty((N,T+1))
    w_path = np.empty((N,T))
    π_path[:,0] = π_prior

    for n in range(N):
        log_odds = np.log(π_prior) - np.log(1 - π_prior)
        π = π_prior
        for t in range(T):
            # draw w from h(w | π)
            if rng.random() <= π:
                w = rng.beta(F_a, F_b)
            else:
                w = rng.beta(G_a, G_b)
            log_odds = update(log_odds, f(w) / g(w))
            π = 1 / (1 + np.exp(-log_odds))
            π_path[n,t+1] = π
            w_path[n,t] = w

    return π_path, w_path

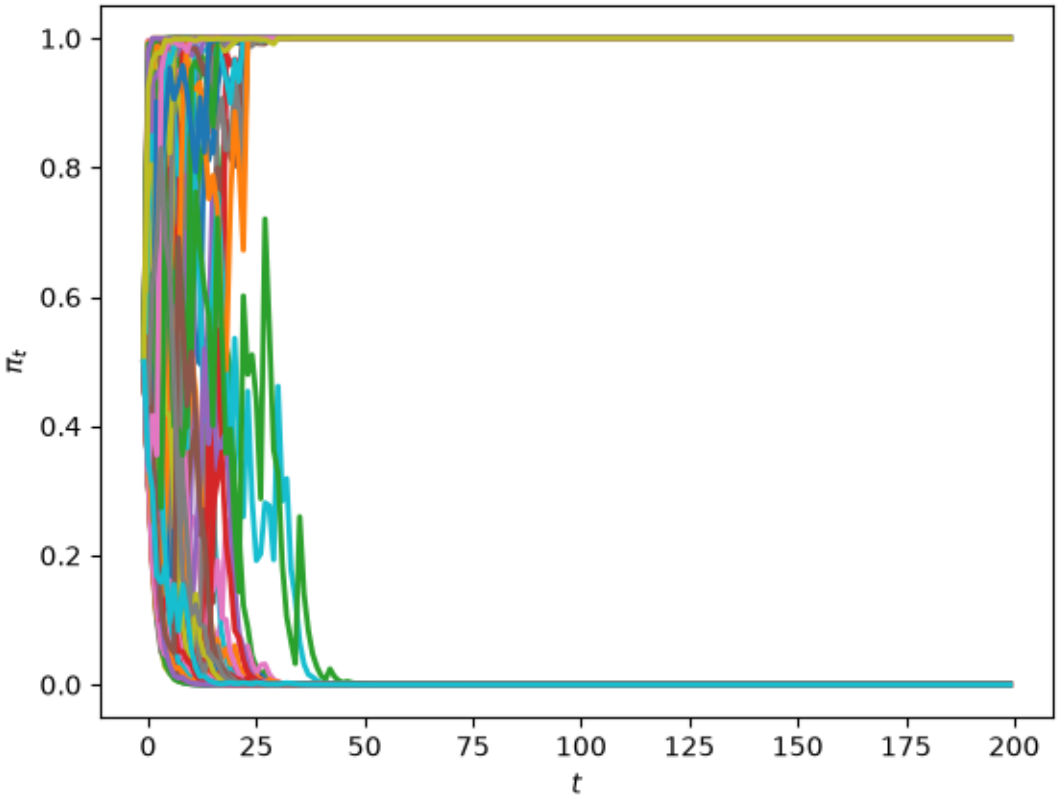
def fraction_0_1(π_prior, rng, N, T, decimals):

    π_path, w_path = martingale_simulate(π_prior, rng, N=N, T=T)
    values, counts = np.unique(np.round(π_path[:,-1], decimals=decimals), return_
↪counts=True)
    return values, counts

def create_table(π_priors, rng, N=10000, T=500, decimals=2):
```

(continues on next page)

(continued from previous page)



```
    outcomes = []
    for π_prior in π_priors:
        values, counts = fraction_0_1(π_prior, rng, N=N, T=T, decimals=decimals)
        freq = counts/N
        outcomes.append(dict(zip(values, freq)))
    table = pd.DataFrame(outcomes).sort_index(axis=1).fillna(0)
    table.index = π_priors
    return table

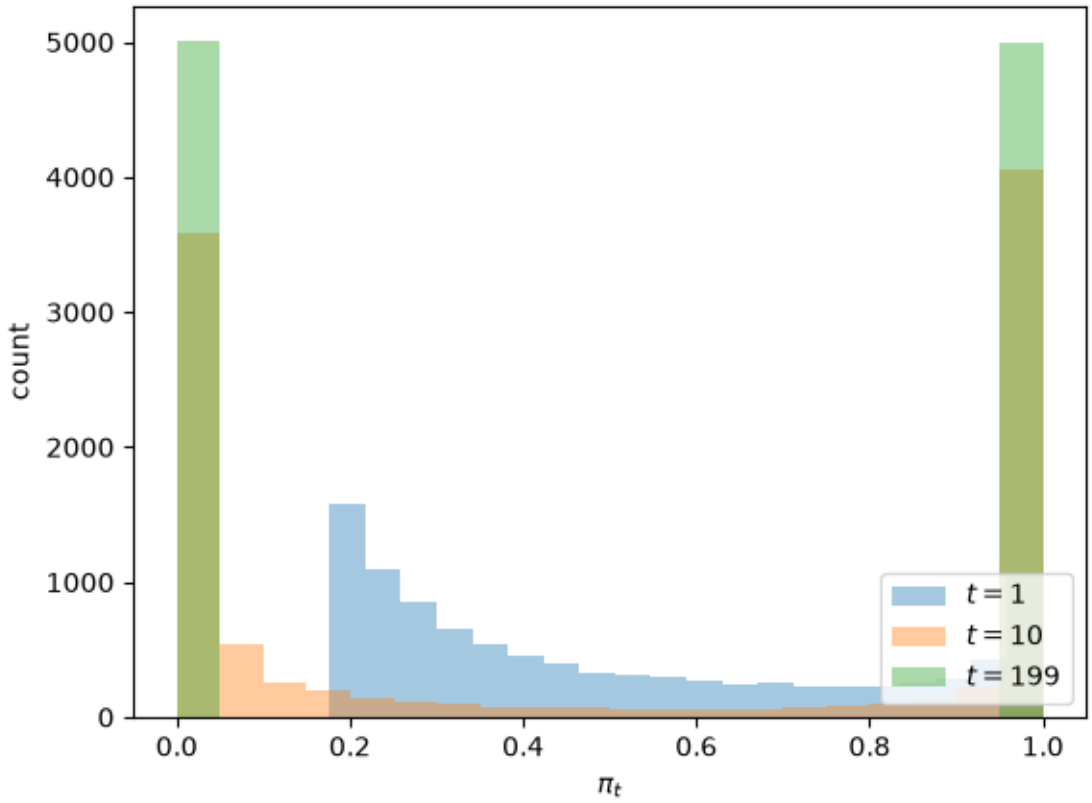
# simulate
T = 200
π_prior = .5

π_path, w_path = martingale_simulate(π_prior=π_prior, rng=rng, T=T, N=10000)
```

```
fig, ax = plt.subplots()
for i in range(100):
    ax.plot(range(-1, T), π_path[i, :], lw=2)

ax.set_xlabel('$t$')
ax.set_ylabel(r'$\pi_t$')
plt.show()
```

The above graph indicates that



- each of the paths converges
- some of the paths converge to 1

- some of the paths converge to 0
- none of the paths converge to a limit point not equal to 0 or 1

Convergence actually occurs pretty fast, as the following graph of the cross-ensemble distribution of π_t for $t = 1, 10,$ and 199 indicates.

```
fig, ax = plt.subplots()
for t in [1, 10, T-1]:
    ax.hist(π_path[:, t+1], bins=20, alpha=0.4, label=f'$t={t}$')

ax.set_ylabel('count')
ax.set_xlabel(r'$\pi_t$')
ax.legend(loc='lower right')
plt.show()
```

The next cell reports the fractions of paths with π_{199} above 0.99, below 0.01, and in between.

```
def report_fractions(π_path):
    π_T = π_path[:, -1]
    print(f"fraction with π_T > 0.99:         {np.mean(π_T > 0.99):.4f}")
    print(f"fraction with π_T < 0.01:         {np.mean(π_T < 0.01):.4f}")
    print(f"fraction with 0.01 <= π_T <= 0.99: {np.mean((π_T >= 0.01) & (π_T <= 0.
↪99)):.4f}")

report_fractions(π_path)
```

```
fraction with π_T > 0.99:         0.4991
fraction with π_T < 0.01:         0.5009
fraction with 0.01 <= π_T <= 0.99: 0.0000
```

Evidently, by $t = 199$, π_t has converged to either 0 or 1 along almost every path.

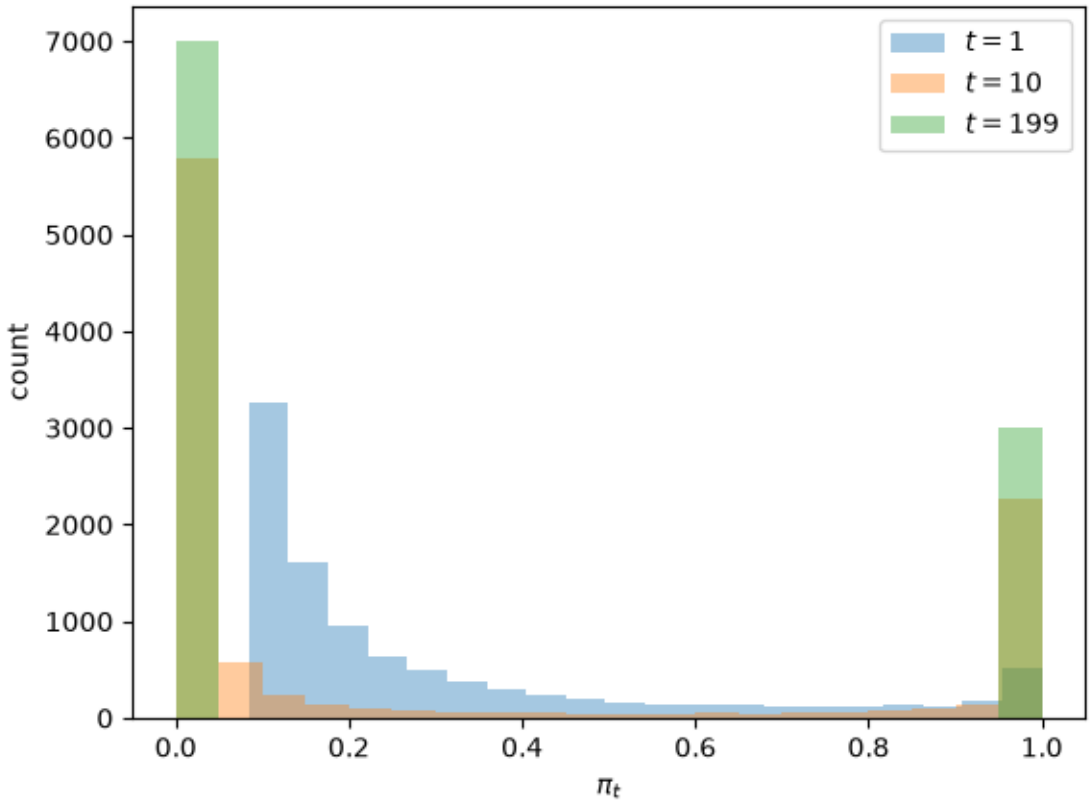
The fraction of paths that have converged to 1 is close to .5.

The fraction of paths that have converged to 0 is also close to .5.

Does the fraction .5 ring a bell?

Yes, it does: it equals the value of $\pi_{-1} = .5$ that we used to generate each sequence in the ensemble.

So let's change π_{-1} to .3 and watch what happens to the distribution of the ensemble of π_t's for various t's.



```
# simulate
T = 200
π_prior = .3

π_path3, w_path3 = martingale_simulate(π_prior=π_prior, rng=rng, T=T, N=10000)
```

```
fig, ax = plt.subplots()
for t in [1, 10, T-1]:
    ax.hist(π_path3[:, t+1], bins=20, alpha=0.4, label=f'$t={t}$')

ax.set_ylabel('count')
ax.set_xlabel(r'$\pi_t$')
ax.legend(loc='upper right')
plt.show()

report_fractions(π_path3)
```

```
fraction with π_T > 0.99:         0.2996
fraction with π_T < 0.01:         0.7004
fraction with 0.01 <= π_T <= 0.99: 0.0000
```

For the preceding ensemble that assumed $\pi_{-1} = .5$, the following graph shows two paths of w_t's and the π_t sequences that gave rise to them.

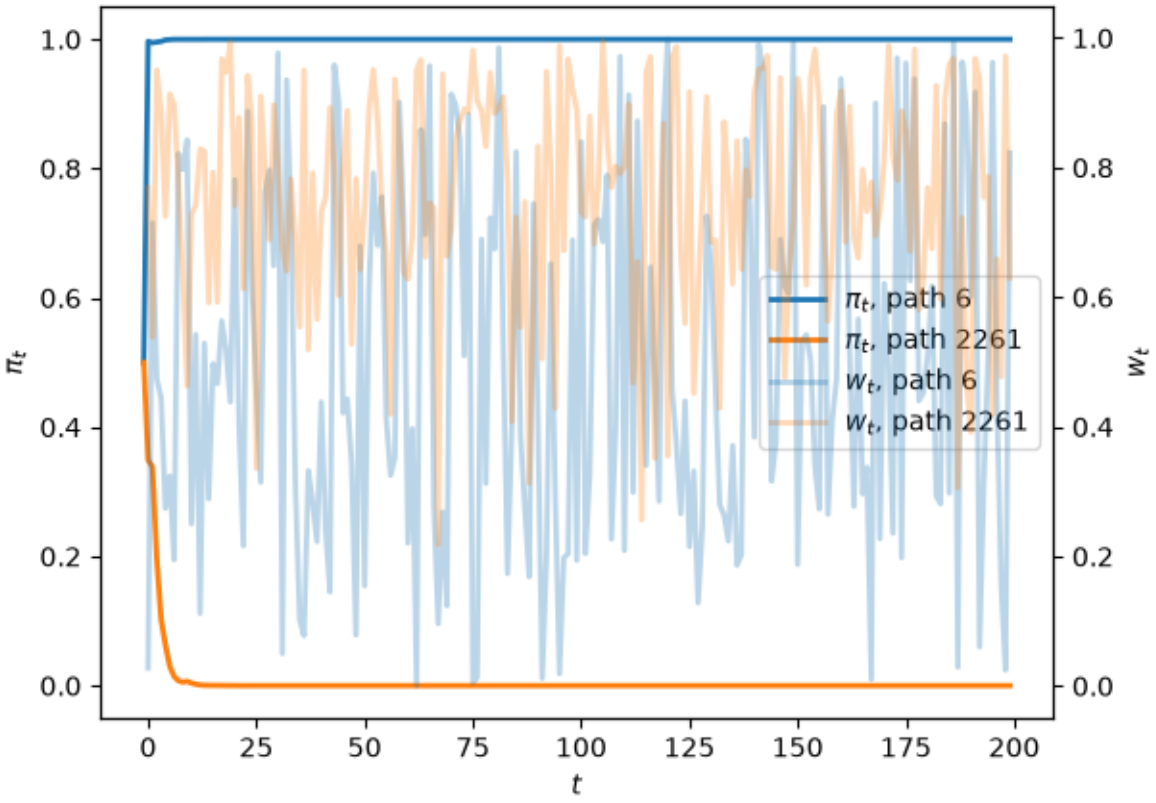
We choose the path with the largest π_{199} and the path with the smallest π_{199}.

Draws $w \in [0.524, 0.999]$ have $\ell(w) < 1$ and push π_t downward (see *Exchangeability and Bayesian Updating*).

The path along which π_t goes to 1 has systematically lower w_t's than the path along which π_t goes to 0.

The luck of the draw early in a simulation pushes the subjective distribution to draw from F more frequently along a sample path, and this pushes π_t toward 1.

Because predictive sampling has the same joint distribution as drawing q once and for all, a path along which $\pi_t \to 1$ looks like a sequence of IID draws from f, and a path along which $\pi_t \to 0$ looks like a sequence of IID draws from g.



```
j_up, j_down = np.argmax(π_path[:, -1]), np.argmin(π_path[:, -1])

fig, ax = plt.subplots()
ax2 = ax.twinx()
for i, j in enumerate([j_up, j_down]):
    ax.plot(range(-1, T), π_path[j, :], color=colors[i],
            label=fr'$\pi_t$, path {j}', lw=2)
    ax2.plot(range(T), w_path[j, :], color=colors[i],
             label=fr'$w_t$, path {j}', alpha=0.3, lw=2)

ax.set_xlabel('$t$')
ax.set_ylabel(r'$\pi_t$')
ax2.set_ylabel(r'$w_t$')
handles = ax.get_legend_handles_labels()[0] + ax2.get_legend_handles_labels()[0]
ax.legend(handles=handles, loc='center right')
plt.show()

for name, j in [('π_t → 1', j_up), ('π_t → 0', j_down)]:
    print(f"path with {name}: mean of w_t = {w_path[j, :].mean():.3f}")

up = π_path[:, -1] > 0.5
print(f"all paths with π_199 > 0.5: mean of w_t = {w_path[up, :].mean():.3f}")
print(f"all paths with π_199 < 0.5: mean of w_t = {w_path[~up, :].mean():.3f}")
print(f"means of f and g: {F_a / (F_a + F_b):.3f}, {G_a / (G_a + G_b):.3f}")
```

```
path with π_t → 1: mean of w_t = 0.496
path with π_t → 0: mean of w_t = 0.755
all paths with π_199 > 0.5: mean of w_t = 0.500
all paths with π_199 < 0.5: mean of w_t = 0.714
means of f and g: 0.500, 0.714
```

Across all paths, the mean of w_t along paths with $\pi_{199} > 0.5$ is close to the mean of f, and the mean of w_t along paths with $\pi_{199} < 0.5$ is close to the mean of g.

29.6 Initial prior is verified by paths drawn from subjective conditional densities

Now let's use our Python code to generate a table that checks out our earlier claims about the probability distribution of the pointwise limits $\pi_\infty(\omega)$.

We'll use our simulations to generate a histogram of this distribution.

In the following table, the left column in bold face reports an assumed value of π_{-1}.

The second column reports the fraction of $N = 10000$ simulations for which π_t had converged to 0 at the terminal date $T = 500$ for each simulation.

The third column reports the fraction of $N = 10000$ simulations for which π_t had converged to 1 at the terminal date $T = 500$ for each simulation.

```
# create table
table = create_table(list(np.linspace(0,1,11)), rng, N=10000, T=500)
table
```

```
        0.0     1.0
0.0  1.0000  0.0000
0.1  0.9010  0.0990
0.2  0.7991  0.2009
0.3  0.6962  0.3038
0.4  0.6033  0.3967
0.5  0.5034  0.4966
0.6  0.3991  0.6009
0.7  0.2936  0.7064
0.8  0.2047  0.7953
0.9  0.0955  0.9045
1.0  0.0000  1.0000
```

The fraction of simulations for which π_t had converged to 1 is indeed always close to π_{-1}, as anticipated.

29.7 Drilling down a little bit

To understand how the local dynamics of π_t behaves, it is enlightening to consult the variance of π_t conditional on π_{t-1}.

Under the subjective distribution this conditional variance is defined as

$$\sigma^2(\pi_t|\pi_{t-1}) = \int \Big[\frac{\pi_{t-1}f(w)}{\pi_{t-1}f(w) + (1-\pi_{t-1})g(w)} - \pi_{t-1}\Big]^2 \Big[\pi_{t-1}f(w) + (1-\pi_{t-1})g(w)\Big] dw$$

We can use a Monte Carlo simulation to approximate this conditional variance.

We approximate it for a grid of points $\pi_{t-1} \in [0, 1]$.

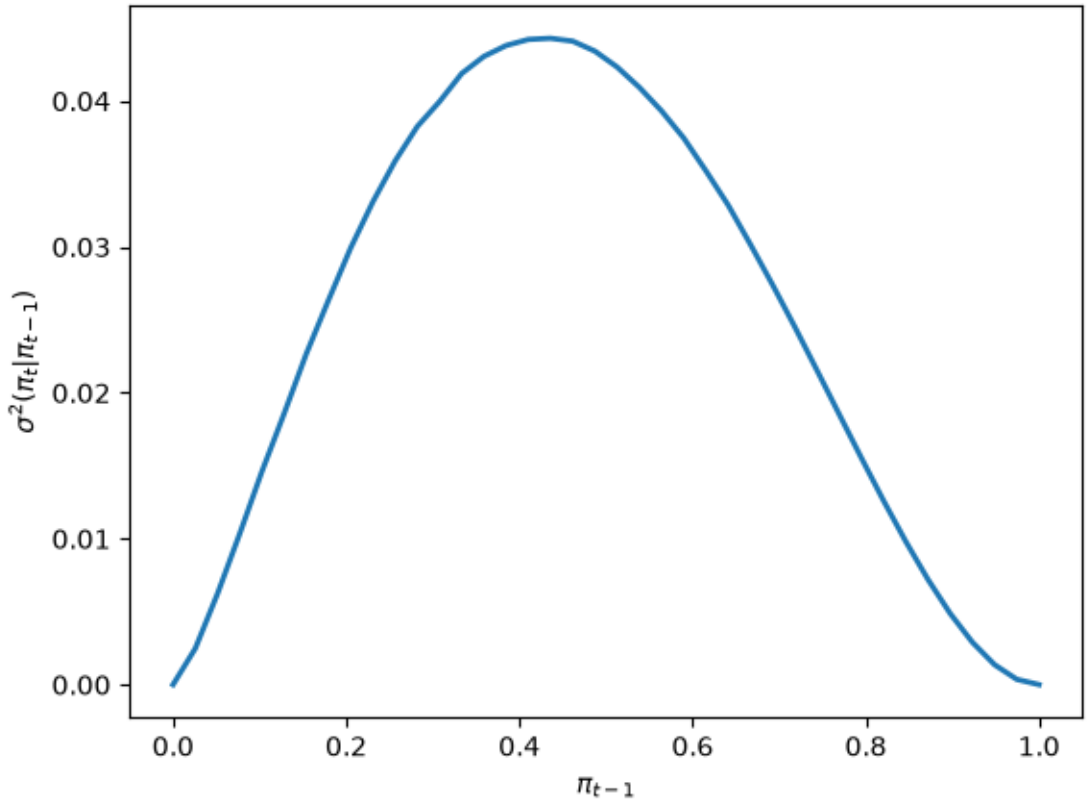
Then we'll plot it.

```
@jit
def compute_cond_var(π, rng, mc_size=int(1e6)):
    # Create Monte Carlo draws
    mc_draws = np.zeros(mc_size)

    for i in range(mc_size):
        if rng.random() <= π:
            mc_draws[i] = rng.beta(F_a, F_b)
        else:
            mc_draws[i] = rng.beta(G_a, G_b)

    dev = π*f(mc_draws)/(π*f(mc_draws) + (1-π)*g(mc_draws)) - π
    return np.mean(dev**2)

π_array = np.linspace(0, 1, 40)
cond_var_array = []



for π in π_array:
    cond_var_array.append(compute_cond_var(π, rng))

fig, ax = plt.subplots()
ax.plot(π_array, cond_var_array, lw=2)
```

(continues on next page)

(continued from previous page)

```
ax.set_xlabel(r'$\pi_{t-1}$')
ax.set_ylabel(r'$\sigma^{2}(\pi_{t}\vert \pi_{t-1})$')
plt.show()
```

The shape of the conditional variance as a function of π_{t-1} is informative about the behavior of sample paths of $\{\pi_t\}$.

Notice how the conditional variance approaches 0 for π_{t-1} near either 0 or 1.

The conditional variance is nearly zero only when the agent is almost sure that w_t is drawn from F, or is almost sure it is drawn from G.

The conditional variance is positive at every $\pi_{t-1} \in (0, 1)$.

Because π_t is a martingale, the expected sum of the conditional variances along a path is bounded:

$$E_{-1} \sum_{t=0}^{\infty} \sigma^2(\pi_t|\pi_{t-1}) = E_{-1} \sum_{t=0}^{\infty} (\pi_t - \pi_{t-1})^2 = E_{-1}\pi_\infty^2 - \pi_{-1}^2 \leq \pi_{-1}(1 - \pi_{-1}).$$

So $\sigma^2(\pi_t|\pi_{t-1}) \to 0$ along almost every path, and π_t must approach a point at which the conditional variance is zero, namely 0 or 1.

Exercise Exercise 29.9.2 fills in the details.

29.8 Related lectures

This lecture has been devoted to building some useful infrastructure that will help us understand inferences that are the foundations of results described in *Job Search IX: Search with Learning*, *A Problem that Stumped Milton Friedman*, and *Bayesian versus Frequentist Decision Rules*.

Other lectures that build on it include

- *Exchangeability and Bayesian Updating*, which describes the exchangeable joint distribution of $w_0, w_1, \ldots$ that underlies this lecture's subjective distribution
- *Incorrect Models*, which studies Bayesian learning when nature mixes f and g anew each period
- *Merging of Opinions: The Blackwell–Dubins Theorem*, which studies when the posteriors of two Bayesians with different priors merge
- *Heterogeneous Beliefs and Financial Markets*, which studies likelihood ratio processes and Bayesian learning in further settings
- *A Bayesian Formulation of Friedman and Wald's Problem*, which uses the posterior π_t as the state variable of a sequential decision problem

29.9 Exercises

Exercise 29.9.1

Consider two ways to simulate a history $w_0, w_1, \ldots, w_{T-1}$:

- method (i): draw q once and for all with Prob$(q = f) = \pi_{-1}$, then draw $w_0, w_1, \ldots$ IID from q
- method (ii): draw each w_t from the predictive density $h(w_t|\pi_{t-1})$, as in `martingale_simulate`

1. Prove that $\prod_{s=0}^{t} h(w_s|\pi_{s-1}) = \pi_{-1} f(w^t) + (1-\pi_{-1}) g(w^t)$, so that the two methods give the same joint distribution of w^t for every t.
2. With $\pi_{-1} = 0.3$, simulate 10,000 paths with each method. Compare the distributions of π_t at $t = 1, 10, 100$ with two-sample Kolmogorov–Smirnov tests.
3. Under method (i), check that π_t approaches 1 along paths with $q = f$ and approaches 0 along paths with $q = g$.

Solution

Part 1.

Let $D_s = \pi_{-1} f(w^s) + (1-\pi_{-1}) g(w^s)$ for $s \geq 0$, and let $D_{-1} = 1$.

By (29.3), $\pi_{s-1} = \pi_{-1} f(w^{s-1})/D_{s-1}$ and $1 - \pi_{s-1} = (1-\pi_{-1}) g(w^{s-1})/D_{s-1}$.

Therefore

$$h(w_s|\pi_{s-1}) = \frac{\pi_{-1} f(w^{s-1}) f(w_s) + (1-\pi_{-1}) g(w^{s-1}) g(w_s)}{D_{s-1}} = \frac{D_s}{D_{s-1}}.$$

The product over $s = 0, \ldots, t$ telescopes to $D_t / D_{-1} = D_t$.

Part 2.

Both methods produce paths of log odds, and we compare log odds.

The Kolmogorov–Smirnov statistic is invariant to the increasing transformation that maps log odds into probabilities.

```
@jit
def draw_q_once(π_prior, rng, N, T):
    """
    Method (i). Returns log odds of π_t (column t+1 holds π_t)
    and the indicator of q = f for each path.
    """
    log_odds = np.empty((N, T+1))
    q_is_f = np.empty(N, dtype=np.bool_)
    for n in range(N):
        q_is_f[n] = rng.random() < π_prior
        log_odds[n, 0] = np.log(π_prior) - np.log(1 - π_prior)
        for t in range(T):
            if q_is_f[n]:
                w = rng.beta(F_a, F_b)
            else:
                w = rng.beta(G_a, G_b)
            log_odds[n, t+1] = update(log_odds[n, t], f(w) / g(w))
    return log_odds, q_is_f

@jit
def predictive_sampling(π_prior, rng, N, T):
    "Method (ii). Returns log odds of π_t (column t+1 holds π_t)."
    log_odds = np.empty((N, T+1))
    for n in range(N):
        log_odds[n, 0] = np.log(π_prior) - np.log(1 - π_prior)
        for t in range(T):
            π = 1 / (1 + np.exp(-log_odds[n, t]))
            if rng.random() < π:
                w = rng.beta(F_a, F_b)
            else:
                w = rng.beta(G_a, G_b)
            log_odds[n, t+1] = update(log_odds[n, t], f(w) / g(w))
    return log_odds

π_prior, N_ex, T_ex = 0.3, 10_000, 200
rng_ex = np.random.default_rng(1)
lo_i, q_is_f = draw_q_once(π_prior, rng_ex, N_ex, T_ex)
lo_ii = predictive_sampling(π_prior, rng_ex, N_ex, T_ex)

for t in [1, 10, 100]:
    res = ks_2samp(lo_i[:, t+1], lo_ii[:, t+1])
    print(f"t = {t:3d}: KS statistic = {res.statistic:.4f}, p-value = {res.pvalue:.
↪3f}")
```

```
t =   1: KS statistic = 0.0182, p-value = 0.073
t =  10: KS statistic = 0.0143, p-value = 0.258
t = 100: KS statistic = 0.0125, p-value = 0.415
```

At the 5 percent level, the tests do not reject the hypothesis that the two methods produce the same distribution of π_t.

Part 3.

```
π_T = expit(lo_i[:, -1])
print(f"fraction of paths with q = f: {q_is_f.mean():.4f}")
print(f"among paths with q = f, fraction with π_{T_ex-1} > 0.99: {np.mean(π_T[q_is_
↪f] > 0.99):.4f}")
print(f"among paths with q = g, fraction with π_{T_ex-1} < 0.01: {np.mean(π_T[~q_
↪is_f] < 0.01):.4f}")
```

```
fraction of paths with q = f: 0.3065
among paths with q = f, fraction with π_199 > 0.99: 1.0000
among paths with q = g, fraction with π_199 < 0.01: 1.0000
```

Under method (i), π_t discovers q along every simulated path, as Doob's theorem asserts.

Exercise 29.9.2

Let $\Delta_t = \pi_t - \pi_{t-1}$ for $t \geq 0$.

1. Show that $E[\Delta_t^2 \mid w^{t-1}] = \sigma^2(\pi_t|\pi_{t-1})$ and that
$$\sigma^2(\pi_t|\pi_{t-1}) = \pi_{t-1}^2(1-\pi_{t-1})^2 \int \frac{(f(w)-g(w))^2}{h(w|\pi_{t-1})} dw.$$
2. Use the martingale property to show that $E_{-1}\sum_{s=0}^{t}\Delta_s^2 = E_{-1}\pi_t^2 - \pi_{-1}^2$. Deduce that $E_{-1}\sum_{t=0}^{\infty}\Delta_t^2 = E_{-1}\pi_\infty^2 - \pi_{-1}^2 \leq \pi_{-1}(1-\pi_{-1})$, with equality when $\pi_\infty \in \{0,1\}$ with probability one.
3. Verify the equality by simulation for $\pi_{-1} = 0.3$ and $\pi_{-1} = 0.5$.
4. Use parts 1 and 2 to give a second proof that $\pi_\infty \in \{0,1\}$ with probability one.

Solution

Part 1.

Conditional on w^{t-1}, w_t has density $h(w_t|\pi_{t-1})$ and $E[\pi_t|w^{t-1}] = \pi_{t-1}$, so $E[\Delta_t^2|w^{t-1}]$ is the conditional variance $\sigma^2(\pi_t|\pi_{t-1})$.

Write $\pi = \pi_{t-1}$.

Then $\pi_t - \pi = \pi f/h(w|\pi) - \pi = \pi(1-\pi)(f-g)/h(w|\pi)$, and

$$\sigma^2(\pi_t|\pi_{t-1}) = \int \frac{\pi^2(1-\pi)^2(f(w)-g(w))^2}{h(w|\pi)^2} h(w|\pi)dw = \pi^2(1-\pi)^2 \int \frac{(f(w)-g(w))^2}{h(w|\pi)} dw.$$

The integral is positive when $f \neq g$, so σ^2 is positive on $(0,1)$.

A random variable with values in $[0,1]$ and mean π has variance at most $\pi(1-\pi)$, so $\sigma^2 \to 0$ as $\pi \to 0$ or $\pi \to 1$.

Part 2.

Since $E[\Delta_t|w^{t-1}] = 0$,

$$E_{-1}\pi_t^2 = E_{-1}(\pi_{t-1}+\Delta_t)^2 = E_{-1}\pi_{t-1}^2 + E_{-1}\Delta_t^2 + 2E_{-1}[\pi_{t-1}E[\Delta_t|w^{t-1}]] = E_{-1}\pi_{t-1}^2 + E_{-1}\Delta_t^2.$$

Summing from 0 to t gives $E_{-1}\sum_{s=0}^{t}\Delta_s^2 = E_{-1}\pi_t^2 - \pi_{-1}^2$.

Let $t \to \infty$.

The left side converges by monotone convergence, and the right side converges to $E_{-1}\pi_\infty^2 - \pi_{-1}^2$ by bounded convergence.

Because $0 \leq \pi_\infty \leq 1$, $\pi_\infty^2 \leq \pi_\infty$, so $E_{-1}\pi_\infty^2 \leq E_{-1}\pi_\infty = \pi_{-1}$.

Equality holds if and only if $\pi_\infty^2 = \pi_\infty$, that is, $\pi_\infty \in \{0, 1\}$, with probability one.

Part 3.

```
for π_prior in [0.3, 0.5]:
    π_path_ex, _ = martingale_simulate(π_prior, rng_ex, N=20_000, T=500)
    sum_sq = np.sum(np.diff(π_path_ex, axis=1)**2, axis=1)
    print(f"π_-1 = {π_prior}: mean of sum of squared increments = {sum_sq.mean():.
↪4f}, "
          f"π_-1 (1 - π_-1) = {π_prior * (1 - π_prior):.4f}")
```

```
π_-1 = 0.3: mean of sum of squared increments = 0.2094, π_-1 (1 - π_-1) = 0.2100
π_-1 = 0.5: mean of sum of squared increments = 0.2500, π_-1 (1 - π_-1) = 0.2500
```

Part 4.

By parts 1 and 2,

$$E_{-1}\sum_{t=0}^{\infty}\sigma^2(\pi_t|\pi_{t-1}) = E_{-1}\sum_{t=0}^{\infty}\Delta_t^2 \leq \pi_{-1}(1-\pi_{-1}) < \infty,$$

so $\sum_t \sigma^2(\pi_t|\pi_{t-1}) < \infty$ and $\sigma^2(\pi_t|\pi_{t-1}) \to 0$ with probability one.

The function $\pi \mapsto \sigma^2$ is continuous on $[0, 1]$, positive on $(0, 1)$, and zero at 0 and 1.

Since $\pi_t \to \pi_\infty$, continuity implies that σ^2 evaluated at π_∞ is zero, so $\pi_\infty \in \{0, 1\}$.

Exercise 29.9.3

Two Bayesians observe the same history w^t but start from different priors, $\pi_{-1}^1 = 0.2$ and $\pi_{-1}^2 = 0.8$.

1. Show that the difference between their log odds is the same at every date.
2. Show that $\frac{1}{t+1}\log|\pi_t^1 - \pi_t^2|$ converges to $-KL(f, g)$ with probability one when nature draws from f and to $-KL(g, f)$ with probability one when nature draws from g.
3. Verify part 2 by simulation.

Merging of Opinions: The Blackwell–Dubins Theorem studies when the opinions of Bayesians with different priors merge in general.

Solution

Part 1.

By (29.6), each Bayesian adds the same $\log \ell(w_t)$ to his log odds at each date, so the difference c between their log odds equals its initial value $\log\frac{0.2}{0.8} - \log\frac{0.8}{0.2} = -2\log 4$.

Part 2.

Let x_i be the log odds of Bayesian i, so that $\pi_t^i = 1/(1 + e^{-x_i})$.

Direct computation gives

$$\pi_t^1 - \pi_t^2 = \frac{\sinh(c/2)}{2\cosh(x_1/2)\cosh(x_2/2)}.$$

Since $\log\cosh(x/2) = |x|/2 - \log 2 + o(1)$ as $|x| \to \infty$ and $x_i = x_i(-1) + \log L(w^t)$,

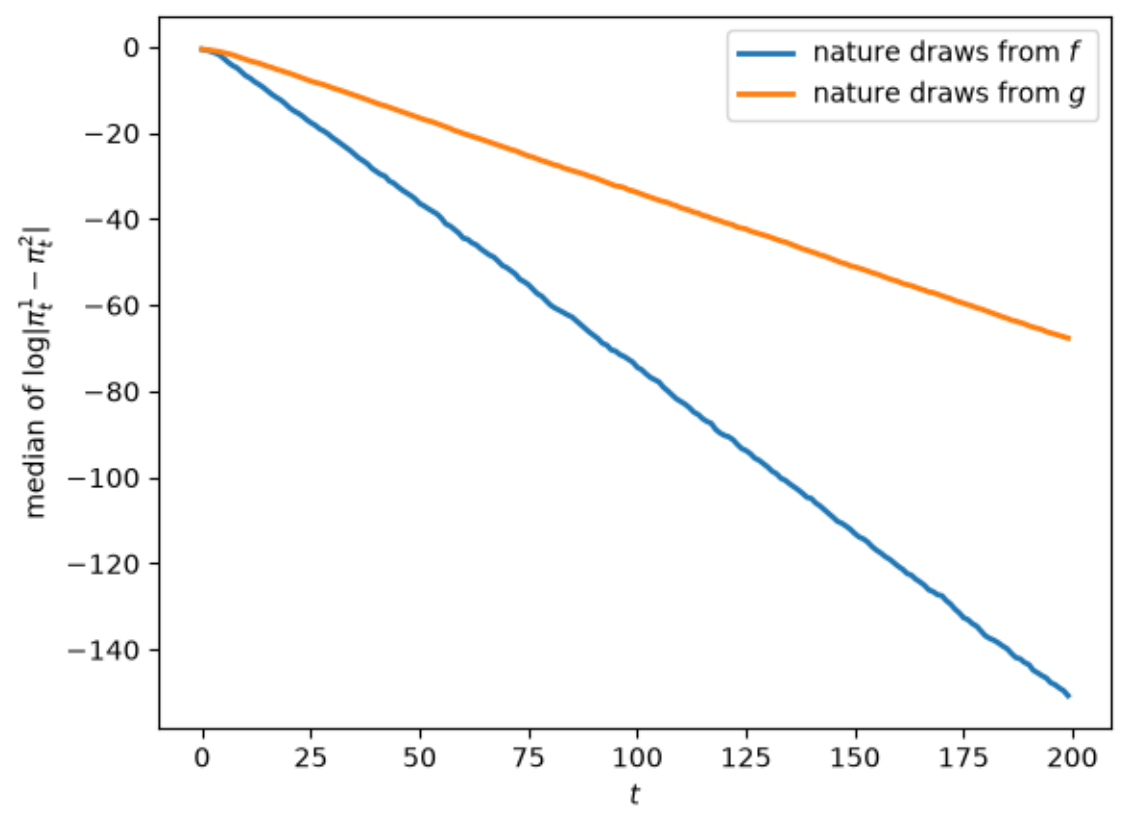
$$\log|\pi_t^1 - \pi_t^2| = -|\log L(w^t)| + O(1).$$

By the strong law of large numbers, $\frac{1}{t+1}\log L(w^t)$ converges to $KL(f,g)$ under f and to $-KL(g,f)$ under g.

Part 3.

We compute $\log|\pi_t^1 - \pi_t^2|$ from the formula in part 2.

Computing $\pi_t^1 - \pi_t^2$ directly would return zero once both probabilities round to 1 or to 0.



```
def log_gap(x1, x2):
    "log |expit(x1) - expit(x2)|, computed without cancellation."
    log_cosh_half = lambda x: np.logaddexp(x / 2, -x / 2) - np.log(2)
    c = x1 - x2
    return (np.log(np.abs(np.sinh(c / 2))) - np.log(2)
            - log_cosh_half(x1) - log_cosh_half(x2))

KL_fg = compute_KL(f, g)
KL_gf = compute_KL(g, f)

T_m, N_m = 200, 1000
t_m = np.arange(T_m)
fig, ax = plt.subplots()
for name, (a, b), KL in [('f', (F_a, F_b), KL_fg), ('g', (G_a, G_b), KL_gf)]:
    log_L = np.cumsum(np.log(simulate(a, b, rng_ex, T=T_m, N=N_m)), axis=1)
    gap = log_gap(logit(0.2) + log_L, logit(0.8) + log_L)
    med = np.median(gap, axis=0)
    slope = np.polyfit(t_m[50:], med[50:], 1)[0]
    ax.plot(t_m, med, lw=2, label=f'nature draws from ${name}$')
    print(f"nature draws from {name}: slope of median log gap = {slope:.3f}, "
          f"-KL = {-KL:.3f}")

ax.set_xlabel('$t$')
ax.set_ylabel(r'median of $\log|\pi^1_t - \pi^2_t|$')
ax.legend()
plt.show()
```

```
nature draws from f: slope of median log gap = -0.768, -KL = -0.759
nature draws from g: slope of median log gap = -0.344, -KL = -0.344
```

The slopes match $-KL(f,g)$ and $-KL(g,f)$.

The two Bayesians' opinions merge exponentially fast, faster when nature draws from f than when nature draws from g.

30.1 Overview

This lecture studies *Blackwell's theorem* [Blackwell, 1951, Blackwell, 1953] on ranking statistical experiments.

Our presentation brings in findings from a Bayesian interpretation of Blackwell's theorem by Kihlstrom [1984].

Blackwell and Kihlstrom study statistical model-selection questions closely related to those encountered in this QuantEcon lecture *Likelihood Ratio Processes and Bayesian Learning*.

To appreciate the connection involved, it is helpful to appreciate how Blackwell's notion of an **experiment** is related to the concept of a "probability distribution" or "parameterized statistical model" appearing in *Likelihood Ratio Processes and Bayesian Learning*

Blackwell studies a situation in which a decision maker wants to know the value of a state s that lives in a space S.

For Blackwell, an **experiment** is a **conditional probability model** $\{\mu(\cdot \mid s) : s \in S\}$, i.e., a family of probability distributions that are conditioned by the same state $s \in S$.

We are free to interpret the "state" as a "parameter" or "parameter vector".

In a two-state case $S = \{s_1, s_2\}$, the two conditional densities $f(\cdot) = \mu(\cdot \mid s_1)$ and $g(\cdot) = \mu(\cdot \mid s_2)$ are the ones used repeatedly in our studies of classical hypothesis testing and Bayesian inference in this QuantEcon lecture *Likelihood Ratio Processes and Bayesian Learning* as well as several other lectures in this suite of QuantEcon lectures.

Kihlstrom [1984] interprets the question *which experiment is more informative?* as asking which conditional probability model allows a Bayesian decision maker with a prior over $\{s_1, s_2\}$ to gather higher expected utility.

We'll use the terms "signal" and "experiment" as synonyms.

Thus, suppose that two signals, $\tilde{x}_\mu$ and $\tilde{x}_\nu$, are both informative about an unknown state $\tilde{s}$.

Signal μ is **at least as informative as** signal ν if every Bayesian decision maker can attain weakly higher expected utility with μ than with ν.

This economic criterion is equivalent to two statistical criteria:

- *Sufficiency* (Blackwell): $\tilde{x}_\nu$ can be generated from $\tilde{x}_\mu$ by an additional randomization.
- *Uncertainty reduction* (DeGroot [1962]): $\tilde{x}_\mu$ lowers expected uncertainty at least as much as $\tilde{x}_\nu$ for every concave uncertainty function.

Kihlstrom's formulation focuses on the *posterior distribution*.

More informative experiments generate posterior distributions that are more dispersed in convex order.

In the two-state case, this becomes a mean-preserving-spread comparison on $[0, 1]$, which can be checked with the integrated-CDF test used for second-order stochastic dominance.

Incentives for Information Transfer, *Information and Market Equilibrium*, and *The Design and Price of Information* build on the results of this lecture.

The lecture proceeds as follows.

1. We define experiments as Markov matrices and garblings as stochastic transformations.
2. We state three equivalent criteria for ranking experiments and Blackwell's theorem.
3. We develop Kihlstrom's Bayesian interpretation through standard experiments, mean-preserving spreads, and convex order.
4. We study DeGroot's uncertainty functions and two applications.
5. We connect Blackwell's order to the data processing inequality and to the likelihood-ratio learning of *Likelihood Ratio Processes and Bayesian Learning*.

Python simulations illustrate each step.

We begin with some imports.

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.optimize import minimize
```

30.2 Experiments and stochastic transformations

30.2.1 The state space and experiments

Let $S = \{s_1, \ldots, s_N\}$ be a finite set of possible states of the world.

An **experiment** is described by the conditional distribution of an observed signal $\tilde{x}$ given the state $\tilde{s}$.

When the signal space is also finite, say $X = \{x_1, \ldots, x_M\}$, an experiment reduces to an $N \times M$ *Markov matrix*

$$\mu = [\mu_{ij}], \qquad \mu_{ij} = \Pr(\tilde{x}_\mu = x_j \mid \tilde{s} = s_i) \geq 0, \quad \sum_{j=1}^{M} \mu_{ij} = 1 \; \forall \, i.$$

Each row i gives the distribution of signals when the true state is s_i.

```
μ = np.array([[0.6, 0.3, 0.1],
              [0.1, 0.3, 0.6]])

Q = np.array([[1.0, 0.0],
              [0.5, 0.5],
              [0.0, 1.0]])

ν = μ @ Q

print("Experiment μ (3 signals, rows sum to 1):")
print(μ)
print("\nStochastic transformation Q (3 × 2):")
print(Q)
print("\nExperiment ν = μ @ Q (2 signals):")
print(ν)
print("\nRow sums μ:", μ.sum(axis=1))
print("Row sums ν:", ν.sum(axis=1))
```

```
Experiment μ (3 signals, rows sum to 1):
[[0.6 0.3 0.1]
 [0.1 0.3 0.6]]

Stochastic transformation Q (3 × 2):
[[1.  0. ]
 [0.5 0.5]
 [0.  1. ]]

Experiment ν = μ @ Q (2 signals):
[[0.75 0.25]
 [0.25 0.75]]

Row sums μ: [1. 1.]
Row sums ν: [1. 1.]
```

30.2.2 Stochastic transformations

A **stochastic transformation** Q maps signals from one experiment to signals from another by further randomization.

In the discrete setting with M input signals and K output signals, Q is an $M \times K$ Markov matrix: $q_{lk} \geq 0$ and $\sum_k q_{lk} = 1$ for every row l.

Definition 30.2.1 (Sufficiency)

Experiment μ is *sufficient for* ν if there exists a stochastic transformation Q (an $M \times K$ Markov matrix) such that

$$\nu = \mu\, Q,$$

meaning that an observer of $\tilde{x}_\mu$ can generate the distribution of $\tilde{x}_\nu$ by passing their signal through Q.

With general signal spaces, Q is a Markov kernel and the condition reads $\nu_i(E) = \int Q(x, E)\, \mu_i(dx)$ for every measurable set E of ν's signals and every state s_i.

We write $\mu \geq \nu$ when μ is sufficient for ν, and we call ν a **garbling** of μ.

If you observe the more informative signal $\tilde{x}_\mu$, then you can always *throw away* information to reproduce a less informative signal.

The reverse generally fails: a garbling cannot restore what it discards.

We can verify this numerically using the two experiments μ and ν defined above.

The function below searches for a stochastic transformation Q that minimizes $\|\nu - \mu\, Q\|$.

If an exact Q exists the residual will be close to zero; otherwise it will be large.

```
def find_stochastic_transform(μ, ν, tol=1e-8):
    """
    Find a row-stochastic matrix Q that minimizes ||ν - μ @ Q||.
    """
    _, M = μ.shape
    _, K = ν.shape

    def unpack(q_flat):
        return q_flat.reshape(M, K)

    def objective(q_flat):
        Q = unpack(q_flat)
        return np.linalg.norm(ν - μ @ Q)**2

    constraints = [
        {"type": "eq", "fun": lambda q_flat,
        row=i: unpack(q_flat)[row].sum() - 1.0}
        for i in range(M)
    ]
    bounds = [(0.0, 1.0)] * (M * K)
    Q0 = np.full((M, K), 1 / K).ravel()

    result = minimize(
        objective,
        Q0,
        method="SLSQP",
        bounds=bounds,
```

(continues on next page)

(continued from previous page)

```
        constraints=constraints,
        options={"ftol": tol, "maxiter": 1_000},
    )

    Q = unpack(result.x)
    residual = np.linalg.norm(ν - μ @ Q)
    return Q, residual

# Forward: find Q such that ν = μ @ Q  (should succeed)
Q_fwd, res_fwd = find_stochastic_transform(μ, ν)
print("Forward (μ to ν):")
print(f"  residual = {res_fwd:.2e}")
print(f"  exact transformation exists: {res_fwd < 1e-6}")

# Reverse: find Q' such that μ = ν @ Q'  (should fail)
Q_rev, res_rev = find_stochastic_transform(ν, μ)
print("\nReverse (ν to μ):")
print(f"  residual = {res_rev:.2e}")
print(f"  exact transformation exists: {res_rev < 1e-6}")
```

```
Forward (μ to ν):
  residual = 5.05e-09
  exact transformation exists: True

Reverse (ν to μ):
  residual = 1.44e-01
  exact transformation exists: False
```

The forward residual is close to zero: a stochastic transformation from μ to ν exists, confirming that μ is sufficient for ν.

The reverse residual is large: no stochastic transformation can recover μ from ν.

Exercise 30.13.1 proves that no stochastic transformation maps ν into μ.

A garbling can only pull posterior beliefs toward the prior, and μ generates posteriors farther from the prior than ν can reach.

30.3 Three equivalent criteria

Blackwell's theorem establishes that three different ways of comparing experiments all turn out to be equivalent.

30.3.1 Criterion 1: the economic criterion

The first criterion compares experiments by their value to decision makers.

Let A be a compact set of actions and $u : A \times S \to \mathbb{R}$ a bounded continuous utility function.

A decision maker observes $x \in X$ and then chooses an action, possibly at random.

A **decision rule** δ assigns to each signal x a probability distribution $\delta(\cdot \mid x)$ over actions.

Let $p = (p_1, \ldots, p_N)$ be the prior over states, and write

$$P = \{(p_1, \ldots, p_N) : p_i \geq 0,\ \textstyle\sum_i p_i = 1\}$$

for the probability simplex.

For fixed A and u, the set of *achievable expected-utility vectors* under experiment μ is

$$B(\mu, A, u) = \left\{ v \in \mathbb{R}^N : v_i = \int_X \int_A u(a, s_i)\, \delta(da \mid x)\, \mu_i(dx) \text{ for some decision rule } \delta \right\}.$$

Each $v \in B(\mu, A, u)$ lists the expected utilities that one decision rule delivers in each state.

Randomized rules make $B(\mu, A, u)$ convex.

They also make the replication argument below exact: a decision maker who sees $\tilde{x}_\mu$ can draw a synthetic $\tilde{x}_\nu$ and then follow any rule designed for ν.

Definition 30.3.1 (Economic criterion)

μ is **at least as informative as** ν in the economic sense if

$$B(\mu, A, u) \supseteq B(\nu, A, u)$$

for every compact action set A and every bounded continuous utility function $u : A \times S \to \mathbb{R}$.

This criterion says that experiment μ is better than experiment ν if anything a decision maker can achieve after seeing ν, they can also achieve after seeing μ.

The reason is that a more informative experiment lets the agent imitate a less informative one by *ignoring* or *garbling* some of the extra information.

But the reverse need not be possible.

So $B(\mu, A, u) \supseteq B(\nu, A, u)$ means that μ gives the decision maker at least as many feasible expected-utility outcomes as ν.

Blackwell's theorem below implies an equivalent comparison of values.

For every prior $p \in P$, every A, and every u, the maximized expected utility $\max_{v \in B(\mu,A,u)} \sum_i p_i v_i$ is at least as large under μ as under ν.

A Bayesian decision maker attains that maximum with a deterministic rule that chooses an optimal action at each posterior; randomization matters only for the comparison of sets.

30.3.2 Criterion 2: the sufficiency criterion

The second criterion is the sufficiency relation of *Definition 30.2.1*: $\mu \geq \nu$ if $\nu = \mu Q$ for some stochastic transformation Q.

30.3.3 Criterion 3: the uncertainty criterion

The third criterion compares experiments by how much they reduce uncertainty about the state.

DeGroot [1962] calls any concave function $U : P \to \mathbb{R}$ an **uncertainty function**.

The prototypical example is Shannon entropy:

$$U(p) = -\sum_{i=1}^{N} p_i \log p_i.$$

Definition 30.3.2 (DeGroot uncertainty criterion)

μ **reduces expected uncertainty at least as much as** ν if, for every prior $p \in P$ and every concave $U : P \to \mathbb{R}$,

$$\int_P U(q)\,\hat{\mu}^p(dq) \;\leq\; \int_P U(q)\,\hat{\nu}^p(dq),$$

where $\hat{\mu}^p$ is the distribution of posterior beliefs induced by experiment μ under prior p.

Every experiment weakly lowers expected uncertainty.

To see why, let $\tilde{\pi} = p^\mu(\tilde{x}_\mu)$ denote the random posterior induced by experiment μ.

Then $\tilde{\pi}$ has distribution $\hat{\mu}^p$, so

$$\mathbb{E}[U(\tilde{\pi})] = \int_P U(q)\,\hat{\mu}^p(dq).$$

The posterior has mean p (*Property 30.5.1* below), so Jensen's inequality gives

$$\mathbb{E}[U(\tilde{\pi})] \leq U(\mathbb{E}[\tilde{\pi}]) = U(p).$$

Hence

$$\int_P U(q)\,\hat{\mu}^p(dq) \leq U(p),$$

so any experiment weakly lowers expected uncertainty.

Criterion 3 quantifies over every prior p.

Blackwell's theorem implies that one prior with full support suffices: if the inequality holds for every concave U at one such prior, it holds at every prior.

Kihlstrom's construction below exploits this fact by working with a fixed prior c, often the uniform prior $(1/N, \ldots, 1/N)$.

30.4 The main theorem

Theorem 30.4.1 (Blackwell's theorem)

The following three conditions are equivalent:

(i) Economic criterion: $B(\mu, A, u) \supseteq B(\nu, A, u)$ for every compact A and every bounded continuous utility function u.

(ii) Sufficiency criterion: There exists a stochastic transformation Q from the signal space of μ to the signal space of ν such that $\nu = \mu Q$.

(iii) Uncertainty criterion: $\int_P U(q)\,\hat{\mu}^p(dq) \leq \int_P U(q)\,\hat{\nu}^p(dq)$ for every concave U, at every prior $p \in P$, or equivalently at one prior with full support.

See also Blackwell [1951], Bohnenblust *et al.* [1949], and DeGroot [1962].

The hard part is the equivalence between the economic and sufficiency criteria.

Sketch (ii $\Rightarrow$ i): If $\nu = \mu Q$, then any decision rule based on $\tilde{x}_\nu$ can be replicated by first observing $\tilde{x}_\mu$, then drawing a synthetic $\tilde{x}_\nu$ from Q, and then applying the same rule.

Sketch (i ⇒ ii): Since $B(\mu, A, u) \supseteq B(\nu, A, u)$ for every A and u, a separating-hyperplane (duality) argument implies that the posterior distribution of μ is a mean-preserving spread of that of ν, and Strassen's theorem [Strassen, 1965] then supplies a posterior-space mean-preserving kernel D sending the standard experiment of ν into that of μ. Passing from these posterior laws back to the original signal spaces then yields the required garbling Q with $\nu = \mu Q$. Thus D is an intermediate randomization on posterior beliefs, not literally the signal-space kernel Q.

Sketch (ii ⇒ iii): Under a garbling, the posterior from the coarser experiment is the conditional expectation of the posterior from the finer experiment, so Jensen's inequality gives the result for every concave U.

Sketch (iii ⇒ ii): The converse, that the inequality for all concave U forces the existence of Q, is proved in [Blackwell, 1953]. Kihlstrom's posterior-based representation makes the geometry transparent.

30.5 Kihlstrom's Bayesian interpretation

30.5.1 Posteriors and standard experiments

The key object in Kihlstrom's analysis is the *posterior belief vector*.

When prior p holds and experiment μ produces signal x, Bayes' rule gives

$$p_i^{\mu}(x) = \Pr(\tilde{s} = s_i \mid \tilde{x}_\mu = x) = \frac{\mu_{ix}\, p_i}{\sum_j \mu_{jx}\, p_j}, \qquad i = 1, \dots, N.$$

The posterior $p^{\mu}(x) \in P$ is a random point in the simplex.

Property 30.5.1 (Mean preservation)

The prior p is the expectation of the posterior:

$$\mathbb{E}[p^{\mu}] = \sum_x \Pr(\tilde{x}_\mu = x)\, p^{\mu}(x) = p.$$

This is sometimes called the *law of iterated expectations for beliefs*.

For a fixed prior c, Kihlstrom's **standard experiment** replaces the raw signals of μ with the posterior beliefs they generate.

Let $\hat{\mu}^c$ denote the distribution over posteriors induced by μ under prior c. Mean preservation implies $\int_P q\, \hat{\mu}^c(dq) = c$.

Two experiments are **informationally equivalent** when they induce the same posterior distribution.

The standard experiment strips away every detail of the signal except its posterior, so it provides a canonical Bayesian representation for comparing experiments.

A stochastic kernel on posterior beliefs lives on the simplex P, whereas a Blackwell garbling Q lives on the original signal space. Kihlstrom's construction uses the former to study convex order and then recovers the latter after passing to standard experiments.

Any two experiments that generate the same distribution over posteriors lead to identical decisions for every Bayesian decision maker, regardless of how different their raw signal spaces may look.

30.5.2 Mean-preserving spreads and Blackwell's order

Kihlstrom's key reformulation is the following.

Theorem 30.5.1 (Kihlstrom's Reformulation)

$\mu \geq \nu$ in Blackwell's sense if and only if $\hat{\mu}^c$ is a **mean-preserving spread** of $\hat{\nu}^c$; that is,

$$\int_P g(p)\,\hat{\mu}^c(dp) \;\geq\; \int_P g(p)\,\hat{\nu}^c(dp)$$

for every convex function $g : P \to \mathbb{R}$.

Equivalently, $\hat{\mu}^c$ is larger than $\hat{\nu}^c$ in convex order.

The prior c can be any prior with full support; the comparison does not depend on which one.

A better experiment spreads posterior beliefs farther from the prior while preserving their mean.

To see this concretely, we define two experiments for the two-state case and compute their posteriors.

```
def compute_posteriors(μ, prior, tol=1e-14):
    """
    Compute the posterior distribution for each signal realisation.
    """
    N, M = μ.shape
    signal_probs = μ.T @ prior
    numerators = μ.T * prior
    posteriors = np.zeros((M, N))
    np.divide(
        numerators,
        signal_probs[:, None],
        out=posteriors,
        where=signal_probs[:, None] > tol,
    )
    return posteriors, signal_probs

def check_mean_preservation(posteriors, signal_probs, prior):
    """Verify E[posterior] == prior."""
    expected_posterior = (posteriors * signal_probs[:, None]).sum(axis=0)
    return expected_posterior, np.allclose(expected_posterior, prior)

N = 2
prior = np.array([0.5, 0.5])

μ_info = np.array([[0.8, 0.2],
                   [0.2, 0.8]])

ν_info = np.array([[0.6, 0.4],
                   [0.4, 0.6]])

post_μ, probs_μ = compute_posteriors(μ_info, prior)
post_ν, probs_ν = compute_posteriors(ν_info, prior)

print("Experiment μ (more informative):\n")
```

(continues on next page)

(continued from previous page)

```
print("Signal probabilities:", probs_μ.round(3))
print("Posteriors (row = signal, col = state):")
print(post_μ.round(3))
mean_μ, ok_μ = check_mean_preservation(post_μ, probs_μ, prior)
print(f"E[posterior] = {mean_μ.round(4)}  (equals prior: {ok_μ})")

print("\n Experiment ν (less informative):\n")
print("Signal probabilities:", probs_ν.round(3))
print("Posteriors:")
print(post_ν.round(3))
mean_ν, ok_ν = check_mean_preservation(post_ν, probs_ν, prior)
print(f"E[posterior] = {mean_ν.round(4)}  (equals prior: {ok_ν})")
```

```
Experiment μ (more informative):

Signal probabilities: [0.5 0.5]
Posteriors (row = signal, col = state):
[[0.8 0.2]
 [0.2 0.8]]
E[posterior] = [0.5 0.5]  (equals prior: True)

 Experiment ν (less informative):

Signal probabilities: [0.5 0.5]
Posteriors:
[[0.6 0.4]
 [0.4 0.6]]
E[posterior] = [0.5 0.5]  (equals prior: True)
```

For $N = 2$ states, the simplex P is the unit interval $[0, 1]$ (the probability of state s_1).

We can directly plot the distribution of posteriors under experiments μ and ν.

```
def plot_posterior_distributions(μ_matrix, ν_matrix, prior,

```

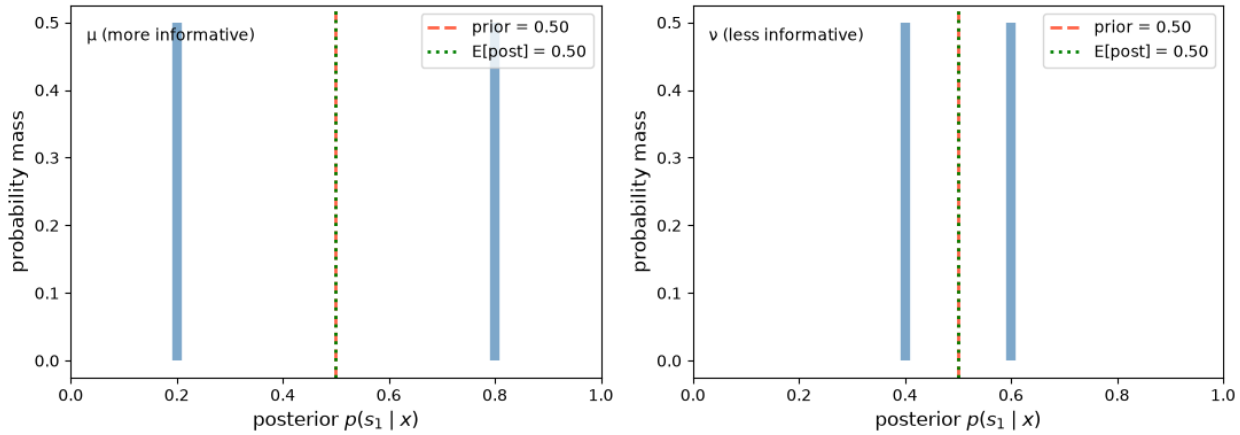

Fig. 30.1: Posterior distributions in the two-state case

This is the mean-preserving spread in action: both distributions have the same mean (equal to the prior), but the more informative experiment μ spreads its posteriors farther apart.

We can verify the mean-preserving spread condition numerically.

The key fact is that, up to an affine term, any convex function can be represented as a mixture of "call option" payoffs $g_t(p) = \max(p - t, 0)$.

Because the two posterior distributions being compared have the same mean, that affine term cancels in the comparison.

So it suffices to check $E[g_t(p^\mu)] \geq E[g_t(p^\nu)]$ for all thresholds $t \in [0, 1]$.

```
def check_mps_convex_functions(μ_matrix, ν_matrix, prior, n_functions=200):
    """
    Verify the mean-preserving spread condition using
    convex functions g(p) = max(p - t, 0).
    """
    posts_μ, probs_μ = compute_posteriors(μ_matrix, prior)
    posts_ν, probs_ν = compute_posteriors(ν_matrix, prior)

    p_μ = posts_μ[:, 0]
    p_ν = posts_ν[:, 0]

    thresholds = np.linspace(0, 1, n_functions)
    diffs = []
    for t in thresholds:
        Eg_μ = (np.maximum(p_μ - t, 0) * probs_μ).sum()
        Eg_ν = (np.maximum(p_ν - t, 0) * probs_ν).sum()
```

(continues on next page)

(continued from previous page)

```
        diffs.append(Eg_μ - Eg_ν)

    fig, ax = plt.subplots(figsize=(8, 4))
    ax.plot(thresholds, diffs, color="steelblue", linewidth=2)
    ax.axhline(0, color="tomato", linestyle="--", linewidth=2)
    ax.fill_between(thresholds, diffs, 0,
                    where=np.array(diffs) >= 0,
                    alpha=0.25, color="steelblue",
                    label="$E[g(p^μ)] - E[g(p^ν)] \\geq 0$")
    ax.set_xlabel("threshold $t$", fontsize=12)

    plt.tight_layout()
    plt.show()

    all_non_negative = all(d >= -1e-10 for d in diffs)
    print(f"μ is a mean-preserving spread of ν: {all_non_negative}")
    return diffs

_ = check_mps_convex_functions(μ_info, ν_info, prior)
```

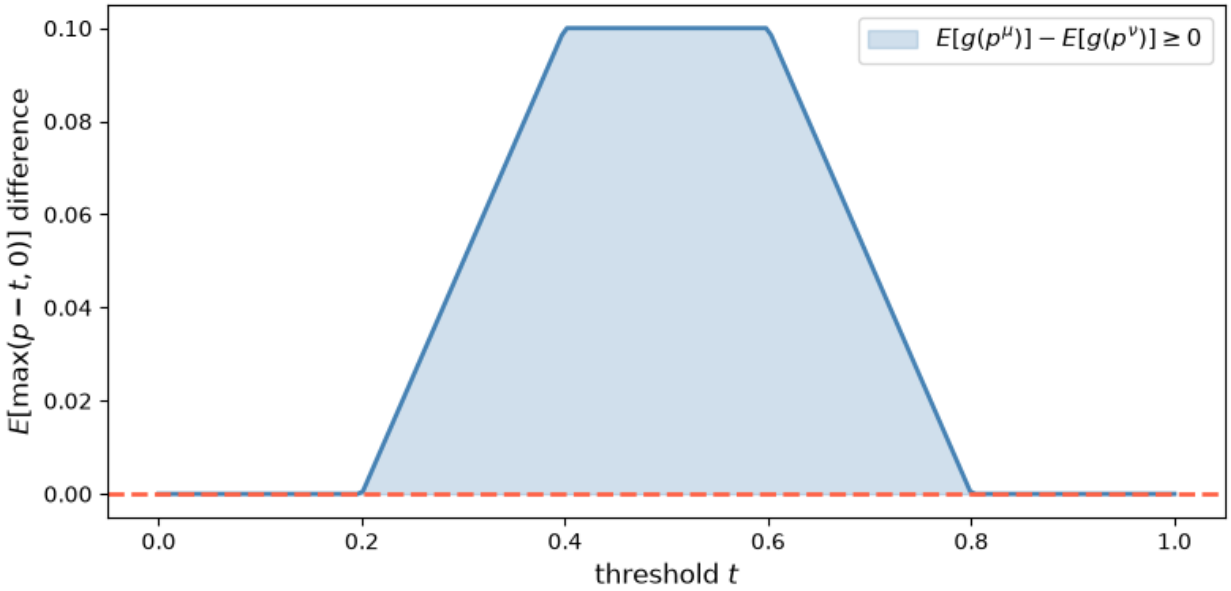

Fig. 30.2: Convex-order check in the two-state case

```
μ is a mean-preserving spread of ν: True
```

The difference $E[g_t(p^\mu)] - E[g_t(p^\nu)]$ is non-negative for every threshold t, confirming that $\hat{\mu}^c$ is a mean-preserving spread of $\hat{\nu}^c$ and therefore $\mu \succeq \nu$ in the Blackwell order.

30.5.3 Convex order and second-order stochastic dominance

A random variable X dominates Y in the **concave order** if $E[u(X)] \geq E[u(Y)]$ for every concave function u.

Taking $u(x) = x$ and $u(x) = -x$ shows that the two means must be equal.

X dominates Y in the concave order if and only if Y is a mean-preserving spread of X.

Second-order stochastic dominance uses only increasing concave u and allows the means to differ; when the means are equal it coincides with the concave order.

Because uncertainty functions are concave, the condition

$$\mathbb{E}[U(p^\mu)] \leq \mathbb{E}[U(p^\nu)] \quad \text{for all concave } U$$

says that the posterior under ν dominates the posterior under μ in the concave order, so that $\hat{\mu}^c$ dominates $\hat{\nu}^c$ in convex order on P.

When $N = 2$, posterior beliefs are scalars in $[0, 1]$, and the comparison reduces to the classical integrated-CDF test.

Given equal means, $\hat{\mu}^c$ is a mean-preserving spread of $\hat{\nu}^c$ if and only if $\int_0^t F_\mu(s)\, ds \geq \int_0^t F_\nu(s)\, ds$ for all $t \in [0, 1]$, where F_μ and F_ν are the CDFs of the posterior on s_1 under each experiment.

Both posterior distributions have mean equal to the prior, so the test applies.

We verify it for the two-state example above.

```

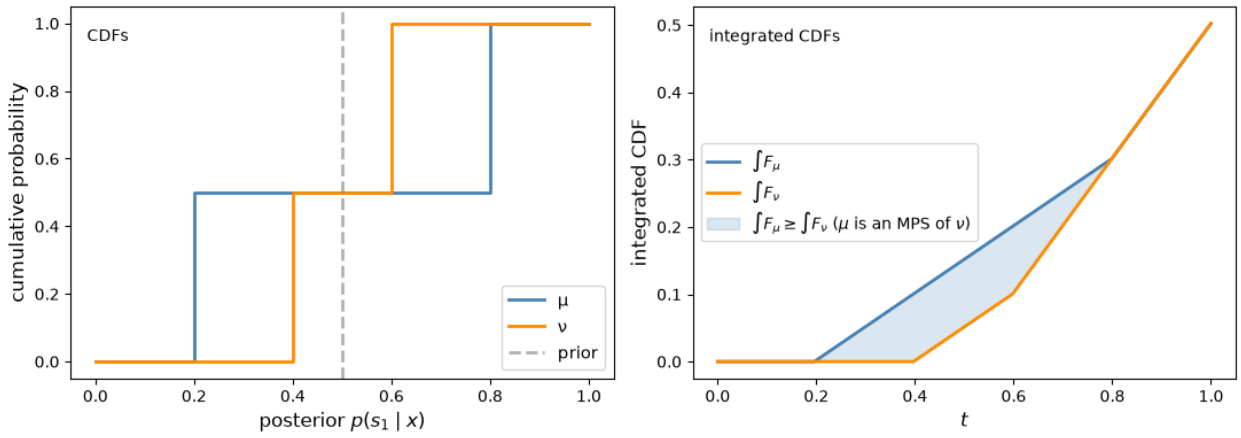

Fig. 30.3: Integrated-CDF check in the two-state case

30.6 Simulating the Blackwell order with many states

We now move to a three-state example.

Experiment μ is strongly correlated with the state, and experiment ν is a garbling of μ.

```
N3 = 3
prior3 = np.array([1/3, 1/3, 1/3])

μ3 = np.array([[0.7, 0.2, 0.1],
               [0.1, 0.7, 0.2],
               [0.2, 0.1, 0.7]])

Q3 = np.array([[0.9, 0.05, 0.05],
               [0.05, 0.8, 0.15],
               [0.05, 0.15, 0.8]])

ν3 = μ3 @ Q3

print("μ (3×3):")
print(np.round(μ3, 2))
print("\nQ (garbling):")
print(np.round(Q3, 2))
print("\nν = μ @ Q:")
print(np.round(ν3, 3))
```

```
μ (3×3):
[[0.7 0.2 0.1]
 [0.1 0.7 0.2]
 [0.2 0.1 0.7]]

Q (garbling):
[[0.9  0.05 0.05]
 [0.05 0.8  0.15]
 [0.05 0.15 0.8 ]]

ν = μ @ Q:
[[0.645 0.21  0.145]
 [0.135 0.595 0.27 ]
 [0.22  0.195 0.585]]
```

For three states, posterior beliefs live in a 2-simplex.

Let's plot the posterior atoms under μ and ν, with marker area proportional to probability

```
def simplex_to_cart(pts):
    """Convert barycentric coordinates on the 2-simplex to 2-D Cartesian coordinates."
 ↪""
    corners = np.array([[0.0, 0.0],
                        [1.0, 0.0],
                        [0.5, np.sqrt(3)/2]])
    return pts @ corners

def plot_simplex_posteriors(μ_matrix, ν_matrix, prior3):

plot_simplex_posteriors(μ3, ν3, prior3)
```

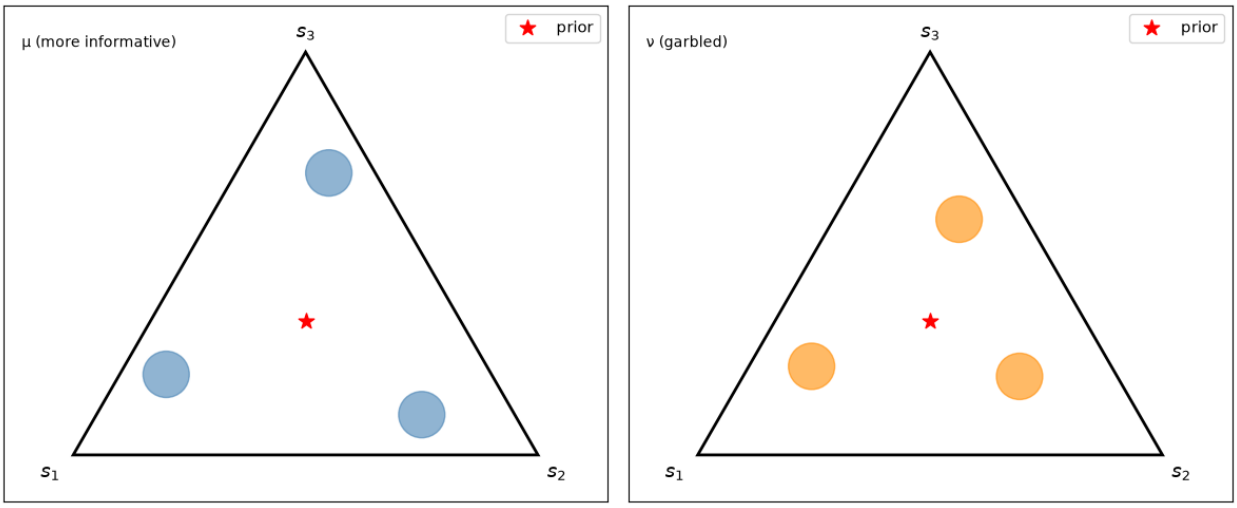

Fig. 30.4: Posterior atoms on the 2-simplex

Under μ, the posterior atoms lie farther toward the vertices.

Under the garbled experiment ν, they lie closer to the prior.

The call-option test does not extend to the simplex.

The garbling Q_3 itself certifies that $\mu_3 \succeq \nu_3$, and the next section checks several concave uncertainty functions in this example.

30.7 The DeGroot uncertainty function

30.7.1 Concave uncertainty functions and the value of information

[DeGroot, 1962] formalizes the value of information through an **uncertainty function** $U : P \to \mathbb{R}$.

DeGroot's definition requires only concavity, so that observing any signal weakly reduces expected uncertainty.

Common examples, such as Shannon entropy, are also symmetric in the components of p and maximized at the uniform prior.

Blackwell's equivalence uses every concave U, symmetric or not; Exercise 30.13.2 shows why asymmetric functions matter.

The *value of experiment μ given prior p* is

$$I(\tilde{x}_\mu;\, \tilde{s};\, U) = U(p) - \mathbb{E}[U(p^\mu)],$$

This quantity is the expected reduction in uncertainty.

Blackwell's order is equivalent to the statement that $I(\tilde{x}_\mu; \tilde{s}; U) \geq I(\tilde{x}_\nu; \tilde{s}; U)$ for *every* concave U.

30.7.2 Shannon entropy as a special case

The canonical uncertainty function is Shannon entropy

$$U_H(p) = -\sum_{i=1}^{N} p_i \log p_i.$$

For any prior p, DeGroot's value formula becomes

$$I(\tilde{x}_\mu, p;\, U_H) = H(\tilde{s}) - H(\tilde{s} \mid \tilde{x}_\mu),$$

where $H(\tilde{s}) = U_H(p)$ is the entropy of the prior and $H(\tilde{s} \mid \tilde{x}_\mu)$ is the conditional entropy of the state given the signal.

Under the uniform prior, $H(\tilde{s}) = \log N$.

To see why, write $H(\tilde{s} \mid \tilde{x}_\mu) = \sum_x \Pr(\tilde{x}_\mu = x)\, H(\tilde{s} \mid \tilde{x}_\mu = x)$, where each conditional entropy term equals $-\sum_i p_i^\mu(x) \log p_i^\mu(x) = U_H(p^\mu(x))$.

Substituting into DeGroot's formula gives $I = U_H(p) - \mathbb{E}[U_H(p^\mu)] = H(\tilde{s}) - H(\tilde{s} \mid \tilde{x}_\mu)$, which is exactly the *mutual information* between $\tilde{x}_\mu$ and $\tilde{s}$.

> **Note**
>
> Blackwell's order implies the entropy inequality.
>
> Because entropy is strictly concave, a strict Blackwell improvement raises mutual information strictly.
>
> The converse fails: a ranking by mutual information does not imply a ranking by Blackwell's order.

Two experiments can be incomparable in Blackwell's order while one has higher mutual information, or while both have the same mutual information, as in Exercise 30.13.2.

The full Blackwell ordering requires the inequality to hold for *every* concave U, not just Shannon entropy.

```

```

As predicted by the theorem, $I(\mu) \geq I(\nu)$ for every concave uncertainty function in both examples, because $\mu \geq \nu$ in the Blackwell sense.

30.7.3 Value of information as a function of experiment quality

We now parameterize a continuum of experiments between the uninformative and perfectly informative cases.

For $N = 2$ states, a natural family is

$$\mu(\theta) = (1-\theta) \cdot \tfrac{1}{2}\mathbf{1}\mathbf{1}^\top + \theta \cdot I_2, \quad \theta \in [0,1],$$

The first term is the completely mixed matrix and I_2 is the identity.

The family is ordered by Blackwell's criterion: for $\theta' < \theta$, $\mu(\theta') = \mu(\theta)\,\mu(\theta'/\theta)$, so a lower-quality experiment is a garbling of a higher-quality one.

```
def make_experiment(θ, N=2):
    """Parameterized experiment: θ=0 is uninformative, θ=1 is perfect."""
    return (1 - θ) * np.ones((N, N)) / N + θ * np.eye(N)

θs = np.linspace(0, 1, 100)
prior2 = np.array([0.5, 0.5])

fig, ax = plt.subplots(figsize=(9, 4))
for name, U in uncertainty_functions.items():
    values = [degroot_value(make_experiment(θ), prior2, U) for θ in θs]

ax.legend(fontsize=10)
plt.tight_layout()
plt.show()
```

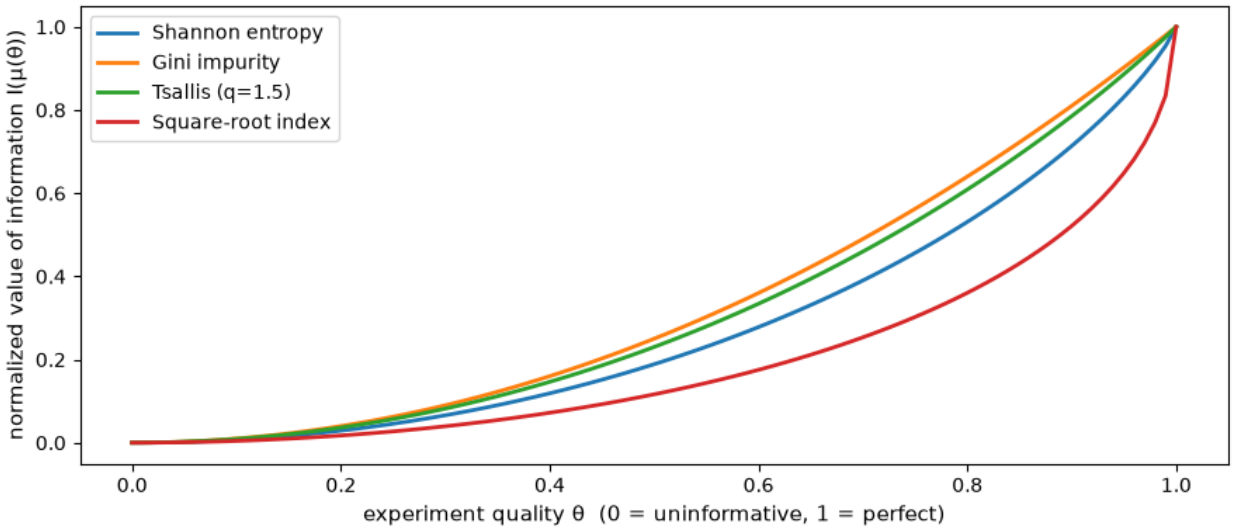

Fig. 30.5: Value of information and experiment quality

Every concave uncertainty function assigns weakly higher value to a more informative experiment.

30.8 Application 1: demand for information about product quality

Kihlstrom [1974] applies Blackwell's theorem to a consumer's demand for information about product quality.

- The unknown state $\tilde{s}$ is the quality of a product.
- A consumer can purchase λ units of information at cost $c\lambda^2$.
- As λ rises, the experiment becomes more informative in Blackwell's sense.

Absent costs, the Blackwell order says that more information is better for every expected-utility maximizer.

With costs, the consumer chooses λ to maximize the net value of information.

We let the accuracy of the experiment rise with diminishing returns, $\phi(\lambda) = 1 - e^{-a\lambda}$, and feed it into the family $\mu(\phi)$ above.

We measure the gross value of information by DeGroot's entropy value, a stand-in for the consumer's expected-utility gain in Kihlstrom [1974].

The Design and Price of Information studies the sale of information to buyers whose values for it differ.

```
def gross_value(λ, prior2, U=entropy, rate=2):
    """Gross value of buying λ units of information."""
    accuracy = 1 - np.exp(-rate * λ)
    return degroot_value(make_experiment(accuracy), prior2, U)

λ_grid = np.linspace(0, 1, 200)
c = 0.6

gross_vals = np.array([gross_value(λ, prior2) for λ in λ_grid])
cost_vals = c * λ_grid**2
net_vals = gross_vals - cost_vals
marginal_vals = np.gradient(gross_vals, λ_grid)
marginal_cost = 2 * c * λ_grid
opt_idx = int(np.argmax(net_vals))

fig, axes = plt.subplots(1, 2, figsize=(12, 4))

ax = axes[0]
ax.plot(λ_grid, gross_vals, label="Gross value I(λ)",
        color="steelblue", linewidth=2)
ax.plot(λ_grid, cost_vals, label=r"Cost $c\lambda^2$",
        color="tomato", linestyle="--", linewidth=2)
ax.plot(λ_grid, net_vals, label="Net value", color="green", linewidth=2)
ax.axvline(λ_grid[opt_idx], color="green", linestyle=":", linewidth=2,
           label=f"λ* ≈ {λ_grid[opt_idx]:.2f}")
ax.set_xlabel("information purchased λ", fontsize=11)
ax.set_ylabel("value (entropy units)", fontsize=11)
ax.legend(fontsize=10)

ax2 = axes[1]
ax2.plot(λ_grid, marginal_vals, label="Marginal value I'(λ)",
         color="steelblue", linewidth=2)
ax2.plot(λ_grid, marginal_cost, label=r"Marginal cost $2c\lambda$",
         color="tomato", linestyle="--", linewidth=2)
ax2.axvline(λ_grid[opt_idx], color="green", linestyle=":", linewidth=2,
            label=f"λ* ≈ {λ_grid[opt_idx]:.2f}")
ax2.set_xlabel("information purchased λ", fontsize=11)
ax2.set_ylabel("marginal value / cost", fontsize=11)
ax2.legend(fontsize=10)

plt.tight_layout()
plt.show()
```

The optimal purchase λ^* occurs where marginal value equals marginal cost.

The marginal value first rises and then falls.

Near $\lambda = 0$ the value of information is convex: it grows only quadratically in the accuracy of the experiment.

Radner and Stiglitz [1984] show that this nonconcavity of the value of information is general, so that demand for information can jump from zero to a positive amount as its price falls.

Because accuracy has diminishing returns, the marginal value eventually falls below the rising marginal cost, which yields an interior optimum here.

Raising c shifts the marginal cost curve up and reduces λ^*, while a more asymmetric prior shifts the marginal value curve and changes the optimum.

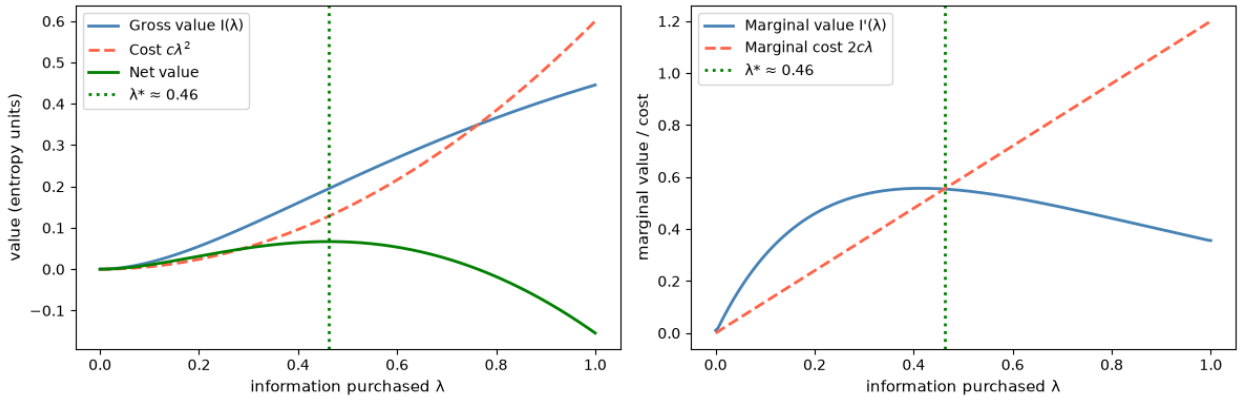

Fig. 30.6: Demand for information with a quadratic cost

30.9 Application 2: sequential experimental design

DeGroot [1962] applies the uncertainty-function framework to *sequential experimental design*.

Each period a statistician observes one draw and updates the posterior.

The question is which sequence of experiments minimizes cumulative expected uncertainty.

If one experiment is more informative than another at every stage, then the Blackwell order favors using the better experiment at every date.

A Problem that Stumped Milton Friedman and *A Bayesian Formulation of Friedman and Wald's Problem* study a complementary question: when to stop sampling from a fixed experiment.

We now simulate sequential belief updating for experiments of different quality.

```
def sequential_update(μ_matrix, prior, T=20, seed=0):
    """Simulate T sequential belief updates under experiment μ."""
    rng = np.random.default_rng(seed)
    N, M = μ_matrix.shape
    beliefs = np.zeros((T + 1, N))
    beliefs[0] = prior.copy()

    true_state = rng.choice(N, p=prior)

    for t in range(T):
        p = beliefs[t]
        signal = rng.choice(M, p=μ_matrix[true_state])
        unnorm = μ_matrix[:, signal] * p
        beliefs[t + 1] = unnorm / unnorm.sum()

    return beliefs, true_state

def plot_sequential_beliefs(θs_compare, prior2, T=25):
    fig, axes = plt.subplots(1, len(θs_compare), figsize=(14, 4), sharey=True)

    for ax, θ in zip(axes, θs_compare):
        μ_t = make_experiment(θ, N=2)
        for seed in range(15):
            beliefs, ts = sequential_update(μ_t, prior2, T=T, seed=seed)
```

(continues on next page)

(continued from previous page)

```
            c = "steelblue" if ts == 0 else "darkorange"
            ax.plot(beliefs[:, 0], alpha=0.35, color=c, linewidth=2)
        ax.axhline(prior2[0], linestyle="--", color="gray", linewidth=2,
                   label="prior")
        ax.axhline(1.0, linestyle=":", color="steelblue", linewidth=2)
        ax.axhline(0.0, linestyle=":", color="darkorange", linewidth=2)
        ax.set_xlabel(r"period $t$", fontsize=11)
        if θ == θs_compare[0]:
            ax.set_ylabel(r"posterior $p(s_1 \mid x^t)$", fontsize=11)
        ax.set_ylim(-0.05, 1.05)
        ax.text(0.03, 0.94, f"θ = {θ}", transform=ax.transAxes, va="top")
        ax.legend(fontsize=9)

    plt.tight_layout()
    plt.show()

plot_sequential_beliefs([0.2, 0.5, 0.9], prior2, T=30)
```

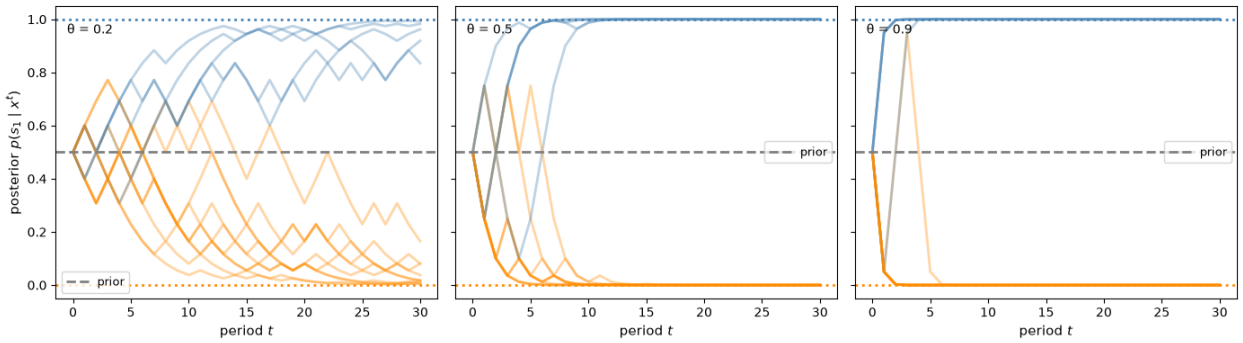

Fig. 30.7: Sequential posterior paths for different experiment qualities

More informative experiments make beliefs converge faster to the truth.

Likelihood Ratio Processes shows that the log likelihood ratio drifts at a rate equal to a Kullback–Leibler divergence between the two rows of the experiment, and that divergence rises with θ.

Under the correct prior, the posterior process is a martingale.

```
def check_martingale_mean(μ_matrix, prior, T=15, n_paths=2000, seed=0):
    """
    Simulate many belief paths and check E[p_t] = p_0.
    """
    rng = np.random.default_rng(seed)
    N, M = μ_matrix.shape
    all_paths = np.zeros((n_paths, T + 1, N))

    for k in range(n_paths):
        true_state = rng.choice(N, p=prior)
        p = prior.copy()
        all_paths[k, 0] = p
        for t in range(T):
            signal = rng.choice(M, p=μ_matrix[true_state])
            unnorm = μ_matrix[:, signal] * p
```

(continues on next page)

(continued from previous page)

```
            p = unnorm / unnorm.sum()
            all_paths[k, t + 1] = p

    mean_path = all_paths[:, :, 0].mean(axis=0)

    fig, ax = plt.subplots(figsize=(8, 4))
    ax.plot(mean_path, color="steelblue", linewidth=2,
            label=r"$\bar p_t(s_1)$ (mean over paths)")
    ax.axhline(prior[0], linestyle="--", color="tomato", linewidth=2,
               label=fr"Prior $p_0 = {prior[0]:.2f}$")
    ax.set_xlabel(r"period $t$", fontsize=12)
    ax.set_ylabel(r"$E[p_t(s_1)]$", fontsize=12)
    ax.legend(fontsize=11)
    ax.set_ylim(0, 1)
    plt.tight_layout()
    plt.show()

    print(f"Prior = {prior[0]:.4f}")
    print(f"Average mean belief across dates: {mean_path.mean():.4f}")

check_martingale_mean(μ_info, prior, T=20, n_paths=5000)
```

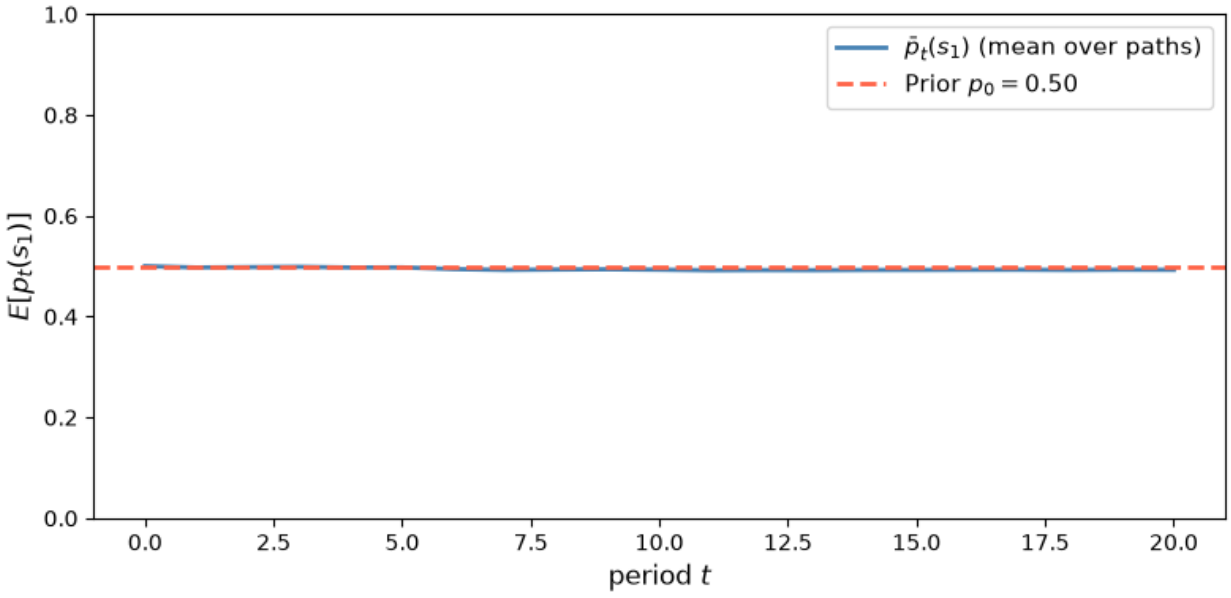

Fig. 30.8: Unconditional implication of the posterior martingale property

```
Prior = 0.5000
Average mean belief across dates: 0.4942
```

The simulated cross-sectional mean stays close to the prior at every date.

This is the unconditional implication of the posterior martingale property.

Merging of Opinions: The Blackwell–Dubins Theorem studies the almost-sure convergence of such belief martingales and the Blackwell–Dubins theorem on the merging of opinions.

30.10 The Data Processing Inequality and Coarse-Graining

Blackwell's condition that $\nu = \mu Q$ for some Markov kernel Q is the same mathematical operation that underlies the **data processing inequality** (DPI) and the **coarse-graining theorem** in information theory, information geometry, and machine learning.

30.10.1 The DPI for f-divergences

An **f-divergence** between two probability distributions P and Q over a finite space Ω is

$$D_f(P\|Q) = \sum_{\omega\in\Omega} q_\omega \, f\left(\frac{p_\omega}{q_\omega}\right),$$

where $f : (0,\infty) \to \mathbb{R}$ is a convex function with $f(1) = 0$.

Special cases include:

Divergence	Generator $f(t)$
KL-divergence	$t \log t$
Squared Hellinger H^2	$(\sqrt{t}-1)^2/2$
Total variation TV	$\lvert t-1\rvert/2$
Chi-squared χ^2	$(t-1)^2$

The class of f-divergences was introduced independently by Ali and Silvey [1966], Csiszár [1963], and Morimoto [1963]; see also Liese [2012].

Statistical Divergence Measures studies several of these divergences for continuous distributions.

Theorem 30.10.1 (Data Processing Inequality)

For any f-divergence D_f and any Markov kernel (stochastic transformation) κ, with $P\kappa$ denoting the image of P under κ, we have

$$D_f(P\|Q) \geq D_f(P\kappa\|Q\kappa).$$

If κ is induced by a sufficient statistic for the pair $\{P, Q\}$, then equality holds.

A converse of this form requires additional hypotheses; a clean binary-model characterization is given below.

The proof follows from Jensen's inequality applied to the convex function f, using the fact that κ is a stochastic matrix [Csiszár, 1963].

30.10.2 Connection to Blackwell's sufficiency condition

In Blackwell's framework, μ and ν are experiments over the same state space $S = \{s_1, \dots, s_N\}$.

For two states, each experiment has two rows: $\mu_1 = \mu(s_1, \cdot)$ and $\mu_2 = \mu(s_2, \cdot)$.

If $\nu = \mu Q$ (i.e., ν is a garbling of μ), then the pair $(\nu_1, \nu_2) = (\mu_1 Q, \mu_2 Q)$ is obtained by applying the Markov kernel Q to the pair (μ_1, μ_2).

The coarse-graining theorem then implies immediately:

$$D_f(\mu_1 \| \mu_2) \geq D_f(\nu_1 \| \nu_2) \quad \text{for every f-divergence } D_f,$$

whenever $\mu \geq \nu$ in the Blackwell order.

For two states the converse also holds, with the usual conventions for zero probabilities: if $D_f(\mu_1 \| \mu_2) \geq D_f(\nu_1 \| \nu_2)$ for every convex f, then $\mu \geq \nu$.

With more than two states, divergences between pairs of rows do not characterize Blackwell's order.

So a more informative experiment always produces *more separated* conditional signal distributions, in the sense of every f-divergence simultaneously.

The DPI is thus a statement about the *distinguishability* of states: garbling an experiment makes the states harder to tell apart under every statistical measure of separability.

For binary experiments, the equality condition links the DPI directly back to Blackwell: $D_f(\mu_1 Q \| \mu_2 Q) = D_f(\mu_1 \| \mu_2)$ for some strictly convex f if and only if Q is a sufficient statistic for (μ_1, μ_2).

Once sufficiency holds, equality follows for every convex f [Liese, 2012].

30.10.3 Information geometry: Chentsov's theorem

The DPI has an infinitesimal, differential-geometric companion.

Chentsov's theorem [Čencov, 1981] states that the **Fisher information metric** is, up to a constant factor, the *unique* Riemannian metric on the probability simplex that is invariant under Markov embeddings, the transformations induced by sufficient statistics.

The Fisher information matrix $I_F(\theta)$ also contracts under every Markov kernel:

$$I_F(\theta;\, \mu) \succeq I_F(\theta;\, \mu\kappa) \quad \text{for every differentiable family } \{\mu_\theta\} \text{ and every Markov kernel } \kappa.$$

Equality holds if and only if κ is a sufficient statistic for θ.

The uniqueness clause says that invariance under sufficient statistics singles out the Fisher metric among all Riemannian metrics.

In *Which Moments to Match?*, the Fisher information of the structural model sets the efficiency bound that score matching attains when the auxiliary model nests the structural model.

See Amari and Nagaoka [2000] for a thorough treatment of information geometry and its connections to sufficiency.

30.10.4 The information bottleneck in machine learning

The **information bottleneck** method of Tishby *et al.* [1999] provides a prominent application of the DPI in machine learning.

Given a joint distribution $p(X, Y)$ over an input X and a target Y, the goal is to find a compressed representation T, formed by a stochastic mapping $p(T \mid X)$, that retains as much information about Y as possible while using as few bits as possible to describe X.

The method minimizes the Lagrangian

$$\mathcal{L}[p(T \mid X)] = I(X;\, T) - \beta\, I(T;\, Y),$$

where $I(\cdot\,;\,\cdot)$ denotes mutual information and $\beta \geq 0$ governs the compression–relevance trade-off.

Because $Y - X - T$ forms a Markov chain (T is derived from X alone), the DPI implies

$$I(T;\, Y) \leq I(X;\, Y),$$

with equality if and only if T is a **sufficient statistic** of X for Y, that is, if $Y - T - X$ is also a Markov chain.

The Blackwell ordering explains why no deterministic or random post-processing of X can increase the mutual information with Y: any Markov kernel applied to X is a garbling in Blackwell's sense, and the DPI is the mutual-information form of the coarse-graining theorem.

In machine learning language the information bottleneck searches among all garblings of X for the one that best preserves relevant information about Y subject to a compression budget.

In a deep neural network with input X and target Y and layers $X \to T_1 \to T_2 \to \cdots \to T_L \to \hat{Y}$, each layer's representation is a garbling of the previous one.

The DPI then implies the chain of inequalities

$$I(X;\, Y) \geq I(T_1;\, Y) \geq I(T_2;\, Y) \geq \cdots \geq I(T_L;\, Y),$$

so successive layers can only lose, never gain, information about Y.

This observation was placed at the center of the study of what deep networks learn by [Shwartz-Ziv and Tishby, 2017].

Fig. 30.5 already illustrates this: as experiment quality θ increases, every measure of informativeness rises monotonically.

The DPI says the same thing in reverse: garbling (decreasing θ) can only contract these measures.

30.10.5 Summary of the DPI–Blackwell correspondence

The table below collects the precise correspondence between Blackwell's framework and the data-processing and coarse-graining literature.

Blackwell / DeGroot	Data processing / coarse-graining
Garbling $\nu = \mu Q$	Applying Markov kernel κ to a pair $(P, Q) = (\mu_1, \mu_2)$
$\mu \geq \nu$ in Blackwell order	$D_f(\mu_1 \mid \mu_2) \geq D_f(\nu_1 \mid \nu_2)$ for every f-divergence
Sufficiency (Q discards nothing)	Equality in DPI; in binary models, one strictly convex f already characterizes sufficiency
DeGroot value $I(\mu; U_H)$	Mutual information $I(\tilde{x}_\mu;\ \tilde{s})$ (Shannon DPI)
Posterior spreads under μ vs ν	D_f between rows larger under μ
Blackwell theorem for two states	D_f dominance for every $f \Leftrightarrow$ a single Markov kernel witnesses dominance
Chentsov's uniqueness theorem	Fisher information is the unique metric invariant under Markov embeddings (sufficient statistics); it also contracts under Markov kernels
Information bottleneck $I(T; Y) \leq I(X; Y)$	DPI for mutual information applied to Markov chain $Y - X - T$

30.11 Relation to Bayesian likelihood-ratio learning

The lecture *Likelihood Ratio Processes and Bayesian Learning* is a dynamic two-state special case of the framework developed here.

Let $S = \{s_1, s_2\}$ with $s_1 \leftrightarrow f$ and $s_2 \leftrightarrow g$, where f and g are the two candidate data-generating densities.

Then a single observation is a Blackwell experiment with rows $f(\cdot)$ and $g(\cdot)$, and the history $w^t = (w_1, \ldots, w_t)$ defines a richer experiment μ_t.

Here we date the first draw $t = 1$ and write the prior as π_0, as in *Likelihood Ratio Processes*; *Likelihood Ratio Processes and Bayesian Learning* dates the first draw $t = 0$ and writes the prior as π_{-1}.

Because one can always discard the last $t - s$ observations, μ_t Blackwell-dominates μ_s for every $t > s$.

The likelihood-ratio process

$$L(w^t) = \prod_{i=1}^{t} \frac{f(w_i)}{g(w_i)}$$

is a sufficient statistic for μ_t, and the posterior

$$\pi_t = \Pr(s_1 \mid w^t) = \frac{\pi_0 L(w^t)}{\pi_0 L(w^t) + 1 - \pi_0}$$

is Kihlstrom's standard experiment in this two-state setting.

Its martingale property, $E[\pi_t] = \pi_0$, is exactly the mean-preservation result proved above for posterior distributions.

Likewise, $\mu_t \geq \mu_s$ implies that the distribution of π_t is a mean-preserving spread of the distribution of π_s, so additional data pushes beliefs farther toward 0 and 1 while lowering expected uncertainty under every concave uncertainty function.

30.11.1 Summary table

The table below records the dictionary between the two lectures without repeating the earlier arguments.

Concept in *Likelihood Ratio Processes and Bayesian Learning*	Concept in this lecture
States $\{f, g\}$	State space $S = \{s_1, s_2\}$
Densities $f(\cdot)$, $g(\cdot)$	Rows of experiment matrix μ
Single draw w_t	Blackwell experiment with continuous signal space
History w^t of t IID draws	Richer experiment μ_t Blackwell-dominating μ_s, $s < t$
Likelihood ratio $L(w^t)$	Sufficient statistic for μ_t
Prior π_0	Prior $p \in P$ on the 1-simplex $[0, 1]$
Posterior π_t	Posterior on $P = [0, 1]$ (Kihlstrom's standard experiment)
Distribution of π_t across histories	$\hat{\mu}^c$ (Kihlstrom's posterior distribution)
Martingale property $E[\pi_t] = \pi_0$	Mean preservation of $\hat{\mu}^c$
$\pi_t \to 0$ or 1 almost surely	Posteriors spread to vertices (MPS in the limit)
Expected fall in the entropy of π_t	DeGroot value $I(\mu_t; U_H)$, the mutual information
More draws $\Rightarrow$ better for all decision makers	Blackwell ordering $\mu_t \geq \mu_s$
Garbling (discard last $t - s$ draws)	Stochastic transformation Q with $\mu_s = \mu_t Q$

30.12 Summary

Blackwell's theorem identifies a *partial order* on statistical experiments with three equivalent characterizations:

Criterion	Condition
Economic	Every decision maker weakly prefers μ to ν: $B(\mu, A, u) \supseteq B(\nu, A, u)$
Sufficiency	ν is a garbling of μ: $\nu = \mu Q$ for some Markov Q
Uncertainty	μ reduces expected uncertainty more for every prior p and every concave U

Kihlstrom's Bayesian exposition places the *posterior distribution* at the center.

A more informative experiment generates a more dispersed posterior distribution with the same mean prior.

The right probabilistic language is convex order on the simplex of posterior beliefs.

In the two-state case this reduces to the familiar SOSD / integrated-CDF test on $[0, 1]$.

DeGroot's contribution is to extend the comparison from particular utility functions to the full class of concave uncertainty functions.

Blackwell's order implies the data processing inequality for every f-divergence, and the likelihood-ratio learning of *Likelihood Ratio Processes and Bayesian Learning* is a dynamic special case of the framework.

Incentives for Information Transfer shows that a decision maker can prefer a less informative experiment when the signal is observed by an agent whose interests differ from hers and who must be induced to report it.

30.13 Exercises

Exercise 30.13.1

The first section found that no stochastic transformation maps $\nu = \mu Q$ back into μ, but it offered only a numerical residual as evidence.

This exercise supplies a proof.

Suppose that $\mu = \nu Q'$ for some Markov matrix Q', so that $\tilde{x}_\mu$ is generated from $\tilde{x}_\nu$ by a randomization that does not depend on $\tilde{s}$.

1. Show that each posterior under μ is a weighted average of posteriors under ν:
$$p^\mu(x) = \sum_y \Pr(\tilde{x}_\nu = y \mid \tilde{x}_\mu = x)\, p^\nu(y).$$
2. Under the uniform prior, compute the posterior probabilities of s_1 that μ and ν from the first section generate.
3. Conclude that μ is not a garbling of ν.

Solution

For part 1, the state and the two signals form a Markov chain $\tilde{s} \to \tilde{x}_\nu \to \tilde{x}_\mu$, because Q' does not depend on the state.

Hence $\Pr(\tilde{s} = s_i \mid \tilde{x}_\nu = y, \tilde{x}_\mu = x) = \Pr(\tilde{s} = s_i \mid \tilde{x}_\nu = y)$, and

$$p^\mu_i(x) = \sum_y \Pr(\tilde{x}_\nu = y \mid \tilde{x}_\mu = x)\, \Pr(\tilde{s} = s_i \mid \tilde{x}_\nu = y) = \sum_y \Pr(\tilde{x}_\nu = y \mid \tilde{x}_\mu = x)\, p^\nu_i(y).$$

Every posterior of a garbled experiment therefore lies in the convex hull of the posteriors of the original experiment.

```
c2 = np.array([0.5, 0.5])
post_μ1, _ = compute_posteriors(μ, c2)
post_ν1, _ = compute_posteriors(ν, c2)

lo, hi = post_ν1[:, 0].min(), post_ν1[:, 0].max()
outside = (post_μ1[:, 0] < lo - 1e-12) | (post_μ1[:, 0] > hi + 1e-12)

print("posteriors on s1 under μ:", post_μ1[:, 0].round(4))
print("posteriors on s1 under ν:", post_ν1[:, 0].round(4))
print(f"interval spanned by ν's posteriors: [{lo:.4f}, {hi:.4f}]")
print("μ's posteriors outside that interval:", post_μ1[outside, 0].round(4))
```

```
posteriors on s1 under μ: [0.8571 0.5    0.1429]
posteriors on s1 under ν: [0.75 0.25]
interval spanned by ν's posteriors: [0.2500, 0.7500]
μ's posteriors outside that interval: [0.8571 0.1429]
```

Under ν the posteriors on s_1 are $3/4$ and $1/4$.

Under μ they are $6/7$, $1/2$ and $1/7$.

The posteriors $6/7$ and $1/7$ lie outside $[1/4, 3/4]$, so no Markov matrix Q' produces μ from ν.

The argument explains the large residual in the first section: a garbling can only pull posteriors toward the prior, and μ places posteriors farther from the prior than ν can reach.

Exercise 30.13.2

Blackwell's order is a partial order, and *The Design and Price of Information* builds on that fact.

Consider two experiments with two states and two signals,

$$\mu_a = \begin{bmatrix} 1 & 0 \\ 0.5 & 0.5 \end{bmatrix}, \qquad \mu_b = \begin{bmatrix} 0.5 & 0.5 \\ 0 & 1 \end{bmatrix},$$

and the uniform prior.

1. Compute the distribution of the posterior probability of s_1 under each experiment, and the mutual information between signal and state.
2. Use the call-option test $\mathbb{E}[\max(p-t,0)]$ to show that neither posterior distribution is a mean-preserving spread of the other.
3. For the concave uncertainty functions $U_t(p) = -\max(p_1 - t, 0)$ with $t = 0.2$ and $t = 0.6$, compute DeGroot's value of each experiment and interpret the result.

Solution

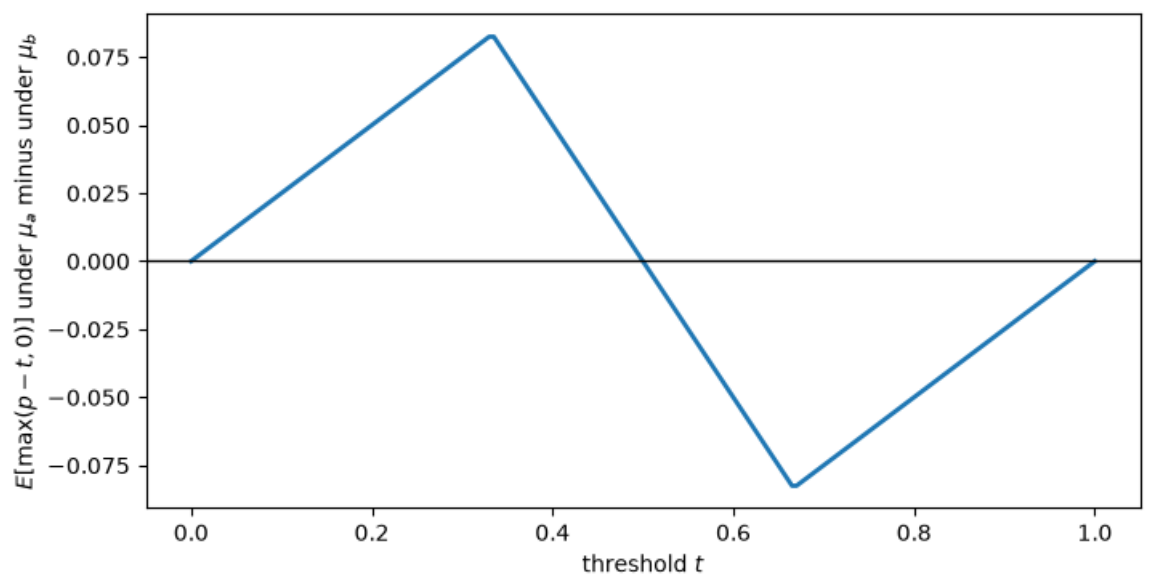
Under μ_a, signal x_2 occurs only in state s_2, so it reveals s_2.

Under μ_b, signal x_1 occurs only in state s_1, so it reveals s_1.

```
μ_a = np.array([[1.0, 0.0],
                [0.5, 0.5]])
μ_b = np.array([[0.5, 0.5],
                [0.0, 1.0]])

for name, m in [("μ_a", μ_a), ("μ_b", μ_b)]:
    posts, probs = compute_posteriors(m, c2)
    print(f"{name}: posteriors on s1 = {posts[:, 0].round(4)}, "
          f"probabilities = {probs.round(4)}, "
          f"mutual information = {degroot_value(m, c2, entropy):.4f}")
```

```
μ_a: posteriors on s1 = [0.6667 0.    ], probabilities = [0.75 0.25], mutual␣
↪information = 0.2158
μ_b: posteriors on s1 = [1.     0.3333], probabilities = [0.25 0.75], mutual␣
↪information = 0.2158
```



The two posterior distributions are mirror images.

Relabeling states and signals maps one experiment into the other, so the two have the same mutual information.

```
def call_values(m, prior, ts):
    "E[max(p_1 - t, 0)] under experiment m for each threshold t."
    posts, probs = compute_posteriors(m, prior)
    return np.array([(np.maximum(posts[:, 0] - t, 0) * probs).sum() for t in ts])

ts = np.linspace(0, 1, 201)
diff_ab = call_values(μ_a, c2, ts) - call_values(μ_b, c2, ts)

fig, ax = plt.subplots(figsize=(8, 4))
ax.plot(ts, diff_ab, linewidth=2)
ax.axhline(0, color="black", linewidth=1)
ax.set_xlabel("threshold $t$")
ax.set_ylabel(r"$E[\max(p - t, 0)]$ under $\mu_a$ minus under $\mu_b$")
plt.show()
```

The difference changes sign.

Neither posterior distribution is a mean-preserving spread of the other, so by Kihlstrom's theorem neither experiment is Blackwell sufficient for the other.

```
def U_call(t):
    "The concave uncertainty function -max(p_1 - t, 0)."
    return lambda p: -max(p[0] - t, 0.0)

for t in (0.2, 0.6):
    print(f"t = {t}:  I(μ_a) = {degroot_value(μ_a, c2, U_call(t)):.4f},  "
          f"I(μ_b) = {degroot_value(μ_b, c2, U_call(t)):.4f}")
```

```
t = 0.2:  I(μ_a) = 0.0500,  I(μ_b) = 0.0000
t = 0.6:  I(μ_a) = 0.0500,  I(μ_b) = 0.1000
```

With $t = 0.2$, μ_a has value 0.05 and μ_b has value zero.

With $t = 0.6$, the ranking reverses.

Up to sign and an affine term, U_t is the value function of a decision maker who chooses between two actions and switches actions at the belief t.

A decision maker who switches at $t = 0.2$ values only signals that push the posterior below 0.2, and μ_b never does so.

A decision maker who switches at $t = 0.6$ values μ_b's signal that reveals s_1 more than μ_a's signal that raises the posterior to $2/3$.

Mutual information ranks the two experiments equally, yet decision makers disagree about them.

A single uncertainty function cannot settle a Blackwell comparison.

Exercise 30.13.3

This exercise connects Blackwell's order to the learning dynamics of *Likelihood Ratio Processes and Bayesian Learning*.

Let a single draw come from the experiment `make_experiment(θ)` with $\theta = 0.3$, so that the signal matches the state with probability $(1+\theta)/2$.

Observe t independent draws.

1. Explain why the number k of draws equal to x_1 is a sufficient statistic, and write the $2 \times (t+1)$ experiment matrix μ_t for k.
2. Construct the Markov matrix Q_t that discards the last of $t+1$ draws, and verify numerically that $\mu_t = \mu_{t+1} Q_t$.
3. Under the uniform prior, use the call-option test to verify that the posterior distribution after $t+1$ draws is a mean-preserving spread of the posterior distribution after t draws, for $t = 1, \ldots, 29$.
4. Plot the mutual information between k and the state against t, and compare it with its upper bound $\log 2$.

Solution

Write $a = (1+\theta)/2$ and $b = (1-\theta)/2$.

The likelihood of t draws containing k copies of x_1 is $a^k b^{t-k}$ in state s_1 and $b^k a^{t-k}$ in state s_2.

The likelihood ratio depends on the data only through k, so k is sufficient.

The rows of μ_t are the binomial distributions $\text{Bin}(t, a)$ and $\text{Bin}(t, b)$.

The draws are exchangeable, as in *Exchangeability and Bayesian Updating*.

Given k' copies of x_1 among $t+1$ draws, the last draw equals x_1 with probability $k'/(t+1)$ in either state.

Discarding it moves k' to $k'-1$ with that probability and leaves k' unchanged otherwise.

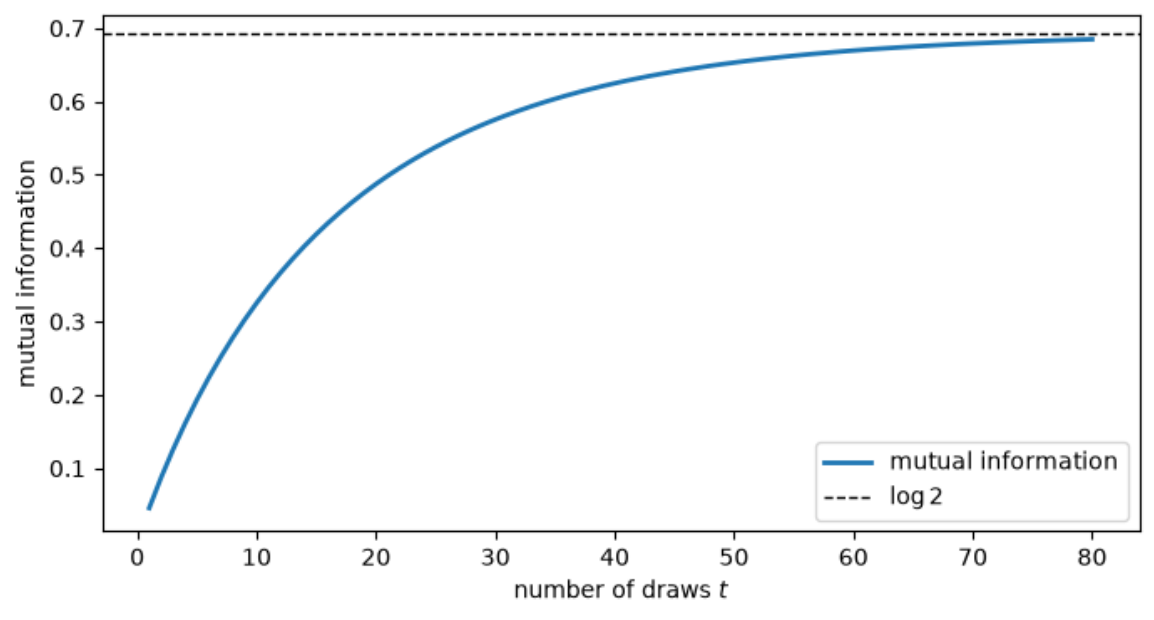
The kernel does not depend on the state, so it is a garbling.

```
from scipy.stats import binom

def draws_experiment(θ, t):
    "Experiment matrix for the number of x_1 signals in t independent draws."
    a, b = (1 + θ) / 2, (1 - θ) / 2
    k = np.arange(t + 1)
    return np.vstack([binom.pmf(k, t, a), binom.pmf(k, t, b)])

def discard_last(t):
    "Markov matrix from k' in {0, ..., t+1} to k in {0, ..., t}."
    Q_t = np.zeros((t + 2, t + 1))
    for kp in range(t + 2):
        if kp >= 1:
            Q_t[kp, kp - 1] = kp / (t + 1)
        if kp <= t:
            Q_t[kp, kp] = 1 - kp / (t + 1)
    return Q_t

θ_ex = 0.3
for t in (1, 4, 9):
    err = np.abs(draws_experiment(θ_ex, t + 1) @ discard_last(t)
                 - draws_experiment(θ_ex, t)).max()
    print(f"t = {t}:  max |μ_(t+1) Q_t - μ_t| = {err:.1e}")



is_mps = all(
    (call_values(draws_experiment(θ_ex, t + 1), c2, ts)
     - call_values(draws_experiment(θ_ex, t), c2, ts)).min() >= -1e-12
    for t in range(1, 30))
print(f"\nposteriors after t + 1 draws are an MPS of those after t draws: {is_mps}
↪")
```

```
t = 1:  max |μ_(t+1) Q_t - μ_t| = 1.1e-16
t = 4:  max |μ_(t+1) Q_t - μ_t| = 9.7e-17
t = 9:  max |μ_(t+1) Q_t - μ_t| = 1.1e-16

posteriors after t + 1 draws are an MPS of those after t draws: True
```

```
t_grid = np.arange(1, 81)
mi = [degroot_value(draws_experiment(θ_ex, t), c2, entropy) for t in t_grid]

fig, ax = plt.subplots(figsize=(8, 4))
ax.plot(t_grid, mi, linewidth=2, label="mutual information")
ax.axhline(np.log(2), color="black", linestyle="--", linewidth=1, label=r"$\log 2$
↪")
ax.set_xlabel("number of draws $t$")
ax.set_ylabel("mutual information")
ax.legend()
plt.show()
```

Each additional draw spreads the posterior distribution while its mean stays at the prior, the martingale property studied in *Likelihood Ratio Processes and Bayesian Learning*.

Mutual information rises toward log 2, the entropy of the uniform prior, as the posterior concentrates on the true state.

31.1 Overview

In many organizations the person who gathers information is not the person who acts on it.

A stockbroker studies a firm and a client decides whether to buy its stock.

A physician examines a patient and the patient chooses a treatment.

A division manager knows local conditions and headquarters allocates capital among divisions.

When the informant and the decision maker want different things, the informant may misreport what he has seen.

Green [1982] studies a decision maker, the **planner**, who must elicit an observation from an **agent** whose preferences over the planner's actions differ from hers.

The planner moves first and commits to an **action plan**, a rule that maps each possible report into a probability distribution over actions.

The agent then observes a signal drawn from a statistical experiment, forms a posterior, and sends whichever report the action plan rewards most.

Green obtains the following results.

1. The planner loses nothing by confining herself to plans under which the agent prefers to report truthfully, so the planner's problem is a single linear program.
2. With two actions, the planner can do no better than either ignoring the agent or letting him have his way; with two actions and two signals, she either attains her first-best outcome or gains nothing from the agent.
3. With more than two actions, the optimal plan can randomize, and it can put positive probability on an action that the planner would never take if she saw the signal herself.
4. Truthful reporting does not mean that all information is used: the optimal plan can pool some signals while distinguishing others.
5. Giving the agent a more informative experiment, in the sense of *Blackwell's Theorem on Comparing Experiments*, can lower the planner's expected utility.
6. That cannot happen when both experiments have only two signals.

Results 5 and 6 connect Green's model to Blackwell's theorem.

A decision maker who sees a signal herself never prefers a less informative experiment.

A planner who must elicit the signal from someone else sometimes does, because a sharper signal can open a conflict of interest that a coarser signal hides.

To compare experiments, Green uses a characterization of Blackwell's order in terms of posterior probabilities that is due to Marschak and Miyasawa [1968].

We will see that their characterization turns the question "is one experiment a garbling of another?" into a transport problem of the kind studied in *Optimal Transport*, with one additional set of constraints.

The paper was published with comments by Postlewaite [1982] and Riley [1982].

The exercises work through their examples and through a comparison of information conditions from Marschak and Miyasawa [1968].

The lecture proceeds as follows.

1. We set up a statistical decision problem in Green's notation.
2. We add an agent, state Green's revelation principle, and solve the planner's linear program.
3. We study economies with two actions, and Green's examples of randomization and of pooled signals.
4. We use the Marschak–Miyasawa characterization to compare experiments, show how better information can hurt the planner, and prove that it cannot when both experiments have two signals.
5. We report what the discussants added, and relate Green's model to other lectures and to later work on communication and delegation.

We begin with some imports.

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.optimize import linprog
from itertools import product

np.set_printoptions(precision=4, suppress=True)
```

31.2 A statistical decision problem

31.2.1 States, signals, and actions

There are M states of nature $\theta_1, \dots, \theta_M$ with prior probabilities $\pi = (\pi_1, \dots, \pi_M)$.

Before acting, someone observes one of N signals $y_1, \dots, y_N$.

The $M \times N$ **likelihood matrix** $\Lambda = [\lambda_{mn}]$, which we also call an **experiment**, has entries

$$\lambda_{mn} = \Pr(y_n \mid \theta_m),$$

so each row of Λ is a probability distribution over signals.

The signal probabilities and the posterior probabilities of the states are

$$q = \Lambda^\top \pi, \qquad p_{mn} = \Pr(\theta_m \mid y_n) = \frac{\lambda_{mn}\pi_m}{q_n}. \tag{31.1}$$

We collect the posteriors in the $M \times N$ matrix $P = [p_{mn}]$, whose nth column p_n is the posterior after signal y_n.

There are K actions $a_1, \dots, a_K$.

A $K \times M$ utility matrix $U = [u_{km}]$ gives the utility u_{km} of action a_k in state θ_m.

The (k, n) entry of the $K \times N$ matrix UP is the expected utility of action a_k after signal y_n.

A decision maker who observes the signal herself takes, in each column of UP, the action with the largest entry.

We call this rule her **first-best plan** and her expected utility

$$v(\Lambda) = \sum_{n=1}^{N} q_n \max_k (UP)_{kn} \tag{31.2}$$

her **first-best value**.

Without a signal she takes the action that maximizes $(U\pi)_k$, and her expected utility is $v_0 = \max_k (U\pi)_k$.

The following functions compute posteriors and the two benchmark values $v(\Lambda)$ and v_0.

```
def posteriors(Λ, π):
    """Signal probabilities q and the M x N matrix P of posteriors."""
    joint = π[:, None] * Λ
    q = joint.sum(axis=0)
    if np.any(q <= 0):
        raise ValueError("every signal must have positive probability")
    return q, joint / q

def bayes_value(U, Λ, π):
    """Expected utility of a decision maker who sees the signal herself."""
    q, P = posteriors(Λ, π)
    return q @ (U @ P).max(axis=0)

def no_info_value(U, π):
    """Expected utility of the best action taken without a signal."""
    return (U @ π).max()
```

31.3 A planner and an agent

31.3.1 Action plans and reports

Now suppose that the signal is observed not by the decision maker but by an agent.

From here on we call the decision maker the planner.

The agent cares about the planner's action and the state, and his utilities are the entries of a $K \times M$ matrix $W = [w_{km}]$.

Green writes U' for the agent's matrix; we use W and keep primes for alternative experiments.

The planner and the agent share the prior π, and both know Λ, U, and W.

Events unfold as follows.

1. The planner announces an action plan, an $N \times K$ Markov matrix $Z = [z_{nk}]$, that is, a nonnegative matrix whose rows sum to one; z_{nk} is the probability that she takes action a_k when the agent reports y_n.
2. The agent observes a signal y_n, and his posterior is p_n.
3. The agent reports some signal y_r, which need not equal y_n.
4. The planner draws an action from row r of Z.

Let

$$V = ZWP.$$

The (r, n) entry of the $N \times N$ matrix V is the agent's expected utility when he has seen y_n and reports y_r.

So the agent's best reports are the largest entries in each column of V.

The planner is committed: once the agent has spoken, she carries out the announced randomization even if, given the report, another action looks better to her.

Green stresses that this includes the draw itself.

After report y_r she must take whatever action the lottery in row r produces; she cannot substitute her favorite among the actions that the row allows and claim that the lottery chose it.

In this sense the planner is a Stackelberg leader, as in Stackelberg plans.

Commitment lets her make threats, such as the dominated action in Green's first example below, that she would not carry out if she could reoptimize after hearing the report.

The value of being able to commit is also the theme of *The Credibility Problem*, which studies the Kydland–Prescott model of monetary policy.

Without commitment the planner would take her best action given her beliefs after each report, and we would be in the cheap-talk world of Crawford and Sobel [1982].

31.3.2 The revelation principle

A plan Z induces a **response rule** ρ: after observing y_n, the agent reports $y_{\rho(n)}$.

Following Green, a response rule is a deterministic map from observations to reports.

Green's first result says that the planner can restrict herself to plans whose response rule is the identity.

Theorem 31.3.1 (Revelation principle (Green's Theorem 1))

The highest expected utility that the planner can attain over all action plans, when the agent responds to each plan with a response rule that is optimal for him, equals the value of the linear program

$$\max_{Z} \sum_{n=1}^{N} q_n \sum_{k=1}^{K} z_{nk} \, (UP)_{kn}$$

subject to $z_{nk} \geq 0$, $\sum_k z_{nk} = 1$ for every n, and the **truth-telling constraints** $V_{nn} \geq V_{rn}$ for all n and r, that is,

$$\sum_{k=1}^{K} z_{nk} \, (WP)_{kn} \;\geq\; \sum_{k=1}^{K} z_{rk} \, (WP)_{kn} \quad \text{for all } n \text{ and } r.$$

The theorem is a version of the revelation principle of mechanism design; Myerson [1979] is the reference that Green cites as closest to his analysis.

Here is the argument.

Suppose that plan Z induces the response rule ρ.

Build a new plan $\hat{Z}$ whose nth row is row $\rho(n)$ of Z.

The rows of $\hat{Z}$ are among the rows of Z, so the agent has no new options.

After observing y_n he chose row $\rho(n)$ of Z before, so he is willing to choose row n of $\hat{Z}$, which is the same lottery.

Under $\hat{Z}$ and truthful reports, the planner's action after each observation has the same distribution as under Z and the original reports, so her expected utility is the same.

Green writes the truth-telling constraints as weak inequalities, so an indifferent agent is assumed to report truthfully.

We write $\hat{v}(\Lambda)$ for the value of the linear program.

A plan that ignores the agent's report satisfies the truth-telling constraints, and no plan can do better than a planner who sees the signal herself, so

$$v_0 \;\leq\; \hat{v}(\Lambda) \;\leq\; v(\Lambda).$$

Riley [1982] remarks that, appropriately interpreted, the revelation principle is essentially definitional: the agent simply picks one lottery from the menu formed by the rows of Z.

That reading makes Green's planner a designer of a menu from which a better-informed subordinate chooses, a theme of the work on delegation discussed at the end of this lecture.

Truth-telling does not mean that all information gets through: if two rows of Z are equal, the planner treats the two corresponding signals identically, as Green's second example will show.

31.3.3 Solving the linear program

We stack the entries of Z row by row into a vector of length NK and pass the problem to SciPy's `linprog`.

The constraints that each row of Z sums to one then take the Kronecker-product form `np.kron(np.eye(N), np.ones(K))`.

Optimal Transport stacks columns instead, so there the same form encodes column sums.

Because `linprog` minimizes, we pass the negative of the planner's objective.

```
def solve_planner(U, W, Λ, π, ties=None):
    """
    Solve the planner's linear program of Green's revelation principle.

```

When the planner has several optimal plans, the agent's expected utility can differ across them.

With `ties=None`, `solve_planner` reports the agent's utility at whichever optimal plan the solver finds.

With `ties="agent_best"` or `ties="agent_worst"`, it solves a second linear program that holds the planner at her optimal value and makes the agent as well off, or as badly off, as possible.

31.4 Economies with two actions

With two actions the planner's problem becomes simple, as Green's next two results show.

Green proves the first one for two states, but the argument below works for any number of states and signals.

Theorem 31.4.1 (Two actions (Green's Theorem 3))

If $K = 2$, the planner has an optimal plan that either ignores the agent's report or takes, after every signal, the action that the agent would choose if he were the decision maker.

In the second case the planner implements the agent's first-best plan, not her own.

With two actions, a row of Z is determined by z_{n1}, the probability of a_1 after report y_n, which in this section we write simply as z_n.

After observing y_n, the agent values a report y_r at

$$(WP)_{2n} + z_r \left[(WP)_{1n} - (WP)_{2n}\right],$$

so whatever signal he has seen, the agent ranks the rows of Z by z_r alone.

He reports the signal with the largest z_r when he prefers a_1 at his posterior, and the one with the smallest z_r when he prefers a_2.

Truth-telling therefore forces z_n to take one common value z_{hi} on the signals after which the agent prefers a_1, and another common value $z_{\text{lo}} \leq z_{\text{hi}}$ on the others, at least when the agent is never exactly indifferent.

If the agent prefers the same action after every signal, all the z_n are equal and the plan ignores the report.

Otherwise the planner's expected utility is linear in $(z_{\text{lo}}, z_{\text{hi}})$ on the triangle $0 \leq z_{\text{lo}} \leq z_{\text{hi}} \leq 1$, so it reaches its maximum at a vertex.

Two vertices, $(0, 0)$ and $(1, 1)$, ignore the report, and the third, $(0, 1)$, gives the agent his preferred action after every signal.

So $\hat{v}(\Lambda) = \max\{v_0, v_A(\Lambda)\}$, where $v_A(\Lambda)$ is the planner's expected utility when she takes the agent's preferred action after every signal; if the agent is sometimes indifferent, his ties should be broken in the planner's favor.

The theorem says that *an* optimal plan takes one of the two forms.

When the planner's objective is constant along an edge of the triangle, the plans in between are optimal too, and they can give the agent different payoffs.

Green states that the solution "must be" one of the two types, but his own third example, studied below, has optimal plans of neither type.

With two signals as well as two actions, the planner gets all or nothing.

Corollary 31.4.1 (Two actions and two signals (Green's Theorem 2))

If $K = N = 2$, then either $\hat{v}(\Lambda) = v(\Lambda)$, so that the planner attains her first best, or $\hat{v}(\Lambda) = v_0$, so that the agent's information is worthless to her.

If the two players' first-best plans coincide, the planner announces hers, the agent reports truthfully, and $\hat{v}(\Lambda) = v(\Lambda)$.

Suppose instead that the plans differ, and, to keep the argument short, that neither player is ever indifferent.

By *Theorem 31.4.1*, $\hat{v}(\Lambda) = \max\{v_0, v_A(\Lambda)\}$, so it suffices to show that $v_A(\Lambda) \leq v_0$.

- If the agent prefers the same action after both signals, his first-best plan takes a single action, which is worth at most v_0 to the planner.
- If the agent's preferred action differs across the signals and the planner's does not, then $v_A(\Lambda) \leq v(\Lambda) = v_0$.
- If both players' preferred actions differ across the signals, then they are reversed, so the agent's first-best plan gives the planner the action she likes less after both signals, and either action taken after both signals does better.

In each case $\hat{v}(\Lambda) = v_0$.

This proves the corollary and sharpens it: with two actions and two signals, unless the players have a first-best plan in common, the agent's information is worthless to the planner.

To check both results numerically, we draw random economies in which the players' first-best plans differ after at least one signal, since otherwise the planner trivially attains her first best.

The two players' utilities are positively correlated, so that they agree often but not always.

```
def random_economy(M, K, N, rng, corr=0.8):
    """Random prior, likelihood matrix, and utilities with correlation corr."""
    π = rng.dirichlet(np.ones(M))
    Λ = rng.dirichlet(np.ones(N), size=M)
    U = rng.normal(size=(K, M))
    W = corr * U + np.sqrt(1 - corr**2) * rng.normal(size=(K, M))
    return U, W, Λ, π

def plans_differ(U, W, Λ, π):
    """True if the players' preferred actions differ after some signal."""
    _, P = posteriors(Λ, π)
    return np.any((U @ P).argmax(axis=0) != (W @ P).argmax(axis=0))

def agent_plan_value(U, W, Λ, π):
    """Planner's expected utility when the agent's preferred action is taken."""
    q, P = posteriors(Λ, π)
    k = (W @ P).argmax(axis=0)
    return q @ (U @ P)[k, np.arange(len(q))]

rng = np.random.default_rng(1234)

gaps, agent_wins = [], 0
while len(gaps) < 500:
```

(continues on next page)

(continued from previous page)

```
    M, N = rng.integers(2, 5), rng.integers(2, 6)
    U, W, Λ, π = random_economy(M, 2, N, rng)
    if not plans_differ(U, W, Λ, π):
        continue
    v_hat = solve_planner(U, W, Λ, π)[1]
    v_0, v_A = no_info_value(U, π), agent_plan_value(U, W, Λ, π)
    gaps.append(abs(v_hat - max(v_0, v_A)))
    agent_wins += v_A > v_0 + 1e-10
print(f"K = 2: largest gap {max(gaps):.1e}; letting the agent have his way "
      f"beats ignoring him in {agent_wins} of {len(gaps)} draws")

gaps = []
while len(gaps) < 500:
    U, W, Λ, π = random_economy(rng.integers(2, 5), 2, 2, rng)
    if not plans_differ(U, W, Λ, π):
        continue
    gaps.append(abs(solve_planner(U, W, Λ, π)[1] - no_info_value(U, π)))
print(f"K = N = 2: largest gap between v_hat and v_0 {max(gaps):.1e}")
```

```
K = 2: largest gap 1.5e-15; letting the agent have his way beats ignoring him in␣
↪48 of 500 draws
K = N = 2: largest gap between v_hat and v_0 8.9e-16
```

In every draw, the value of the linear program equals the value $\max\{v_0, v_A(\Lambda)\}$ that the theorem predicts, up to rounding error.

With two actions and two signals, it always equals v_0, as the sharpened version of *Corollary 31.4.1* says.

With more signals, letting the agent have his way sometimes beats ignoring him, but in most draws it does not.

31.5 Dominated actions as threats

With two actions a lottery is just a probability of a_1, so the agent's ranking of lotteries is fixed by which action he prefers, and the planner can do no better than ignoring him or deferring to him.

With three actions, the agent's ranking of lotteries can change with his posterior even when his ranking of the actions themselves does not, and that lets the planner do better than both.

Green's first example has two states, two signals, and three actions.

The prior is uniform and

$$\Lambda = \begin{bmatrix} 3/4 & 1/4 \\ 1/4 & 3/4 \end{bmatrix}, \qquad U = \begin{bmatrix} -2 & 3 \\ 0 & 0 \\ -1 & -1 \end{bmatrix}, \qquad W = \begin{bmatrix} 0 & -1 \\ 2 & 0 \\ 0 & -4 \end{bmatrix}.$$

The posterior probability of θ_1 is $3/4$ after y_1 and $1/4$ after y_2.

If the planner saw the signal, she would take a_2 after y_1 and a_1 after y_2.

The agent prefers a_2 after either signal, so if the planner announced her first-best plan, an agent who saw y_2 would report y_1.

Action a_3 yields the planner -1 in both states, while a_2 yields 0, so a planner who saw the signal would never take a_3.

Let's solve the planner's linear program.

```
π_ex1 = np.array([1/2, 1/2])
Λ_ex1 = np.array([[3/4, 1/4],
                  [1/4, 3/4]])
U_ex1 = np.array([[-2.0, 3.0],
                  [0.0, 0.0],
                  [-1.0, -1.0]])
W_ex1 = np.array([[0.0, -1.0],
                  [2.0, 0.0],
                  [0.0, -4.0]])

Z_ex1, v_ex1, _ = solve_planner(U_ex1, W_ex1, Λ_ex1, π_ex1)
print("optimal plan Z =\n", Z_ex1)
print(f"planner: {v_ex1:.4f}"
      f"   first best: {bayes_value(U_ex1, Λ_ex1, π_ex1):.4f}"
      f"   no information: {no_info_value(U_ex1, π_ex1):.4f}")
```

```
optimal plan Z =
 [[0.     0.6429 0.3571]
 [1.     0.     0.    ]]
planner: 0.6964   first best: 0.8750   no information: 0.5000
```

The optimal plan takes a_1 after report y_2; after report y_1 it takes a_2 with probability $9/14$ and the dominated action a_3 with probability $5/14$.

The planner's expected utility is $\hat{v}(\Lambda) = 39/56 \approx 0.696$, between the $v_0 = 0.5$ she gets by ignoring the agent and the $v(\Lambda) = 0.875$ she would get if she saw the signal herself.

Green reports 0.696 and the probabilities 0.643 and 0.357.

Why does a dominated action help?

The plan must deter an agent who has seen y_2 from reporting y_1, so it attaches to report y_1 an action that this agent dislikes.

Measure each candidate threat against a_2, the action the planner would like to take after y_1.

At the truthful posterior $3/4$, action a_3 costs the planner 1, while at the posterior $1/4$ of an agent who lies, it costs him $1/2 - (-3) = 7/2$.

Action a_1 would cost the planner only $3/4$, but it would cost the lying agent only $1/2 - (-3/4) = 5/4$.

So a_3 imposes $7/2$ on a liar per unit of cost to the planner, against $5/3$ for a_1.

It is the cheaper threat because it hurts the agent most in state θ_2, which an agent who has seen y_2 thinks likely.

An agent who has seen y_2 gets $-3/4$ from telling the truth, so the threat must lower what he gets from claiming y_1 by $1/2 - (-3/4) = 5/4$.

With a_3 that takes probability $(5/4)/(7/2) = 5/14$, which leaves him exactly indifferent between telling the truth and lying; with a_1 it would take probability one.

Randomization and the dominated action are needed together.

Deterministic plans fail: after either signal the agent ranks the actions in the same order, a_2, then a_1, then a_3, so any plan that takes different actions after the two reports tempts an agent who has seen one of the signals to lie, and the best plan that takes the same action after both reports is worth v_0.

Without a_3 there are only two actions, and the agent prefers a_2 at both posteriors, so by the argument behind *Theorem 31.4.1* truth-telling forces the plan to treat the two reports alike; the best such plan takes a_1 after both reports and is worth only v_0.

```
v_no_threat = solve_planner(U_ex1[:2], W_ex1[:2], Λ_ex1, π_ex1)[1]
print(f"planner's value without a_3: {v_no_threat:.4f}")
```

```
planner's value without a_3: 0.5000
```

The figure below plots each player's expected utility from each action against the posterior probability of θ_1.

The dashed line is the expected utility of the lottery that the plan attaches to report y_1, and the dotted vertical lines mark the two posteriors.

```
p_grid = np.linspace(0, 1, 200)
lottery = Z_ex1[0]

fig, axes = plt.subplots(1, 2, figsize=(10, 4))
for ax, mat, who, loc in zip(axes, (U_ex1, W_ex1), ("planner", "agent"),
                             ("upper right", "lower right")):
    for k in range(3):
        ax.plot(p_grid, mat[k, 0] * p_grid + mat[k, 1] * (1 - p_grid),
                lw=2, label=f"$a_{k+1}$")
    mix = lottery @ mat
    ax.plot(p_grid, mix[0] * p_grid + mix[1] * (1 - p_grid),
            "k--", lw=2, label="plan after report $y_1$")
    for p_n in (1/4, 3/4):
        ax.axvline(p_n, color="0.6", lw=1, ls=":")
    ax.set_xlabel(r"posterior probability of $\theta_1$")
    ax.set_ylabel(f"expected utility of the {who}")
    ax.legend(loc=loc)

plt.tight_layout()
plt.show()
```

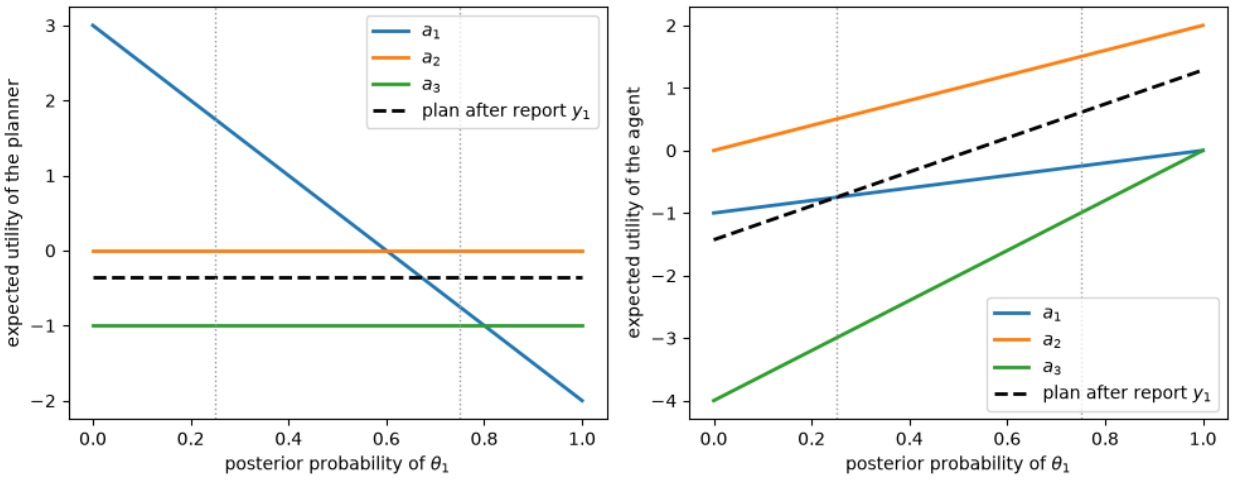

Fig. 31.1: Expected utilities in Green's first example

In the right panel the dashed line meets the agent's line for a_1 exactly at the posterior $1/4$, where the agent who has seen y_2 is indifferent.

At the posterior $3/4$ the dashed line lies far above the line for a_1, so an agent who has seen y_1 strictly prefers to report it.

In the left panel the dashed line lies below the line for a_2.

The gap at the posterior $3/4$, $5/14$, is the planner's loss after report y_1.

Since y_1 has probability $1/2$, her expected cost of eliciting the truth is $5/28 = v(\Lambda) - \hat{v}(\Lambda)$.

31.6 Truthful but coarse reports

Green's second example shows a different way in which incentives can cost the planner information.

There are three signals with equal probabilities, and Green specifies the expected-utility matrices directly:

$$WP = \begin{bmatrix} 1 & 3/2 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \qquad UP = \begin{bmatrix} 5 & -1 & -1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}.$$

We can represent these by three equally likely states, a uniform prior, and a perfectly informative experiment $\Lambda = I$, for which $P = I$.

```
π_ex2 = np.full(3, 1/3)
Λ_ex2 = np.eye(3)
U_ex2 = np.array([[5.0, -1.0, -1.0],
                  [0.0, 0.0, 0.0],
                  [0.0, 0.0, 0.0]])
W_ex2 = np.array([[1.0, 1.5, 0.0],
                  [0.0, 1.0, 0.0],
                  [0.0, 0.0, 1.0]])

Z_ex2, v_ex2, _ = solve_planner(U_ex2, W_ex2, Λ_ex2, π_ex2)
print("optimal plan Z =\n", Z_ex2)
print(f"planner: {v_ex2:.4f}"
      f"   first best: {bayes_value(U_ex2, Λ_ex2, π_ex2):.4f}"
      f"   no information: {no_info_value(U_ex2, π_ex2):.4f}")
```

```
optimal plan Z =
 [[1. 0. 0.]
 [1. 0. 0.]
 [0. 1. 0.]]
planner: 1.3333   first best: 1.6667   no information: 1.0000
```

The planner wants a_1 only after y_1, but an agent who has seen y_2 also likes a_1, which is worth $3/2$ to him, more than either other action.

Suppose that after report y_1 the plan takes a_1 with probability α and fills the rest of the row with a_3, the action that an agent who has seen y_2 likes least, and that after report y_2 it takes a_1 with probability β and a_2 otherwise.

An agent who has seen y_2 gets $1 + \beta/2$ from telling the truth and $3\alpha/2$ from claiming y_1, so truth requires $\beta \geq 3\alpha - 2$.

So the best plan that never takes a_1 after report y_2 takes it with probability $2/3$ after report y_1, which is worth $10/9$ to the planner.

Beyond $\alpha = 2/3$, each unit of probability on a_1 after report y_1 gains the planner 5 but forces three units on a_1 after report y_2, each costing her 1, so she raises α all the way to 1.

The optimal plan therefore gives the same lottery, a_1 for sure, after reports y_1 and y_2, and the linear program confirms that no plan outside this family does better.

The agent reports truthfully, but the planner treats the first two signals identically and earns $4/3$, which lies between the 1 of ignoring the agent and the $5/3$ of the first best.

The third row of Z is not pinned down: after report y_3 the planner is indifferent between a_2 and a_3, and the agent's expected utility depends on which she takes.

```
for ties in ("agent_worst", "agent_best"):
    agent = solve_planner(U_ex2, W_ex2, Λ_ex2, π_ex2, ties=ties)[2]
    print(f"{ties}: agent {agent:.4f}")
```

```
agent_worst: agent 0.8333
agent_best: agent 1.1667
```

Across the planner's optimal plans, the agent's expected utility ranges from $5/6$ to $7/6$.

31.7 Comparing experiments

31.7.1 Blackwell's order through posteriors

To ask whether the planner wants her agent to be better informed, Green needs a way to rank experiments.

Let Λ' be another experiment, with N' signals $y'_1, \dots, y'_{N'}$, and let primes mark everything computed from it, such as q' and P'.

By *Theorem 30.4.1*, $v(\Lambda) \geq v(\Lambda')$ for every utility matrix U and every prior π if and only if $\Lambda' = \Lambda B$ for some $N \times N'$ Markov matrix B.

When that holds, Λ is (weakly) **more informative** than Λ', and Λ' is a **garbling** of Λ.

Note

In *Blackwell's Theorem on Comparing Experiments*, an experiment is written μ rather than Λ, and the garbling matrix is a stochastic transformation Q rather than B; there $B(\mu, A, u)$ denotes a set of achievable expected-utility vectors.

That lecture also uses N to count states and M to count signals, writes the prior as p, and uses U for an uncertainty function rather than a utility matrix.

As Green remarks, Blackwell's condition can be checked by solving linear inequalities in B, which is far easier than comparing decision makers over all utility matrices.

For Green's purposes, though, a version in terms of posteriors is more useful, because the agent's incentives depend on his posterior.

Marschak and Miyasawa [1968] show that, for a fixed prior with full support, Λ is more informative than Λ' if and only if there is a joint distribution $J = [J_{nn'}]$ of the two signals, with marginals q and q', such that

$$\sum_{n=1}^{N} p_{mn}\, J_{nn'} = p'_{mn'}\, q'_{n'} \quad \text{for all } m \text{ and } n'. \tag{31.3}$$

Each posterior of the less informative experiment is then an average of the posteriors of the more informative one, with weights $J_{nn'}/q'_{n'}$, the conditional distribution of y given $y'_{n'}$.

We call (31.3) the **averaging condition**.

This is the property that Kihlstrom's approach in *Blackwell's Theorem on Comparing Experiments* emphasizes: the distribution of posteriors under Λ is a mean-preserving spread of the distribution under Λ'.

Green states the condition in terms of the matrix $C = J\,\mathrm{diag}(q')^{-1}$ of these weights, whose columns are probability vectors:

$$P' = PC \qquad \text{and} \qquad q = Cq'. \tag{31.4}$$

This is Green's equation (12), which he takes from Marschak and Miyasawa.

Given J, the matrix $B = \mathrm{diag}(q)^{-1}J$, the conditional distribution of y' given y, is Blackwell's garbling.

This is Green's equation (13), which is equation (8.23) of Marschak and Miyasawa.

To verify that $\Lambda' = \Lambda B$, use $\lambda_{mn}/q_n = p_{mn}/\pi_m$ from (31.1) and then (31.3):

$$(\Lambda B)_{mn'} = \frac{1}{\pi_m}\sum_n p_{mn}J_{nn'} = \frac{p'_{mn'}\,q'_{n'}}{\pi_m} = \lambda'_{mn'}.$$

31.7.2 A transport problem

Finding J is a linear feasibility problem, which we solve with the tools of linear programming.

Without the averaging condition, J could be any transport plan of *Optimal Transport*, a joint distribution with marginals q and q', and the independent coupling $J = qq'^{\top}$ would always do.

The averaging condition is an extra set of linear constraints, which make the transport plan a **martingale coupling** of the two distributions of posteriors.

There is no cost to minimize, so we pass `linprog` a zero objective.

The column-sum constraints are implied by (31.3), because the posteriors in each column of P sum to one, so we impose only the row sums and (31.3).

```
def garbling(Λ, Λ_prime, π):
    """
    Look for a joint distribution J of the signals of Λ and Λ_prime under
    which every posterior of Λ_prime is the J-weighted average of
    posteriors of Λ.

    Returns Blackwell's Markov matrix B, with Λ_prime = Λ B, or None if
    the solver reports that no such J exists.
    """
    if np.any(π <= 0):
        raise ValueError("the prior must give every state positive probability")
    q, P = posteriors(Λ, π)
    q_prime, P_prime = posteriors(Λ_prime, π)
    N, N_prime = len(q), len(q_prime)

    # Entry n * N_prime + j of the decision vector is J[n, j]
    A_eq = np.vstack([np.kron(np.eye(N), np.ones(N_prime)),   # row sums
                      np.kron(P, np.eye(N_prime))])            # averaging
    b_eq = np.concatenate([q, (P_prime * q_prime).ravel()])
    # As in solve_planner, we switch off presolve, so that a spurious
    # infeasibility report cannot pass for a missing garbling
    res = linprog(np.zeros(N * N_prime), A_eq=A_eq, b_eq=b_eq,
                  bounds=(0, None), method="highs",
                  options={"presolve": False})
    if res.status == 2:                  # infeasible
        return None
    if res.status != 0:
```

(continues on next page)

(continued from previous page)

```
        raise RuntimeError(res.message)
    J = np.maximum(res.x, 0.0).reshape(N, N_prime) + 0.0
    return J / q[:, None]
```

Unlike the least-squares search in *Blackwell's Theorem on Comparing Experiments*, this function either finds a garbling, exact up to the solver's numerical tolerance, or reports that none exists.

31.8 Better information can hurt the planner

31.8.1 Green's third example

When the agent's information improves, two things change.

The planner could make better decisions with the better signals, but the better signals can also change which reports the agent is willing to make truthfully.

Green's third example shows that the second effect can dominate.

There are two states with a uniform prior, two actions, and

$$U = \begin{bmatrix} 2 & 0 \\ 0 & 4 \end{bmatrix}, \qquad W = \begin{bmatrix} 4 & 0 \\ 0 & 2 \end{bmatrix}.$$

The planner prefers a_1 when the posterior probability of θ_1 exceeds $2/3$, and the agent prefers a_1 when it exceeds $1/3$.

The coarse experiment Λ' has two signals, with posteriors $3/4$ and $1/4$ for θ_1, each with probability $1/2$.

The fine experiment Λ has three signals, with posteriors $3/4$, $1/2$, and 0, and probabilities $1/2$, $1/4$, and $1/4$.

The next function builds a two-state likelihood matrix from a list of posteriors for θ_1 and their probabilities.

The probabilities must sum to one, and the weighted average of the posteriors must equal the prior probability of θ_1; otherwise the rows of Λ do not sum to one.

```
def experiment(post, probs, π):
    """Two-state likelihood matrix with the given posteriors of θ_1."""
    post, probs = np.asarray(post), np.asarray(probs)
    if not (np.isclose(probs.sum(), 1) and np.isclose(probs @ post, π[0])):
        raise ValueError("the probabilities must sum to one and the "
                         "posteriors must average to the prior")
    P = np.array([post, 1 - post])
    return P * probs / π[:, None]

π_ex3 = np.array([1/2, 1/2])
U_ex3 = np.array([[2.0, 0.0],
                  [0.0, 4.0]])
W_ex3 = np.array([[4.0, 0.0],
                  [0.0, 2.0]])
Λ_coarse = experiment([3/4, 1/4], [1/2, 1/2], π_ex3)
Λ_fine = experiment([3/4, 1/2, 0], [1/2, 1/4, 1/4], π_ex3)

print("B =\n", garbling(Λ_fine, Λ_coarse, π_ex3))
print("reverse garbling:", garbling(Λ_coarse, Λ_fine, π_ex3))
```

```
B =
 [[1. 0.]
 [0. 1.]
 [0. 1.]]
reverse garbling: None
```

The garbling B merges the second and third signals of the fine experiment, so the fine experiment is more informative, and no garbling runs the other way.

Let's compare the planner's values.

```
for name, Λ in (("coarse", Λ_coarse), ("fine", Λ_fine)):
    v_hat = solve_planner(U_ex3, W_ex3, Λ, π_ex3)[1]
    print(f"{name}: planner {v_hat:.4f}, "
          f"first best {bayes_value(U_ex3, Λ, π_ex3):.4f}")
print(f"no information: {no_info_value(U_ex3, π_ex3):.4f}")
```

```
coarse: planner 2.2500, first best 2.2500
fine: planner 2.0000, first best 2.2500
no information: 2.0000
```

With the coarse experiment the two players agree after both signals, since $3/4$ exceeds both cutoffs and $1/4$ is below both.

So the planner announces her own first-best plan, the agent reports truthfully, and both players earn $9/4$.

The fine experiment splits the signal with posterior $1/4$ into signals with posteriors $1/2$ and 0.

At the posterior $1/2$ the players disagree: the planner wants a_2 and the agent wants a_1.

By *Theorem 31.4.1*, the planner can either ignore the agent or let him have his way.

Each option is worth 2 to the planner, less than $9/4$, so the planner would rather her agent knew less.

In fact every plan in between is optimal too, and the agent's payoff varies along them.

```
for ties in ("agent_worst", "agent_best"):
    Z, v_hat, agent = solve_planner(U_ex3, W_ex3, Λ_fine, π_ex3, ties=ties)
    print(f"{ties}: planner {v_hat:.4f}, agent {agent:.4f}, plan\n{Z}")
```

```
agent_worst: planner 2.0000, agent 1.0000, plan
[[0. 1.]
 [0. 1.]
 [0. 1.]]
agent_best: planner 2.0000, agent 2.5000, plan
[[1. 0.]
 [1. 0.]
 [0. 1.]]
```

Every plan that takes a_2 after the signal with posterior 0 and takes a_1 with a common probability $z \in [0, 1]$ after the other two signals is worth 2 to the planner.

The agent's expected utility along these plans is $1 + 3z/2$, which runs from 1 when the planner ignores him to $5/2$ when she lets him have his way.

The agent also has a reason to acquire the finer information in secret.

Suppose the planner believes that the agent has the coarse experiment and announces her first-best plan for it, while the agent actually observes the fine signal.

After the signal with posterior $1/2$ the agent prefers a_1, so he reports the coarse signal with posterior $3/4$.

His expected utility rises from $9/4$ to $5/2$, and the planner's falls from $9/4$ to 2.

This illustrates a general point: for a fixed plan, the agent is a single decision maker choosing from the menu formed by the rows of Z, so by Blackwell's theorem better information can never hurt him.

When better information does hurt the agent, it is because the planner, knowing what the agent knows, chooses a different plan.

Postlewaite [1982] makes the point about secret acquisition for his own examples and raises what he calls the question of "information about the information": the planner can rely on the coarse experiment only if she knows that the agent has not secretly improved it.

31.8.2 A family of refinements

We can see the trade-off more fully by splitting the coarse signal with posterior $1/4$ into signals with posteriors s and 0, for s between $1/4$ and 1.

The signal with posterior s has probability $1/(8s)$, which keeps the average posterior equal to the prior.

Raising s makes the experiment more informative in Blackwell's sense, as the code below checks along the grid.

The grid starts just above $1/4$, because at $s = 1/4$ the signal with posterior 0 has probability zero and the refinement is the coarse experiment itself.

```
def refined(s):
    """Green's example with the posterior 1/4 split into s and 0."""
    w = 1 / (8 * s)
    return experiment([3/4, s, 0], [1/2, w, 1/2 - w], π_ex3)

s_grid = np.linspace(0.26, 1, 150)
nested = all(garbling(refined(s_hi), refined(s_lo), π_ex3) is not None
             for s_lo, s_hi in zip(s_grid[:-1], s_grid[1:]))
print("each experiment is more informative than the previous one:", nested)

v_hat_grid = np.array([solve_planner(U_ex3, W_ex3, refined(s), π_ex3)[1]
                       for s in s_grid])
v_grid = np.array([bayes_value(U_ex3, refined(s), π_ex3) for s in s_grid])
```

```
each experiment is more informative than the previous one: True
```

The figure plots the planner's value $\hat{v}$ from the linear program and her first-best value v against s.

The dotted vertical lines mark the agent's cutoff $1/3$ and the planner's cutoff $2/3$.

```
fig, ax = plt.subplots()
ax.plot(s_grid, v_grid, lw=5, alpha=0.4, label="planner observes the signal")
# v_hat jumps at s = 1/3, so we draw the two pieces separately
for piece, label in ((s_grid < 1/3, "agent observes the signal"),
                     (s_grid > 1/3, None)):
    ax.plot(s_grid[piece], v_hat_grid[piece], color="C1", lw=2, label=label)
ax.axhline(no_info_value(U_ex3, π_ex3), color="0.6", lw=1, ls="--",
           label="no information")
for cutoff in (1/3, 2/3):
    ax.axvline(cutoff, color="0.6", lw=1, ls=":")
ax.set_xlabel("posterior $s$ of the refined signal")
ax.set_ylabel("planner's expected utility")
ax.legend()
plt.show()
```

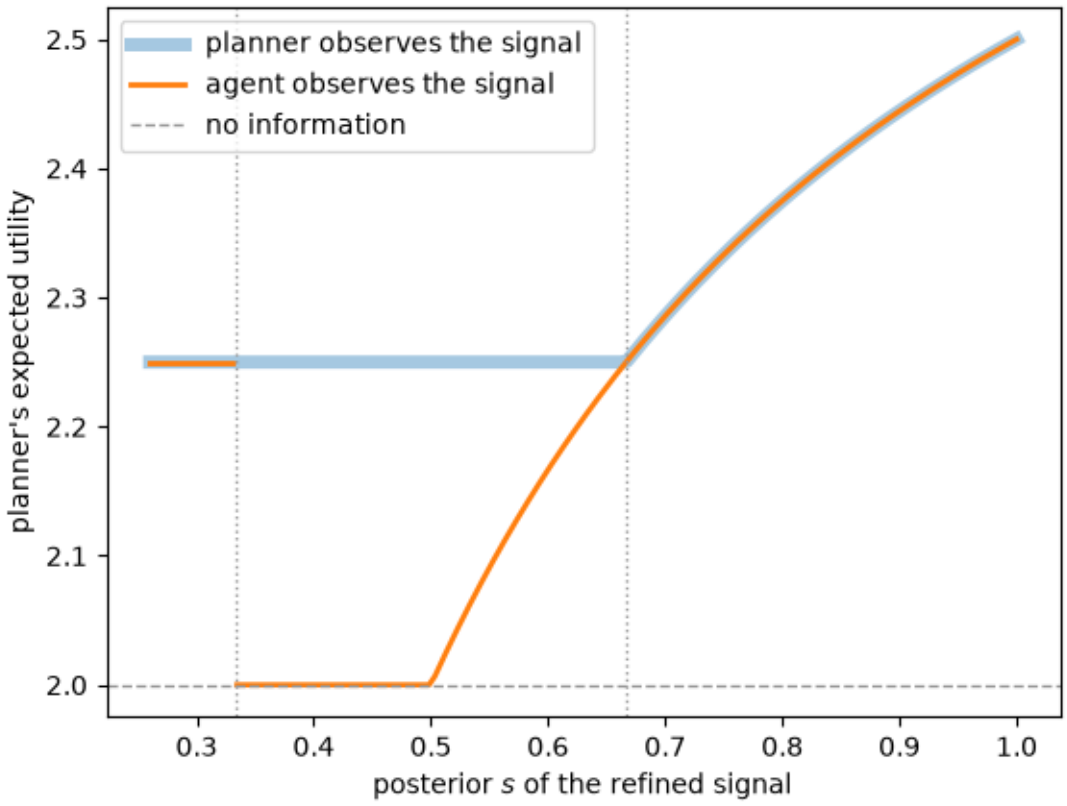

Fig. 31.2: Planner's value as information improves

The first-best value v never falls as s rises, as Blackwell's theorem requires, but the planner's value $\hat{v}$ does.

For $s < 1/3$, both players want a_2 after either refined signal, so the refinement is harmless and useless.

For $1/3 < s < 2/3$, the players disagree after the signal with posterior s.

The planner then either ignores the agent, which is worth 2, or lets him have his way, which is worth $3 - 1/(2s)$.

So $\hat{v}$ jumps down from $9/4$ to 2 at $s = 1/3$, stays at 2 until $s = 1/2$, and climbs back toward $9/4$ as s approaches $2/3$.

Only for $s > 2/3$, where the planner and the agent agree again, does the refinement improve the planner's decisions.

31.8.3 Experiments with two signals

In Green's example the harm comes from a refinement that splits one signal into two.

His last result says that this cannot happen when both experiments are **binomial channels**, Green's term for experiments with two signals.

Theorem 31.8.1 (Binomial channels (Green's Theorem 4))

If Λ is more informative than Λ' and both have two signals, then $\hat{v}(\Lambda) \geq \hat{v}(\Lambda')$, for any number of states and actions.

Here is a proof.

Let p_1 and p_2 be the posteriors of Λ, and p'_1 and p'_2 those of Λ'.

By (31.3), each $p'_{n'}$ is an average of p_1 and p_2, so both lie on the segment joining p_1 and p_2.

If $p'_1 = p'_2$, then Λ' is uninformative, $\hat{v}(\Lambda') = v_0$, and there is nothing to prove.

Otherwise, label the signals of Λ' so that p'_1 is closer to p_1 than p'_2 is.

Let Z be an optimal plan under Λ', and let ℓ_1 and ℓ_2 be its rows, the lotteries after reports y'_1 and y'_2.

Use the same plan under Λ, taking lottery ℓ_n after report y_n.

At a posterior p, the agent's gain from the lottery ℓ_1 over the lottery ℓ_2 is $\phi(p) = (\ell_1 - \ell_2)Wp$, and the planner's is $\psi(p) = (\ell_1 - \ell_2)Up$.

Both are linear in p.

1. Truth-telling under Λ' means $\phi(p'_1) \geq 0 \geq \phi(p'_2)$. The four posteriors lie on the segment in the order p_1, p'_1, p'_2, p_2, so a linear function with these signs at p'_1 and p'_2 keeps them at p_1 and p_2. Hence $\phi(p_1) \geq 0 \geq \phi(p_2)$, and the plan makes truthful reports optimal under Λ.
2. Optimality of Z under Λ' implies $\psi(p'_1) \geq 0 \geq \psi(p'_2)$. For if $\psi(p'_1) < 0$, the planner would do better by using the lottery ℓ_2 after both reports, a plan that ignores the agent and so satisfies the truth-telling constraints; similarly if $\psi(p'_2) > 0$. By the argument of step 1, $\psi(p_1) \geq 0 \geq \psi(p_2)$.
3. Let J be the joint distribution of the two signals in (31.3). Since $q'_{n'}p'_{n'} = \sum_n J_{nn'}\, p_n$ and $q_n = \sum_{n'} J_{nn'}$, the planner's expected utility from the plan under Λ minus that under Λ' is

$$\sum_n q_n \ell_n U p_n - \sum_{n'} q'_{n'} \ell_{n'} U p'_{n'} = \sum_{n,n'} J_{nn'} (\ell_n - \ell_{n'}) U p_n = J_{12}\, \psi(p_1) - J_{21}\, \psi(p_2) \;\geq\; 0.$$

The planner can do at least as well as this plan under Λ, so $\hat{v}(\Lambda) \geq \hat{v}(\Lambda')$.

Note

Green's proof follows the same route, but it has two gaps.

First, it labels the signals so that each row of the garbling B has its largest entry on the diagonal.

That is not always possible: for $B = \begin{bmatrix} 0.9 & 0.1 \\ 0.6 & 0.4 \end{bmatrix}$, both rows have their largest entry in the same column, whatever the labels.

The labeling that the argument needs is the one used above, which is equivalent to $b_{11} \geq b_{21}$, that is, $\det B \geq 0$.

Second, Green's last step applies to the planner's payoffs a sign property that his preceding lemma proves only for the agent's; step 2 above supplies it from the optimality of Z.

To check the theorem numerically, we draw random binomial channels with up to four states and three or four actions.

We keep only draws in which the theorem does some work.

If $\hat{v}(\Lambda') = v_0$ or $\hat{v}(\Lambda) = v(\Lambda)$, the conclusion follows from $v_0 \leq \hat{v} \leq v$ and Blackwell's theorem alone, so we skip those draws.

With two actions, *Corollary 31.4.1* says that $\hat{v}$ is either v_0 or v, so, if the theorem holds, every draw would be skipped; that is why we use three or four actions.

```
rng = np.random.default_rng(4321)

gains, tries = [], 0
while len(gains) < 100:
    tries += 1
    M, K = rng.integers(2, 5), rng.integers(3, 5)
    U, W, Λ, π = random_economy(M, K, 2, rng)
    if not plans_differ(U, W, Λ, π):          # then v_hat(Λ) = v(Λ)
        continue
    Λ_prime = Λ @ rng.dirichlet(np.ones(2), size=2)
    v_hat_prime = solve_planner(U, W, Λ_prime, π)[1]
    if v_hat_prime < no_info_value(U, π) + 1e-8:
        continue
    v_hat = solve_planner(U, W, Λ, π)[1]
    if v_hat > bayes_value(U, Λ, π) - 1e-8:
        continue
    gains.append(v_hat - v_hat_prime)
print(f"{len(gains)} informative draws out of {tries}")
print(f"smallest gain from better information: {min(gains):.4f}")
```

```
100 informative draws out of 10076
smallest gain from better information: 0.0080
```

The planner gains from better information in every one of these draws.

When the finer experiment has three or more signals the theorem does not apply, but a loss still requires the players to disagree at some posterior of the finer experiment, as they do at s when $1/3 < s < 2/3$; otherwise the planner attains $\hat{v}(\Lambda) = v(\Lambda) \geq v(\Lambda') \geq \hat{v}(\Lambda')$.

31.9 What the discussants added

Postlewaite [1982] builds four-state examples, his Cases I to IV, in which a more informative experiment helps both players, hurts both, helps the agent and hurts the planner, or helps the planner and hurts the agent.

Exercise 31.12.2 checks them with the linear program.

In our random draws, Cases I and IV always come out as he says.

In Case II, with h close to j as Postlewaite assumes, the agent loses in every draw, but the planner loses in only about half of them.

In Case III the agent loses rather than gains in every draw, while the planner gains in some draws and loses in others.

Postlewaite asks why the agent cannot simply ignore better information, and answers that the planner, knowing that the agent is informed, can design her plan so that an agent who ignored the information would be even worse off.

As we saw after Green's third example, under a fixed plan better information cannot hurt the agent, so "even worse off" always holds weakly.

In his examples it holds only weakly: Exercise 31.12.2 studies a family of plans that contains the planner's optimal plan in both the Case II and the Case III example, and shows that, under her preferred plan in that family, an agent who ignored the finer information would get exactly what he gets by using it.

The agent loses only because the planner, knowing that he is better informed, chooses a different plan; that is why Postlewaite adds that the agent would like to commit to the less informative experiment, if he could convince the planner that he had done so.

Postlewaite also asks who chooses the experiment, and what happens if the agent rather than the planner commits first.

He asserts that it is easy to construct examples in which both players are better off with the roles reversed; Exercise 31.12.3 confirms this when the agent commits to a deterministic response rule, as Green defines it.

Riley [1982] explains Green's examples with diagrams of expected utility against the posterior, like Fig. 31.1, and gives a two-state example in which unscrambling a garbled message makes both players worse off.

He concludes that "we cannot expect to obtain more than a multitude of special cases unless the model is refined in some way," and suggests two refinements.

One is to pay the agent "a fee contingent upon the eventual state of nature."

The other is to account for "the repetitive nature of informational exchanges," because long-term relationships, such as those between brokers and clients or physicians and patients, let each party learn the other's interests.

Repetition can also let reputation stand in for commitment, though *Credible Government Policies* shows that reputation can support many outcomes, not only the one that commitment would deliver.

Exercise 31.12.1 shows that, when utilities are linear in money, a fee contingent on the state alone cannot change the agent's reports, while pay contingent on both the report and the state reduces, but in Riley's example does not remove, the harm from better information.

31.10 Relation to other lectures

The Design and Price of Information studies a seller who designs and prices Blackwell experiments and screens buyers, whose prior beliefs are private, with a menu of experiments.

Green's planner also screens with a menu, but the menu offers lotteries over the planner's own actions and the private information is the agent's signal.

In *Information and Market Equilibrium*, an outside observer can infer an insider's private information from the equilibrium price, so information travels through a market rather than through a report.

In *Expected Utilities of Random Responses*, the designer of a randomized response survey deliberately makes each answer less informative, so that respondents are willing to answer truthfully.

The designer accepts a garbled but truthful answer over a sharper but untruthful one, much as the planner in Green's third example prefers an agent with the coarser experiment.

Green's planner cannot pay the agent, so she buys truthful reports with distortions in her own actions.

When transfers are available, as in the Groves–Clarke mechanism of *Multiple Good Allocation Mechanisms* and Groves [1973], payments can do that job instead; Exercise 31.12.1 adds them to Green's model.

31.10.1 Later work on communication and delegation

Green's model belongs to a family of models of strategic communication that differ in who commits to what.

In the language of this literature, the agent is the **sender** and the planner the **receiver**.

- In Green's model the receiver commits to a plan for acting on reports.
- In the cheap-talk model of Crawford and Sobel [1982], no one commits, and the receiver acts optimally on whatever she hears.
- In the persuasion model of Kamenica and Gentzkow [2011], the sender commits to the experiment that generates the signal.
- In Postlewaite's reversal, studied in Exercise 31.12.3, the sender commits to a deterministic rule for reporting what he has observed, which is persuasion restricted to partitions of the signals of Λ; if the rule may randomize, it is persuasion restricted to garblings of Λ.

Riley's reading of Green's plan as a menu connects it to the delegation problem of Holmström [1984], in which a principal chooses a set of actions and lets the agent pick one; Green's menu contains lotteries over actions instead.

Melumad and Shibano [1991] study communication with and without commitment when transfers are ruled out, and Alonso and Matouschek [2008] characterize the optimal set of actions to delegate.

Kováč and Mylovanov [2009] allow randomized plans like Green's and show that, with quadratic payoffs and a regularity condition, the optimal plan does not randomize.

Green's finding that the planner can prefer a less informed agent also has descendants.

Fischer and Stocken [2001] show that in cheap talk a less precisely informed sender can leave the receiver better informed, and Ivanov [2010] studies a principal who limits the precision of her agent's information before he communicates.

31.11 Concluding remarks

Green's model separates the person who sees a signal from the person who acts on it.

Commitment lets the planner turn the agent's incentive problem into a linear program, whose solutions can randomize, use dominated actions as threats, and pool signals.

Because incentive constraints depend on posteriors, the comparison of experiments runs through posteriors as well, and the Marschak–Miyasawa characterization turns Blackwell's order into a transport problem.

The central lesson concerns the value of information.

Blackwell's theorem ranks experiments for a decision maker who sees the signal herself, but once the signal must be elicited, a better-informed agent can be worth less to the planner, except when both experiments have only two signals.

31.12 Exercises

Exercise 31.12.1

Riley [1982] illustrates how better information can hurt both players with a diagram of a two-state, two-action example, in which he calls signals "messages."

Here are numbers that reproduce the pattern in his figure C3.4.

Riley's text names the two actions the other way around from his figure; our labels follow the figure.

The prior is uniform, and with p the posterior probability of θ_1, the planner's expected utilities are p from a_1 and 0.7 from a_2, while the agent's are p from a_1 and $(1-p)/2$ from a_2.

In the coarse experiment the agent's posterior is 0.8 or 0.2, each with probability $1/2$.

In the fine experiment the signal with posterior 0.2 is unscrambled into signals with posteriors 0.4 and 0, each with probability $1/4$.

1. Use `garbling` to confirm that the fine experiment is more informative than the coarse one. Then solve the planner's linear program under both experiments, compare both players' expected utilities, and use *Theorem 31.4.1* to explain the result.
2. Riley suggests paying the agent "a fee contingent upon the eventual state of nature." Assume that both players' utilities are linear in money, so that a payment adds to the agent's utility and subtracts from the planner's. Show that payments that depend only on the state cannot change the agent's reports.
3. Now let the planner pay the agent $t(r, \theta) \geq 0$ when he reports y_r and the state turns out to be θ. Extend the linear program to choose the plan and the payments together, and solve it for the fine experiment. Do the same when payments can depend only on the report. Does pay remove the harm from better information?

Solution

Here is one solution.

For part 1, we build the two experiments, check the garbling, and solve the linear program under each.

```
π_ri = np.array([1/2, 1/2])
U_ri = np.array([[1.0, 0.0],
                 [0.7, 0.7]])
W_ri = np.array([[1.0, 0.0],
```

```
                  [0.0, 0.5]])
Λ_ri_coarse = experiment([0.8, 0.2], [1/2, 1/2], π_ri)
Λ_ri_fine = experiment([0.8, 0.4, 0.0], [1/2, 1/4, 1/4], π_ri)

print("B =\n", garbling(Λ_ri_fine, Λ_ri_coarse, π_ri))
print("reverse garbling:", garbling(Λ_ri_coarse, Λ_ri_fine, π_ri))

for name, Λ in (("coarse", Λ_ri_coarse), ("fine", Λ_ri_fine)):
    Z, v_hat, agent = solve_planner(U_ri, W_ri, Λ, π_ri)
    print(f"{name}: planner {v_hat:.4f}, agent {agent:.4f}, plan\n{Z}")

print(f"fine, agent's first-best plan: "
      f"planner {agent_plan_value(U_ri, W_ri, Λ_ri_fine, π_ri):.4f}, "
      f"agent {bayes_value(W_ri, Λ_ri_fine, π_ri):.4f}")
```

```
B =
 [[1. 0.]
 [0. 1.]
 [0. 1.]]
reverse garbling: None
coarse: planner 0.7500, agent 0.6000, plan
[[1. 0.]
 [0. 1.]]
fine: planner 0.7000, agent 0.2500, plan
[[0. 1.]
 [0. 1.]
 [0. 1.]]
fine, agent's first-best plan: planner 0.6750, agent 0.6250
```

Under the coarse experiment the players agree after both signals: both want a_1 at 0.8 and a_2 at 0.2.

So the planner gets 0.75 and the agent 0.6.

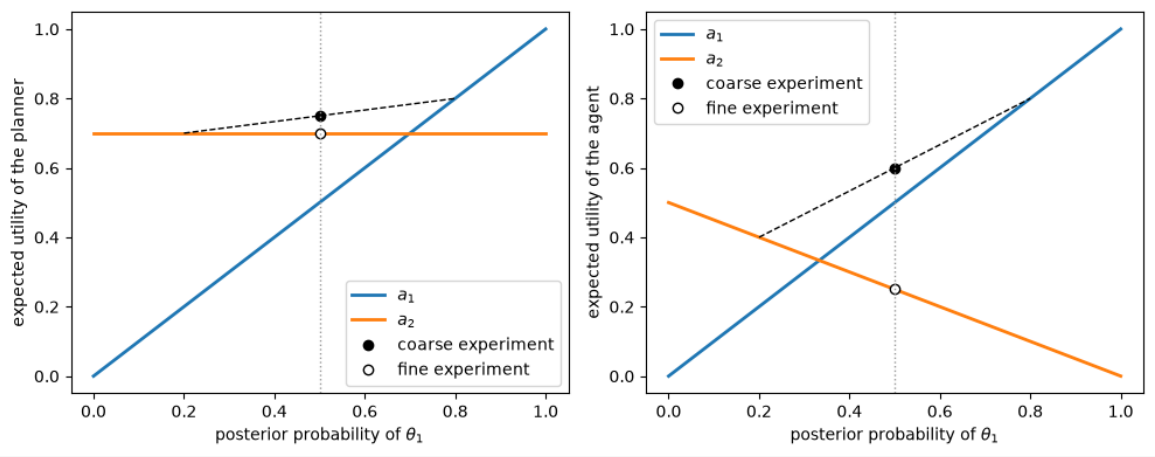
Under the fine experiment they disagree at the posterior 0.4, where the planner wants a_2 and the agent wants a_1.

By *Theorem 31.4.1*, the planner either lets the agent have his way, which is worth 0.675 to her and 0.625 to him, or ignores him, which is worth 0.7 to her.

She ignores him and always takes a_2, which leaves the agent only 0.25.

Unscrambling the signal makes both players worse off, as in Riley's figure.

The figure below has the same structure as Riley's.



In each panel the solid lines are a player's expected utilities from the two actions, and the dotted vertical line marks the prior $1/2$.

Under the coarse experiment the planner takes a_2 at 0.2 and a_1 at 0.8, so each player's expected utility is the height at the prior of the dashed chord joining that player's utilities at those two posteriors (filled dot).

Under the fine experiment the planner always takes a_2, so each player's expected utility is the height of that player's line for a_2 at the prior (open dot).

```
fig, axes = plt.subplots(1, 2, figsize=(10, 4))
for ax, mat, who in zip(axes, (U_ri, W_ri), ("planner", "agent")):
    for k in range(2):
        ax.plot(p_grid, mat[k, 0] * p_grid + mat[k, 1] * (1 - p_grid),
                lw=2, label=f"$a_{k+1}$")
    # coarse experiment: a_2 at the posterior 0.2 and a_1 at the posterior 0.8
    ends = [mat[1] @ [0.2, 0.8], mat[0] @ [0.8, 0.2]]
    ax.plot([0.2, 0.8], ends, "k--", lw=1)
    ax.plot(0.5, np.mean(ends), "ko", label="coarse experiment")
```

```
    # fine experiment: a_2 after every signal
    ax.plot(0.5, mat[1] @ [0.5, 0.5], "o", mfc="white", mec="k",
            label="fine experiment")
    ax.axvline(0.5, color="0.6", lw=1, ls=":")
    ax.set_xlabel(r"posterior probability of $\theta_1$")
    ax.set_ylabel(f"expected utility of the {who}")
    ax.legend()
plt.tight_layout()
plt.show()
```

In both panels the open dot lies below the filled dot: 0.70 against 0.75 for the planner and 0.25 against 0.6 for the agent.

For part 2, a payment $t(\theta_m)$ in state θ_m adds $t(\theta_m)$ to every entry in column m of W.

After observing y_n, the agent then gets an extra $\sum_m p_{mn} t(\theta_m)$ from every report, so the payment does not change which report is best.

More fundamentally, it does not change the agent's ranking of actions in any state, so it cannot reduce the conflict between him and the planner.

To change the agent's incentives, pay has to depend on something that he controls, such as his report.

For part 3, we add the payments to the decision vector.

Pay that depends on the report r and the state adds $\sum_m p_{mn} t(r, \theta_m)$ to the agent's expected utility from report y_r after signal y_n; pay that depends only on the report adds $t(r)$.

So the truth-telling constraints and the planner's expected payment are still linear.

Some payments, such as one after the report with posterior 0 in state θ_1, are never made when the agent tells the truth, so they cost the planner nothing and are not pinned down; a tiny cost on every payment breaks the tie in favor of zero.

```
def solve_with_pay(U, W, Λ, π, on_state):
    """
    Green's linear program when the planner can also pay the agent.

    If on_state is True the planner pays t[r, m] >= 0 when the agent
    reports y_r and the state is θ_m; otherwise she pays t[r] >= 0 after
    report y_r. Returns the plan, the payments, and the planner's
    expected utility net of expected payments.
    """

```

With pay on the report and the state, the planner announces her first-best plan and pays 0.25 when the agent reports the posterior 0.4 and the state turns out to be θ_1.

An agent who has seen 0.4 expects $0.4 \times 0.25 = 0.1$ from that payment, exactly his gain $0.4 - 0.3$ from claiming to have seen 0.8.

The payment is cheap because it is aimed at him: an agent who has seen 0 expects nothing from it, and one who has seen 0.8 is not tempted.

The expected payment is $(1/4)(0.4)(0.25) = 0.025$, so the planner gets 0.725.

With pay on the report alone, the planner pays $1/12$ after report 0.4 and also takes a_1 there with probability $1/6$, for a net value of $43/60 \approx 0.717$.

Either way, pay shrinks the harm from better information but does not remove it: both values lie between the 0.70 the planner gets without pay and the 0.75 she gets under the coarse experiment, where no pay is needed.

Two features of these payments matter.

Pay that depends on the state requires that the state be observed afterward, as a stock's return is.

And the payments must be nonnegative: Green's model has no participation constraint, so without that restriction the planner could charge the agent an arbitrarily large fee, and the linear program would be unbounded.

Exercise 31.12.2

Postlewaite [1982] studies four equally likely states $\theta_1, \ldots, \theta_4$ and four actions.

With positive parameters b, c, d, e for the planner and f, g, h, j for the agent, the payoff matrices (rows are actions, columns are states) are

$$U = 2\begin{bmatrix} b & 0 & c & 0 \\ 0 & c & 0 & b \\ d & 0 & e & 0 \\ 0 & e & 0 & d \end{bmatrix}, \qquad W = 2\begin{bmatrix} 0 & f & 0 & g \\ g & 0 & f & 0 \\ h & 0 & j & 0 \\ 0 & j & 0 & h \end{bmatrix}.$$

In the fine experiment the agent observes the state.

In the coarse experiment he learns only whether the state is in $\{\theta_1, \theta_2\}$ or in $\{\theta_3, \theta_4\}$.

1. Postlewaite's Case II assumes $b > d + e > (b + c)/2 > c$ and $f > h + j > (f + g)/2 > g$, and he concludes that "if the assumed inequalities hold and also if h is sufficiently close to j," the fine experiment leaves both players worse off. Take $(b, c, d, e) = (10, 4, 5, 3)$ and $(f, g, h, j) = (10, 4.5, 3.9, 4)$. Use `garbling` to confirm that the fine experiment is more informative than the coarse one. Solve the planner's linear program under both experiments, and compare both players' expected utilities. How much probability does the optimal plan under the fine experiment put on actions a_3 and a_4, which are dominated for the planner when $b > d$ and $c > e$?

2. Consider plans under the fine experiment that take a_1 with probability x and a_3 otherwise after reports θ_1 and θ_3, and a_2 with probability x and a_4 otherwise after reports θ_2 and θ_4. Show that truthful reporting is optimal if and only if $x \leq x^* = \min\{h/(h + g),\ j/(j + f)\}$, and find both players' expected utilities as functions of x. Postlewaite writes that the probability that can be placed on a_1 and a_2 "becomes arbitrarily small as h gets arbitrarily close to j." Is that right?

3. Postlewaite's Case III assumes $b > c > d > e$, $b > d + e$, $f > g > j > h$, and $f < j + h$, and he concludes that, when h is very close to j, under the fine experiment "the agent is better off and the principal worse off." Solve the linear program for $(b, c, d, e) = (10, 6, 4, 3)$ and $(f, g, h, j) = (10, 8, 5.9, 6)$. Then show that, under the Case III inequalities, the plan in the family of part 2 that the planner prefers gives the agent less than he gets under the coarse experiment.

4. Postlewaite's Case I assumes $e > d > b > c$ and $j > h > f > g$, and he concludes that better information helps both players. His Case IV assumes $b > c > d > e$, $b < d + e$, $f > g > j > h$, and $f > j + h$, and he concludes that, when h is close to j, it helps the planner and hurts the agent. For each of the four cases, draw many parameter vectors uniformly from $[0, 10]^8$ subject to the case's inequalities, with h within 0.1 of j

in Cases II to IV, and record how often each player gains or loses. Since the planner may have several optimal plans, compare the agent's payoffs across all of them. Which of Postlewaite's four conclusions hold in every draw?

Solution

Here is one solution.

We build the payoff matrices and the two experiments.

Under the coarse experiment the likelihood matrix sends states θ_1 and θ_2 to the first signal and states θ_3 and θ_4 to the second, so it is also the garbling.

```
def postlewaite(b, c, d, e, f, g, h, j):
    """Payoffs in Postlewaite's example (rows: actions, columns: states)."""
    U = 2 * np.array([[b, 0, c, 0],
                      [0, c, 0, b],
                      [d, 0, e, 0],
                      [0, e, 0, d]], dtype=float)
    W = 2 * np.array([[0, f, 0, g],
                      [g, 0, f, 0],
                      [h, 0, j, 0],
                      [0, j, 0, h]], dtype=float)
    return U, W

π_pw = np.full(4, 1/4)
Λ_pw_fine = np.eye(4)
Λ_pw_coarse = np.array([[1.0, 0.0],
                        [1.0, 0.0],
                        [0.0, 1.0],
                        [0.0, 1.0]])

print("B =\n", garbling(Λ_pw_fine, Λ_pw_coarse, π_pw))
```

```
B =
 [[1. 0.]
 [1. 0.]
 [0. 1.]
 [0. 1.]]
```

The next function reports the planner's value and the range of the agent's expected utility across the planner's optimal plans, and `compare` prints them for both experiments.

```
def payoffs(U, W, Λ, π):
    """
    Planner's value, the agent's lowest and highest payoffs across the
    planner's optimal plans (up to the tolerance in solve_planner), and a
    plan that gives the highest.
    """
    _, v_hat, agent_lo = solve_planner(U, W, Λ, π, ties="agent_worst")
    Z, _, agent_hi = solve_planner(U, W, Λ, π, ties="agent_best")
    return v_hat, agent_lo, agent_hi, Z

def compare(params):
    """Print both players' payoffs; return the plan for the fine experiment."""
    U, W = postlewaite(**params)
    for name, Λ in (("coarse", Λ_pw_coarse), ("fine", Λ_pw_fine)):
        v_hat, lo, hi, Z = payoffs(U, W, Λ, π_pw)
        agent = f"{lo:.4f}" if np.isclose(lo, hi) else f"{lo:.4f} to {hi:.4f}"
        print(f"{name}: planner {v_hat:.4f}, agent {agent}")
    return Z
```

```
coarse: planner 10.0000, agent 10.0000
fine: planner 9.7143, agent 5.6429
optimal plan under the fine experiment:
 [[0.2857 0.     0.7143 0.    ]
 [0.     0.2857 0.     0.7143]
 [0.2857 0.     0.7143 0.    ]
 [0.     0.2857 0.     0.7143]]
```

Under the coarse experiment the plan "a_1 after the first signal, a_2 after the second" gives the planner $b = 10$ and the agent $f = 10$, the largest expected payoffs available to either of them under that experiment.

Under the fine experiment the planner gets about 9.71 and the agent about 5.64, so both lose.

The optimal plan under the fine experiment puts probability $5/7 \approx 0.71$ on the dominated actions a_3 and a_4, which Postlewaite describes as "placing most of the probability on a_3 and a_4."

For part 2, an agent who sees θ_1 gets $2h(1-x)$ from the truth and $2gx$ from reporting θ_2 or θ_4.

Reporting θ_3 gives the same lottery as the truth.

So he reports truthfully if and only if $h(1-x) \geq gx$, that is, $x \leq h/(h+g)$.

Similarly, in state θ_4 truth requires $x \leq h/(h+g)$, and in states θ_2 and θ_3 it requires $j(1-x) \geq fx$, that is, $x \leq j/(j+f)$.

The planner's expected utility is $(b+c)x + (d+e)(1-x)$, which rises with x when $b + c > d + e$, so she sets $x = x^*$.

The agent's expected utility is $(h+j)(1-x)$.

```
def family_values(b, c, d, e, f, g, h, j):
    """x*, and both players' payoffs at x*, in the family of part 2."""
    x_star = min(h / (h + g), j / (j + f))
    planner = (b + c) * x_star + (d + e) * (1 - x_star)
    return x_star, planner, (h + j) * (1 - x_star)

x_star, v_family, a_family = family_values(**case_2)
print(f"x* = {x_star:.4f}, planner {v_family:.4f}, agent {a_family:.4f}")
```

```
x* = 0.2857, planner 9.7143, agent 5.6429
```

These match the linear program.

When an agent who sees θ_1 lies, he gets a lottery over a_2 and a_4, which pay him $2g$ and 0 in that state, so his truth-telling constraint compares h with g, and j does not enter it.

So the bound x^* depends on how h compares with g and how j compares with f, not on how h compares with j.

So Postlewaite's claim is not right: the weight on a_1 and a_2 stays bounded away from zero as h approaches j, and here it is $2/7$.

An agent who knows only which pair of states occurred gets $\max\{xf + (1-x)h,\ xg + (1-x)j\}$ under such a plan.

At $x = x^*$ this equals $(1-x^*)(h+j)$, exactly what the informed agent gets.

If $x^* = j/(j+f)$, as in this example, the first term equals $(1-x^*)(h+j)$ and the second is no larger, because $x^* \leq h/(h+g)$; if $x^* = h/(h+g)$, the roles of the two terms are reversed.

So under the planner's preferred plan in the family, ignoring the finer information would leave the agent exactly as well off, not worse off.

For part 3, we solve Case III and compare with the family of part 2.

```
case_3 = dict(b=10, c=6, d=4, e=3, f=10, g=8, h=5.9, j=6)
compare(case_3)
x_star, v_family, a_family = family_values(**case_3)
print(f"family of part 2: x* = {x_star:.4f}, planner {v_family:.4f}, "
      f"agent {a_family:.4f}")
```

```
coarse: planner 10.0000, agent 10.0000
fine: planner 10.3750, agent 7.4375
family of part 2: x* = 0.3750, planner 10.3750, agent 7.4375
```

Under the coarse experiment both players get 10, while under the fine experiment the planner gets 10.375 and the agent 7.4375: the planner gains and the agent loses, the opposite of Postlewaite's conclusion.

In fact, whenever the Case III inequalities hold, the agent loses under the plan in the family of part 2 that the planner prefers.

Since $b > d + e$, the planner sets $x = x^*$.

Under the coarse experiment the agent gets f, and under that plan he gets $(h + j)(1 - x^*)$.

Plans with smaller x would give him more, up to $h + j > f$ at $x = 0$, but the planner does not choose them.

If $x^* = h/(h + g)$, his payoff is $(h + j)g/(h + g)$, which is less than f because $g(j - f) < 0 < h(f - g)$.

If $x^* = j/(j + f)$, his payoff is $(h + j)f/(j + f)$, which is less than f because $h < f$.

Postlewaite's argument breaks down because he treats the weight on a_1 and a_2 as negligible, which amounts to evaluating the agent's payoff near $x = 0$.

For part 4, we draw parameters for each case.

For Cases I, III, and IV, sorting uniform draws gives a uniform draw from the region where they are ordered, which is much faster than rejecting unordered draws.

In Cases II to IV we draw h within 0.1 of j.

```
def draw_case(case, rng, gap=0.1):
    """
    Uniform draw from [0, 10]^8 subject to the inequalities of a case and,
    in Cases II to IV, to h being within gap of j.
    """
    def decreasing(n):
        return np.sort(rng.uniform(0, 10, n))[::-1]
    while True:
        if case == "I":
            e, d, b, c = decreasing(4)
            j, h, f, g = decreasing(4)
            ok = True
        elif case == "II":
            b, c, d, e, f, g, j = rng.uniform(0, 10, 7)
            h = j + rng.uniform(-gap, gap)
            ok = (0 < h < 10 and b > d + e > (b + c) / 2 > c
                  and f > h + j > (f + g) / 2 > g)
        else:
            b, c, d, e = decreasing(4)
            f, g, j = decreasing(3)
            h = j - rng.uniform(0, gap)
            if case == "III":
                ok = h > 0 and b > d + e and f < j + h
            else:
                ok = h > 0 and b < d + e and f > j + h
        if ok:
            return dict(b=b, c=c, d=d, e=e, f=f, g=g, h=h, j=j)
```

```
tol, n_draws = 1e-6, 300
for case in ("I", "II", "III", "IV"):
    rng = np.random.default_rng(0)
    counts = dict(planner_gains=0, planner_loses=0,
```

```
Case I: planner_gains 100%, planner_loses 0%, agent_gains 100%, agent_loses 0%
Case II: planner_gains 53%, planner_loses 47%, agent_gains 0%, agent_loses 100%
Case III: planner_gains 60%, planner_loses 40%, agent_gains 0%, agent_loses 100%
Case IV: planner_gains 100%, planner_loses 0%, agent_gains 0%, agent_loses 100%
```

Cases I and IV come out as Postlewaite says in every draw: in Case I both players gain, and in Case IV the planner gains and the agent loses.

His argument for Case IV repeats the claim that h close to j makes the weight on a_1 and a_2 negligible, which part 2 shows is false.

His conclusion about the planner does not need that claim: under the Case IV inequalities, every plan in the family of part 2 is worth $(b+c)x + (d+e)(1-x) > b$ to her, since both $b+c$ and $d+e$ exceed b.

Family plans also give the agent $(h+j)(1-x) < f$, but the planner's optimal plan sometimes lies outside the family, so the agent's loss rests on the draws.

In Case II, the agent loses in every draw, but the planner gains in about half of them, so "both worse off" holds only for some parameters.

Here is an example that satisfies the Case II inequalities, with h close to j, in which the planner gains.

```
case_2_gain = dict(b=10, c=9, d=5, e=4.8, f=10, g=4.5, h=3.9, j=4)
_ = compare(case_2_gain)
```

```
coarse: planner 10.0000, agent 10.0000
fine: planner 12.4286, agent 5.6429
```

The planner rises from 10 to about 12.43 while the agent falls from 10 to about 5.64.

Postlewaite's condition that h be close to j matters for the agent's side of Case II: without it, the agent can gain.

```
case_2_far = dict(b=9, c=3, d=2.5, e=4, f=8, g=7.8, h=1, j=6.95)
_ = compare(case_2_far)
```

```
coarse: planner 9.0000, agent 8.0000
fine: planner 8.5000, agent 10.8500
```

These parameters satisfy the Case II inequalities, with h far from j, and the agent rises from 8 to 10.85 while the planner falls from 9 to 8.5, the pattern that Postlewaite attributes to Case III.

In Case III, the agent loses in every draw, whichever of the planner's optimal plans is used, and the planner gains in more than half of them.

Part 3 proves the agent's loss only for the planner's preferred plan in the family; the draws suggest that it also holds for the linear program's optimal plans, some of which lie outside the family.

The shares depend on how the parameters are drawn, so they describe the uniform distribution on each region rather than the cases themselves.

Postlewaite's broader point survives: better information can make both players worse off, or help one and hurt the other.

Exercise 31.12.3

Postlewaite [1982] asks what happens if the roles are reversed: the agent commits first to a response rule, and the planner then takes the action she likes best given what she hears.

Postlewaite uses Green's term, and Green's response rules are deterministic; part 1 also lets the agent randomize.

1. Argue that the agent loses nothing by recommending actions that the planner is willing to follow. Write the agent's problem, when he may also randomize, as a linear program in an $N \times K$ Markov matrix $\Gamma = [\gamma_{nk}]$, where γ_{nk} is the probability that the agent recommends a_k after observing y_n, subject to **obedience constraints** for the planner. Assume that a planner who is indifferent follows the recommendation.
2. Solve the linear program for the fine experiment of Riley's example in Exercise 31.12.1, for Green's first example, and for the Case II example of Exercise 31.12.2. Then find the agent's best deterministic rule, in which every γ_{nk} is 0 or 1, by checking all of them. Compare both players' expected utilities with those when the planner leads.
3. Postlewaite says that "it is straightforward to construct examples where both principal and agent are better off with the roles of leader-follower reversed." Do these examples support him?

Solution

Here is one solution.

For part 1, any rule for sending messages leads the planner to some action after each message.

Merge all messages after which she takes the same action a_k into a single message "take a_k."

Her posterior after the merged message is an average of her posteriors after the original messages, and she preferred a_k at each of them, so by linearity she still prefers a_k.

The merged rule produces the same joint distribution of signals and actions, so both players' expected utilities are unchanged, and a deterministic rule stays deterministic.

The planner follows recommendation a_k if, for every other action $a_{k'}$,

$$\sum_{n=1}^{N} q_n \, \gamma_{nk} \, [(UP)_{kn} - (UP)_{k'n}] \;\geq\; 0,$$

and the agent maximizes $\sum_n q_n \sum_k \gamma_{nk} (WP)_{kn}$ subject to these constraints.

This is the persuasion problem of Kamenica and Gentzkow [2011], except that the agent can only garble his own signal rather than design any experiment he likes.

For part 2, `solve_agent_leads` solves the linear program and `best_deterministic_rule` checks every deterministic rule; `obedience_rows` and `leader_payoffs` are helpers that both use.

```
def obedience_rows(U, Λ, π):
    """Rows of the obedience constraints, A @ vec(Γ) <= 0."""
    q, P = posteriors(Λ, π)
    UP = U @ P
    K, N = UP.shape
    # Entry n * K + k of vec(Γ) is y_{nk}; for each recommended action k
    # and alternative j: sum_n q_n y_{nk} [(UP)_{jn} - (UP)_{kn}] <= 0
    rows = []
    for k in range(K):
        for j in range(K):
            if j != k:
                row = np.zeros((N, K))
                row[:, k] = q * (UP[j] - UP[k])
                rows.append(row.ravel())
    return np.array(rows)

def leader_payoffs(Γ, U, W, Λ, π):
```

```
    """Expected utilities of the planner and the agent under Γ."""
    q, P = posteriors(Λ, π)
    return q @ (Γ * (U @ P).T).sum(axis=1), q @ (Γ * (W @ P).T).sum(axis=1)

def solve_agent_leads(U, W, Λ, π):
    """
    The agent's best randomized recommendation rule.

            ("Case II", U_c2, W_c2, Λ_pw_fine, π_pw))
for name, U, W, Λ, π in examples:
    _, v_lead, a_lead = solve_planner(U, W, Λ, π)
    _, v_rand, a_rand = solve_agent_leads(U, W, Λ, π)
    _, v_det, a_det = best_deterministic_rule(U, W, Λ, π)
    print(f"{name}: planner leads ({v_lead:.4f}, {a_lead:.4f}); "
```

```
        f"agent leads, deterministic ({v_det:.4f}, {a_det:.4f}), "
        f"randomized ({v_rand:.4f}, {a_rand:.4f})")
```

```
Riley: planner leads (0.7000, 0.2500); agent leads, deterministic (0.7500, 0.
↪6000), randomized (0.7000, 0.6167)
Green's first: planner leads (0.6964, -0.0714); agent leads, deterministic (0.
↪8750, 0.3750), randomized (0.5000, 0.6429)
Case II: planner leads (9.7143, 5.6429); agent leads, deterministic (10.0000,␣
↪10.0000), randomized (7.0000, 11.3500)
```

Each pair lists the planner's expected utility first and the agent's second.

With a deterministic rule, the agent's best choice in Riley's example and in Green's first example is to tell the truth.

Committing to the truth lets the planner act on everything he knows, which gives the planner her first-best value, and it gives the agent more than he gets when the planner leads.

In Case II, his best deterministic rule reports only which pair of states occurred, which commits him to the coarse experiment, just as Postlewaite says he would like to do; both players then get 10.

In these three examples, a randomized rule lets the agent do better still, at the planner's expense.

In Riley's example he recommends a_1 after the posterior 0.4 with probability $2/3$, just often enough that a planner told to take a_1, who then puts probability 0.7 on θ_1, is willing to follow.

In Green's first example the planner falls to $v_0 = 0.5$, and in Case II to 7.

For part 3, Postlewaite is right for the reversal he describes: with a deterministic response rule, reversing the roles makes both players strictly better off in all three examples.

In these examples, an agent who can also randomize takes the planner's gain for himself, and the planner is no better off, and sometimes much worse off, than when she leads.

That is not a general rule.

Obedience guarantees the planner at least v_0, because she could always take one action regardless of the recommendation, so when her own plan gives her only v_0, she cannot lose by letting the agent lead, even with a randomized rule.

In Riley's example she merely breaks even, but in the next example both players gain strictly.

Here is an example with two states, a uniform prior, and a perfectly informative experiment.

```
U_rv = np.array([[0.0, 2.0],
                 [2.0, 1.0],
                 [3.0, 0.0]])
W_rv = np.array([[2.0, 2.0],
                 [0.0, 0.0],
                 [1.0, 2.0]])
Λ_rv, π_rv = np.eye(2), np.array([1/2, 1/2])

v_lead = solve_planner(U_rv, W_rv, Λ_rv, π_rv)[1]
a_best = solve_planner(U_rv, W_rv, Λ_rv, π_rv, ties="agent_best")[2]
_, v_rand, a_rand = solve_agent_leads(U_rv, W_rv, Λ_rv, π_rv)
print(f"planner leads: planner {v_lead:.4f}, agent at most {a_best:.4f}")
print(f"agent leads, randomized: planner {v_rand:.4f}, agent {a_rand:.4f}")
```

```
planner leads: planner 1.5000, agent at most 1.5000
agent leads, randomized: planner 1.7500, agent 1.7500
```

When the planner leads she gets only $v_0 = 1.5$, and the agent gets at most 1.5; when the agent leads with a randomized rule, both get 1.75.

Exercise 31.12.4

Marschak and Miyasawa [1968] compare several conditions on posterior probabilities.

One, which we call the **convex-hull condition**, requires every posterior of Λ' to lie in the convex hull of the posteriors of Λ.

Another is the existence of a joint distribution J of the two signals, with marginals q and q', that satisfies (31.3); it is equivalent to Blackwell's order.

Take two states with a uniform prior.

Experiment Λ has posteriors 0.9, 0.5, and 0.1 for θ_1, with probabilities 0.05, 0.9, and 0.05.

Experiment Λ' has posteriors 0.7 and 0.3, each with probability $1/2$.

1. Show that the convex-hull condition holds for Λ against Λ', but that Λ is not more informative than Λ'. Explain why, using the variance of the posterior. Is Λ' more informative than Λ?
2. The **equivocation** of an experiment is the expected entropy of the posterior, $-\sum_n q_n \sum_m p_{mn} \log p_{mn}$. Compute it for both experiments. Marschak and Miyasawa's Theorem 12.3 says that lower equivocation is necessary but not sufficient for being more informative. Illustrate this by finding two decision makers who rank Λ and Λ' in opposite orders. Compare with the treatment of entropy in *Blackwell's Theorem on Comparing Experiments*.
3. Marschak and Miyasawa's Theorem 10.1 says that the convex-hull condition is sufficient when Λ has only two signals. Explain why, and check it numerically with two states. How does this relate to the proof of *Theorem 31.8.1*?

Solution

Here is one solution.

For part 1, the posteriors of Λ', 0.7 and 0.3, lie in the interval $[0.1, 0.9]$ spanned by those of Λ, so the convex-hull condition holds.

```
π_mm = np.array([1/2, 1/2])
Λ_mm = experiment([0.9, 0.5, 0.1], [0.05, 0.9, 0.05], π_mm)
Λ_mm_prime = experiment([0.7, 0.3], [1/2, 1/2], π_mm)

print("Λ more informative than Λ':",
      garbling(Λ_mm, Λ_mm_prime, π_mm) is not None)
print("Λ' more informative than Λ:",
      garbling(Λ_mm_prime, Λ_mm, π_mm) is not None)

for name, Λ in (("Λ", Λ_mm), ("Λ'", Λ_mm_prime)):
    q, P = posteriors(Λ, π_mm)
    print(f"variance of the posterior under {name}: {q @ (P[0] - 0.5)**2:.4f}")
```

```
Λ more informative than Λ': False
Λ' more informative than Λ: False
variance of the posterior under Λ: 0.0160
variance of the posterior under Λ': 0.0400
```

Λ is not more informative than Λ'.

The convex-hull condition compares only the locations of the posteriors and ignores how likely they are.

Under Λ the posterior is usually 0.5, so its variance is 0.016, while under Λ' the variance is 0.04.

A mean-preserving spread raises the variance, so the distribution of posteriors under Λ cannot be a mean-preserving spread of the distribution under Λ'.

What rules it out is the requirement that J have marginal q.

To write the posterior 0.7 as an average of 0.9, 0.5, and 0.1, at least half of the weight must go on 0.9, so J would have to put probability at least $1/4$ on the posterior 0.9, which Λ produces only with probability 0.05.

Nor is Λ' more informative than Λ: the posteriors 0.9 and 0.1 of Λ lie outside the convex hull $[0.3, 0.7]$ of the posteriors of Λ'.

The convex-hull condition is necessary for Blackwell's order, because each posterior of the less informative experiment is an average of posteriors of the more informative one, so it fails here, and `garbling` confirms it.

The two experiments are not comparable.

For part 2, we compute the equivocation of each experiment.

```
def equivocation(Λ, π):
    """Expected entropy of the posterior."""
    q, P = posteriors(Λ, π)
    logs = np.log(P, where=P > 0, out=np.zeros_like(P))
    return -q @ (P * logs).sum(axis=0)

for name, Λ in (("Λ", Λ_mm), ("Λ'", Λ_mm_prime)):
    print(f"equivocation of {name}: {equivocation(Λ, π_mm):.4f}")
```

```
equivocation of Λ: 0.6563
equivocation of Λ': 0.6109
```

Λ' has the lower equivocation, but it is not more informative than Λ.

Consider decision makers who choose between a bet that pays 1 in state θ_1 and loses x in state θ_2, and no bet.

The bet is worth taking when the posterior exceeds $x/(1+x)$.

```
def bet_utility(x):
    """Bet paying 1 in θ_1 and losing x in θ_2, against no bet."""
    return np.array([[1.0, -x],
                     [0.0, 0.0]])

for x in (4.0, 1.5):
    U_bet = bet_utility(x)
    print(f"x = {x}: threshold {x / (1 + x):.2f}, "
          f"value with Λ {bayes_value(U_bet, Λ_mm, π_mm):.4f}, "
          f"with Λ' {bayes_value(U_bet, Λ_mm_prime, π_mm):.4f}")
```

```
x = 4.0: threshold 0.80, value with Λ 0.0250, with Λ' 0.0000
x = 1.5: threshold 0.60, value with Λ 0.0375, with Λ' 0.1250
```

A cautious bettor who bets only above a posterior of 0.8 values Λ, which sometimes delivers the posterior 0.9, and gets nothing from Λ'.

A bolder bettor with threshold 0.6 prefers Λ'.

This is Marschak and Miyasawa's point that equivocation, unlike informativeness, orders all experiments, and so cannot capture the dependence of the value of information on the user's payoffs.

Blackwell's Theorem on Comparing Experiments makes the same point in DeGroot's terms: Blackwell's order requires the uncertainty reduction to be larger for every concave uncertainty function, not only for entropy.

For part 3, suppose that Λ has two signals with distinct posteriors p_1 and p_2, and that every posterior of Λ' lies on the segment joining them.

Write each posterior $p'_{n'}$ of Λ' as a mixture of p_1 and p_2, and split signal $y'_{n'}$ according to the mixture weights.

This gives a joint distribution J whose columns sum to q' and which satisfies (31.3).

Its row sums put probabilities on p_1 and p_2 whose average is $\sum_{n'} q'_{n'} p'_{n'} = \pi$.

Only one distribution on two distinct points has mean π, so the row sums are q, and Λ is more informative than Λ'.

The requirement that the row sums of J equal q, which failed in part 1, holds automatically, for any number of states.

We check this by drawing random experiments Λ' and a two-signal Λ whose posteriors bracket those of Λ'.

```
rng = np.random.default_rng(2468)

found = []
for _ in range(500):
    N_prime = rng.integers(2, 6)
    post = rng.uniform(0.05, 0.95, N_prime)
    probs = rng.dirichlet(np.ones(N_prime))
    π = np.array([probs @ post, 1 - probs @ post])
    lo = rng.uniform(0, post.min())
    hi = rng.uniform(post.max(), 1)
    w_hi = (π[0] - lo) / (hi - lo)
    Λ_binary = experiment([hi, lo], [w_hi, 1 - w_hi], π)
    Λ_other = experiment(post, probs, π)
    found.append(garbling(Λ_binary, Λ_other, π) is not None)
print("garbling found in every draw:", all(found))
```

```
garbling found in every draw: True
```

The proof of *Theorem 31.8.1* uses the information order through two facts: the posteriors of Λ' lie on the segment joining those of Λ, and there is a joint distribution J satisfying (31.3).

When Λ has two signals, the argument above shows that the first fact delivers the second, so Blackwell's order is then a condition on where the posteriors lie, not on how likely they are.

32.1 Overview

This lecture studies two questions about the **informational role of prices** posed and answered by Kihlstrom and Mirman [1975].

1. *When do prices transmit inside information?*
   - An informed insider observes a private signal correlated with an unknown state of the world and adjusts demand accordingly.
   - Equilibrium prices shift.
   - Under what conditions can an outside observer *infer* the insider's posterior distribution from the equilibrium price?
2. *Do Bayesian price expectations converge?*
   - In a stationary stochastic exchange economy, an uninformed observer uses the history of market prices and Bayes' Law to form beliefs about the economy's structure and hence about its induced price distribution.
   - Do those expectations eventually agree with those of a fully informed observer?

Kihlstrom and Mirman's answers rely on two classical ideas from statistics:

- **Blackwell sufficiency**: a random variable $\tilde{y}$ is said to be *sufficient* for a random variable $\tilde{y}'$ with respect to an unknown state if knowing $\tilde{y}$ gives all the information about the state that $\tilde{y}'$ contains.

- **Bayesian consistency**: as the sample grows, posterior beliefs eliminate models that imply the wrong **price distribution**, so even when structure is not identified from prices the posterior mass on the true **reduced form** still converges to one.

Important findings of Kihlstrom and Mirman [1975] are:

- Equilibrium prices transmit inside information *if and only if* the map from the insider's posterior distribution to the equilibrium price is one-to-one on the set of posteriors that can actually arise from the signal.
  - For the two-state case ($S = 2$), invertibility holds when the informed agent's utility is homothetic and the elasticity of substitution is everywhere either below one or above one.
- In the dynamic economy, as information accumulates, Bayesian price expectations converge to **rational expectations**, even when the deep structure is not identified from prices alone.

Note

Kihlstrom and Mirman [1975] use the terms "structure" and "reduced form" as careful econometricians do.

A structure is a complete specification of the economy's primitives, here a parameter vector λ.

Each structure implies a probability distribution of observable variables, here the distribution of equilibrium prices, and that distribution is the reduced form.

Several structures can imply the same reduced form.

We call the set of structures that imply the same reduced form a reduced-form class; price data identify the class but not the structure within it.

The lecture is organized as follows.

1. Set up the static two-commodity model and define equilibrium.
2. State the price-revelation theorem and the invertibility conditions.
3. Illustrate invertibility and its failure with numerical examples using CES and Cobb-Douglas preferences.
4. Introduce the dynamic stochastic economy and derive the Bayesian convergence result.
5. Simulate Bayesian learning from price observations.

This lecture builds on ideas in *Blackwell's Theorem on Comparing Experiments* and *Likelihood Ratio Processes and Bayesian Learning*.

Incentives for Information Transfer studies a different channel, in which an informed agent reports to a planner who has committed to how she will act on the report.

We start by importing some Python packages.

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.optimize import brentq
from scipy.stats import norm
```

32.2 Setup

32.2.1 Preferences, endowments, and the unknown state

The economy has two goods.

Good 2 is the numeraire (price normalized to 1).

Good 1 trades at price $p > 0$.

An unknown parameter $\bar{a}$ affects the value of good 1.

Agent i's expected utility from a bundle (x_1^i, x_2^i) is

$$U^i(x_1^i, x_2^i) = \sum_{s=1}^{S} u^i(a_s x_1^i,\ x_2^i)\, P^i(\bar{a} = a_s),$$

where P^i is agent i's subjective probability distribution over the finite state space $A = \{a_1, \dots, a_S\}$.

Each agent starts with an endowment w^i of good 2 and a share θ^i of the representative firm.

In the paper's formal model, a single firm transforms good 2 into good 1 according to $y_1 = f(y_2)$ with $f' < 0$ and chooses production to maximize

$$\pi(p) = \max_{y_2 \le 0} \{p f(y_2) + y_2\}.$$

The firm's profit π is then distributed to households according to the shares θ^i.

Agent i's budget constraint is

$$p x_1^i + x_2^i = w^i + \theta^i \pi.$$

Agents maximize expected utility subject to their budget constraints.

A **competitive equilibrium** is a price $\hat{p}$ that clears both markets simultaneously.

Under the maintained convexity assumptions equilibrium exists, and following Kihlstrom and Mirman [1975] we assume the equilibrium price is unique.

We write $\hat{p} = p(\mu, P^2, \dots, P^n)$ for the equilibrium price when agent 1 holds beliefs μ and the other agents hold beliefs $P^2, \dots, P^n$.

The beliefs $P^2, \dots, P^n$ stay fixed throughout the static analysis, so we abbreviate the price function to $p(\mu)$.

For most of what follows, the production side matters only through the induced equilibrium price map, so when we turn to numerical illustrations we will suppress production and use a pure-exchange / portfolio interpretation to keep the calculations transparent.

32.2.2 The informed agent's problem

Suppose **agent 1** (the insider) observes a private signal $\tilde{y}$ correlated with $\bar{a}$ before trading, where $\tilde{y}$ takes values in a finite set Y.

Before the signal arrives, agent 1 has prior beliefs $\mu_0 = P^1$.

Upon observing $\tilde{y} = y$, agent 1 updates to the **posterior** $\mu_y = (\mu_{y1}, \dots, \mu_{yS})$ via Bayes' rule:

$$\mu_{ys} = P(\bar{a} = a_s \mid \tilde{y} = y).$$

Because agent 1's demand depends on μ_y, the new equilibrium price satisfies

$$\hat{p} = p(\mu_y).$$

Outside observers who see $\hat{p}$ but not $\tilde{y}$ can try to *back out* the insider's posterior from the price.

Define the set of realized posteriors

$$M = \{\mu_y : y \in Y,\ P(\tilde{y} = y) > 0\}.$$

The key question is whether the map $\mu \mapsto p(\mu)$ is one-to-one on M.

To answer that question, we now translate "information in prices" into Blackwell's language of sufficiency.

32.3 Price revelation

32.3.1 Blackwell sufficiency

The price variable $p(\mu_{\tilde{y}})$ *accurately transmits* the insider's private information if observing the equilibrium price is just as informative about $\bar{a}$ as observing the signal $\tilde{y}$ directly.

In Blackwell's language (Blackwell [1951] and Blackwell [1953]), this means $p(\mu_{\tilde{y}})$ is **sufficient** for $\tilde{y}$.

Definition 32.3.1 (Sufficiency)

A random variable $\tilde{y}$ is *sufficient* for $\tilde{y}'$ with respect to $\bar{a}$ if there exists a conditional distribution $P(y' \mid y)$, **independent of** $\bar{a}$, such that

$$\phi'_a(y') = \sum_{y \in Y} P(y' \mid y)\, \phi_a(y) \quad \text{for all } a \text{ and all } y',$$

where $\phi_a(y) = P(\tilde{y} = y \mid \bar{a} = a)$.

Thus, once $\tilde{y}$ is known, $\tilde{y}'$ provides no additional information about $\bar{a}$.

This is the garbling relation of *Definition 30.2.1* in *Blackwell's Theorem on Comparing Experiments*: the likelihoods $\phi_a(y)$ form the more informative experiment, the likelihoods $\phi'_a(y')$ form its garbling, and $P(y' \mid y)$ is the Markov matrix Q.

Kihlstrom and Mirman [1975] show that

Lemma 32.3.1 (Posterior Sufficiency)

The posterior distribution $\mu_{\tilde{y}}$ is a sufficient statistic for $\tilde{y}$.

Proof. (Sketch) The posterior $\mu_{\tilde{y}}$ satisfies

$$P(\bar{a} = a_s \mid \mu_{\tilde{y}} = \mu_y,\ \tilde{y} = y) = \mu_{ys} = P(\bar{a} = a_s \mid \mu_{\tilde{y}} = \mu_y).$$

This identity says that once the posterior is known, conditioning on the original signal $\tilde{y}$ does not change beliefs about $\bar{a}$.

Equivalently, the conditional law of $\tilde{y}$ given $\mu_{\tilde{y}}$ is independent of $\bar{a}$, so $\mu_{\tilde{y}}$ is sufficient for $\tilde{y}$ in Blackwell's sense.

The lemma is Kihlstrom's standard-experiment point, described under "Posteriors and standard experiments" in *Blackwell's Theorem on Comparing Experiments*: replacing each signal by the posterior it induces loses no information about $\bar{a}$.

Now let's think about the mapping from belief to price.

Theorem 32.3.1 (Price Revelation)

In the model outlined above, the price random variable $p(\mu_{\tilde{y}})$ is sufficient for the random variable $\tilde{y}$ if and only if the function $p(\cdot)$ is invertible on the set of prices

$$\mathcal{P} = \Big\{ p(\mu_y) : y \in Y,\ P(\tilde{y} = y) = \sum_{a \in A} \phi_a(y)\, \mu_0(a) > 0 \Big\}.$$

The logic is

$$\tilde{y} \quad \longrightarrow \quad \mu_{\tilde{y}} \quad \longrightarrow \quad p(\mu_{\tilde{y}}).$$

The first arrow loses no information about $\bar{a}$ by *Lemma 32.3.1*, and the theorem asks when the second arrow also loses no information.

The proof has two parts.

If $p(\cdot)$ is one-to-one on M, then observing the price is equivalent to observing the posterior itself because

$$P(\mu_{\tilde{y}} = \mu \mid p(\mu_{\tilde{y}}) = p) = \begin{cases} 1 & \text{if } \mu = p^{-1}(p), \\ 0 & \text{otherwise.} \end{cases}$$

This conditional distribution is independent of the state, so price is sufficient for the posterior; together with *Lemma 32.3.1*, price is therefore sufficient for the signal.

Conversely, suppose that two different posteriors $\mu_y \neq \mu_{y'}$ in M generate the same price p.

Conditional on that price, an observer's posterior about $\bar{a}$ is a mixture, with positive weights, of the posteriors μ_z for which $p(\mu_z) = p$.

A mixture with positive weight on two different posteriors cannot equal both of them, so learning $\tilde{y}$ after seeing p would change the observer's beliefs about $\bar{a}$ for at least one of y and y'.

The price is therefore not sufficient for $\tilde{y}$.

Before turning to invertibility itself, it helps to keep in mind the two economic interpretations emphasized in the paper.

32.3.2 Two interpretations

Insider trading in a stock market

Good 1 is a risky asset with random return $\bar{a}$; good 2 is "money".

An insider's demand reveals private information about the return.

If the invertibility condition holds, outside observers can read the insider's posterior distribution – the useful information the insider's signal carries about $\bar{a}$ – from the equilibrium stock price.

Price as a quality signal

Good 1 has uncertain quality $\bar{a}$.

Experienced consumers (who have sampled the good) observe a signal correlated with quality and buy accordingly.

Uninformed consumers can infer quality from the market price, provided invertibility holds.

32.3.3 Uninformed traders who learn from prices

Kihlstrom and Mirman's uninformed traders hold fixed beliefs $P^2, \ldots, P^n$ and do not learn from the price.

Theorem 32.3.1 describes what an outside observer who knows the map $p(\cdot)$ could infer.

If the uninformed traders themselves knew $p(\cdot)$ and conditioned on the price, their beliefs and demands would depend on the price, and equilibrium would become a rational expectations equilibrium.

Grossman [1976] constructs a rational expectations equilibrium in which the price fully reveals the informed traders' information.

Radner [1979] shows that with finitely many states fully revealing rational expectations equilibria exist generically.

Grossman and Stiglitz [1980] add a cost of acquiring information.

If the price revealed everything, no trader would pay for information; if no trader paid for information, the price would have nothing to reveal.

They resolve the paradox with a noisy supply of the risky asset, which makes the price reveal information only partially.

Rational Learning and Rational Expectations studies Bayesian traders who learn from prices inside a rational expectations equilibrium.

32.4 Invertibility and the elasticity of substitution

When does the belief-to-price map fail to be invertible?

Theorem 32.4.1 shows that for a two-state economy ($S = 2$), the answer depends on the **elasticity of substitution** σ of agent 1's utility function.

Before stating the theorem, it helps to see the two intermediate steps in the paper's argument.

Lemma 32.4.1 (Same Price Implies Same Allocation)

Assume that u^i has continuous first partial derivatives and that u^i is strictly quasi-concave.

Let $p \in \mathcal{P}$.

If there exist two measures μ^* and μ' in M such that $p(\mu^*) = p(\mu') = p$, then

$$x^i(\mu^*) = x^i(\mu'), \quad i = 1, \ldots, n,$$

where $x^i(\mu)$ is trader i's equilibrium bundle when agent 1's beliefs are μ and the other agents' beliefs are $P^2, \ldots, P^n$.

Fix the beliefs of all agents except agent 1.

The lemma says that if two posterior beliefs μ^* and μ' for agent 1 both support the same equilibrium price p, then they support the same equilibrium allocation for every trader.

The intuition is that when the price is unchanged, the demands of the uninformed traders are unchanged too, so market clearing forces the informed agent's bundle to be unchanged as well.

Strict quasi-concavity makes each trader's demand a single-valued function of the price, and the uninformed traders' beliefs $P^2, \ldots, P^n$ do not move with the price.

This lemma lets us define the informed agent's equilibrium bundle as a function of price alone:

$$x(p) = (x_1(p), x_2(p)).$$

Throughout, u^i_j denotes the partial derivative of u^i with respect to its j-th argument.

Whenever the informed agent consumes positive amounts of both goods, optimality of $x(p)$ under posterior μ gives the interior first-order condition

$$p = \frac{\sum_{s=1}^{S} a_s u^1_1(a_s x_1(p), x_2(p))\, \mu(a_s)}{\sum_{s=1}^{S} u^1_2(a_s x_1(p), x_2(p))\, \mu(a_s)}.$$

For a fixed price p, the bundle $x(p)$ is fixed too, so invertibility boils down to whether this equation admits a unique posterior μ.

Lemma 32.4.2 (Unique Posterior at a Given Price)

Assume that the first partial derivatives of u^1 exist and that u^1 is strictly quasi-concave.

Also assume that agent 1 always consumes positive quantities of both goods.

Then $p(\cdot)$ is invertible on $\mathcal{P}$ if for each $p \in \mathcal{P}$ there exists a unique probability measure $\mu \in M$ such that

$$\frac{\sum_{s=1}^{S} a_s\, u^1_1(a_s x_1(p), x_2(p))\, \mu(a_s)}{\sum_{s=1}^{S} u^1_2(a_s x_1(p), x_2(p))\, \mu(a_s)} = p.$$

If two different posteriors gave the same price, then by *Lemma 32.4.1* they would share the same bundle $x(p)$, contradicting uniqueness of the posterior that solves the first-order condition at that price.

32.4.1 The two-state first-order condition

With $S = 2$ and $\mu = (q,\ 1-q)$, define

$$\alpha_s(p) = a_s\, u^1_1(a_s x_1(p),\ x_2(p)), \qquad \beta_s(p) = u^1_2(a_s x_1(p),\ x_2(p)), \qquad s = 1, 2.$$

Then the first-order condition becomes

$$p = \frac{\alpha_1(p)\, q + \alpha_2(p)\, (1-q)}{\beta_1(p)\, q + \beta_2(p)\, (1-q)}.$$

At a fixed price p, the quantities $\alpha_s(p)$ and $\beta_s(p)$ are constants, so uniqueness of the posterior is the same as uniqueness of the scalar q solving this equation.

Theorem 32.4.1 (Invertibility Conditions)

Assume that the first partial derivatives of u^1 exist and that u^1 is quasi-concave and homothetic.

Also suppose that the informed agent always consumes positive quantities of both goods in all equilibrium allocations.

If $S = 2$ and the elasticity of substitution of u^1 is either always less than one or always greater than one, then $p(\cdot)$ is invertible on $\mathcal{P}$.

If u^1 is Cobb-Douglas (elasticity of substitution constant and equal to one), then $p(\cdot)$ is constant on M.

When $\sigma = 1$ the income and substitution effects exactly cancel, so agent 1's demand for good 1 does not respond to changes in beliefs about $\bar{a}$.

Because the demand is unchanged, the market-clearing price is unchanged too, and the price reveals nothing about the insider's signal.

32.4.2 CES utility

For concreteness we work with a simplified example with the **constant-elasticity-of-substitution** (CES) utility function

$$u(c_1, c_2) = \Big(\frac{c_1^\rho + c_2^\rho}{2}\Big)^{1/\rho}, \qquad \rho \in (-\infty, 0) \cup (0, 1),$$

whose elasticity of substitution is $\sigma = 1/(1-\rho)$.

- $\rho \to 0$: Cobb-Douglas ($\sigma = 1$), $u \to \sqrt{c_1 c_2}$.
- $\rho < 0$: $\sigma < 1$ (complements).
- $0 < \rho < 1$: $\sigma > 1$ (substitutes).

The factor $1/2$ inside the parentheses makes u converge to $\sqrt{c_1 c_2}$ as $\rho \to 0$; without it, u diverges as $\rho \downarrow 0$ and vanishes as $\rho \uparrow 0$.

The factor rescales u_1 and u_2 by a common constant, so it does not affect marginal rates of substitution or prices.

Pertinent partial derivatives are

$$u_1(c_1, c_2) = \frac{1}{2}\Big(\frac{c_1^\rho + c_2^\rho}{2}\Big)^{1/\rho - 1} c_1^{\rho-1}, \qquad u_2(c_1, c_2) = \frac{1}{2}\Big(\frac{c_1^\rho + c_2^\rho}{2}\Big)^{1/\rho - 1} c_2^{\rho-1}.$$

This CES example is only an illustration, because the theorem itself covers any homothetic utility with elasticity everywhere above one or everywhere below one.

With that example in hand, we can compute the equilibrium price directly as a function of the posterior.

32.4.3 Equilibrium price as a function of the posterior

We suppress production.

Uninformed traders own one unit of good 1, have no use for it, and sell it at any positive price, so at equilibrium agent 1 absorbs the unit and $x_1 = 1$.

Agent 1 owns W_1 units of good 2 and no shares of the firm ($\theta^1 = 0$), so his wealth $W_1 = w^1$ does not depend on p.

Agent 1's budget constraint then reduces to $x_2 = W_1 - p$, and the equilibrium price is the unique $p \in (0, W_1)$ satisfying the first-order condition

$$p\big[q\, u_2(a_1,\, W_1 - p) + (1-q)\, u_2(a_2,\, W_1 - p)\big] = q\, a_1\, u_1(a_1,\, W_1 - p) + (1-q)\, a_2\, u_1(a_2,\, W_1 - p).$$

For Cobb-Douglas utility ($\sigma = 1$), the first-order condition becomes $p = W_1 - p$, giving $p^* = W_1/2$ regardless of the posterior q, confirming that no information is transmitted through the price in the Cobb-Douglas case.

We compute first-order conditions numerically below.

```
def ces_derivatives(c1, c2, ρ):
    """
    Return CES marginal utilities.

    Use the Cobb-Douglas limit near rho = 0.
    """
    if abs(ρ) < 1e-4:
        u1 = 0.5 * np.sqrt(c2 / c1)
        u2 = 0.5 * np.sqrt(c1 / c2)
    else:
        common = 0.5 * ((c1**ρ + c2**ρ) / 2)**(1 / ρ - 1)
        u1 = common * c1**(ρ - 1)
        u2 = common * c2**(ρ - 1)
    return u1, u2

def eq_price(q, a1, a2, W1, ρ):
    """Return the equilibrium price for posterior q."""
    def residual(p):
        x2 = W1 - p
        u1_s1, u2_s1 = ces_derivatives(a1, x2, ρ)
        u1_s2, u2_s2 = ces_derivatives(a2, x2, ρ)
        lhs = p * (q * u2_s1 + (1 - q) * u2_s2)
        rhs = q * a1 * u1_s1 + (1 - q) * a2 * u1_s2
        return lhs - rhs

    try:
        return brentq(residual, 1e-6, W1 - 1e-6, xtol=1e-10)
    except ValueError:
        return np.nan
```

```
a1, a2 = 2.0, 0.5     # state values (a1 > a2)
W1 = 4.0

q_grid = np.linspace(0.05, 0.95, 200)

ρ_values = [-0.5, 0.0, 0.5]
ρ_labels = [
    r"$\rho = -0.5$ ($\sigma = 0.67$, complements)",
    r"$\rho = 0$ ($\sigma = 1$, Cobb-Douglas)",
    r"$\rho = 0.5$ ($\sigma = 2$, substitutes)",
]

fig, ax = plt.subplots(figsize=(8, 5))

for ρ, label in zip(ρ_values, ρ_labels):
    prices = [eq_price(q, a1, a2, W1, ρ) for q in q_grid]
    ax.plot(q_grid, prices, label=label, lw=2)

ax.set_xlabel(r"posterior probability $q = \Pr(\bar{a} = a_1)$", fontsize=12)
ax.set_ylabel("equilibrium price $p^*(q)$", fontsize=12)
ax.legend(fontsize=10)
plt.tight_layout()
plt.show()
```

The plot confirms *Theorem 32.4.1*.

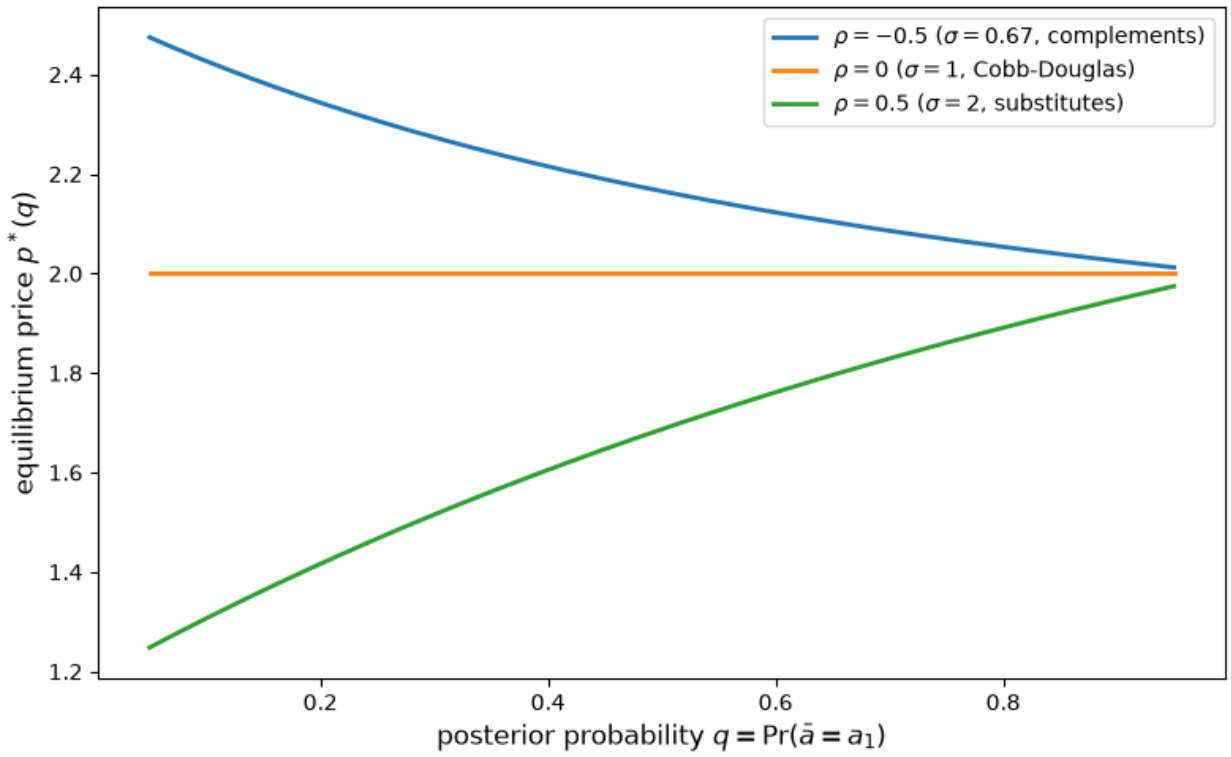

Fig. 32.1: equilibrium price vs posterior

For CES with $\sigma \neq 1$, the equilibrium price is strictly monotone in q.

The price falls with q when $\sigma < 1$ and rises with q when $\sigma > 1$.

When the goods are complements, good news about $\bar{a}$ lowers the price: a higher a_s lowers the marginal rate of substitution $a_s u_1/u_2$ (see *Why monotonicity depends on \sigma*), so the insider values the unit of good 1 less.

An outside observer who knows the equilibrium map $p^*(\cdot)$ can therefore invert the price uniquely to recover q, so the inside information is fully transmitted.

For Cobb-Douglas ($\sigma = 1$), the price is flat in q, so information is never transmitted through the market.

```
p_cd = [eq_price(q, a1, a2, W1, ρ=0.0) for q in q_grid]

print(f"Cobb-Douglas (rho=0): min p* = {min(p_cd):.6f}, "
      f"max p* = {max(p_cd):.6f}, "
      f"range = {max(p_cd)-min(p_cd):.2e}")
print(f"Analytical CD price  = W1/2 = {W1/2:.6f}")
```

```
Cobb-Douglas (rho=0): min p* = 2.000000, max p* = 2.000000, range = 8.88e-16
Analytical CD price  = W1/2 = 2.000000
```

Every entry equals $W_1/2 = 2.0$ up to rounding error, confirming numerically that the Cobb-Douglas equilibrium price is independent of q and of the state values a_1, a_2.

The numerical plot shows monotonicity, and the next subsection connects that pattern back to the proof of *Theorem 32.4.1*.

32.4.4 Why monotonicity depends on σ

Fix a price p and treat $\alpha_s(p)$ and $\beta_s(p)$ as constants.

The right-hand side of the two-state first-order condition

$$\frac{\alpha_1(p)\,q + \alpha_2(p)\,(1-q)}{\beta_1(p)\,q + \beta_2(p)\,(1-q)}$$

is then a function of q alone, with derivative

$$\frac{\partial}{\partial q}\frac{\alpha_1 q + \alpha_2(1-q)}{\beta_1 q + \beta_2(1-q)} = \frac{\alpha_1\beta_2 - \alpha_2\beta_1}{\left[\beta_1 q + \beta_2(1-q)\right]^2}.$$

So the sign is determined by $\alpha_1\beta_2 - \alpha_2\beta_1$, and if that sign is constant then for each fixed price there is at most one posterior weight q consistent with the first-order condition, which is exactly what *Theorem 32.4.1* requires.

Using

$$\frac{\alpha_s}{\beta_s} = \frac{a_s\,u_1(a_s x_1, x_2)}{u_2(a_s x_1, x_2)} = a_s^{(\sigma-1)/\sigma}\left(\frac{x_2}{x_1}\right)^{1/\sigma},$$

one can show

$$\frac{\partial}{\partial a}\frac{\alpha}{\beta} = \frac{(\sigma-1)}{\sigma}\,a^{-1/\sigma}\left(\frac{x_2}{x_1}\right)^{1/\sigma}.$$

For the CES specification, this derivative is positive when $\sigma > 1$, negative when $\sigma < 1$, and *zero when* $\sigma = 1$.

In other words, for CES utility the ratio α_s/β_s moves monotonically with the state value a_s unless $\sigma = 1$, which makes the fixed-price first-order-condition expression monotone in q and in turn delivers invertibility.

The vanishing derivative in the Cobb-Douglas case means the marginal rate of substitution is independent of a_s, so the informed agent's demand, and hence the equilibrium price, does not respond to changes in beliefs.

Let us visualize the ratio α_s/β_s as a function of a_s for different values of σ:

```
a_vals = np.linspace(0.3, 3.0, 300)
x1_fix, x2_fix = 1.0, 1.0

fig, ax = plt.subplots(figsize=(7, 4))
for ρ in [-0.5, -1e-6, 0.5]:
    σ = 1 / (1 - ρ) if abs(ρ) > 1e-8 else 1.0
    ratios = []
    for a in a_vals:
        u1, u2 = ces_derivatives(a * x1_fix, x2_fix, ρ)
        ratios.append(a * u1 / u2)
    ax.plot(a_vals, ratios, label=rf"$\sigma = {σ:.2f}$", lw=2)

ax.set_xlabel(r"state value $a_s$", fontsize=12)
ax.set_ylabel(r"$\alpha_s / \beta_s = a_s u_1 / u_2$", fontsize=12)
ax.axhline(y=1.0, color="black", lw=0.8, ls="--")
ax.legend(fontsize=10)
plt.tight_layout()
plt.show()
```

When $\sigma = 1$ the ratio is constant across all a_s values, so information about the state has no effect on the marginal rate of substitution.

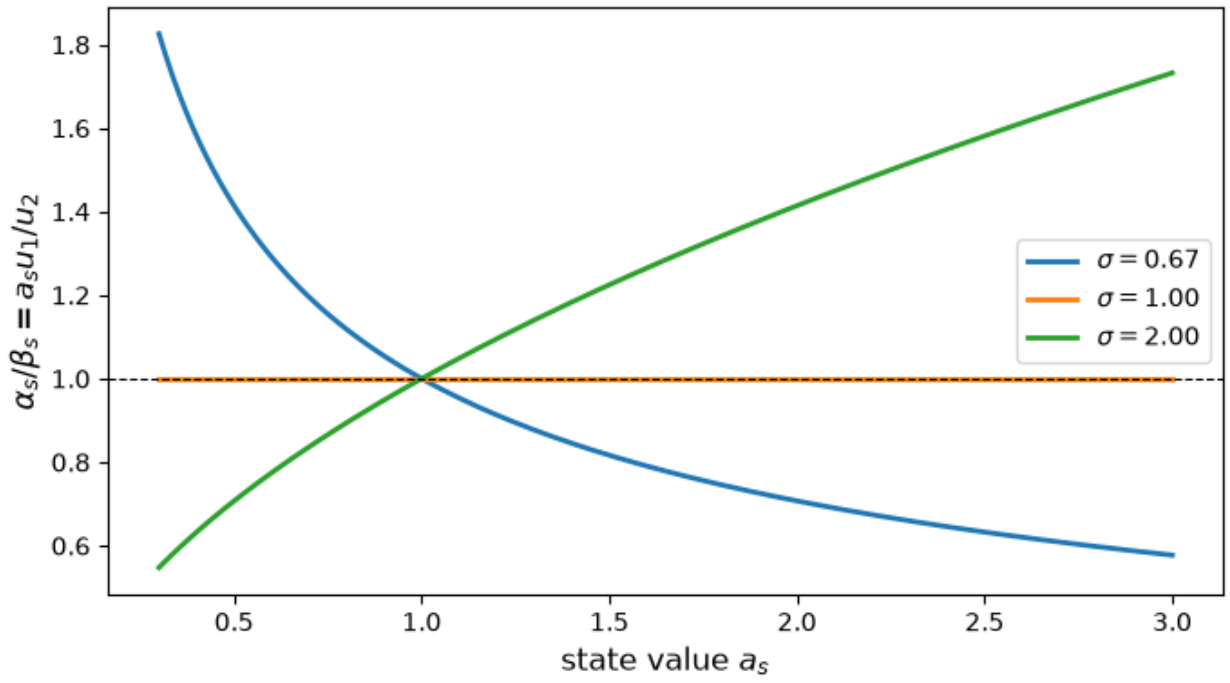

Fig. 32.2: marginal rate of substitution

For $\sigma < 1$ the ratio is decreasing in a_s, and for $\sigma > 1$ it is increasing, making the equilibrium price strictly monotone in the posterior q in both cases.

The static analysis asks whether a current price reveals current private information, whereas the next section asks what a whole history of prices reveals over time.

32.5 Bayesian price expectations in a dynamic economy

We now turn to a question addressed in Section 3 of Kihlstrom and Mirman [1975].

32.5.1 A stochastic exchange economy

Time is discrete: $t = 1, 2, \ldots$

In each period t:

1. Consumer i receives a random endowment ω_i^t.
2. Markets open; competitive prices $p^t = p(\omega^t)$ clear all markets.
3. Consumers trade and consume.

The structural parameter vector $\lambda = (\lambda_1, \ldots, \lambda_K)$ is *fixed but unknown*; it takes values in a finite or countable set $\Lambda \subset \mathbb{R}^K$.

Conditional on λ, the endowment vectors $\{\tilde{\omega}^t\}$ are **i.i.d.** with density $f(\omega^t \mid \lambda)$.

The equilibrium price at time t is a deterministic function of ω^t, so conditional on λ the prices $\{p^t\}$ are also i.i.d.

An observer who does not know λ and puts a prior over Λ regards the price sequence as exchangeable, a mixture of i.i.d. sequences, as in *Exchangeability and Bayesian Updating*.

Let P_λ denote the probability distribution of $\{\omega^t, p^t\}_{t\geq 1}$ under structure λ.

For any measurable set of prices B, let

$$W(B) = \{\omega^t : p(\omega^t) \in B\}.$$

Then

$$P_\lambda(p^t \in B) = P_\lambda(\omega^t \in W(B)) = \int_{W(B)} f(\omega^t \mid \lambda)\, d\omega^t.$$

The induced price density is denoted by $g(p^t \mid \lambda)$.

For a given structure λ, this density is the observable implication of the model, and when several structures imply the same density we group them into a single reduced-form class.

The next issue is therefore what an observer can and cannot infer about the structure from price data alone.

32.5.2 The identification problem

Because price observations identify only the induced price density $g(\cdot \mid \lambda)$, and because the structural-to-reduced-form map $\lambda \mapsto g(\cdot \mid \lambda)$ may be many-to-one, price data may identify only a reduced-form class rather than the exact structure.

In particular, it may be impossible to recover λ from $g(p \mid \lambda)$ even with infinite price data.

To handle this, partition Λ into equivalence classes η such that $\lambda \in \eta$ and $\lambda' \in \eta$ whenever $g(p \mid \lambda) = g(p \mid \lambda')$ for all p.

We use η for reduced-form classes to keep μ for the insider's posterior in the static model.

The equivalence class η containing the true λ is the **reduced form** relevant for price data.

An observer who knows the infinite price history learns η but not necessarily λ.

Once that distinction is clear, Bayesian updating can be written down directly.

32.5.3 Bayesian updating

An uninformed observer begins with a prior $h(\lambda)$ over $\lambda \in \Lambda$.

If the observer could see endowments directly, the posterior would be

$$h(\lambda \mid \omega^1, \dots, \omega^t) = \frac{h(\lambda)\, \prod_{\tau=1}^t f(\omega^\tau \mid \lambda)}{\sum_{\lambda' \in \Lambda} h(\lambda') \prod_{\tau=1}^t f(\omega^\tau \mid \lambda')},$$

and the paper appeals to a Bayesian consistency result to conclude that this posterior concentrates on the true structure $\bar{\lambda}$.

That conclusion requires $h(\bar{\lambda}) > 0$ and identification of the structure from endowments: $f(\cdot \mid \lambda) \neq f(\cdot \mid \lambda')$ whenever $\lambda \neq \lambda'$.

After observing the price sequence $(p^1, \dots, p^t)$, the observer's Bayesian posterior is

$$h(\lambda \mid p^1, \dots, p^t) = \frac{h(\lambda)\, \prod_{\tau=1}^t g(p^\tau \mid \lambda)}{\sum_{\lambda' \in \Lambda} h(\lambda') \prod_{\tau=1}^t g(p^\tau \mid \lambda')}.$$

Price data cannot distinguish structures inside the same reduced-form class.

Indeed, if λ and λ' belong to the same class η, then $g(\cdot \mid \lambda) = g(\cdot \mid \lambda')$, so

$$\frac{h(\lambda \mid p^1, \dots, p^t)}{h(\lambda' \mid p^1, \dots, p^t)} = \frac{h(\lambda)}{h(\lambda')}$$

for every sample history, so the relative odds within an observationally equivalent class never change.

At time t, the observer's price expectations for the next period are

$$g(p^{t+1} \mid p^1, \dots, p^t) = \sum_{\lambda \in \Lambda} g(p^{t+1} \mid \lambda)\, h(\lambda \mid p^1, \dots, p^t).$$

32.5.4 The convergence theorem

Theorem 32.5.1 (Bayesian Convergence)

Let $\bar{\lambda}$ be the true structural parameter and $\bar{\eta}$ the reduced form that contains $\bar{\lambda}$.

Assume the prior assigns positive probability to the reduced-form class $\bar{\eta}$.

Define the posterior mass on a reduced-form class by

$$H_t(\eta) = \sum_{\lambda \in \eta} h(\lambda \mid p^1, \dots, p^t).$$

Because all structures inside a class imply the same $g(\cdot \mid \lambda)$, the predictive density can equivalently be written as

$$g(p^{t+1} \mid p^1, \dots, p^t) = \sum_{\eta} g(p^{t+1} \mid \eta)\, H_t(\eta).$$

Then

$$\lim_{t \to \infty} H_t(\eta) = \begin{cases} 1 & \text{if } \eta = \bar{\eta}, \\ 0 & \text{otherwise,} \end{cases}$$

with $P_{\bar{\lambda}}$-probability one.

Consequently,

$$\lim_{t \to \infty} \left\| g(\cdot \mid p^1, \dots, p^t) - g(\cdot \mid \bar{\eta}) \right\|_{\mathrm{TV}} = 0,$$

where $g(\cdot \mid \bar{\eta})$ is the rational-expectations price distribution for a fully informed observer.

Note

The theorem only requires the prior to assign positive probability to the reduced-form class $\bar{\eta}$ that contains the true structure $\bar{\lambda}$.

This is the absolute-continuity condition of *Merging of Opinions: The Blackwell–Dubins Theorem*, explained below.

It is implied by, but weaker than, assigning positive probability to the true structural parameter $\bar{\lambda}$ itself.

A prior could place zero mass on $\bar{\lambda}$ while still placing positive mass on other structures inside $\bar{\eta}$.

The important distinction is that price observers need not learn $\bar{\lambda}$ itself.

They only learn which reduced-form class is correct.

That is enough for forecasting because every $\lambda \in \bar{\eta}$ generates the same price density $g(\cdot \mid \bar{\eta})$.

Rational price expectations emerge from learning the reduced form, not from identifying every structural detail of the economy.

Here "rational expectations" means that the observer's predictive distribution for next period's price matches the objective price distribution generated by the true reduced form.

32.5.5 Connection to merging of opinions

Theorem 32.5.1 is an instance of the merging theorem of Blackwell and Dubins [1962] studied in *Merging of Opinions: The Blackwell–Dubins Theorem*.

Let Q^* denote the distribution of the price sequence under the true structure, $P_{\bar{\lambda}}$, and let P denote its distribution under the observer's subjective mixture $\sum_\lambda h(\lambda) P_\lambda$.

Every structure in $\bar{\eta}$ induces the same distribution Q^* of prices, so $P(A) \geq H_0(\bar{\eta})\, Q^*(A)$ for every event A, where $H_0(\bar{\eta}) = \sum_{\lambda \in \bar{\eta}} h(\lambda)$.

Hence $Q^*(A) \leq P(A)/H_0(\bar{\eta})$, and $Q^* \ll P$ whenever $H_0(\bar{\eta}) > 0$.

Theorem 35.4.1 then implies that, Q^*-almost surely, the observer's conditional distribution of the entire future price sequence merges in total variation with the true one.

For a class $\eta \neq \bar{\eta}$, prices are i.i.d. with a density $g(\cdot \mid \eta)$ that differs from $g(\cdot \mid \bar{\eta})$.

Theorem 35.7.1 then makes the two distributions of the price sequence mutually singular, and the likelihood ratio $\prod_{\tau=1}^{t} g(p^\tau \mid \eta)/g(p^\tau \mid \bar{\eta})$ converges to zero Q^*-almost surely.

With finitely many classes this gives $H_t(\bar{\eta}) \to 1$.

Exercise 32.7.5 shows that the merging distance for the entire future equals $1 - H_t(\bar{\eta})$, so Blackwell and Dubins's theorem delivers $H_t(\bar{\eta}) \to 1$ with countably many classes as well.

Let's now turn to a simple simulation.

32.6 Simulating Bayesian learning from prices

We illustrate the theorem with a two-model example.

Two possible reduced forms η_1 and η_2 generate prices $p^t \sim N(\bar{p}_i, \sigma_p^2)$ for $i = 1, 2$ respectively.

The observer knows the two possible price distributions (the reduced forms) but not which one governs the data.

This is a **Bayesian model selection** problem we have seen in *Likelihood Ratio Processes and Bayesian Learning*.

With a prior h_0 on η_1 and the observed price p^t, the posterior weight on η_1 after period t is

$$h_t = \frac{h_{t-1}\, g(p^t \mid \eta_1)}{h_{t-1}\, g(p^t \mid \eta_1) + (1 - h_{t-1})\, g(p^t \mid \eta_2)}.$$

We consider a numerical example with two normal distributions with different means

```
def simulate_bayesian_learning(
    p_bar_true, p_bar_alt, σ_p, T, h0, n_paths, seed=42
):
    """Simulate posterior learning between two Gaussian reduced forms."""
```

(continues on next page)

(continued from previous page)

```
    rng = np.random.default_rng(seed)
    h_paths = np.zeros((n_paths, T + 1))
    h_paths[:, 0] = h0

    for path in range(n_paths):
        h = h0
        prices = rng.normal(p_bar_true, σ_p, size=T)
        for t, p in enumerate(prices):
            g_true = norm.pdf(p, loc=p_bar_true, scale=σ_p)
            g_alt = norm.pdf(p, loc=p_bar_alt, scale=σ_p)
            denom = h * g_true + (1 - h) * g_alt
            h = h * g_true / denom
            h_paths[path, t + 1] = h

    return h_paths

def plot_bayesian_learning(h_paths, p_bar_true, p_bar_alt, ax):
    """Plot posterior beliefs over time."""
    T = h_paths.shape[1] - 1
    t_grid = np.arange(T + 1)

    for path in h_paths:
        ax.plot(t_grid, path, alpha=0.25, lw=0.8, color="steelblue")

    median_path = np.median(h_paths, axis=0)
    ax.plot(t_grid, median_path, color="navy", lw=2, label="median posterior")

    ax.axhline(
        y=1.0,
        color="black",
        ls="--",
        lw=1.2,
        label="true model weight = 1",
    )
    ax.set_xlabel("period $t$", fontsize=12)
    ax.set_ylabel(r"$h_t$ = posterior weight on true model", fontsize=12)
    ax.legend(fontsize=10)
```

We consider two cases, one that is easy to learn and another one that is harder to learn, using $T = 300$ periods, $n = 40$ simulated paths, a diffuse prior $h_0 = 0.5$, and common standard deviation $\sigma_p = 0.4$.

- *Easy case*: true model $N(2.0,\, 0.4^2)$, alternative $N(1.2,\, 0.4^2)$.
- *Hard case*: true model $N(2.0,\, 0.4^2)$, alternative $N(1.8,\, 0.4^2)$.

Whether easy or hard to learn depends on "how close" the true distribution is compared to the alternative hypothesis, as measured by the Kullback–Leibler divergence of *Statistical Divergence Measures* (Exercise 32.7.2).

```
T = 300
h0 = 0.5      # diffuse prior
n_paths = 40
σ_p = 0.4

fig, axes = plt.subplots(1, 2, figsize=(12, 5))

# Distinct reduced forms
```

(continues on next page)

(continued from previous page)

```
p_bar_true, p_bar_alt = 2.0, 1.2
h_paths = simulate_bayesian_learning(p_bar_true, p_bar_alt, σ_p, T, h0, n_paths)
plot_bayesian_learning(h_paths, p_bar_true, p_bar_alt, axes[0])

# Similar reduced forms
p_bar_true, p_bar_alt = 2.0, 1.8
h_paths_hard = simulate_bayesian_learning(
    p_bar_true, p_bar_alt, σ_p, T, h0, n_paths
)
plot_bayesian_learning(h_paths_hard, p_bar_true, p_bar_alt, axes[1])

plt.tight_layout()
plt.show()
```

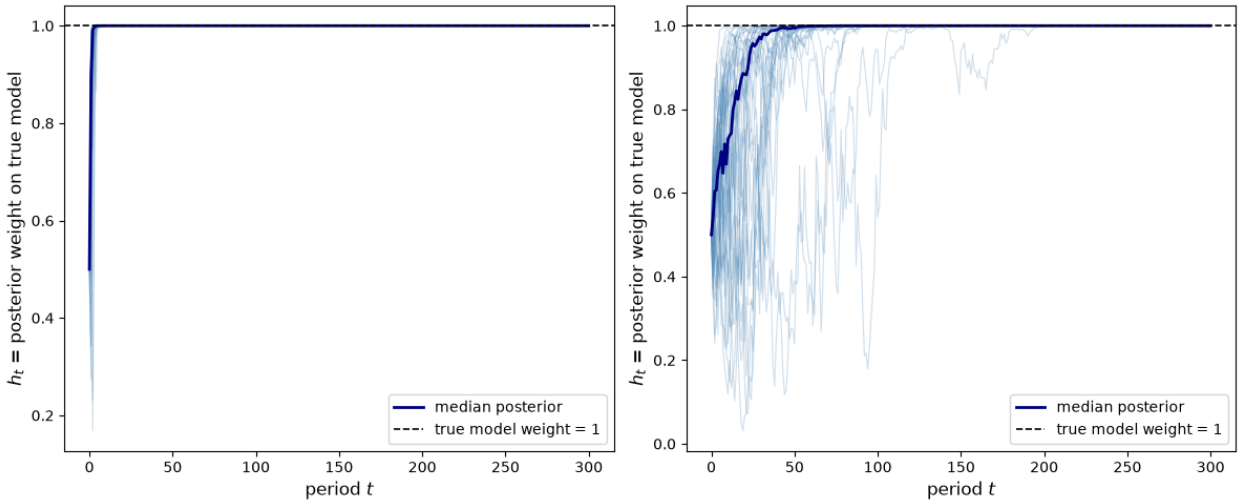

Fig. 32.3: bayesian learning across paths

In both panels the posterior weight on the true model converges to 1 with probability one, though convergence is slower when the two price distributions are similar (right panel).

32.6.1 Price expectations vs. rational expectations

We now verify that the observer's price expectations converge to the rational-expectations distribution $g(p \mid \bar{\eta})$.

We use the parameterization of the "hard-to-learn" example above ($\bar{p}_{\text{true}} = 2.0$, $\bar{p}_{\text{alt}} = 1.8$, $\sigma_p = 0.4$), extending to $T = 1{,}000$ periods with a single simulated path and prior $h_0 = 0.5$

```

```

The sequence of predictive densities (shades of blue) converges to the rational-expectations density (dashed black line) as experience accumulates.

Convergence need not be monotone.

On this path $h_{25} = 0.183$, below the prior $h_0 = 0.5$, before h_t rises toward one, because the log posterior odds follow a random walk whose positive drift dominates only in long samples.

This illustrates *Theorem 32.5.1*.

We can now sharpen the point by looking at a case in which the reduced form is learned but the underlying structure is not.

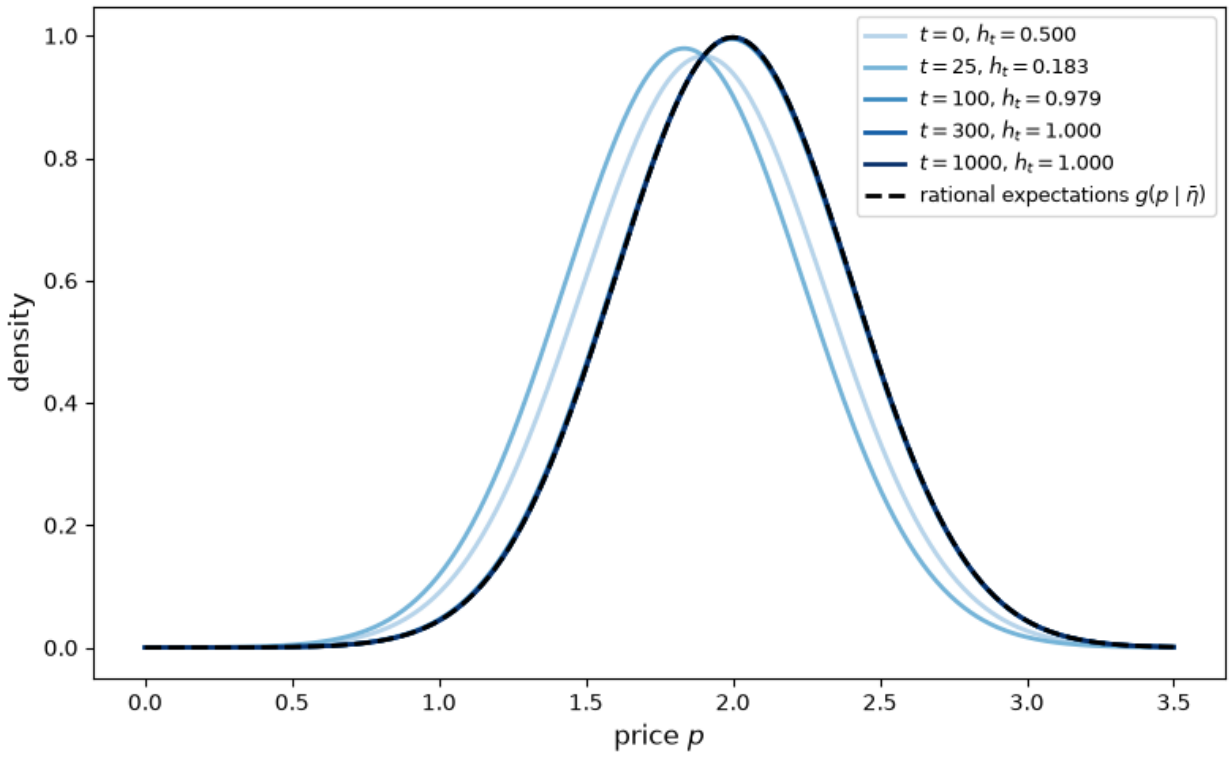

Fig. 32.4: price distribution convergence

32.6.2 Learning the reduced form without identifying the structure

The convergence result is particularly striking because the observer converges to *rational expectations* even when the underlying **structure** λ is *not identified* by prices.

To illustrate this, consider a case with *three* possible structures $\lambda^{(1)}, \lambda^{(2)}, \lambda^{(3)}$ but only *two* reduced forms $\eta_1 = \{\lambda^{(1)}, \lambda^{(2)}\}$ and $\eta_2 = \{\lambda^{(3)}\}$ (because $\lambda^{(1)}$ and $\lambda^{(2)}$ generate the same price distribution).

We continue with the hard-to-learn parameterization, so the three structures have price means $\bar{p}_1 = \bar{p}_2 = 2.0$ and $\bar{p}_3 = 1.8$, with common standard deviation $\sigma_p = 0.4$, a uniform prior $h_0 = (1/3, 1/3, 1/3)$, and $T = 400$ periods over 30 paths.

The true structure is $\lambda^{(1)}$.

```
def simulate_learning_3struct(
    T, h0_vec, p_bar_vec, σ_p, true_idx, n_paths, seed=0
):
    """Simulate learning with three structures and two reduced forms."""
    rng = np.random.default_rng(seed)
    h_paths = np.zeros((n_paths, T + 1, 3))
    h_paths[:, 0, :] = h0_vec

    for path in range(n_paths):
        h = np.array(h0_vec, dtype=float)
        prices = rng.normal(p_bar_vec[true_idx], σ_p, size=T)
        for t, p in enumerate(prices):
            likelihoods = norm.pdf(p, loc=p_bar_vec, scale=σ_p)
            h = h * likelihoods
```

(continues on next page)

(continued from previous page)

```
            h /= h.sum()
            h_paths[path, t + 1, :] = h

    return h_paths

# Structures 0 and 1 share the same reduced form
p_bar_vec = np.array([2.0, 2.0, 1.8])
h0_vec = np.array([1 / 3, 1 / 3, 1 / 3])
σ_p = 0.4
T = 400
true_idx = 0      # Structure 0 is observationally equivalent to 1

h_paths_3 = simulate_learning_3struct(
    T, h0_vec, p_bar_vec, σ_p, true_idx, n_paths=30
)
t_grid = np.arange(T + 1)

fig, axes = plt.subplots(1, 3, figsize=(13, 4), sharey=True)
struct_labels = [
    r"$\lambda^{(1)}$",
    r"$\lambda^{(2)}$",

plt.tight_layout()
plt.show()
```

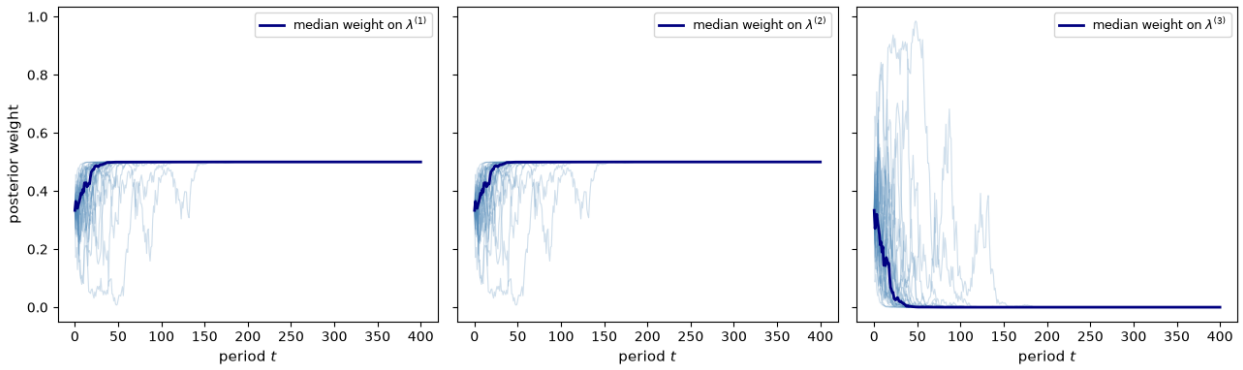

Fig. 32.5: learning with non-identification

The observer correctly rules out $\lambda^{(3)}$ (the wrong reduced form) with probability one, but cannot distinguish $\lambda^{(1)}$ from $\lambda^{(2)}$ because they generate an identical price distribution.

Nevertheless, the observer's **price expectations** converge to rational expectations because both structures imply the same reduced form $\bar{\eta}$.

The next figure plots the posterior mass on the true class, $H_t(\bar{\eta}) = h_t(\lambda^{(1)}) + h_t(\lambda^{(2)})$, and the share of that mass assigned to $\lambda^{(1)}$.

```
H_true = h_paths_3[:, :, 0] + h_paths_3[:, :, 1]
share_1 = h_paths_3[:, :, 0] / H_true

fig, axes = plt.subplots(1, 2, figsize=(11, 4))
for path_H, path_s in zip(H_true, share_1):
    axes[0].plot(t_grid, path_H, alpha=0.25, lw=0.8, color="steelblue")
    axes[1].plot(t_grid, path_s, alpha=0.25, lw=0.8, color="steelblue")
axes[0].plot(t_grid, np.median(H_true, axis=0), color="navy", lw=2,
             label="median")
axes[0].set_ylabel(r"$H_t(\bar\eta)$", fontsize=11)
axes[1].set_ylabel(r"$h_t(\lambda^{(1)}) / H_t(\bar\eta)$", fontsize=11)
axes[1].set_ylim(0, 1)
for ax in axes:
    ax.set_xlabel("period $t$", fontsize=11)
axes[0].legend(fontsize=9)
plt.tight_layout()
plt.show()

print(f"max over paths of 1 - H_T:          {(1 - H_true[:, -1]).max():.1e}")
print(f"max deviation of share from 1/2:  {np.abs(share_1 - 0.5).max():.1e}")
```

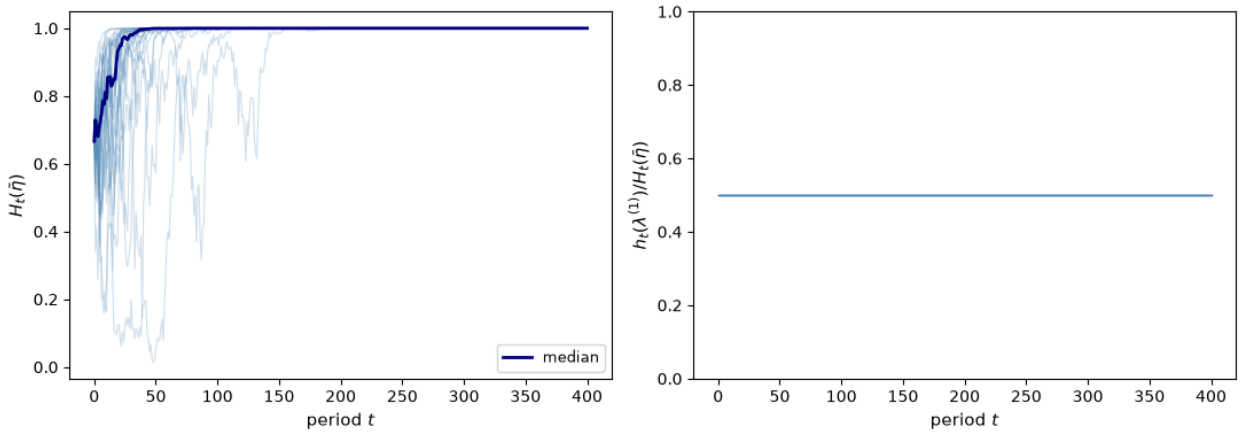

Fig. 32.6: posterior mass on the true reduced-form class

```
max over paths of 1 - H_T:          1.3e-13
max deviation of share from 1/2:  0.0e+00
```

$H_t(\bar{\eta})$ converges to one on every path.

The share $h_t(\lambda^{(1)})/H_t(\bar{\eta})$ stays at its prior value $1/2$ for every t, because $\lambda^{(1)}$ and $\lambda^{(2)}$ assign the same likelihood to every price.

32.7 Exercises

Exercise 32.7.1

CARA portfolio utility and the stock-market interpretation.

Consider a two-state economy ($a_1 = 2$, $a_2 = 0.5$) where the informed agent has **CARA** (constant absolute risk aversion) preferences over portfolio wealth:

$$u(W) = -e^{-\gamma W}, \quad W = x_2 + \bar{a}\, x_1.$$

The agent chooses x_1 to maximize

$$q\, u(W_1) + (1-q)\, u(W_2), \quad W_s = w - p\, x_1 + a_s\, x_1,$$

subject to the budget constraint $p\, x_1 + x_2 = w$.

Total supply of good 1 is $X_1 = 1$.

1. Derive the first-order condition for the informed agent's optimal x_1.
2. Use the market-clearing condition $x_1 = 1$ (the informed agent absorbs the entire supply) to obtain an implicit equation for the equilibrium price $p^*(q)$, and solve it numerically for $q \in (0,1)$ and several values of γ.
3. Show *analytically* that $p^*(q)$ admits the closed form

$$p^*(q) = \frac{a_2 + R(q,\gamma)\, a_1}{1 + R(q,\gamma)}, \qquad R(q,\gamma) = \frac{q}{1-q}\, e^{-\gamma(a_1 - a_2)},$$

and verify that $p^*(q)$ is strictly increasing in q.

Solution

For the first-order condition, define $W_s = w + (a_s - p)\, x_1$ for $s = 1, 2$.

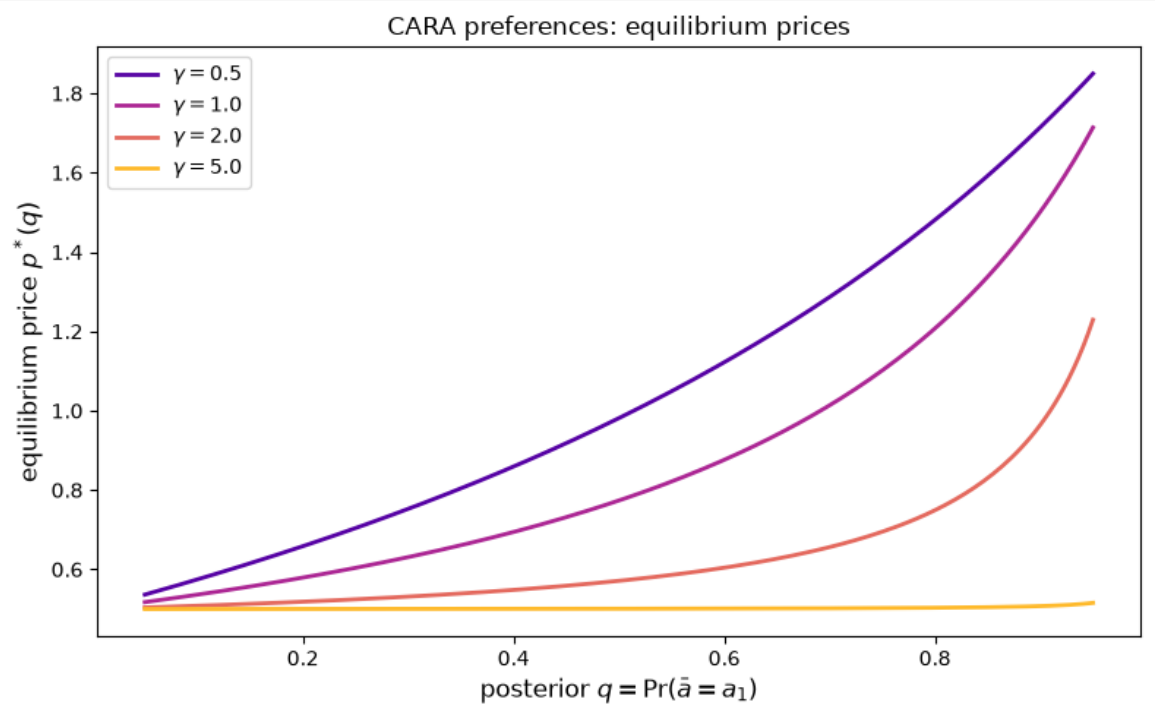
Then the FOC is

$$q\,(a_1 - p)\,\gamma\, e^{-\gamma W_1} = (1-q)\,(p - a_2)\,\gamma\, e^{-\gamma W_2},$$

or equivalently, after dividing both sides by $\gamma e^{-\gamma w}$,

$$q\,(a_1 - p)\, e^{-\gamma(a_1 - p)x_1} = (1-q)\,(p - a_2)\, e^{\gamma(p - a_2)x_1}.$$

Setting $x_1 = 1$ (the informed agent absorbs all supply), this becomes a scalar root-finding problem in p:



$$F(p;\, q, \gamma) \equiv q\,(a_1 - p)\, e^{-\gamma(a_1 - p)} - (1-q)\,(p - a_2)\, e^{\gamma(p - a_2)} = 0.$$

```
def F_cara(p, q, a1, a2, γ, x1=1.0):
    """Residual for the CARA equilibrium condition."""
    return (q * (a1 - p) * np.exp(-γ * (a1 - p) * x1)
            - (1 - q) * (p - a2) * np.exp(γ * (p - a2) * x1))

a1, a2 = 2.0, 0.5
q_grid = np.linspace(0.05, 0.95, 200)
γ_values = [0.5, 1.0, 2.0, 5.0]
colors_sol = plt.cm.plasma(np.linspace(0.15, 0.85, len(γ_values)))
```

```
fig, ax = plt.subplots(figsize=(8, 5))
for γ, color in zip(γ_values, colors_sol):
    p_eq = [brentq(F_cara, a2, a1,
                   args=(q, a1, a2, γ))
            for q in q_grid]
    ax.plot(q_grid, p_eq, lw=2, color=color,
            label=rf"$\gamma = {γ}$")

ax.set_xlabel(r"posterior $q = \Pr(\bar a = a_1)$", fontsize=12)
ax.set_ylabel("equilibrium price $p^*(q)$", fontsize=12)
ax.set_title("CARA preferences: equilibrium prices", fontsize=12)
ax.legend(fontsize=10)
plt.tight_layout()
plt.show()
```

The price is strictly increasing in q for every $\gamma > 0$.

For the closed form, start from the FOC at $x_1 = 1$, divide both sides by $(1-q)(p-a_2)e^{-\gamma(a_1-p)}$, and combine the exponentials:

$$\frac{q\,(a_1 - p)}{(1-q)\,(p-a_2)} = e^{\gamma(a_1 - a_2)}.$$

Rearranging gives

$$\frac{p-a_2}{a_1-p} = \frac{q}{1-q}\,e^{-\gamma(a_1-a_2)} \equiv R(q,\gamma),$$

and solving the resulting linear equation in p yields

$$p^*(q) = \frac{a_2 + R(q,\gamma)\,a_1}{1 + R(q,\gamma)}.$$

Since $R(q,\gamma)$ is strictly increasing in q and $dp^*/dR = (a_1 - a_2)/(1+R)^2 > 0$, the equilibrium price $p^*(q)$ is strictly increasing in q.

The closed form is an exponentially tilted expectation.

With $x_1 = 1$ we have $e^{-\gamma W_s} = e^{-\gamma(w-p)}e^{-\gamma a_s}$, so the first-order condition is $\sum_s \mu_s(a_s - p)e^{-\gamma a_s} = 0$ for a posterior $\mu = (\mu_1, \ldots, \mu_S)$, and

$$p^* = \frac{\sum_s \mu_s\, a_s\, e^{-\gamma a_s}}{\sum_s \mu_s\, e^{-\gamma a_s}}.$$

The price is the expected value of $\bar{a}$ under the probabilities $\tilde{\mu}_s \propto \mu_s e^{-\gamma a_s}$, which tilt the insider's posterior toward low-payoff states.

With $\mu = (q, 1-q)$, dividing the numerator and denominator by $(1-q)e^{-\gamma a_2}$ gives the formula for $p^*(q)$ above.

```
def p_tilted(μ, a, γ):
    """Equilibrium price as an exponentially tilted expectation."""
    weights = np.asarray(μ) * np.exp(-γ * np.asarray(a))
    return weights @ np.asarray(a) / weights.sum()

gap = max(abs(brentq(F_cara, a2, a1, args=(q, a1, a2, γ))
              - p_tilted([q, 1 - q], [a1, a2], γ))
          for γ in γ_values for q in q_grid)
print(f"largest gap between root-finding and closed form: {gap:.1e}")
```

```
largest gap between root-finding and closed form: 5.0e-13
```

This exercise uses the stock-market interpretation emphasized by Kihlstrom and Mirman [1975].

Portfolio wealth is $W = x_2 + \bar{a}\,x_1$, so ax_1 and x_2 are perfect substitutes in each state.

Hence the elasticity of substitution between the two arguments of $u(ax_1, x_2)$ is infinite, corresponding to the $\sigma > 1$ side of *Theorem 32.4.1*.

The difference is that this example is not the full equilibrium model the theorem analyzes, but rather a partial equilibrium model with a single informed agent and a fixed supply of the risky asset.

Exercise 32.7.2

In the Bayesian learning simulation, the speed of convergence to rational expectations is determined by the **Kullback-Leibler divergence** (*Statistical Divergence Measures*) between the two reduced forms.

The KL divergence $D_{KL}(\eta_1 \| \eta_2)$ from $g(\cdot \mid \eta_1)$ to $g(\cdot \mid \eta_2)$, for two normal distributions with means $\bar{p}_1$ and $\bar{p}_2$ and common variance σ_p^2, is

$$D_{KL}(\eta_1 \| \eta_2) = \frac{(\bar{p}_1 - \bar{p}_2)^2}{2\sigma_p^2},$$

which is symmetric in the two means under equal variances.

Let η_1, with $\bar{p}_1 = 2.0$, be the true reduced form, and set $\sigma_p = 0.4$ and $h_0 = 1/2$.

1. Compute D_{KL} for the "easy" case ($\bar{p}_2 = 1.2$), the "hard" case ($\bar{p}_2 = 1.8$), the intermediate cases $\bar{p}_2 \in \{1.4, 1.6\}$, and a harder case $\bar{p}_2 = 1.9$.
2. For each case simulate 1,000 paths and compute the first period $T_{0.99}$ at which $h_t \geq 0.99$.

Plot histograms of $T_{0.99}$ for the easy and hard cases.

3. Show that under the true model the log posterior odds $\ell_t = \log[h_t/(1-h_t)]$ follow a random walk with drift D_{KL} and per-period variance $2D_{KL}$.

   Use Wald's identity to argue that

$$\mathbb{E}[T_{0.99}] \approx \frac{\log\big[(0.99/0.01)\big/(h_0/(1-h_0))\big]}{D_{KL}}$$

   when D_{KL} is small, so that $T_{0.99} \approx C/D_{KL}$ with $C \approx \log 99 \approx 4.6$ for $h_0 = 1/2$.

4. Plot the mean and median of $T_{0.99}$ against D_{KL} on log-log scales, together with the line $\log 99/D_{KL}$, and explain the deviations.

Solution

Here is one solution.

Write $\Delta = \bar{p}_1 - \bar{p}_2$.

The log likelihood ratio of one price is

$$\xi = \log \frac{g(p \mid \eta_1)}{g(p \mid \eta_2)} = \frac{\Delta\,(2p - \bar{p}_1 - \bar{p}_2)}{2\sigma_p^2}.$$

Under the true model $p = \bar{p}_1 + \sigma_p \varepsilon$ with $\varepsilon \sim N(0,1)$, so $\xi = \Delta^2/(2\sigma_p^2) + (\Delta/\sigma_p)\varepsilon$, which has mean D_{KL} and variance $\Delta^2/\sigma_p^2 = 2D_{KL}$.

Bayes' law adds one such increment to ℓ_t each period, so ℓ_t is a random walk with drift D_{KL} and variance $2D_{KL}$ per period.

$T_{0.99}$ is the first time ℓ_t reaches $b = \log 99$.

Wald's identity gives $\mathbb{E}[\ell_T] = \ell_0 + D_{KL}\,\mathbb{E}[T]$, so

$$\mathbb{E}[T_{0.99}]\, D_{KL} = b - \ell_0 + \mathbb{E}[\ell_T - b].$$

The last term is the overshoot of the boundary.

It is of the order of one step's standard deviation $\sqrt{2D_{KL}}$, so it vanishes relative to $b - \ell_0$ as $D_{KL} \to 0$.

```
def log_odds_paths(p_true, p_alt, σ, h0, n_paths, T, seed=42):

plt.tight_layout()
plt.show()
```

Both the mean and the median of $T_{0.99}$ fall roughly in proportion to $1/D_{KL}$, so learning is faster when the two reduced forms are easier to distinguish.

The product $\mathbb{E}[T_{0.99}]D_{KL}$ falls toward $\log 99 = 4.6$ as D_{KL} shrinks.

By Wald's identity the gap equals the expected overshoot, and the columns "mean T*D" and "log 99 + overshoot" agree up to sampling error.

In the easy case a single price moves ℓ_t by about two units, so the boundary is overshot by a wide margin and $\mathbb{E}[T_{0.99}]D_{KL}$ exceeds $\log 99$ substantially.

The median lies below the mean because the first-passage time is skewed to the right.

In the small-D_{KL} limit ℓ_t behaves like a Brownian motion with drift, $T_{0.99}$ is inverse Gaussian with mean $\log 99/D_{KL}$ and shape $(\log 99)^2/(2D_{KL})$, and its median is $0.825\log 99/D_{KL}$.

Exercise 32.7.3

Theorem 32.5.1 requires the prior to assign positive probability to the true reduced-form class $\bar{\eta}$, equivalently to some structure that generates the true price distribution $g(\cdot \mid \bar{\eta})$.

In this exercise the true reduced form itself is excluded from the prior support, so we investigate what happens when no model in the prior generates the true price distribution.

Simulate $T = 1,000$ periods of prices from $N(2.0, 0.4^2)$ but use a prior that places equal weight on two *wrong* models: $N(1.5, 0.4^2)$ and $N(2.3, 0.4^2)$.

Plot the posterior weight on each model over time.

Discuss your findings.

Solution

Here is one solution:

```
def simulate_misspecified(
    T, p_bar_true, p_bar_wrong, σ_p, h0, n_paths, seed=0
):
    """Simulate learning under a misspecified two-model prior."""
    rng = np.random.default_rng(seed)
    h_paths = np.zeros((n_paths, T + 1, 2))
    h_paths[:, 0, :] = h0

Closer misspecified mean: 2.3
```

Here

$$D_{KL}(N(2.0, 0.4^2) \,\|\, N(2.3, 0.4^2)) < D_{KL}(N(2.0, 0.4^2) \,\|\, N(1.5, 0.4^2)),$$

so the model with mean 2.3 is the KL-best approximation among the two wrong models, and in the simulation posterior weight concentrates on that model.

Posterior odds are cumulative *likelihood ratios*.

Write $g_\star$ for the true price density $N(2.0, 0.4^2)$, write g_1 and g_2 for the wrong models $N(1.5, 0.4^2)$ and $N(2.3, 0.4^2)$, and write $h_t^{(1)}, h_t^{(2)}$ for the posterior weights on them.

The log posterior odds on g_2 against g_1 are

$$\log \frac{h_t^{(2)}}{h_t^{(1)}} = \log \frac{h_0^{(2)}}{h_0^{(1)}} + \sum_{\tau=1}^{t} \log \frac{g_2(p^\tau)}{g_1(p^\tau)}.$$

Under $g_\star$ each term in the sum has mean $D_{KL}(g_\star \| g_1) - D_{KL}(g_\star \| g_2) = 0.78125 - 0.28125 = 0.5 > 0$, by the formula in *A helpful formula* of *Likelihood Ratio Processes*.

So the odds drift toward g_2, the model that is closer to $g_\star$ in Kullback–Leibler divergence, and $h_t^{(2)} \to 1$.

The predictive density converges to g_2 rather than to $g_\star$: price expectations settle down, but not on rational expectations.

The prior puts no mass on the true reduced form, so the absolute-continuity condition behind *Theorem 32.5.1* fails.

Incorrect Models studies the same mechanism when the true distribution is a mixture that lies outside the agent's set of models.

Exercise 32.7.4

Theorem 32.4.1 covers two states.

This exercise shows what changes with three.

Use the CES economy of the lecture with $\sigma = 2$ ($\rho = 0.5$), $W_1 = 4$, and three states $(a_1, a_2, a_3) = (2, 1, 0.5)$.

1. Show that at a fixed price p the first-order condition is linear in the posterior μ, so the set of posteriors that support p is the intersection of a line with the simplex.
2. Write a function that computes the equilibrium price for any posterior μ, find two distinct posteriors that support the same price, and verify the result numerically.
3. Plot the level sets of $p(\mu)$ over the simplex.
4. Explain why $p(\cdot)$ can nonetheless be one-to-one on the finite set M of posteriors generated by a signal with finitely many values, and why the two-state theorem is not contradicted.

   Check the claim with randomly drawn signal likelihoods.

Solution

Here is one solution.

At a fixed price the bundle $x(p) = (1, W_1 - p)$ is fixed, and the first-order condition reads

$$\sum_{s=1}^{3} \mu_s \, c_s(p) = 0, \qquad c_s(p) = a_s u_1(a_s, W_1 - p) - p \, u_2(a_s, W_1 - p).$$

The numbers $c_s(p)$ do not depend on μ.

Together with $\sum_s \mu_s = 1$, this is two linear equations in three unknowns.

Their solutions form a line, and the line meets the simplex in a segment of posteriors that all support the price p.

With two states the simplex is itself a segment, and the single equation $q\,c_1(p) + (1-q)\,c_2(p) = 0$ has at most one solution unless $c_1(p) = c_2(p) = 0$, which a constant sign of $\alpha_1\beta_2 - \alpha_2\beta_1$ rules out.

```
def eq_price_S(μ, a, W1, ρ):
    """Equilibrium price when agent 1 holds posterior μ over states a."""
    μ, a = np.asarray(μ, dtype=float), np.asarray(a, dtype=float)

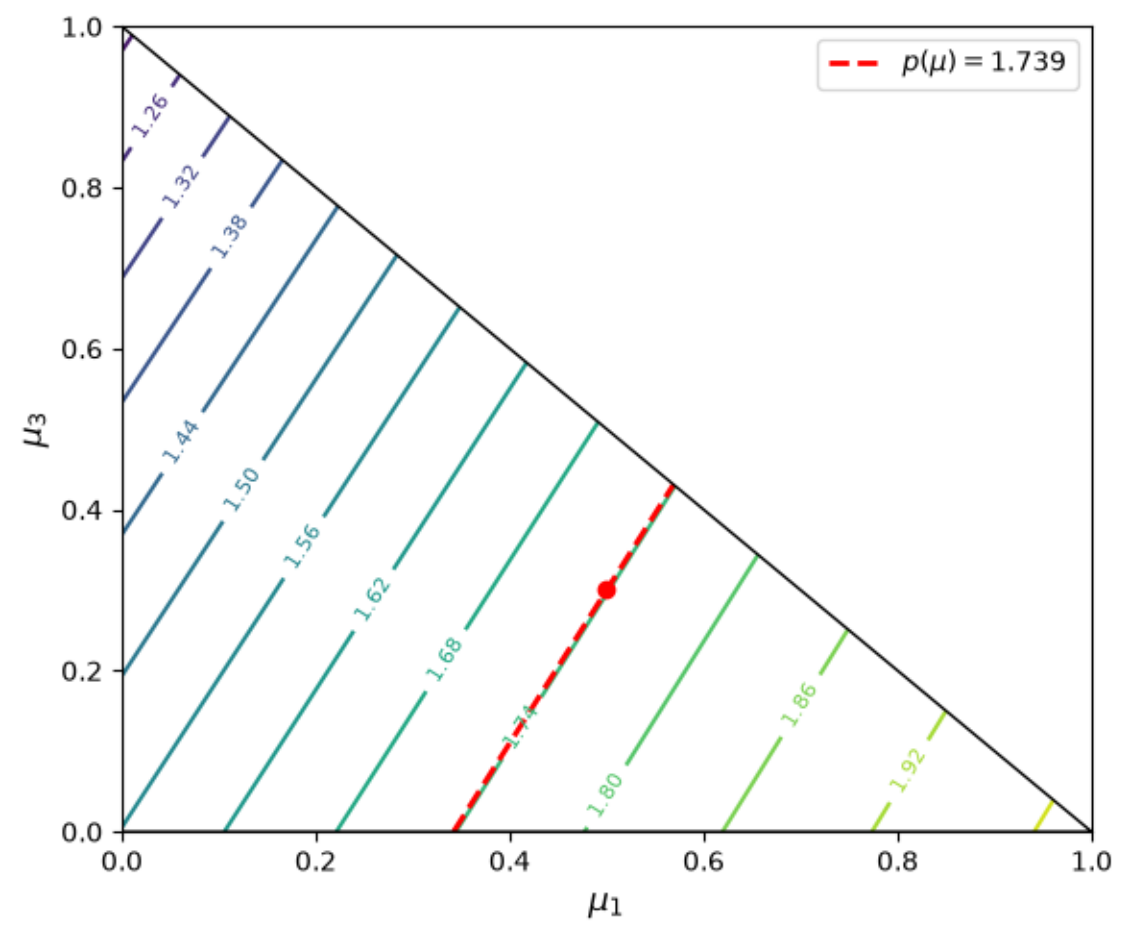
    def residual(p):
        u1, u2 = ces_derivatives(a, W1 - p, ρ)
        return μ @ (a * u1 - p * u2)

    return brentq(residual, 1e-6, W1 - 1e-6, xtol=1e-12)

a3, W1_3, ρ_3 = np.array([2.0, 1.0, 0.5]), 4.0, 0.5
μ_star = np.array([0.5, 0.2, 0.3])
p_star = eq_price_S(μ_star, a3, W1_3, ρ_3)

u1, u2 = ces_derivatives(a3, W1_3 - p_star, ρ_3)
c = a3 * u1 - p_star * u2
v = np.linalg.svd(c, np.ones(3))[-1]          # v @ c = 0 and v.sum() = 0

# range of t with μ_star + t v in the simplex
t_lo = max(-μ_star[i] / v[i] for i in range(3) if v[i] > 0)
t_hi = min(-μ_star[i] / v[i] for i in range(3) if v[i] < 0)
```



```
p(μ_star) = 1.7388112483

μ = [0.3737 0.5663 0.06  ]   p(μ) = 1.7388112483
μ = [0.4369 0.3831 0.18  ]   p(μ) = 1.7388112483
μ = [0.5 0.2 0.3]   p(μ) = 1.7388112483
μ = [0.5276 0.12   0.3524]   p(μ) = 1.7388112483
μ = [0.5552 0.04   0.4048]   p(μ) = 1.7388112483
```

Five distinct posteriors support the same price to ten decimal places.

```
n = 81
grid = np.linspace(0, 1, n)
P = np.full((n, n), np.nan)
for i, m1 in enumerate(grid):
    for j, m3 in enumerate(grid):
        if m1 + m3 <= 1:
            P[j, i] = eq_price_S([m1, 1 - m1 - m3, m3], a3, W1_3, ρ_3)

fig, ax = plt.subplots(figsize=(6, 5))
cs = ax.contour(grid, grid, P, levels=15, cmap="viridis")
ax.clabel(cs, fontsize=8, fmt="%.2f")
ends = np.array([μ_star + t * v for t in [t_lo, t_hi]])
ax.plot(ends[:, 0], ends[:, 2], "r--", lw=2, label=fr"$p(\mu) = {p_star:.3f}$")
ax.plot(μ_star[0], μ_star[2], "ro")
ax.plot([0, 1, 0, 0], [0, 0, 1, 0], color="black", lw=1)
ax.set_xlabel(r"$\mu_1$", fontsize=12)
ax.set_ylabel(r"$\mu_3$", fontsize=12)
ax.legend(fontsize=10)
plt.tight_layout()
plt.show()
```

The level sets of $p(\mu)$ are straight lines across the simplex, so $p(\cdot)$ is not one-to-one on the whole simplex.

Theorem 32.3.1 requires less: $p(\cdot)$ must be one-to-one on the finite set M of posteriors that the signal can generate.

Two posteriors in M share a price only if one lies on the level line through the other.

That coincidence imposes one equation on the signal likelihoods, and a small perturbation of the likelihoods destroys it.

```
rng = np.random.default_rng(1)
μ0 = np.ones(3) / 3
gaps = []
for _ in range(500):
    ψ = rng.dirichlet(np.ones(4), size=3)        # P(signal | state), 4 signals
    joint = μ0[:, None] * ψ
    posteriors = (joint / joint.sum(axis=0)).T  # one posterior per signal
    prices = np.sort([eq_price_S(m, a3, W1_3, ρ_3) for m in posteriors])
    gaps.append(np.diff(prices).min())

print(f"smallest price gap within a draw, over 500 draws: {min(gaps):.2e}")
```

```
smallest price gap within a draw, over 500 draws: 8.10e-05
```

In every draw the four posteriors support four distinct prices, so the price is sufficient for the signal.

With finitely many signal values, invertibility on M holds generically even though it fails on the simplex.

Exercise 32.7.5

This exercise measures merging of opinions in the two-model example.

Take the hard case: the true reduced form $\bar{\eta} = \eta_1$ has $\bar{p}_1 = 2.0$, the alternative η_2 has $\bar{p}_2 = 1.8$, $\sigma_p = 0.4$, and $h_0 = 1/2$.

Write $H_t = H_t(\bar{\eta})$.

1. Show that $\|g(\cdot \mid p^1, \ldots, p^t) - g(\cdot \mid \bar{\eta})\|_{\text{TV}} = (1 - H_t)\,\|g(\cdot \mid \eta_2) - g(\cdot \mid \bar{\eta})\|_{\text{TV}}$, and evaluate the last factor for two normal densities with a common variance.
2. Show that for the joint distribution of the next k prices the distance is $(1 - H_t)\bigl[2\Phi\bigl(\sqrt{k}\,|\bar{p}_1 - \bar{p}_2| / (2\sigma_p)\bigr) - 1\bigr]$, $where \Phi$ is the standard normal distribution function.

   Conclude that the distance d_t between the observer's and the true conditional distributions of the entire future price sequence is $1 - H_t$.
3. Compute and plot both distances along 40 simulated paths of length 300.
4. Relate the results to *Theorem 35.4.1* and *Theorem 35.7.1* in *Merging of Opinions: The Blackwell–Dubins Theorem*.

Solution

Here is one solution.

The predictive density is $H_t\, g(\cdot \mid \bar{\eta}) + (1 - H_t)\, g(\cdot \mid \eta_2)$, so

$$g(\cdot \mid p^1, \ldots, p^t) - g(\cdot \mid \bar{\eta}) = (1 - H_t)\bigl[g(\cdot \mid \eta_2) - g(\cdot \mid \bar{\eta})\bigr],$$

and the total variation distance scales by $1 - H_t$.

Two normal densities with a common variance cross at the midpoint of their means, so

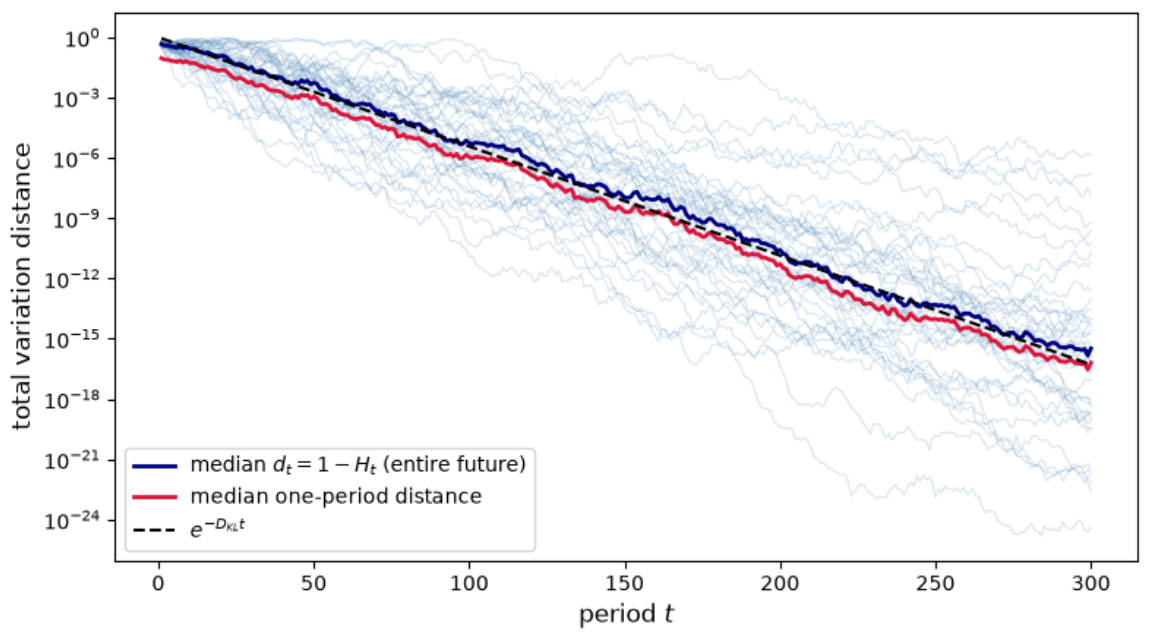
$$\|N(\bar{p}_1, \sigma_p^2) - N(\bar{p}_2, \sigma_p^2)\|_{\text{TV}} = 2\Phi\Bigl(\frac{|\bar{p}_1 - \bar{p}_2|}{2\sigma_p}\Bigr) - 1.$$

Conditional on the reduced form, the next k prices are i.i.d., so the same argument applies to their joint density.

Their sum is a sufficient statistic for the mean, so the distance between the two k-fold products equals the distance between $N(k\bar{p}_1, k\sigma_p^2)$ and $N(k\bar{p}_2, k\sigma_p^2)$, which is $2\Phi(\sqrt{k}\,|\bar{p}_1 - \bar{p}_2|/(2\sigma_p)) - 1$.

As $k \to \infty$ this distance rises to one.

The two i.i.d. price laws are mutually singular, as *Theorem 35.7.1* asserts, so $d_t = 1 - H_t$.



```
from scipy.special import expit

Δ = 2.0 - 1.8
tv_one = 2 * norm.cdf(Δ / (2 * σ_p)) - 1
print(f"one-period distance between the two models: {tv_one:.4f}")
for k in [1, 10, 100, 1_000]:
    print(f"  k = {k:5d}:  2Φ(√k Δ / 2σ) - 1 = "
          f"{2 * norm.cdf(np.sqrt(k) * Δ / (2 * σ_p)) - 1:.4f}")

ell = log_odds_paths(2.0, 1.8, σ_p, h0=0.5, n_paths=40, T=300)
one_minus_H = expit(-ell)                       # 1 - H_t, computed stably
t_vals = np.arange(1, 301)

fig, ax = plt.subplots(figsize=(8, 4.5))
for path in one_minus_H:
    ax.semilogy(t_vals, path, color="steelblue", alpha=0.2, lw=0.8)
ax.semilogy(t_vals, np.median(one_minus_H, axis=0), color="navy", lw=2,
            label=r"median $d_t = 1 - H_t$ (entire future)")
ax.semilogy(t_vals, tv_one * np.median(one_minus_H, axis=0), color="crimson",
            lw=2, label="median one-period distance")
D_hard = Δ**2 / (2 * σ_p**2)
ax.semilogy(t_vals, np.exp(-D_hard * t_vals), "k--", lw=1.5,
            label=r"$e^{-D_{KL} t}$")
ax.set_xlabel("period $t$", fontsize=12)
ax.set_ylabel("total variation distance", fontsize=12)
ax.legend(fontsize=10)
plt.tight_layout()
plt.show()
```

```
one-period distance between the two models: 0.1974
  k =     1:  2Φ(√k Δ / 2σ) - 1 = 0.1974
  k =    10:  2Φ(√k Δ / 2σ) - 1 = 0.5708
  k =   100:  2Φ(√k Δ / 2σ) - 1 = 0.9876
  k =  1000:  2Φ(√k Δ / 2σ) - 1 = 1.0000
```

The observer's subjective distribution of the price sequence is $P = h_0 Q^* + (1 - h_0) Q_2$, where Q^* and Q_2 make prices i.i.d. with densities $g(\cdot \mid \bar{\eta})$ and $g(\cdot \mid \eta_2)$.

Because $h_0 > 0$, $Q^* \ll P$, and *Theorem 35.4.1* asserts that $d_t \to 0$ almost surely under Q^*.

Because Q^* and Q_2 are mutually singular, $d_t = 1 - H_t$, so merging of opinions about the entire future and $H_t \to 1$ are the same event.

With countably many classes the argument is the same.

Each class $\eta \neq \bar{\eta}$ assigns probability zero to some event of Q^*-probability one, and the intersection of these countably many events still has Q^*-probability one, so again $d_t = 1 - H_t(\bar{\eta})$.

The one-period distance is smaller than d_t by the factor 0.197, because one price distinguishes $N(2.0, 0.4^2)$ from $N(1.8, 0.4^2)$ poorly.

Both distances fall at the exponential rate $D_{KL} = 0.125$ per period, the drift of the log posterior odds.

CHAPTER

THIRTYTHREE

INCORRECT MODELS

GPU

This lecture was built using a machine with access to a GPU — although it will also run without one.

Google Colab has a free tier with GPUs that you can access as follows:

1. Click on the "play" icon top right
2. Select Colab
3. Set the runtime environment to include a GPU

```
!pip install numpyro
```

33.1 Overview

This is a sequel to *Likelihood Ratio Processes and Bayesian Learning*.

We discuss two ways to create a compound lottery and their consequences.

A compound lottery can be said to create a *mixture distribution*.

Our two ways of constructing a compound lottery will differ in their *timing*.

- in one, mixing between two possible probability distributions will occur once and for all at the beginning of time
- in the other, mixing between the same two possible probability distributions will occur each period

The statistical setting is close but not identical to the problem studied in that lecture.

In that lecture, there were two IID processes that could possibly govern successive draws of a non-negative random variable W.

Nature decided once and for all whether to make a sequence of IID draws from either f or from g.

That lecture studied an agent who knew both f and g but did not know which distribution nature chose at time -1.

The agent represented that ignorance by assuming that nature had chosen f or g by flipping an unfair coin that put probability π_{-1} on probability distribution f.

That assumption allowed the agent to construct a subjective joint probability distribution over the random sequence $\{W_t\}_{t=0}^{\infty}$.

We studied how the agent would then use the laws of conditional probability and an observed history $w^t = \{w_s\}_{s=0}^t$ to form

$$\pi_t = \mathbb{P}\{q = f \mid w^t\}, \quad t = 0, 1, 2, ...$$

where $q \in \{f, g\}$ denotes the distribution that nature chose.

However, in the setting of this lecture, that rule imputes to the agent an incorrect model.

The reason is that now the wage sequence is actually described by a different statistical model.

Thus, we change the specification in *Likelihood Ratio Processes and Bayesian Learning* in the following way.

Now, **each period** $t \geq 0$, nature flips a possibly unfair coin that comes up f with probability α and g with probability $1 - \alpha$.

Thus, nature perpetually draws from the **mixture distribution** with CDF

$$H(w) = \alpha F(w) + (1 - \alpha)G(w), \quad \alpha \in (0, 1)$$

and density

$$h(w|\alpha) = \alpha f(w) + (1 - \alpha)g(w).$$

We'll study two agents who try to learn about the wage process, but who use different statistical models.

Both types of agent know f and g but neither knows α.

Our first type of agent erroneously thinks that at time -1, nature once and for all chose f or g and thereafter permanently draws from that distribution.

Our second type of agent knows, correctly, that nature mixes f and g with mixing probability $\alpha \in (0, 1)$ each period, though the agent doesn't know the mixing parameter.

Our first type of agent applies the learning algorithm described in *Likelihood Ratio Processes and Bayesian Learning*.

In the context of the statistical model that prevailed in that lecture, that was a good learning algorithm and it enabled the Bayesian learner eventually to learn the distribution that nature had drawn at time -1.

This is because the agent's statistical model was *correct* in the sense of being aligned with the data generating process.

But in the present context, our type 1 decision maker's model is incorrect because the model h that actually generates the data is neither f nor g and so is beyond the support of the models that the agent thinks are possible.

Nevertheless, we'll see that our first type of agent muddles through and eventually learns something interesting and useful, even though it is not *true*.

Instead, it turns out that our type 1 agent who is armed with a wrong statistical model ends up learning whichever probability distribution, f or g, is in a special sense *closest* to the h that actually generates the data.

We'll tell the sense in which it is closest.

Our second type of agent understands that nature mixes between f and g each period with a fixed mixing probability α.

But the agent doesn't know α.

The agent sets out to learn α using Bayes' law applied to his model.

His model is correct in the sense that it includes the actual data generating process h as a possible distribution.

Both agents' statistical models are exchangeable mixtures of IID sequences of the kind described by de Finetti's theorem in *Exchangeability and Bayesian Updating*.

The type 1 agent's mixing measure puts probability π_{-1} on IID draws from f and probability $1 - \pi_{-1}$ on IID draws from g.

The type 2 agent's mixing measure is a prior density $\pi_{-1}(\alpha)$ over IID draws from $h(\cdot|\alpha)$, $\alpha \in (0,1)$.

Nature's process, IID draws from $h(\cdot|\alpha)$, lies inside the support of the type 2 agent's mixing measure and outside the support of the type 1 agent's mixing measure.

That is the sense in which the type 1 agent's model is misspecified.

The two timings of mixing leave different marks on the data.

When nature mixes anew each period, successive draws are independent and $\text{Cov}(W_0, W_1) = 0$.

When nature mixes once and for all with probability π on f, $\text{Cov}(W_0, W_1) = \pi(1-\pi)(\mu_f - \mu_g)^2$, where μ_f and μ_g are the means of f and g; see Exercise Exercise **??** in *Exchangeability and Bayesian Updating*.

Merging of Opinions: The Blackwell–Dubins Theorem studies agents who, like our type 2 agent, mix IID sequences with a prior over a parameter.

In this lecture, we'll learn about

- how nature can *mix* between two distributions f and g to create a new distribution h.
- The Kullback-Leibler statistical divergence that governs statistical learning under an incorrect statistical model
- A useful Python function `numpy.searchsorted` that, in conjunction with a uniform random number generator, can be used to sample from an arbitrary distribution

As usual, we'll start by importing some Python tools.

```
import matplotlib.pyplot as plt
import seaborn as sns
import numpy as np
from scipy.integrate import quad
from scipy.optimize import brentq, minimize_scalar
from scipy.special import expit, logit

import numpyro
import jax
import numpyro.distributions as dist
from numpyro.infer import MCMC, NUTS
import jax.numpy as jnp
import jax.scipy.stats as jsp
from jax import random
from jax.scipy.special import gamma

# Enable JAX to use 64-bit float operations
jax.config.update("jax_enable_x64", True)

colors = sns.color_palette()
```

Let's use Python to generate two Beta distributions.

```
# Parameters in the two beta distributions.
F_a, F_b = 1, 1
G_a, G_b = 3, 1.2

@jax.jit
def p(x, a, b):
    r = gamma(a + b) / (gamma(a) * gamma(b))
    return r * x**(a-1) * (1 - x)**(b-1)

# The two density functions.
```

(continues on next page)

(continued from previous page)

```
f = jax.jit(lambda x: p(x, F_a, F_b))
g = jax.jit(lambda x: p(x, G_a, G_b))
```

33.2 Sampling from compound lottery H

We implement two methods to draw samples from our mixture model $\alpha F + (1-\alpha)G$.

We'll generate samples using each of them and verify that they match well.

Here is pseudo code for a direct "method 1" for drawing from our compound lottery:

- Step one:
  - use a uniform random draw to flip an unfair coin that selects distribution F with prob α and G with prob $1-\alpha$
- Step two:
  - draw from either F or G, as determined by the coin flip.
- Step three:
  - put the first two steps in a big loop and do them for each realization of w

Our second method uses a uniform distribution and the following fact that we also described and used in *Some Probability Distributions*:

- If a random variable X has CDF F, then a random variable $F^{-1}(U)$ also has CDF F, where U is a uniform random variable on $[0, 1]$.

In other words, if $X \sim F(x)$ we can generate a random sample from F by drawing a random sample from a uniform distribution on $[0, 1]$ and computing $F^{-1}(U)$.

We'll use this fact in conjunction with the `numpy.searchsorted` command to sample from H directly.

See the `numpy.searchsorted` documentation for details on the `searchsorted` function.

In the Python code below, we'll use both of our methods and confirm that each of them does a good job of sampling from our target mixture distribution.

```
def draw_lottery(key, α, N):
    """Draw from the compound lottery directly."""
    # split the key: one for the coin flip, one for each distribution
    key_uniform, key_beta1, key_beta2 = jax.random.split(key, 3)

    u = jax.random.uniform(key_uniform, shape=(N,))
    f_draws = jax.random.beta(key_beta1, F_a, F_b, shape=(N,))

plt.hist(sample2, 50, density=True, alpha=0.5, label="MC draws")

xs = np.linspace(0, 1, 1000)
plt.plot(xs, α * f(xs) + (1 - α) * g(xs), color="red", label="density", lw=2)

plt.legend()
plt.show()
```

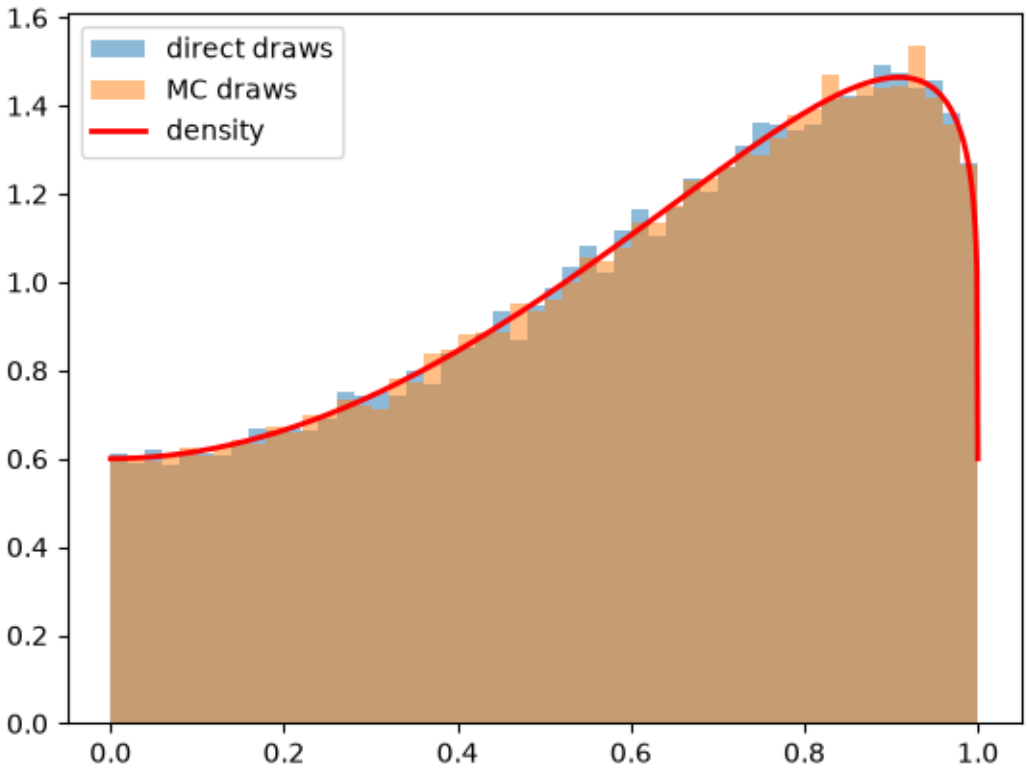

Fig. 33.1: Direct and Monte Carlo draws

33.3 Type 1 agent

We'll now study what our type 1 agent learns.

Remember that our type 1 agent uses the wrong statistical model, thinking that nature mixed between f and g once and for all at time -1.

The type 1 agent thus uses the learning algorithm studied in *Likelihood Ratio Processes and Bayesian Learning*.

We'll briefly review that learning algorithm now.

Let π_t be a Bayesian posterior defined as

$$\pi_t = \mathbb{P}\{q = f \mid w^t\}$$

The likelihood ratio process plays a principal role in the formula that governs the evolution of the posterior probability π_t, an instance of **Bayes' law**.

Bayes' law implies that $\{\pi_t\}$ obeys the recursion

$$\pi_t = \frac{\pi_{t-1}\ell(w_t)}{\pi_{t-1}\ell(w_t) + 1 - \pi_{t-1}} \tag{33.1}$$

with π_{-1} being a Bayesian prior probability that $q = f$, i.e., a personal or subjective belief about q based on our having seen no data.

Here $\ell(w) = f(w)/g(w)$ is the likelihood ratio.

Iterating on (33.1), as in *Likelihood Ratio Processes and Bayesian Learning*, expresses the time t posterior π_t as a function of the prior π_{-1} and the likelihood ratio process $L(w^t) = \prod_{s=0}^{t} \ell(w_s)$:

$$\pi_t = \frac{\pi_{-1} L\left(w^t\right)}{\pi_{-1} L\left(w^t\right) + 1 - \pi_{-1}}. \tag{33.2}$$

Formula (33.2) can be regarded as a one step revision of prior probability π_{-1} after seeing the batch of data $\{w_s\}_{s=0}^{t}$.

In terms of log odds, formula (33.2) is

$$\log \frac{\pi_t}{1-\pi_t} = \log \frac{\pi_{-1}}{1-\pi_{-1}} + \log L(w^t). \tag{33.3}$$

Our code computes π_t from (33.3).

Iterating on (33.1) in floating point arithmetic accumulates rounding errors once π_t gets close to 0 or 1.

33.4 What a type 1 agent learns when mixture H generates data

We now study what happens when the mixture distribution $h(\cdot|\alpha)$ truly generated the data each period.

For all but one value of α, the sequence π_t continues to converge, despite the agent's misspecified model, and the limit is either 0 or 1.

This is true even though in truth nature always mixes between f and g.

After verifying that claim about possible limit points of π_t sequences, we'll drill down and study what fundamental force determines the limiting value of π_t.

Let's set a value of α and then watch how π_t evolves.

```
def simulate_mixed(key, α, T=50, N=500):
    """
    Generate N sets of T observations of the likelihood ratio,
    return as N x T matrix, when the true density is h(·|α)
    """

    w_s = draw_lottery(key, α, N * T).reshape(N, T)
    l_arr = f(w_s) / g(w_s)
    return l_arr

def plot_π_seq(key, α, π1=0.2, π2=0.8, T=200):
    """
    Compute and plot π_t for two priors and the log likelihood ratio process
    when the mixture h(·|α) governs the data.
    """

    l_arr_mixed = simulate_mixed(key, α, T=T, N=1)
    log_L = np.cumsum(np.log(l_arr_mixed[0]))     # log L(w^t), t = 0, ..., T-1

    # plot
    fig, ax1 = plt.subplots()
    for π_init in (π1, π2):
        π_path = expit(logit(π_init) + log_L)
        ax1.plot(
            range(-1, T),
            np.concatenate(([π_init], π_path)),
            label=rf"$\pi_{{-1}}$={π_init}",
            lw=2,
        )

    ax1.plot(
        np.nan, np.nan, "--", color="b",
        label="Log likelihood ratio process", lw=2,
    )
    ax1.set_ylabel(r"$\pi_t$")
    ax1.set_xlabel("$t$")
    ax1.legend()

    ax2 = ax1.twinx()
    ax2.plot(range(T), log_L, "--", color="b", lw=2)
    ax2.set_ylabel(r"$\log(L(w^{t}))$")

    plt.show()
```

```
plot_π_seq(jax.random.key(42), α=0.6)
```

The above graph shows a sample path of the log likelihood ratio process as the blue dashed line, together with sample paths of π_t that start from two distinct initial conditions.

Let's see what happens when we change α.

```
plot_π_seq(jax.random.key(42), α=0.2)
```

Evidently, α is having a big effect on the destination of π_t as $t \to +\infty$.

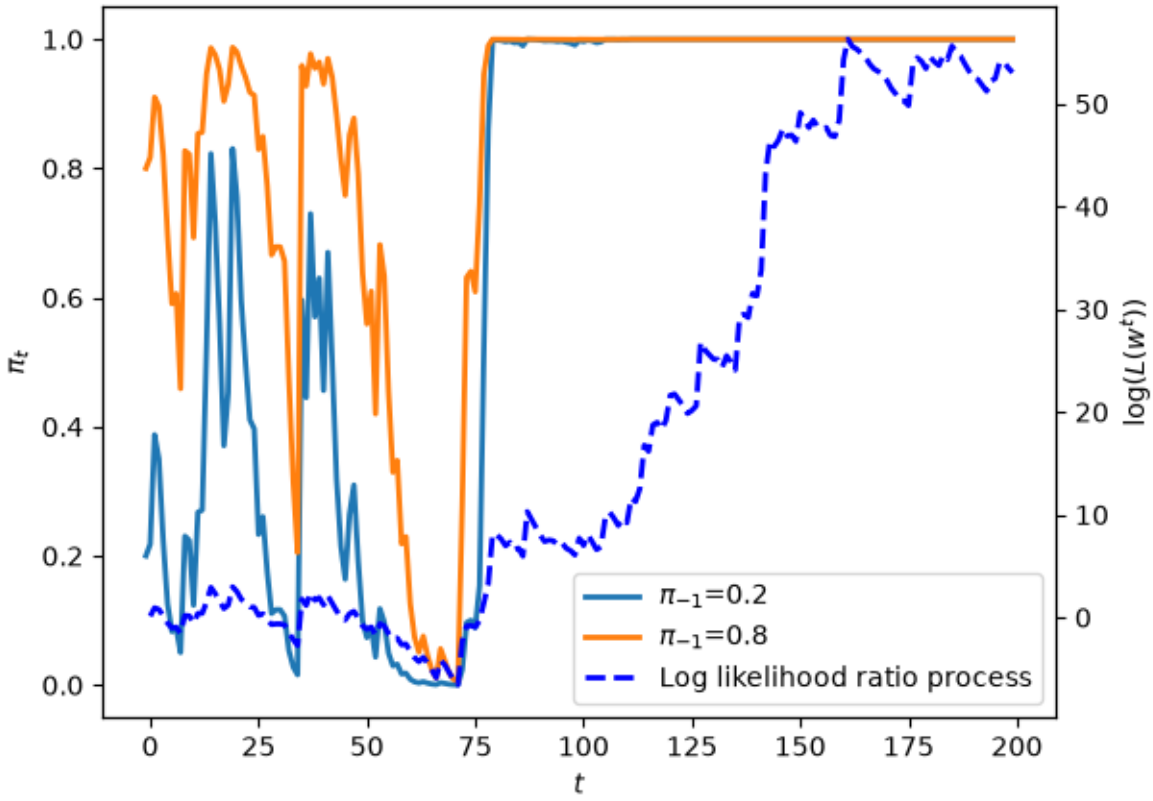

Fig. 33.2: Belief paths, $\alpha = 0.6$

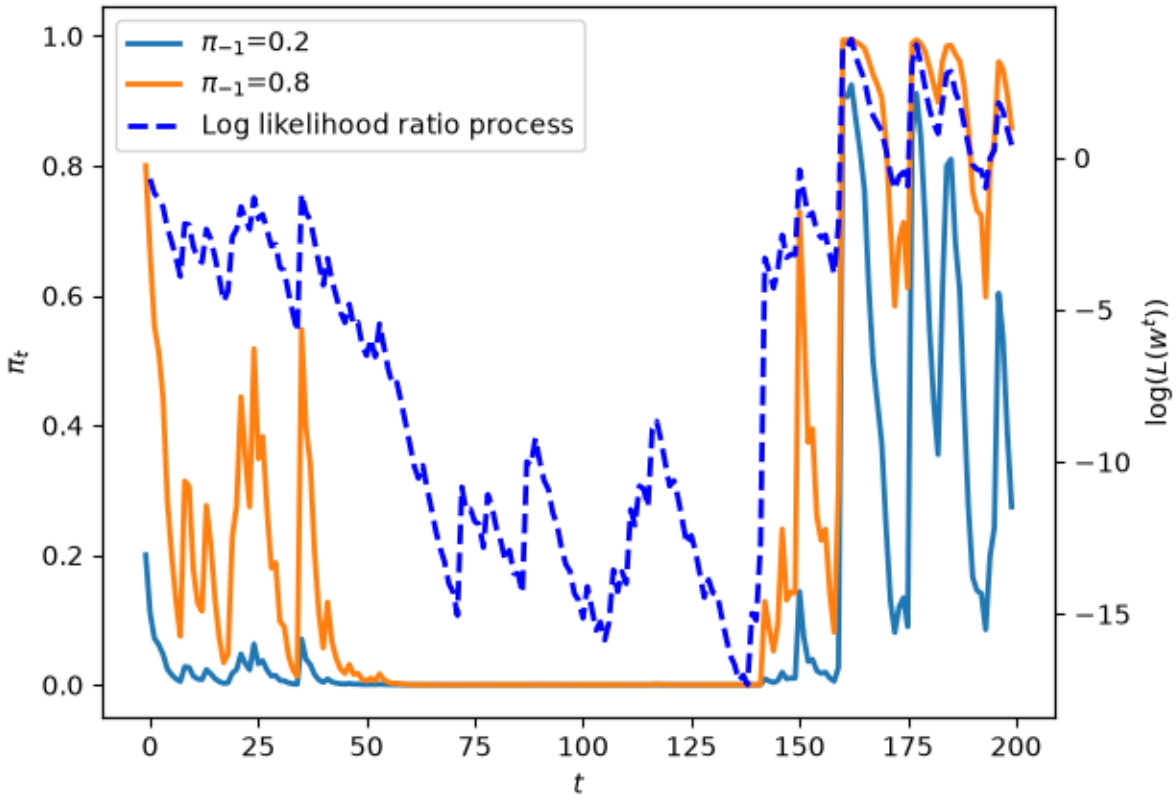

Fig. 33.3: Belief paths, $\alpha = 0.2$

33.5 Kullback-Leibler divergence governs limit of π_t

To understand what determines whether the limit point of π_t is 0 or 1 and how the answer depends on the true value of the mixing probability $\alpha \in (0, 1)$ that generates

$$h(w|\alpha) = \alpha f(w) + (1 - \alpha) g(w)$$

we shall compute the following two Kullback-Leibler divergences

$$KL_g(\alpha) = KL(h, g) = \int \log \left(\frac{h(w|\alpha)}{g(w)} \right) h(w|\alpha) dw$$

and

$$KL_f(\alpha) = KL(h, f) = \int \log \left(\frac{h(w|\alpha)}{f(w)} \right) h(w|\alpha) dw$$

We shall plot both of these functions against α as we use α to vary $h(w|\alpha)$.

Because $\log \ell(w) = \log \frac{h(w|\alpha)}{g(w)} - \log \frac{h(w|\alpha)}{f(w)}$,

$$E_h[\log \ell(w)] = KL_g(\alpha) - KL_f(\alpha),$$

where E_h denotes the expectation under $h(\cdot|\alpha)$; see *A helpful formula* and *A third distribution h* in *Likelihood Ratio Processes*.

By the law of large numbers, $\frac{1}{t+1} \log L(w^t)$ converges to $KL_g(\alpha) - KL_f(\alpha)$ with probability one.

Formula (33.3) then implies that the limit of π_t is determined by

$$\arg \min_{q \in \{f, g\}} KL(h, q).$$

As $t \to +\infty$, π_t goes to one if $KL_f(\alpha) < KL_g(\alpha)$ and goes to zero if $KL_f(\alpha) > KL_g(\alpha)$.

```
@jax.jit
def KL_g(α):
    "Compute the KL divergence KL(h, g)."
    err = 1e-8  # to avoid 0 at end points
    ws = jnp.linspace(err, 1 - err, 10000)
    gs, fs = g(ws), f(ws)
    hs = α * fs + (1 - α) * gs
    return jnp.sum(jnp.log(hs / gs) * hs) / 10000

KL_g_v = jax.vmap(KL_g)

@jax.jit
def KL_f(α):
    "Compute the KL divergence KL(h, f)."
    err = 1e-8  # to avoid 0 at end points
    ws = jnp.linspace(err, 1 - err, 10000)
    gs, fs = g(ws), f(ws)
    hs = α * fs + (1 - α) * gs
    return jnp.sum(jnp.log(hs / fs) * hs) / 10000
```

(continues on next page)

(continued from previous page)

```
KL_f_v = jax.vmap(KL_f)

@jax.jit
def π_lim(key, α, T=5000, π_init=0.4):
    """Compute π_{T-1} from the log odds formula eq:logodds_mix."""
    # Get lottery draws
    l_arr = simulate_mixed(key, α, T, N=1)[0]
    log_odds = jnp.log(π_init / (1 - π_init)) + jnp.sum(jnp.log(l_arr))
    return jax.nn.sigmoid(log_odds)

π_lim_v = jax.vmap(π_lim)
```

Let us first plot the KL divergences $KL_g(\alpha), KL_f(\alpha)$ for each α.

```
α_arr = np.linspace(0, 1, 100)
KL_g_arr = KL_g_v(α_arr)
KL_f_arr = KL_f_v(α_arr)

fig, ax = plt.subplots()

ax.plot(α_arr, KL_g_arr, label="KL(h, g)", lw=2)
ax.plot(α_arr, KL_f_arr, label="KL(h, f)", lw=2)
ax.set_ylabel("KL divergence")
ax.set_xlabel(r"$\alpha$")

ax.legend(loc="upper right")
plt.show()
```

Let's compute the α^* at which the KL divergence between h and g equals that between h and f.

Because $E_h[\log \ell(w)] = \alpha E_f[\log \ell(w)] + (1-\alpha)E_g[\log \ell(w)] = \alpha KL(f,g) - (1-\alpha)KL(g,f)$, the difference $KL_g(\alpha) - KL_f(\alpha)$ is linear in α and

$$\alpha^* = \frac{KL(g,f)}{KL(f,g) + KL(g,f)}.$$

```
def KL(q1, q2):
    "KL(q1, q2) computed with scipy's quad."
    return quad(lambda w: q1(w) * np.log(q1(w) / q2(w)), 0, 1)[0]

KL_fg, KL_gf = KL(f, g), KL(g, f)
α_star = KL_gf / (KL_fg + KL_gf)

h_star = lambda w: α_star * f(w) + (1 - α_star) * g(w)
print(f"α* = {α_star:.4f}")
print(f"KL(h, f) = {KL(h_star, f):.4f}, KL(h, g) = {KL(h_star, g):.4f} at α*")
```

```
α* = 0.3116
KL(h, f) = 0.1435, KL(h, g) = 0.1435 at α*
```

At α^*, f and g both minimize $KL(h,q)$ over $q \in \{f,g\}$.

There $\log L(w^t)$ is a random walk whose increments have mean zero.

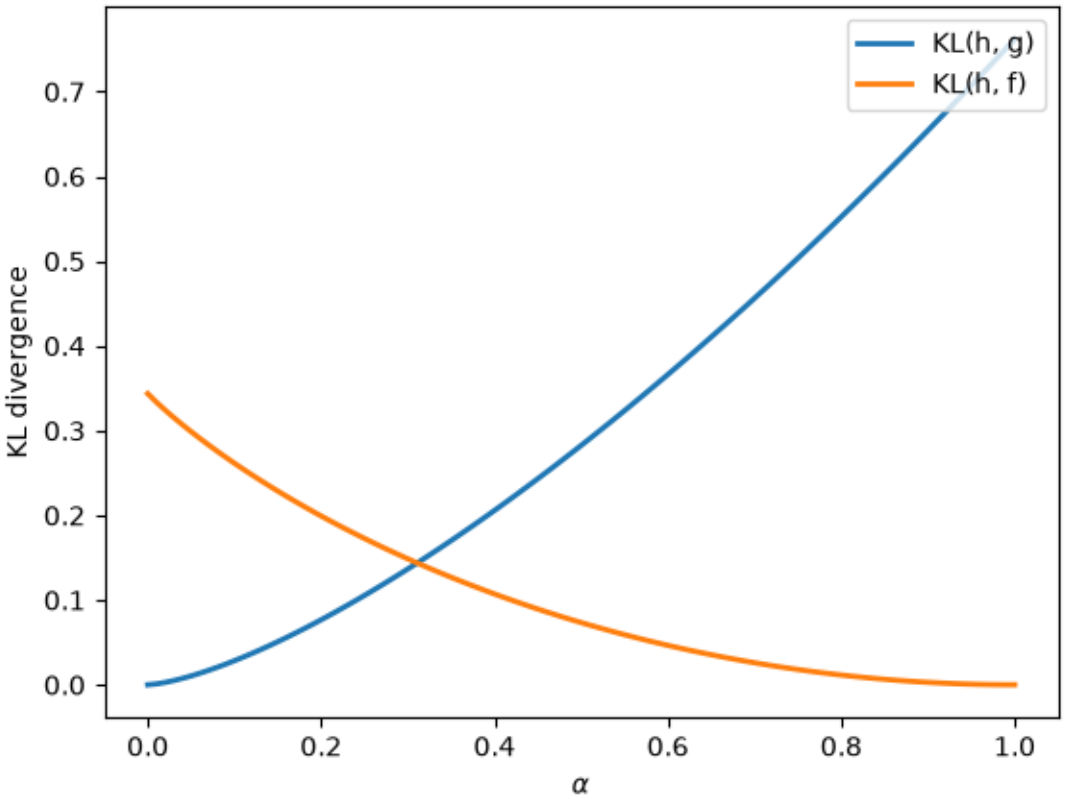

Fig. 33.4: KL divergences against α

Such a random walk is recurrent: with probability one it takes arbitrarily large positive and arbitrarily large negative values infinitely often.

So when $\alpha = \alpha^*$, π_t does not converge; it keeps returning to values near 0 and values near 1.

Exercise Exercise 33.8.2 studies this case.

We can compute and plot π_{T-1} with $T = 5000$ for each α on our grid to verify that the convergence is governed by the KL divergence.

The blue circles show the values of π_{T-1} that simulations discover for different values of α recorded on the x axis.

The dotted vertical line marks α^*.

```
keys = jax.random.split(jax.random.key(42), len(α_arr))
π_lim_arr = π_lim_v(keys, α_arr)

# plot
fig, ax = plt.subplots()

ax.plot(α_arr, KL_g_arr, label="KL(h, g)", lw=2)
ax.plot(α_arr, KL_f_arr, label="KL(h, f)", lw=2)
ax.axvline(α_star, color="k", linestyle=":", lw=1)
ax.set_ylabel("KL divergence")
ax.set_xlabel(r"$\alpha$")

# plot KL
ax2 = ax.twinx()
# plot limit point
ax2.scatter(
    α_arr,
    π_lim_arr,
    facecolors="none",
    edgecolors="tab:blue",
    label=r"$\pi_{T-1}$",
)
ax2.set_ylabel(r"$\pi_{T-1}$")

ax.legend(loc=[0.85, 0.8])
ax2.legend(loc=[0.85, 0.73])
plt.show()

wrong_side = (((α_arr < α_star) & (π_lim_arr > 0.5))
              | ((α_arr > α_star) & (π_lim_arr < 0.5)))
print("values of α at which π_{T-1} lies on the side opposite to its limit:",
      np.round(α_arr[wrong_side], 3))
```

```
values of α at which π_{T-1} lies on the side opposite to its limit: [0.293 0.313]
```

Evidently, our type 1 learner who applies Bayes' law to his misspecified set of statistical models eventually learns an approximating model that is as close as possible to the true model, as measured by its Kullback-Leibler divergence:

- When $\alpha < \alpha^*$, $KL_g < KL_f$, meaning the divergence of g from h is smaller than that of f and so the limit point of π_t is 0.
- When $\alpha > \alpha^*$, $KL_f < KL_g$, meaning the divergence of f from h is smaller than that of g and so the limit point of π_t is 1.

For α close to α^*, the drift $KL_g(\alpha) - KL_f(\alpha)$ of $\log L(w^t)$ is small relative to the standard deviation of $\log \ell(w)$, and 5000 draws are too few to settle where π_t is going.

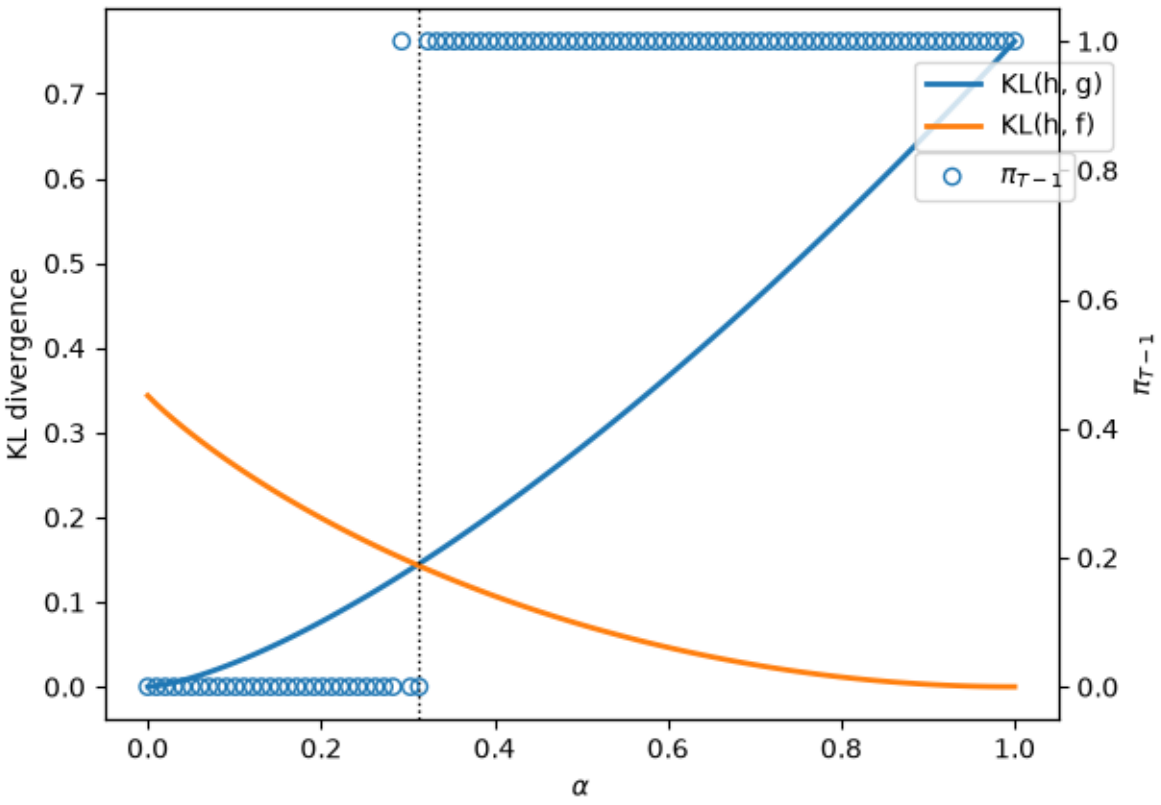

Fig. 33.5: Limit points and KL divergences

That is why the simulated values of π_{T-1} for the values of α printed above, all near α^*, lie on the side opposite to the eventual limit.

33.6 Type 2 agent

We now describe how our type 2 agent formulates his learning problem and what he eventually learns.

Our type 2 agent understands the correct statistical model but does not know α.

We apply Bayes' law to deduce an algorithm for learning α under the assumption that the agent knows that

$$h(w) = h(w|\alpha)$$

but does not know α.

We'll assume that the agent starts out with a prior probability density $\pi_{-1}(\alpha)$ on $\alpha \in (0, 1)$ where the prior has one of the forms that we deployed in *Non-Conjugate Priors*.

We'll fire up `numpyro` and apply it to the present situation.

Bayes' law now takes the form

$$\pi_{t+1}(\alpha) = \frac{h(w_{t+1}|\alpha)\pi_t(\alpha)}{\int h(w_{t+1}|\hat{\alpha})\pi_t(\hat{\alpha})d\hat{\alpha}}$$

where $\pi_t(\alpha)$ is the posterior density of α given w^t.

We'll use numpyro to approximate this equation.

We'll create graphs of the posterior $\pi_t(\alpha)$ as $t \to +\infty$ corresponding to ones presented in *Non-Conjugate Priors*.

We anticipate that a posterior distribution will collapse around the true α as $t \to +\infty$.

Let us try a uniform prior first.

We use the `Mixture` class in numpyro to construct the likelihood function.

```
a = 0.8
sizes = [5, 20, 50, 200, 1000, 25000]

# simulate data with true a
data = draw_lottery(jax.random.key(42), a, max(sizes))

def model(w):
    a = numpyro.sample("a", dist.Uniform(low=0.0, high=1.0))

    y_samp = numpyro.sample(
        "w",
        dist.Mixture(
            dist.Categorical(jnp.array([a, 1 - a])),
            [dist.Beta(F_a, F_b), dist.Beta(G_a, G_b)],
        ),
        obs=w,
    )

def MCMC_run(ws):
    "Compute posterior using MCMC with observed ws"
```

(continues on next page)

(continued from previous page)

```
    kernel = NUTS(model)
    mcmc = MCMC(kernel, num_samples=5000, num_warmup=1000, progress_bar=False)

    mcmc.run(rng_key=random.key(42), w=jnp.array(ws))
    sample = mcmc.get_samples()
    return sample["α"]
```

The following code generates the graph below that displays Bayesian posteriors for α at various history lengths.

```
fig, ax = plt.subplots()

for i in range(len(sizes)):
    sample = MCMC_run(data[: sizes[i]])
    sns.histplot(
        data=sample,
        kde=True,
        stat="density",
        alpha=0.2,
        ax=ax,
        color=colors[i],
        binwidth=0.02,
        linewidth=0.05,
        label=f"t={sizes[i]}",
    )
ax.legend()
ax.set_xlabel(r"$\alpha$")
plt.show()
```

Evidently, the Bayesian posterior narrows in on the true value $\alpha = 0.8$ of the mixing parameter as the length of a history of observations grows.

The posterior standard deviation shrinks in proportion to $1/\sqrt{t}$; Exercise Exercise 33.8.3 computes the constant of proportionality.

33.7 Concluding remarks

Our type 1 agent deploys an incorrect statistical model.

He believes that either f or g generated the w process, but just doesn't know which one.

That is wrong because nature is actually mixing each period with mixing probability α.

Our type 1 agent eventually believes that either f or g generated the w sequence, the outcome being determined by the model, either f or g, whose KL divergence relative to h is smaller.

At the knife-edge value α^*, the two divergences are equal and his beliefs never settle down.

Our type 2 agent has a different statistical model, one that is correctly specified.

He knows the parametric form of the statistical model but not the mixing parameter α.

He knows that he does not know it.

But by using Bayes' law in conjunction with his statistical model and a history of data, he eventually acquires a more and more accurate inference about α.

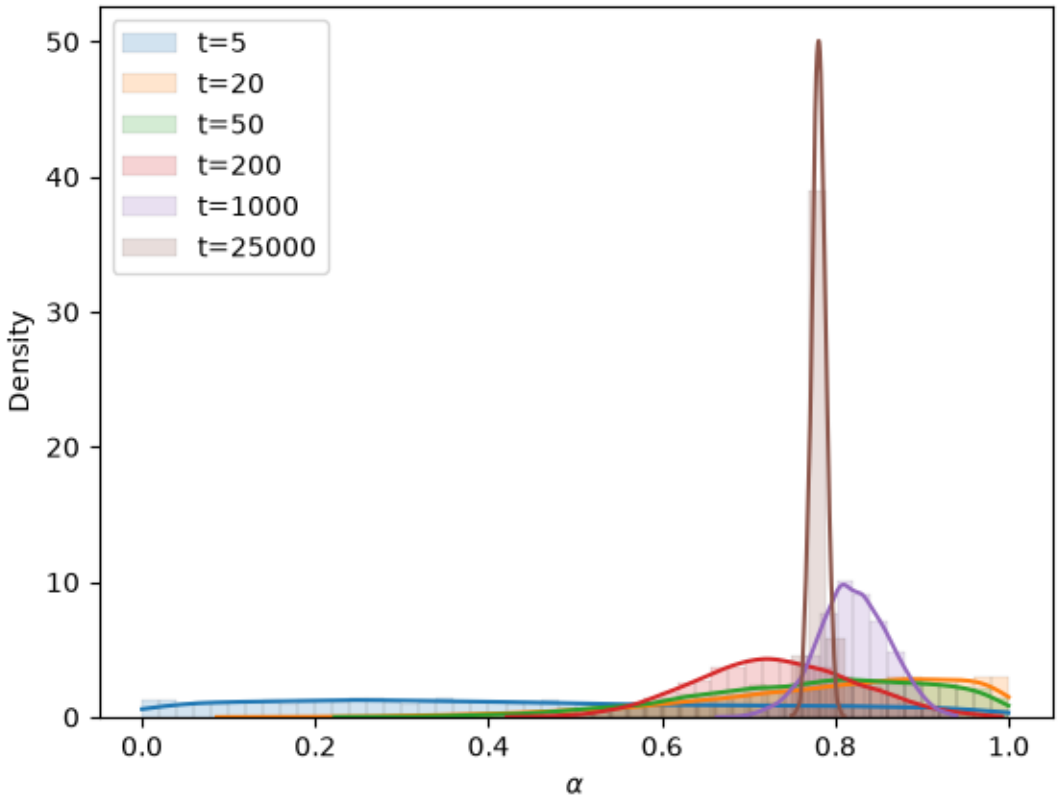

Fig. 33.6: Posterior for α as t grows

This little laboratory exhibits some important general principles that govern outcomes of Bayesian learning of misspecified models.

Thus, the following situation prevails quite generally in empirical work.

A scientist approaches the data with a manifold S of statistical models $s(X|\theta)$, where s is a probability distribution over a random vector X, $\theta \in \Theta$ is a vector of parameters, and Θ indexes the manifold of models.

The scientist with observations that he interprets as realizations x of the random vector X wants to solve an **inverse problem** of somehow *inverting* $s(x|\theta)$ to infer θ from x.

But the scientist's model is misspecified, being only an approximation to an unknown model h that nature uses to generate X.

If the scientist uses Bayes' law or a related likelihood-based method to infer θ from IID observations, then for large sample sizes his inferences concentrate on values of θ that minimize

$$KL(h \,\|\, s_\theta) = \int h(x) \log \frac{h(x)}{s(x|\theta)} dx$$

over $\theta \in \Theta$, where $s_\theta = s(\cdot|\theta)$.

Berk [1966] established this for Bayesian posterior distributions, and White [1982] established it for maximum likelihood estimators.

When the minimizer θ^* is unique, the posterior concentrates on θ^* and the maximum likelihood estimator converges to θ^*.

When several values of θ attain the minimum, the posterior concentrates on the set of minimizers but need not converge.

Our type 1 agent at $\alpha = \alpha^*$ is an instance.

The section on *KL divergence and maximum-likelihood estimation* in *Statistical Divergence Measures* shows that maximum likelihood minimizes the cross-entropy of the model relative to the empirical distribution of the data, the sample analogue of the KL divergence from the data-generating distribution to the model.

Exercise Exercise 33.8.4 studies a type 2 agent whose model is misspecified.

33.8 Exercises

Exercise 33.8.1

In *Likelihood Ratio Processes and Bayesian Learning*, we studied the consequences of applying a likelihood ratio and Bayes' law to a misspecified statistical model, namely, our type 1 agent's model, when the true data generating process is a mixture.

In this lecture, we used `numpyro` to compute posteriors of our type 2 agent, whose model is correctly specified.

This exercise asks you to replicate the type 2 agent's posterior with a grid approximation and compare it with the NUTS posterior.

Here is the algorithm.

First we specify a prior distribution for α given by $\alpha \sim \text{Beta}(a_0, b_0)$ with expectation $\mathbb{E}[\alpha] = \frac{a_0}{a_0+b_0}$.

The likelihood for a single observation w_t is $h(w_t|\alpha) = \alpha f(w_t) + (1-\alpha) g(w_t)$.

For a history $w^t = (w_0, \ldots, w_t)$, the likelihood is $\prod_{s=0}^{t} h(w_s|\alpha)$.

The posterior density is $\pi_t(\alpha) \propto \prod_{s=0}^{t} h(w_s|\alpha) \pi_{-1}(\alpha)$.

Recursively, $\pi_t(\alpha) \propto h(w_t|\alpha)\pi_{t-1}(\alpha)$.

Without a conjugate prior, we can approximate the posterior by discretizing α into a grid.

1. Implement this algorithm in Python.
2. With a uniform prior ($a_0 = b_0 = 1$), compute the posterior of α from the first $5, 20, 50, 200$, and 1000 observations in `data` and compare it with the NUTS posterior.
3. Let the true mixing probability be $\alpha = 0.5$. For a history of 200 draws, compute the paths of posterior means of α for three priors with means 0.25, 0.5, and 0.75. Then compute paths of posterior means with a uniform prior for 20 histories of $10{,}000$ draws.

Solution

Here is one solution.

We put a grid on α and update the log posterior on the grid one observation at a time.

```
α_grid = jnp.linspace(1e-3, 1 - 1e-3, 2000)
Δα = float(α_grid[1] - α_grid[0])

@jax.jit
def learn_α_bayesian(observations, a0, b0):
    """
    Sequential Bayesian learning of the mixing probability α on α_grid.
    Returns the path of posterior means, starting from the prior mean,
    and the final log posterior probabilities on the grid.
    """
    w = jnp.asarray(observations)

    # Log prior
    log_prior = (a0 - 1) * jnp.log(α_grid) + (b0 - 1) * jnp.log1p(-α_grid)
    log_prior = log_prior - jax.nn.logsumexp(log_prior)

    def scan_fn(log_post, wt):
        # h(w_t | α) = α f(w_t) + (1 - α) g(w_t)
        like = α_grid * f(wt) + (1 - α_grid) * g(wt)
        log_post = log_post + jnp.log(like)

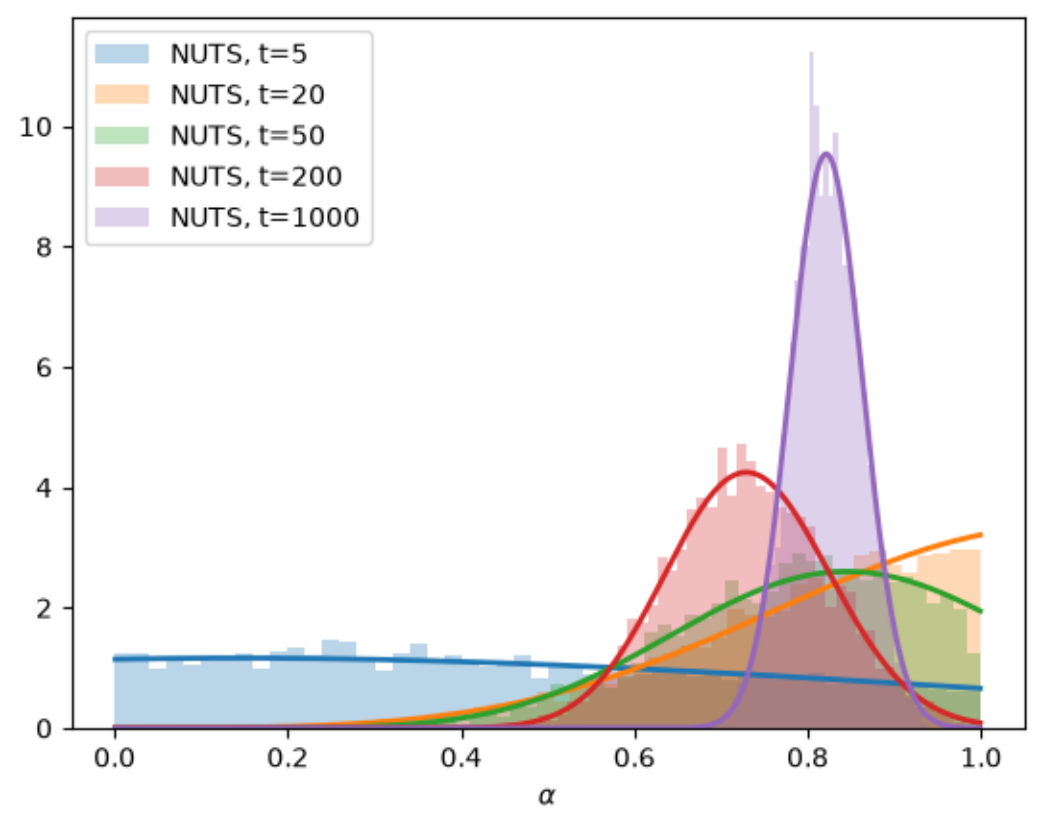
        # Normalize using log-sum-exp trick
        log_post = log_post - jax.nn.logsumexp(log_post)

        # Compute posterior mean
        μ = α_grid @ jnp.exp(log_post)

        return log_post, μ

    # Scan over observations
    log_post, μ_path = jax.lax.scan(scan_fn, log_prior, w)

    # Prepend the prior mean
    μ_prior = a0 / (a0 + b0)
    return jnp.concatenate([jnp.array([μ_prior]), μ_path]), log_post
```



Now we compare the grid posterior densities with the NUTS draws for the data used in the lecture.

```
fig, ax = plt.subplots()

for i, n in enumerate(sizes[:-1]):
    _, log_post = learn_α_bayesian(data[:n], 1.0, 1.0)
    density = np.exp(log_post) / Δα
    sample = MCMC_run(data[:n])
    ax.hist(np.asarray(sample), bins=50, density=True, alpha=0.3,
            color=colors[i], label=f"NUTS, t={n}")
    ax.plot(α_grid, density, color=colors[i], lw=2)
    print(f"t = {n:4d}: grid mean = {float(α_grid @ jnp.exp(log_post)):.4f}, "
          f"NUTS mean = {float(sample.mean()):.4f}")

ax.set_xlabel(r"$\alpha$")
ax.legend()
plt.show()
```

```
t =    5: grid mean = 0.4568, NUTS mean = 0.4487
t =   20: grid mean = 0.7885, NUTS mean = 0.7897
t =   50: grid mean = 0.7753, NUTS mean = 0.7737
t =  200: grid mean = 0.7318, NUTS mean = 0.7302
t = 1000: grid mean = 0.8216, NUTS mean = 0.8206
```

The lines are the grid posteriors and the histograms are the NUTS draws.

They agree up to Monte Carlo error in the NUTS draws.

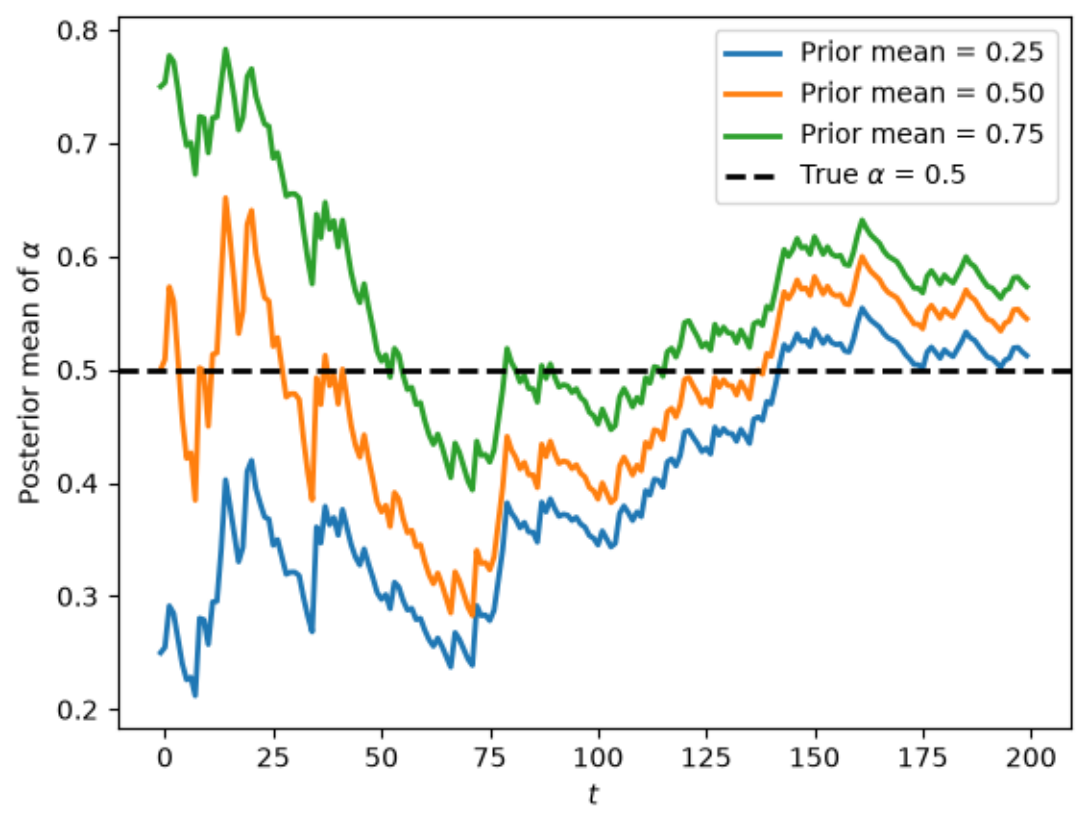
Next we study the paths of posterior means for three priors when $\alpha = 0.5$.

```
α_true = 0.5
T_mix = 200

# Three different priors with means 0.25, 0.5, 0.75
prior_params = [(1, 3), (1, 1), (3, 1)]
prior_means = [a0 / (a0 + b0) for a0, b0 in prior_params]

w_mix = draw_lottery(jax.random.key(42), α_true, T_mix)

α_posterior_means = [learn_α_bayesian(w_mix, float(a0), float(b0))[0]
                     for a0, b0 in prior_params]
```



Let's visualize how the posterior mean of α evolves over time, starting from three different prior beliefs.

```
fig, ax = plt.subplots()

for i, (α_means, mean0) in enumerate(zip(α_posterior_means, prior_means)):
    ax.plot(
        range(-1, T_mix),
        α_means,
        label=rf"Prior mean = ${mean0:.2f}$",
        color=colors[i],
        linewidth=2,
    )

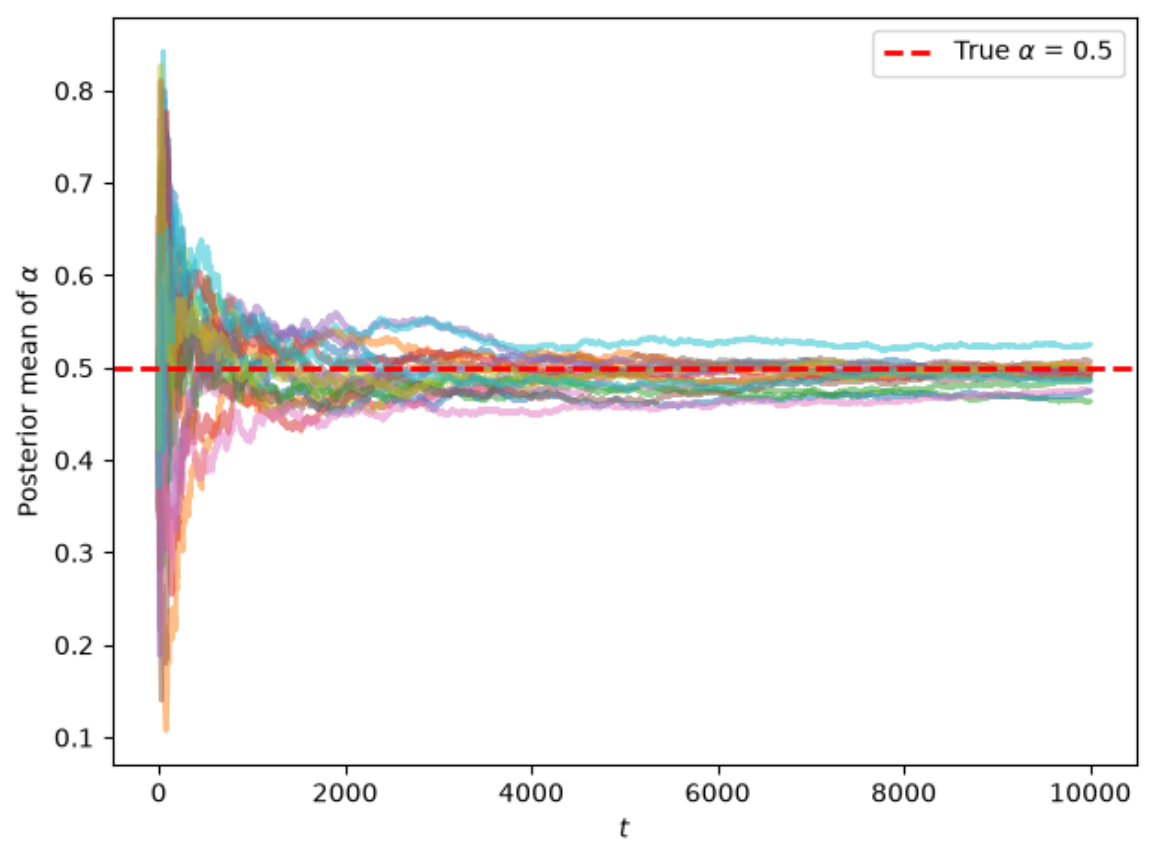
ax.axhline(
    y=α_true,
    color="black",
    linestyle="--",
    label=rf"True $\alpha$ = {α_true}",
    linewidth=2,
)
ax.set_xlabel("$t$")
ax.set_ylabel(r"Posterior mean of $\alpha$")
ax.legend()
plt.show()

for α_means, mean0 in zip(α_posterior_means, prior_means):
    print(f"prior mean {mean0:.2f}: posterior mean at t = {T_mix - 1} is {float(α_
↪means[-1]):.3f}")
```

```
prior mean 0.25: posterior mean at t = 199 is 0.512
prior mean 0.50: posterior mean at t = 199 is 0.545
prior mean 0.75: posterior mean at t = 199 is 0.573
```

All three posterior means move toward the true value $\alpha = 0.5$, and their differences shrink as t grows.

Next, let's look at multiple simulations with a longer time horizon, all starting from a uniform prior.



```
n_paths = 20
T_long = 10_000

keys = jax.random.split(jax.random.key(42), n_paths)

fig, ax = plt.subplots()

for j in range(n_paths):
    w_path = draw_lottery(keys[j], α_true, T_long)
    α_means, _ = learn_α_bayesian(w_path, 1.0, 1.0)  # Uniform prior
    ax.plot(range(-1, T_long), α_means, alpha=0.5, lw=2)

ax.axhline(
    y=α_true,
    color="red",
    linestyle="--",
    label=rf"True $\alpha$ = {α_true}",
    linewidth=2,
)
ax.set_ylabel(r"Posterior mean of $\alpha$")
ax.set_xlabel("$t$")
ax.legend()
plt.tight_layout()
plt.show()
```

We can see that the posterior mean of α converges to the true value $\alpha = 0.5$.

Exercise 33.8.2

This exercise studies the type 1 agent at the knife-edge value α^*.

1. Compute α^* by finding the root of $KL_f(\alpha) - KL_g(\alpha)$ and compare it with the formula $\alpha^* = KL(g,f)/(KL(f,g)+KL(g,f))$.
2. For $\alpha \in \{\alpha^* - 0.05, \alpha^*, \alpha^* + 0.05\}$, simulate 20 paths of $\log L(w^t)$ for $t = 0, \ldots, 19{,}999$ and plot them.
3. For each α, compute π_t from (33.3) with $\pi_{-1} = 0.5$, and count how often each path of π_t crosses $1/2$ during the second half of the sample.

Solution

We compute KL_f and KL_g with `quad` and find their crossing with `brentq`.

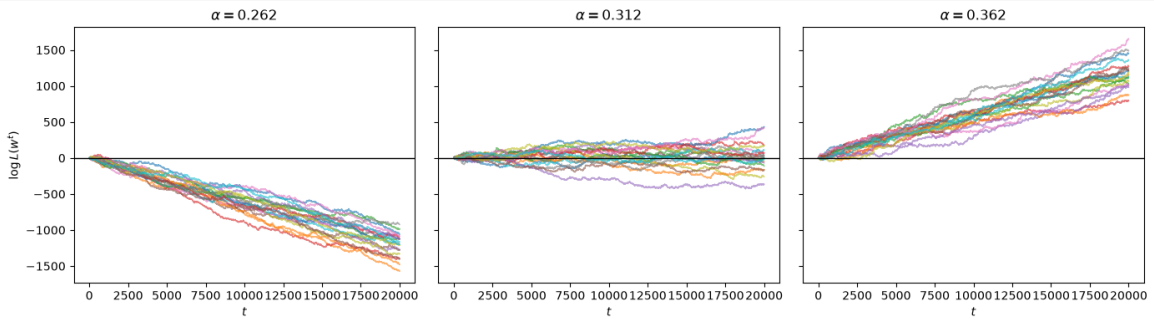
```
def KL_h(a, q):
    "KL(h, q) for h = h(·|a), computed with quad."
    h = lambda w: a * f(w) + (1 - a) * g(w)
    return KL(h, q)

a_root = brentq(lambda a: KL_h(a, f) - KL_h(a, g), 0.05, 0.95)
print(f"root of KL_f - KL_g: {a_root:.5f}")
```

```
print(f"formula:             {α_star:.5f}")
```

```
root of KL_f - KL_g: 0.31156
formula:             0.31156
```

Next we simulate paths of $\log L(w^t)$.



```
T_k, N_k = 20_000, 20
α_values = [α_star - 0.05, α_star, α_star + 0.05]

fig, axes = plt.subplots(1, 3, figsize=(14, 4), sharey=True)
for ax, α_k, key in zip(axes, α_values, jax.random.split(jax.random.key(1), 3)):
    log_L = np.cumsum(np.log(np.asarray(simulate_mixed(key, α_k, T=T_k, N=N_k))),␣
↪axis=1)
    ax.plot(log_L.T, lw=1, alpha=0.6)
    ax.axhline(0, color='k', lw=1)
    ax.set_title(rf"$\alpha = {α_k:.3f}$")
    ax.set_xlabel("$t$")

    π_paths = expit(log_L)            # π_{-1} = 0.5, so the prior log odds are␣
↪zero
    late = π_paths[:, T_k // 2:] > 0.5
    crossings = np.sum(late[:, 1:] != late[:, :-1], axis=1)
    print(f"α = {α_k:.3f}: crossings of 1/2 in second half, by path: {crossings}")

axes[0].set_ylabel(r"$\log L(w^t)$")
plt.tight_layout()
plt.show()
```

```
α = 0.262: crossings of 1/2 in second half, by path: [0 0 0 0 0 0 0 0 0 0 0 0 0␣
↪0 0 0 0 0 0 0]
α = 0.312: crossings of 1/2 in second half, by path: [58 14 11  0 63 44  0 12␣
↪23 39  0  0 41  0  0  0  0 93  0 42]
α = 0.362: crossings of 1/2 in second half, by path: [0 0 0 0 0 0 0 0 0 0 0 0 0␣
↪0 0 0 0 0 0 0]
```

At $\alpha^* \pm 0.05$, every path of $\log L(w^t)$ drifts away from zero and π_t stops crossing $1/2$.

At α^*, the paths wander without drift, and many paths of π_t still cross $1/2$ late in the sample.

A path that does not cross $1/2$ during the second half is not evidence of convergence.

A driftless random walk spends long stretches on one side of zero, and with probability one it returns.

Exercise 33.8.3

The Bernstein–von Mises theorem says that, for a correctly specified model, the posterior distribution of α after t observations is approximately normal with mean near the true α and standard deviation $1/\sqrt{tI(\alpha)}$, where

$$I(\alpha) = \int \frac{(f(w) - g(w))^2}{h(w|\alpha)} dw$$

is the Fisher information of one observation.

1. Derive $I(\alpha)$ from the log likelihood $\log h(w|\alpha)$.
2. For the data in `data` ($\alpha = 0.8$), compute the grid posterior standard deviation after 200, 1000, and 5000 observations with a uniform prior, and compare it with $1/\sqrt{tI(0.8)}$.

Solution

The score of one observation is $\frac{\partial}{\partial \alpha} \log h(w|\alpha) = \frac{f(w) - g(w)}{h(w|\alpha)}$.

Its variance under $h(\cdot|\alpha)$ is the Fisher information

$$I(\alpha) = \int \frac{(f(w) - g(w))^2}{h(w|\alpha)^2} h(w|\alpha) dw = \int \frac{(f(w) - g(w))^2}{h(w|\alpha)} dw,$$

because the score has mean $\int (f - g) dw = 0$.

```
def fisher_info(α):
    return quad(lambda w: (f(w) - g(w))**2 / (α * f(w) + (1 - α) * g(w)), 0, 1)[0]

I_08 = fisher_info(0.8)
print(f"I(0.8) = {I_08:.4f}")

for n in [200, 1000, 5000]:
    _, log_post = learn_α_bayesian(data[:n], 1.0, 1.0)
    post = jnp.exp(log_post)
    mean = α_grid @ post
    sd = jnp.sqrt(((α_grid - mean)**2) @ post)
    print(f"t = {n:4d}: posterior mean = {float(mean):.3f}, posterior sd =
↪{float(sd):.4f}, "
          f"1/sqrt(t I) = {1 / np.sqrt(n * I_08):.4f}")
```

```
I(0.8) = 0.5835
t =  200: posterior mean = 0.732, posterior sd = 0.0925, 1/sqrt(t I) = 0.0926
t = 1000: posterior mean = 0.822, posterior sd = 0.0418, 1/sqrt(t I) = 0.0414
t = 5000: posterior mean = 0.787, posterior sd = 0.0186, 1/sqrt(t I) = 0.0185
```

The posterior standard deviations are close to $1/\sqrt{tI(0.8)}$.

Exercise 33.8.4

Suppose that nature draws IID from $h(w|0.5) = 0.5f(w) + 0.5g(w)$ with $g = \text{Beta}(3, 1.2)$, as in the lecture.

A type 2 agent knows f but wrongly believes that the second component is $\tilde{g} = \text{Beta}(3, 2)$.

His model is $s(w|\alpha) = \alpha f(w) + (1 - \alpha)\tilde{g}(w)$, and he puts a uniform prior on α.

1. Compute $\tilde{\alpha} = \arg\min_\alpha KL(h, s_\alpha)$.

2. Simulate 5000 draws from $h(\cdot|0.5)$ and compute the agent's grid posterior after 200, 1000, and 5000 observations. Where does it concentrate?

Solution

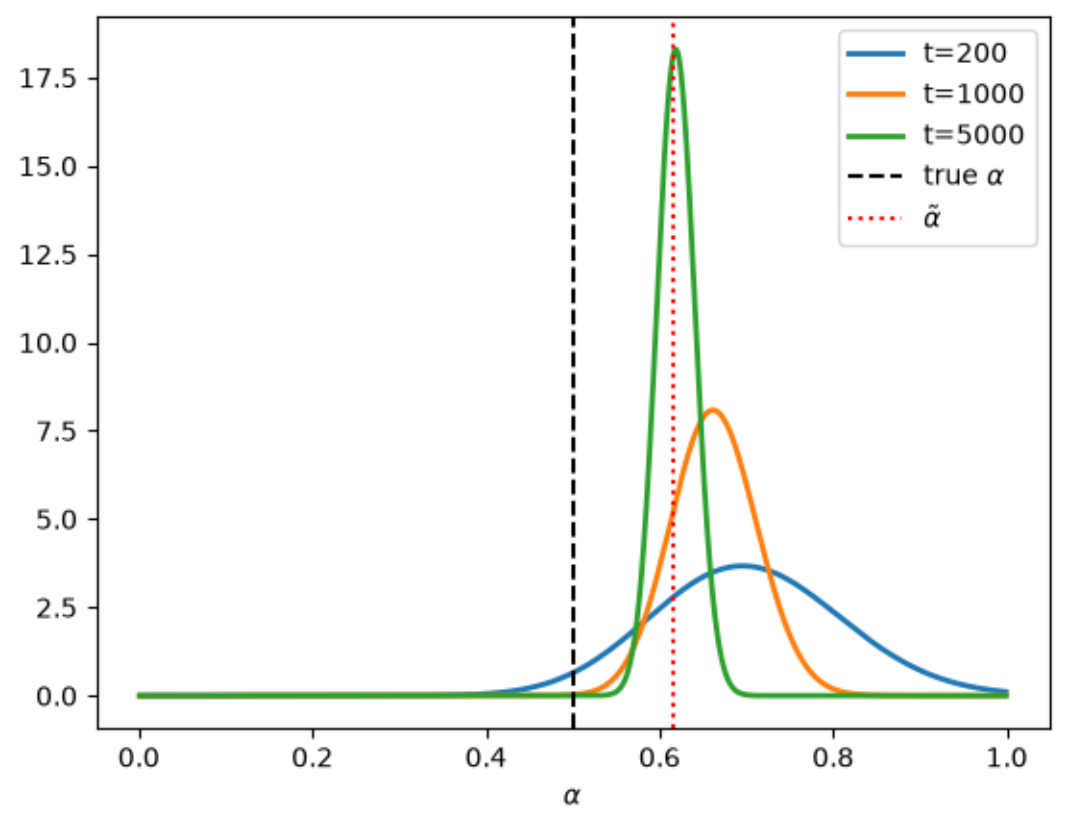
```
g_tilde = jax.jit(lambda x: p(x, 3, 2))
α_true = 0.5
h_true = lambda w: α_true * f(w) + (1 - α_true) * g(w)

def KL_misspecified(α):
    s = lambda w: α * f(w) + (1 - α) * g_tilde(w)
    return KL(h_true, s)

res = minimize_scalar(KL_misspecified, bounds=(1e-3, 1 - 1e-3), method='bounded')
α_tilde = res.x
print(f"pseudo-true value α~ = {α_tilde:.3f}, min KL = {res.fun:.4f}")
```

```
pseudo-true value α~ = 0.616, min KL = 0.0460
```

The agent's grid posterior uses $\tilde{g}$ in place of g.



```
@jax.jit
def log_post_misspecified(observations):
    "Log posterior on α_grid, uniform prior, for the model α f + (1 - α) g~."
    w = jnp.asarray(observations)
    log_like = jnp.log(α_grid[:, None] * f(w) + (1 - α_grid[:, None]) * g_tilde(w))
    log_post = jnp.sum(log_like, axis=1)
    return log_post - jax.nn.logsumexp(log_post)

w_obs = draw_lottery(jax.random.key(7), α_true, 5000)

fig, ax = plt.subplots()
for i, n in enumerate([200, 1000, 5000]):
    post = jnp.exp(log_post_misspecified(w_obs[:n]))
    mean = float(α_grid @ post)
    sd = float(jnp.sqrt(((α_grid - mean)**2) @ post))
    ax.plot(α_grid, post / Δα, color=colors[i], lw=2, label=f"t={n}")
    print(f"t = {n:4d}: posterior mean = {mean:.3f}, posterior sd = {sd:.4f}")

ax.axvline(α_true, color="k", linestyle="--", label=r"true $\alpha$")
ax.axvline(α_tilde, color="r", linestyle=":", label=r"$\tilde \alpha$")
ax.set_xlabel(r"$\alpha$")
ax.legend()
plt.show()
```

```
t =  200: posterior mean = 0.701, posterior sd = 0.1066
t = 1000: posterior mean = 0.663, posterior sd = 0.0493
t = 5000: posterior mean = 0.619, posterior sd = 0.0218
```

The posterior concentrates at the pseudo-true value $\tilde{\alpha}$, not at the true $\alpha = 0.5$.

As Berk [1966] showed, a Bayesian with a misspecified model learns the member of his family of models that is closest to the truth in Kullback–Leibler divergence.

34.1 Overview

This lecture follows up on ideas presented in the following lectures:

- *A Problem that Stumped Milton Friedman*
- *A Bayesian Formulation of Friedman and Wald's Problem*
- *Exchangeability and Bayesian Updating*
- *Likelihood Ratio Processes*
- *Likelihood Ratio Processes and Bayesian Learning*

A Problem that Stumped Milton Friedman described a problem that a Navy Captain presented to Milton Friedman during World War II.

The Navy had told the Captain to use a decision rule for comparing two designs of an ordnance device by firing test rounds.

In particular, the Navy had ordered the Captain to use an instance of a **frequentist decision rule**.

The Captain doubted that that rule was a good one.

Milton Friedman recognized the Captain's conjecture as posing a challenging statistical problem that he and other members of the US Government's Statistical Research Group at Columbia University proceeded to try to solve.

A member of the group, the great mathematician and economist Abraham Wald, soon solved the problem.

A good way to formulate the problem is to use some ideas from Bayesian statistics that we describe in *Exchangeability and Bayesian Updating* and in the section on *likelihood ratio processes and Bayes' law* of *Likelihood Ratio Processes and Bayesian Learning*, which describes the link between Bayesian updating and likelihood ratio processes.

The present lecture uses Python to generate simulations that evaluate expected losses under the Neyman-Pearson **frequentist** procedure that the Navy captain questioned and the **Bayesian** decision rule described in *A Bayesian Formulation of Friedman and Wald's Problem*.

We choose the frequentist rule's sample size and cutoff to minimize expected loss under the prior probability and losses that the Bayesian uses.

The frequentist rule then becomes a Bayes rule whose sample size is fixed in advance.

The Bayesian rule chooses its sample size sequentially.

A rule with a fixed sample size is a special sequential rule, so the best sequential rule has an expected loss no larger than the best fixed-sample rule.

Wald and Wolfowitz [1948] proved that, among all tests with given probabilities of type I and type II errors, Wald's sequential probability ratio test minimizes the expected number of draws under both hypotheses.

Arrow *et al.* [1949] showed how to compute Bayes solutions of sequential decision problems by backward induction.

Our simulations illustrate these theorems and measure how much the Navy Captain's hunch was worth.

34.2 Setup

To formalize the problem that had confronted the Navy Captain, we consider a setting with the following parts.

- Each period a decision maker draws a non-negative random variable Z. He knows that two probability distributions are possible, f_0 and f_1, and that which ever distribution it is remains fixed over time. The decision maker believes that before the beginning of time, nature once and for all had selected either f_0 or f_1 and that the probability that it selected f_0 is probability π^*.
- The decision maker observes a sample $\{z_i\}_{i=1}^t$ from the distribution chosen by nature.

The decision maker wants to decide which distribution actually governs Z.

He is worried about two types of errors and the losses that they will impose on him.

- a loss $\bar{L}_1$ from a **type I error** that occurs if he decides that $f = f_1$ when actually $f = f_0$
- a loss $\bar{L}_0$ from a **type II error** that occurs if he decides that $f = f_0$ when actually $f = f_1$

The decision maker pays a cost c for drawing another z.

Note

This lecture lets π denote the probability of f_0 and defines the likelihood ratio as $L = f_0/f_1$.

Under this convention, high values of π and of L favor f_0, and the Bayesian decision maker accepts f_0 when $\pi \geq A$.

A Bayesian Formulation of Friedman and Wald's Problem lets π denote the probability of f_1; its decision maker accepts f_1 when $\pi \geq A$.

A Problem that Stumped Milton Friedman defines the likelihood ratio as f_1/f_0.

We rewrite the code that we borrow from *A Bayesian Formulation of Friedman and Wald's Problem* for our convention: π and $1-\pi$ trade places in the Bayes update κ, in the expected losses from stopping, and in the Bellman operator $\mathtt{Q}$.

We mainly borrow parameters from the quantecon lecture *A Bayesian Formulation of Friedman and Wald's Problem* except that we increase both $\bar{L}_0$ and $\bar{L}_1$ from 25 to 100 to encourage the Bayesian decision rule to take more draws before deciding.

We set the cost c of taking one more draw at 1.25.

We set the probability distributions f_0 and f_1 to be beta distributions with $a_0 = b_0 = 1$, $a_1 = 3$, and $b_1 = 1.2$, respectively.

Below is some Python code that sets up these objects.

```
@jit
def p(x, a, b):
    "Beta distribution."

    r = gamma(a + b) / (gamma(a) * gamma(b))

    return r * x**(a-1) * (1 - x)**(b-1)
```

We start with defining a `jitclass` that stores parameters and functions we need to solve problems for both the Bayesian and frequentist Navy Captains.

```
wf_data = [
    ('c', float64),           # cost of drawing another z
    ('a0', float64),          # parameters of beta distribution
    ('b0', float64),
    ('a1', float64),
    ('b1', float64),
    ('L0', float64),          # cost of selecting f0 when f1 is true
    ('L1', float64),          # cost of selecting f1 when f0 is true
    ('π_grid', float64[:]),   # grid of beliefs π
    ('π_grid_size', int64),
    ('mc_size', int64),       # size of Monte Carlo simulation
    ('z0', float64[:]),       # sequence of random values
    ('z1', float64[:])        # sequence of random values
]
```

```
@jitclass(wf_data)
class WaldFriedman:

    def __init__(self,
                 c=1.25,
                 a0=1,
                 b0=1,
```

(continues on next page)

(continued from previous page)

```
                a1=3,
                b1=1.2,
                L0=100,
                L1=100,
                π_grid_size=200,
                mc_size=1000):

        self.c, self.π_grid_size = c, π_grid_size
        self.a0, self.b0, self.a1, self.b1 = a0, b0, a1, b1
        self.L0, self.L1 = L0, L1
        self.π_grid = np.linspace(0, 1, π_grid_size)
        self.mc_size = mc_size

        self.z0 = np.random.beta(a0, b0, mc_size)
        self.z1 = np.random.beta(a1, b1, mc_size)

    def f0(self, x):

        return p(x, self.a0, self.b0)

    def f1(self, x):

        return p(x, self.a1, self.b1)

    def κ(self, z, π):
        """
        Updates π using Bayes' rule and the current observation z
        """

        a0, b0, a1, b1 = self.a0, self.b0, self.a1, self.b1

        π_f0, π_f1 = π * p(z, a0, b0), (1 - π) * p(z, a1, b1)
        π_new = π_f0 / (π_f0 + π_f1)

        return π_new
```

The constructor of `WaldFriedman` draws `mc_size` Monte Carlo values of z from each density with numba's random number generator.

Calling `np.random.seed` from Python does not seed numba's generator.

We seed it inside a jitted function.

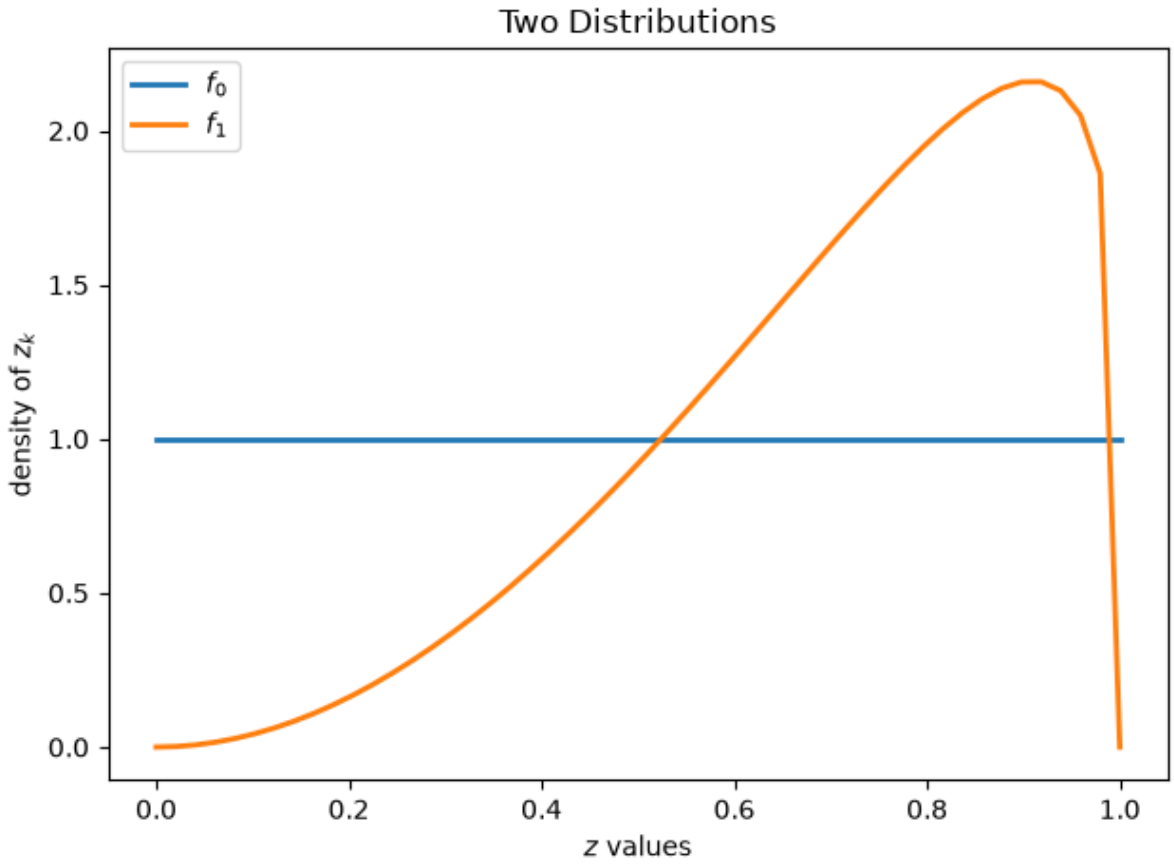
```
@jit
def seed_numba(seed):
    "Seed the random number generator used by numba-compiled code."
    np.random.seed(seed)

seed_numba(1234)
wf = WaldFriedman()

grid = np.linspace(0, 1, 50)

plt.figure()

plt.title("Two Distributions")
plt.plot(grid, wf.f0(grid), lw=2, label="$f_0$")
```



(continues on next page)

(continued from previous page)

```
plt.plot(grid, wf.f1(grid), lw=2, label="$f_1$")

plt.legend()
plt.xlabel("$z$ values")
plt.ylabel("density of $z_k$")

plt.tight_layout()
plt.show()
```

Above, we plot the two possible probability densities f_0 and f_1

34.3 Frequentist Decision Rule

The Navy told the Captain to use a Neyman-Pearson likelihood ratio decision rule.

That decision rule is characterized by

- a sample size t, and
- a cutoff value d of a likelihood ratio

Let $L\left(z^t\right) = \prod_{i=1}^t \frac{f_0(z_i)}{f_1(z_i)}$ be the likelihood ratio associated with observing the sequence $\{z_i\}_{i=1}^t$.

The decision rule associated with a sample size t is:

- decide that f_0 is the distribution if the likelihood ratio is greater than d

- decide that f_1 is the distribution if the likelihood ratio is less than d

For our purposes here, we want to compute an expected loss from using this rule, where we borrow loss parameters $\bar{L}_0$ and $\bar{L}_1$ from *A Bayesian Formulation of Friedman and Wald's Problem*.

Let null and alternative hypotheses be

- null: H_0: $f = f_0$,
- alternative H_1: $f = f_1$.

Given sample size t and cutoff d, under the model described above, the mathematical expectation of total loss is

$$\bar{V}_{fre}(t,d) = ct + \pi^* PFA \times \bar{L}_1 + (1-\pi^*)(1-PD) \times \bar{L}_0 \tag{34.1}$$

$$\text{where} \quad PFA = \Pr\{L(z^t) < d \mid q = f_0\}$$
$$PD = \Pr\{L(z^t) < d \mid q = f_1\}$$

Here

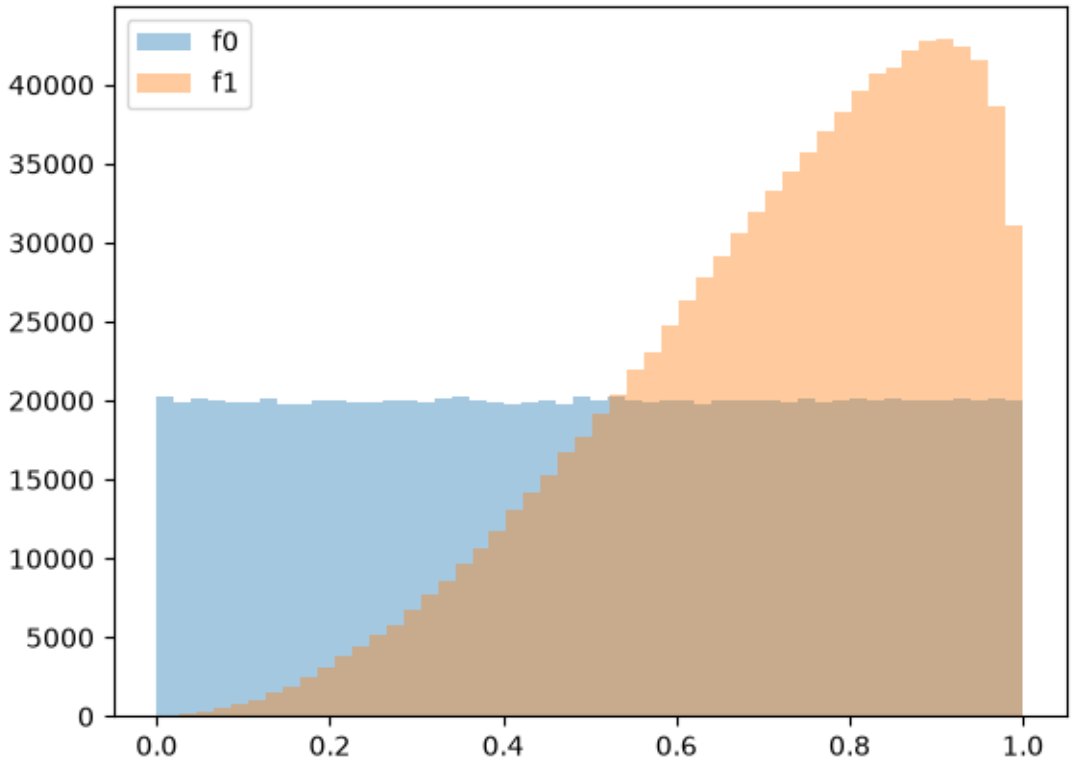
- PFA denotes the probability of a **false alarm**, i.e., rejecting H_0 when it is true
- PD denotes the probability of **detection**, i.e., rejecting H_0 when H_1 is true (the power of the test); $1 - PD$ is the probability of a type II error

For a given sample size t, the pairs (PFA, PD) lie on a **receiver operating characteristic curve**.

- by choosing d, we select a particular pair (PFA, PD) along the curve for a given t

To see some receiver operating characteristic curves, please see this lecture *Likelihood Ratio Processes*.

To solve for $\bar{V}_{fre}(t,d)$ numerically, we first simulate sequences of z when either f_0 or f_1 generates data.



Let's plot empirical distributions, i.e., histograms, associated with f_0 and f_1.

```
N = 10000
T = 100
```

```
rng = np.random.default_rng(1234)

z0_arr = rng.beta(wf.a0, wf.b0, (N, T))
z1_arr = rng.beta(wf.a1, wf.b1, (N, T))
```

```
plt.hist(z0_arr.flatten(), bins=50, alpha=0.4, label='f0')
plt.hist(z1_arr.flatten(), bins=50, alpha=0.4, label='f1')
plt.legend()
plt.show()
```

We can compute sequences of likelihood ratios using simulated samples.

```
l = lambda z: wf.f0(z) / wf.f1(z)
```

```
l0_arr = l(z0_arr)
l1_arr = l(z1_arr)

L0_arr = np.cumprod(l0_arr, 1)
L1_arr = np.cumprod(l1_arr, 1)
```

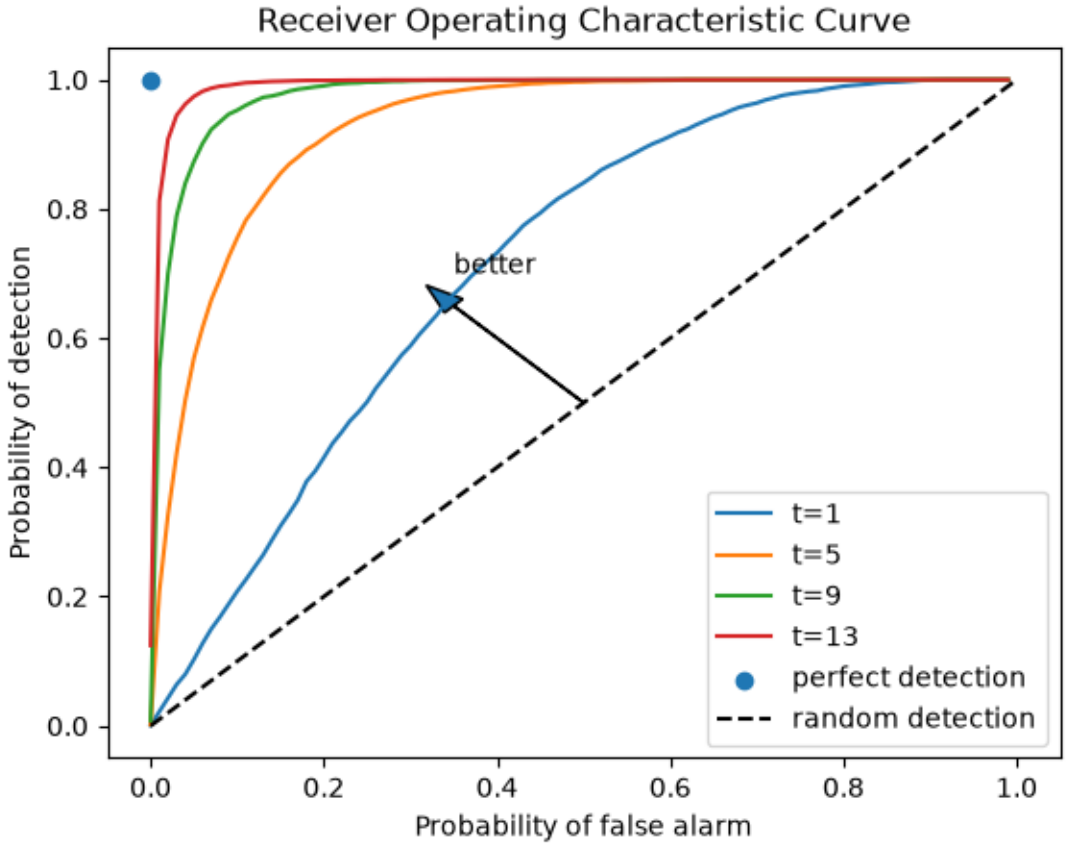
Column `t-1` of `L0_arr` and `L1_arr` holds $L(z^t)$, the likelihood ratio after t draws.

With an empirical distribution of likelihood ratios in hand, we can draw **receiver operating characteristic curves** by enumerating (PFA, PD) pairs given each sample size t.

```
PFA = np.arange(0, 100, 1)

for t in range(1, 15, 4):
    percentile = np.percentile(L0_arr[:, t-1], PFA)
    PD = [np.sum(L1_arr[:, t-1] < p) / N for p in percentile]

    plt.plot(PFA / 100, PD, label=f"t={t}")



plt.scatter(0, 1, label="perfect detection")
plt.plot([0, 1], [0, 1], color='k', ls='--', label="random detection")

plt.arrow(0.5, 0.5, -0.15, 0.15, head_width=0.03)
plt.text(0.35, 0.7, "better")
plt.xlabel("Probability of false alarm")
plt.ylabel("Probability of detection")
```

(continues on next page)

(continued from previous page)

```
plt.legend()
plt.title("Receiver Operating Characteristic Curve")
plt.show()
```

We can minimize the expected total loss presented in equation (34.1) by choosing (t, d).

Doing that delivers an expected loss

$$\bar{V}_{fre} = \min_{t,d} \bar{V}_{fre}(t, d).$$

We let t range over $1, 2, \ldots, T$.[1]

We first consider the case in which $\pi^* = \Pr\{\text{nature selects } f_0\} = 0.5$.

We can solve the minimization problem in two steps.

First, we fix t and find the optimal cutoff d and consequently the minimal $\bar{V}_{fre}(t)$.

For every t, the cutoff

$$d^* = \frac{(1-\pi^*)\bar{L}_0}{\pi^*\bar{L}_1} \tag{34.2}$$

minimizes $\bar{V}_{fre}(t, d)$.

The rule "decide f_1 if $L(z^t) < d^*$" chooses the decision with the smaller posterior expected loss after t draws.

[1] A decision maker can also decide without drawing any z, at expected loss $\min\{\pi^*\bar{L}_1, (1-\pi^*)\bar{L}_0\}$. On our grid of values of π^*, that option beats every $t \geq 1$ at $\pi^* = 0.1, 0.86$, and 0.9. Exercise 34.10.3 lets the fixed-sample rule choose $t = 0$.

The frequentist rule with $d = d^*$ is therefore a Bayes rule whose sample size is fixed in advance.

Exercise 34.10.1 asks you to derive (34.2) and to verify it numerically.

Second, we minimize $\bar{V}_{fre}(t) = \bar{V}_{fre}(t, d^*)$ over t.

Here is Python code that does that and then plots a useful graph.

```
@jit
def V_fre_d_t(d, t, L0_arr, L1_arr, π_star, wf):

    N = L0_arr.shape[0]

    PFA = np.sum(L0_arr[:, t-1] < d) / N
    PD = np.sum(L1_arr[:, t-1] < d) / N

    V = π_star * PFA * wf.L1 + (1 - π_star) * (1 - PD) * wf.L0

    return V
```

```
def d_star(π_star, wf):
    "Cutoff for L = f0/f1 that minimizes expected loss for any t."

    return (1 - π_star) * wf.L0 / (π_star * wf.L1)

def V_fre_t(t, L0_arr, L1_arr, π_star, wf):

    d = d_star(π_star, wf)
    V = V_fre_d_t(d, t, L0_arr, L1_arr, π_star, wf)

    PFA = np.mean(L0_arr[:, t-1] < d)
    PD = np.mean(L1_arr[:, t-1] < d)

    return V, PFA, PD
```

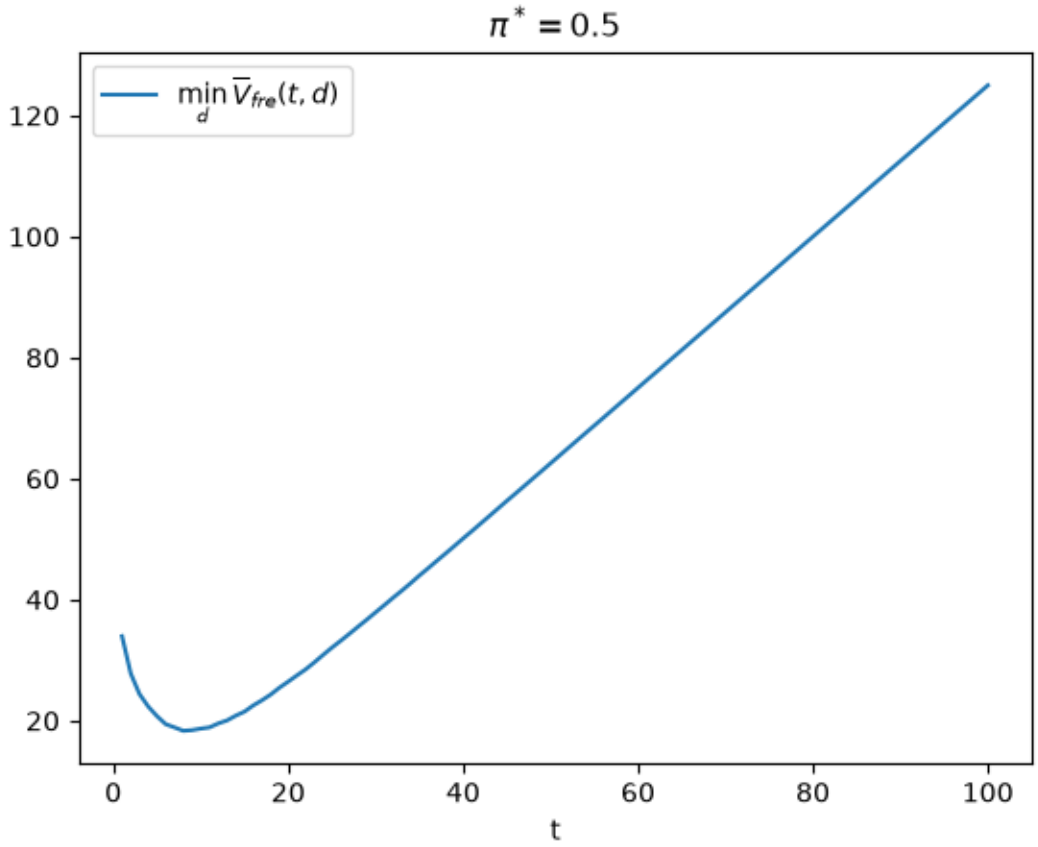
```
def compute_V_fre(L0_arr, L1_arr, π_star, wf):

    T = L0_arr.shape[1]

    V_fre_arr = np.empty(T)
    PFA_arr = np.empty(T)
    PD_arr = np.empty(T)

    for t in range(1, T+1):
        V, PFA, PD = V_fre_t(t, L0_arr, L1_arr, π_star, wf)
        V_fre_arr[t-1] = wf.c * t + V
        PFA_arr[t-1] = PFA
        PD_arr[t-1] = PD

    return V_fre_arr, PFA_arr, PD_arr
```



```
π_star = 0.5
V_fre_arr, PFA_arr, PD_arr = compute_V_fre(L0_arr, L1_arr, π_star, wf)

plt.plot(range(1, T+1), V_fre_arr, label=r'$\min_{d} \overline{V}_{fre}(t,d)$')
plt.xlabel('t')
plt.title(r'$\pi^*=0.5$')
```

(continues on next page)

(continued from previous page)

```
plt.legend()
plt.show()
```

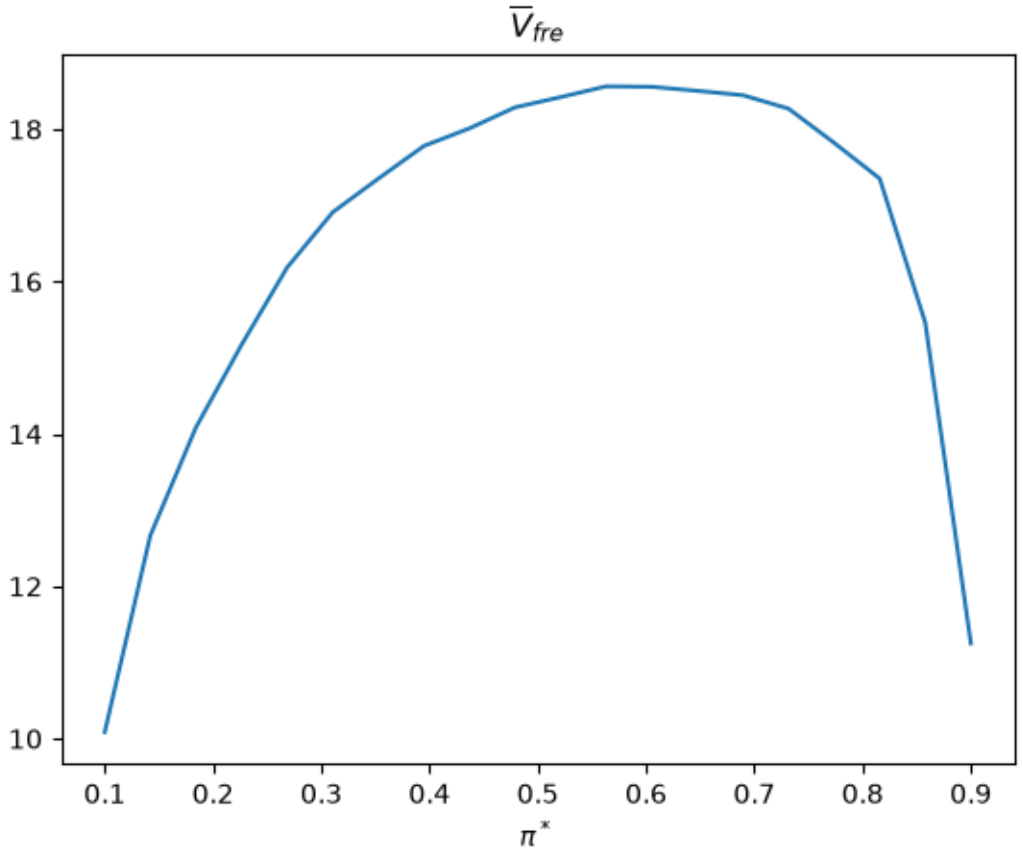
```
t_optimal = np.argmin(V_fre_arr) + 1
```

The above graph illustrates how minimizing over t tells the frequentist to draw t_{optimal} observations and then decide.

Let's now change the value of π^* and watch how the decision rule changes.

```
n_π = 20
π_star_arr = np.linspace(0.1, 0.9, n_π)

V_fre_bar_arr = np.empty(n_π)
t_optimal_arr = np.empty(n_π)
PFA_optimal_arr = np.empty(n_π)
PD_optimal_arr = np.empty(n_π)



for i, π_star in enumerate(π_star_arr):
    V_fre_arr, PFA_arr, PD_arr = compute_V_fre(L0_arr, L1_arr, π_star, wf)
    t_idx = np.argmin(V_fre_arr)

    V_fre_bar_arr[i] = V_fre_arr[t_idx]
    t_optimal_arr[i] = t_idx + 1
    PFA_optimal_arr[i] = PFA_arr[t_idx]
    PD_optimal_arr[i] = PD_arr[t_idx]
```

```
plt.plot(π_star_arr, V_fre_bar_arr)
plt.xlabel(r'$\pi^*$')
plt.title(r'$\overline{V}_{fre}$')

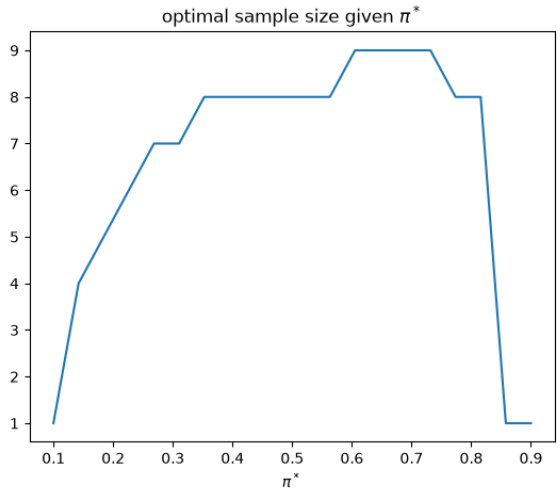
plt.show()

V_no_data = np.minimum(π_star_arr * wf.L1, (1 - π_star_arr) * wf.L0)
print("π* at which deciding without data beats every t ≥ 1:",
      np.round(π_star_arr[V_no_data < V_fre_bar_arr], 2))
```

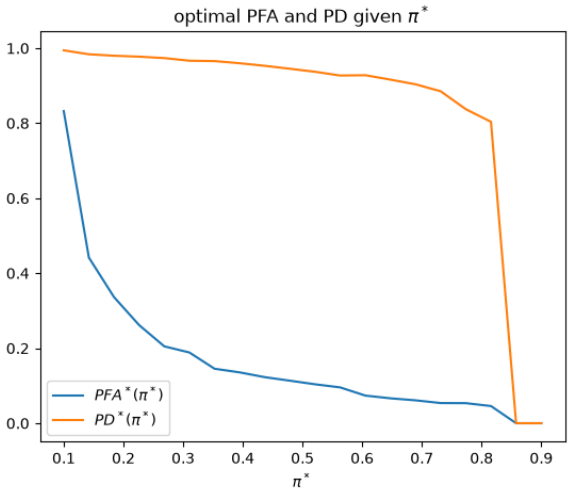
```
π* at which deciding without data beats every t ≥ 1: [0.1  0.86 0.9 ]
```

The following shows how optimal sample size t and targeted (PFA, PD) change as π^* varies.

```
fig, axs = plt.subplots(1, 2, figsize=(14, 5))



axs[0].plot(π_star_arr, t_optimal_arr)
axs[0].set_xlabel(r'$\pi^*$')
axs[0].set_title(r'optimal sample size given $\pi^*$')



axs[1].plot(π_star_arr, PFA_optimal_arr, label=r'$PFA^*(\pi^*)$')
axs[1].plot(π_star_arr, PD_optimal_arr, label=r'$PD^*(\pi^*)$')
axs[1].set_xlabel(r'$\pi^*$')
axs[1].legend()
axs[1].set_title(r'optimal PFA and PD given $\pi^*$')
```

34.4 Bayesian Decision Rule

In *A Problem that Stumped Milton Friedman*, we learned how Abraham Wald confirmed the Navy Captain's hunch that there is a better decision rule.

In *A Bayesian Formulation of Friedman and Wald's Problem* we presented a Bayesian procedure that makes decisions by comparing a Bayesian posterior probability π with cutoff probabilities called A and B.

To proceed, we borrow some Python code from the quantecon lecture *A Bayesian Formulation of Friedman and Wald's Problem* that computes optimal values of A and B.

We rewrite that code for our convention that π is the probability of f_0.

```
@jit(parallel=True)
def Q(h, wf):

    c, π_grid = wf.c, wf.π_grid
    L0, L1 = wf.L0, wf.L1
    z0, z1 = wf.z0, wf.z1
    mc_size = wf.mc_size

    κ = wf.κ

    h_new = np.empty_like(π_grid)
    h_func = lambda p: np.interp(p, π_grid, h)

    for i in prange(len(π_grid)):
        π = π_grid[i]

        # Find the expected value of J by integrating over z
        integral_f0, integral_f1 = 0, 0
        for m in range(mc_size):
            π_0 = κ(z0[m], π)  # Draw z from f0 and update π
            integral_f0 += min((1 - π_0) * L0, π_0 * L1, h_func(π_0))
```

(continues on next page)

(continued from previous page)

```
            π_1 = κ(z1[m], π)  # Draw z from f1 and update π
            integral_f1 += min((1 - π_1) * L0, π_1 * L1, h_func(π_1))

        integral = (π * integral_f0 + (1 - π) * integral_f1) / mc_size

        h_new[i] = c + integral

    return h_new
```

```
@jit

plt.show()
```

```
B = 0.050, A = 0.945
```

The above figure portrays the value function plotted against the decision maker's Bayesian posterior.

It also shows the cutoff probabilities A and B.

The Bayesian decision rule is:

- accept H_0 if $\pi \geq A$
- accept H_1 if $\pi \leq B$
- delay deciding and draw another z if $B < \pi < A$

We can calculate two "objective" loss functions under this situation conditioning on knowing for sure that nature has selected f_0, in the first case, or f_1, in the second case.

1. under f_0,

$$V^0(\pi) = \begin{cases} 0 & \text{if } A \leq \pi, \\ c + E_{f_0} V^0(\pi') & \text{if } B < \pi < A, \\ \bar{L}_1 & \text{if } \pi \leq B. \end{cases}$$

2. under f_1

$$V^1(\pi) = \begin{cases} \bar{L}_0 & \text{if } A \leq \pi, \\ c + E_{f_1} V^1(\pi') & \text{if } B < \pi < A, \\ 0 & \text{if } \pi \leq B. \end{cases}$$

where $\pi' = \frac{\pi f_0(z')}{\pi f_0(z') + (1-\pi) f_1(z')}$ and E_{f_i} integrates over z' drawn from f_i.

Given a prior probability π_0, the expected loss for the Bayesian is

$$\bar{V}_{Bayes}(\pi_0) = \pi^* V^0(\pi_0) + (1 - \pi^*) V^1(\pi_0).$$

Below we write some Python code that computes $V^0(\pi)$ and $V^1(\pi)$ numerically.

The code iterates on the two functional equations at the grid points in the continuation region (B, A).

It replaces each expectation with an average over the `mc_size` Monte Carlo draws stored in `wf`.

It uses the terminal losses exactly when π' leaves (B, A) and interpolates only between grid points inside (B, A).

```
@jit(parallel=True)
def V_q(wf, A, B, flag, tol=1e-5, max_iter=10_000):
    """
    Expected loss of the Bayesian cutoff rule (B, A) when f0 (flag=0)
    or f1 (flag=1) generates the data
    """

    π_grid = wf.π_grid

    if flag == 0:
        z_arr = wf.z0
        loss_f0, loss_f1 = 0.0, wf.L1   # losses from accepting f0, f1
    else:
        z_arr = wf.z1
        loss_f0, loss_f1 = wf.L0, 0.0

    m = len(z_arr)

    # Terminal losses outside the continuation region
    V = np.where(π_grid >= A, loss_f0, np.where(π_grid <= B, loss_f1, 0.0))
```

(continues on next page)

(continued from previous page)

```
    cont = (π_grid > B) & (π_grid < A)
    π_cont = π_grid[cont]
    n_cont = len(π_cont)
    if n_cont == 0:
        return V

    V_cont = np.zeros(n_cont)
    for it in range(max_iter):
        V_old = V_cont.copy()

        for i in prange(n_cont):
            total = 0.0
            for j in range(m):
                π_next = wf.κ(z_arr[j], π_cont[i])
                if π_next >= A:
                    total += loss_f0
                elif π_next <= B:
                    total += loss_f1
                else:
                    total += np.interp(π_next, π_cont, V_old)
            V_cont[i] = wf.c + total / m

plt.xlabel(r'$\pi$')
plt.title(r'Objective value function $V(\pi)$')
plt.legend()
plt.show()
```

Given an assumed value for $\pi^* = \Pr\{\text{nature selects } f_0\}$, we can then compute $\bar{V}_{Bayes}(\pi_0)$.

We can then determine an initial Bayesian prior π_0^* that minimizes this objective concept of expected loss.

A theorem tells us that $\pi_0^* = \pi^*$.

The Bayes rule that starts from the prior π^* minimizes π^*-weighted expected loss over all sequential decision rules.

A Bayesian who starts from another prior π_0 uses one of those rules.

Therefore $\bar{V}_{Bayes}(\pi_0) \geq \bar{V}_{Bayes}(\pi^*)$ for every π_0.

The figure below plots four cases corresponding to $\pi^* = 0.25, 0.3, 0.5, 0.7$.

The numerical minimizers lie near π^* but not exactly at it.

The function $\bar{V}_{Bayes}(\pi_0)$ is flat near its minimum, so small grid and Monte Carlo errors move the computed π_0^*.

```
def compute_V_baye_bar(π_star, V0, V1, wf):

    V_baye = π_star * V0 + (1 - π_star) * V1
    π_idx = np.argmin(V_baye)
    π_optimal = wf.π_grid[π_idx]
    V_baye_bar = V_baye[π_idx]

    return V_baye, π_optimal, V_baye_bar
```

```
π_star_arr = [0.25, 0.3, 0.5, 0.7]

axs[1].set_xlabel(r'$\pi^*$')
axs[1].set_title(r'optimal prior given $\pi^*$')
axs[1].legend()

plt.show()

print(f"largest |π_0^* - π^*| = {np.max(np.abs(π_optimal_arr - π_star_arr)):.3f}")
```

```
largest |π_0^* - π^*| = 0.038
```

The computed π_0^* stays within 0.04 of the 45 degree line.

34.5 Was the Navy Captain's Hunch Correct?

We now compare average losses obtained by our frequentist Neyman-Pearson and Bayesian decision rules.

The comparison is between a rule with a fixed sample size and a sequential rule.

Both rules use the prior π^* and the losses $\bar{L}_0$, $\bar{L}_1$, and c.

A fixed-sample rule (t, d) is a sequential rule that ignores the data until date t and then stops.

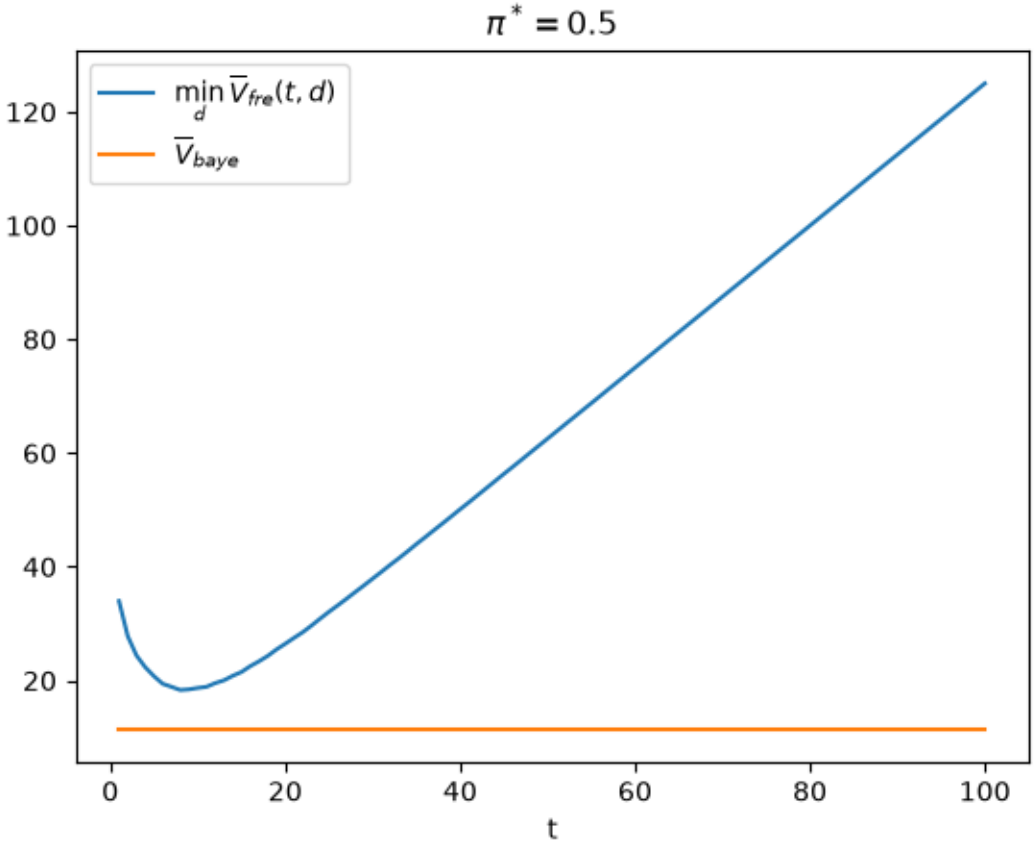
The Bayesian rule minimizes expected loss over all sequential rules.

Therefore $\bar{V}_{Bayes} \leq \bar{V}_{fre}$ for every π^*.

The simulations below illustrate this inequality and measure the gap.

As a starting point, let's compare average loss functions when $\pi^* = 0.5$.

```
π_star = 0.5
```



```
# frequentist
V_fre_arr, PFA_arr, PD_arr = compute_V_fre(L0_arr, L1_arr, π_star, wf)

# bayesian
V_baye = π_star * V0 + (1 - π_star) * V1
V_baye_bar = V_baye.min()

print(f"V_fre = {V_fre_arr.min():.2f} at t = {np.argmin(V_fre_arr) + 1}")
print(f"V_Bayes = {V_baye_bar:.2f}")
```

```
V_fre = 18.33 at t = 8
V_Bayes = 11.36
```

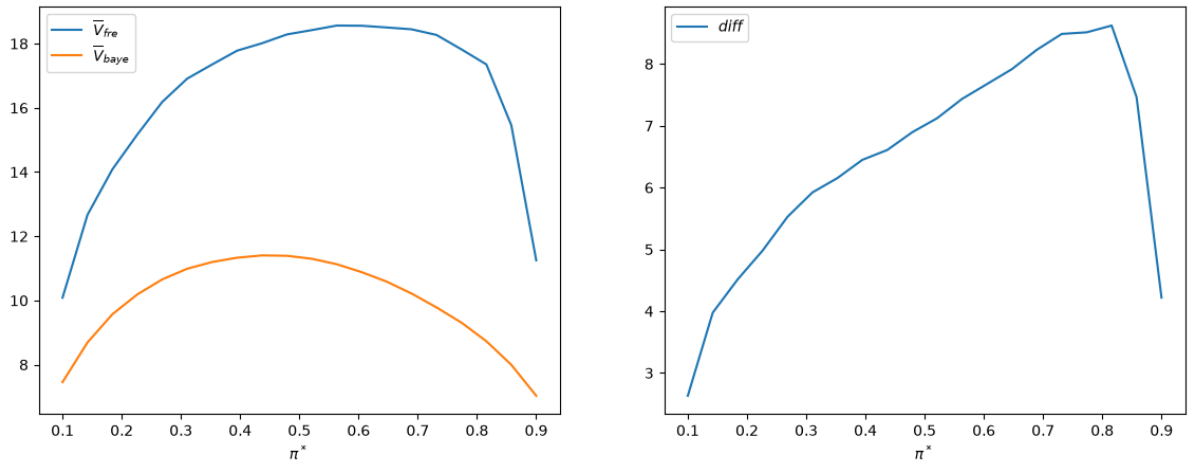
```
plt.plot(range(1, T+1), V_fre_arr, label=r'$\min_{d} \overline{V}_{fre}(t,d)$')
plt.plot([1, T], [V_baye_bar, V_baye_bar], label=r'$\overline{V}_{baye}$')
plt.xlabel('t')
plt.title(r'$\pi^*=0.5$')
plt.legend()
plt.show()
```

Evidently, there is no sample size t at which the Neyman-Pearson decision rule attains a lower loss function than does the Bayesian rule.

At $\pi^* = 0.5$, the best fixed-sample rule draws 8 observations and has expected loss 18.33; the Bayesian rule has expected loss 11.36.

The Bayesian value is computed with the $1{,}000$ Monte Carlo draws stored in `wf.z0` and `wf.z1`, so its last digits are not reliable; the simulation in a later section puts the Bayesian loss near 12.3, still far below 18.33.

The following graph compares the two rules for all values of π^*.



```
fig, axs = plt.subplots(1, 2, figsize=(14, 5))

axs[0].plot(π_star_arr, V_fre_bar_arr, label=r'$\overline{V}_{fre}$')
axs[0].plot(π_star_arr, V_baye_bar_arr, label=r'$\overline{V}_{baye}$')
axs[0].legend()
axs[0].set_xlabel(r'$\pi^*$')

axs[1].plot(π_star_arr, V_fre_bar_arr - V_baye_bar_arr, label='$diff$')
axs[1].legend()
axs[1].set_xlabel(r'$\pi^*$')

plt.show()

diff = V_fre_bar_arr - V_baye_bar_arr
print(f"min diff = {diff.min():.2f} at π* = {π_star_arr[np.argmin(diff)]:.2f}")
print(f"max diff = {diff.max():.2f} at π* = {π_star_arr[np.argmax(diff)]:.2f}")
```

```
min diff = 2.63 at π* = 0.10
max diff = 8.62 at π* = 0.82
```

The right panel of the above graph plots the difference $\bar{V}_{fre} - \bar{V}_{Bayes}$.

It is always positive, as the theorem requires.

The gap is smallest, 2.63, at $\pi^* = 0.1$ and largest, 8.62, at $\pi^* \approx 0.82$.

34.6 More Details

We can provide more insights by focusing on the case in which $\pi^* = 0.5 = \pi_0$.

```
π_star = 0.5
```

Recall that when $\pi^* = 0.5$, the frequentist Neyman-Pearson decision rule sets a sample size `t_optimal` **ex ante**.

For our parameter settings, we can compute its value:

```
t_optimal
```

```
np.int64(8)
```

For convenience, let's define `t_idx` as the Python array index corresponding to `t_optimal` sample size.

```
t_idx = t_optimal - 1
```

34.7 Distribution of Bayesian Decision Rule's Time to Decide

We use simulations to compute the frequency distribution of the time to decide for the Bayesian decision rule and compare that time to the frequentist rule's fixed t.

The following Python code creates a graph that shows the frequency distribution of Bayesian times to decide of Bayesian decision maker, conditional on distribution $q = f_0$ or $q = f_1$ generating the data.

The blue and orange dashed lines show averages for the Bayesian decision rule under f_0 and f_1, while the black dashed line shows the frequentist optimal sample size t.

On average the Bayesian rule decides **earlier** than the frequentist rule when $q = f_0$ and **later** when $q = f_1$.

The function `check_results` records time $T+1$ for a path that has not reached a decision by T.

```
@jit(parallel=True)
def check_results(L_arr, A, B, flag, π0):

    N, T = L_arr.shape

    time_arr = np.full(N, T + 1)                    # T + 1 means no decision by T
    correctness = np.zeros(N, dtype=np.bool_)

    π_arr = π0 * L_arr / (π0 * L_arr + 1 - π0)

    for i in prange(N):
        for t in range(T):

```

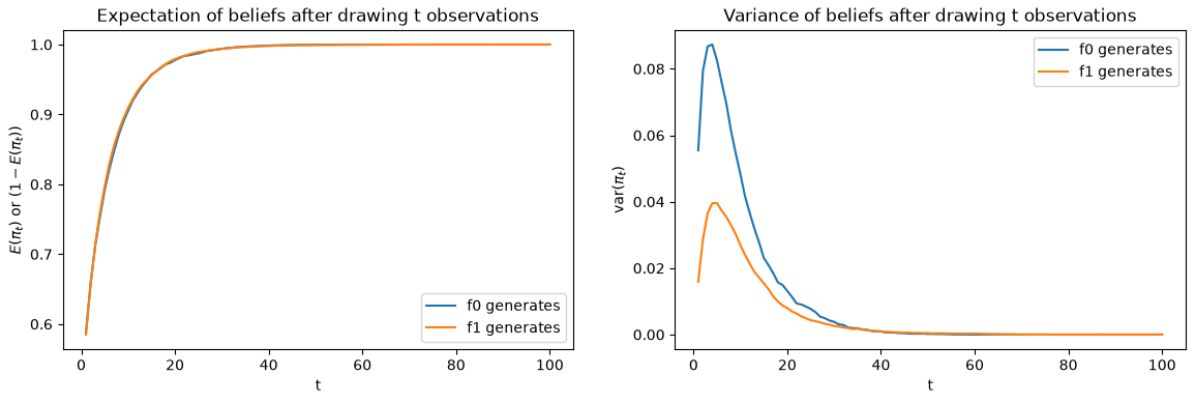
Later we'll figure out how these distributions ultimately affect objective expected values under the Neyman-Pearson and Bayesian decision rules.

To begin, let's look at simulations of the Bayesian's beliefs over time.

We can compute updated beliefs at any time t using the one-to-one mapping from L_t to π_t given π_0 described in the section on *likelihood ratio processes and Bayes' law* of *Likelihood Ratio Processes and Bayesian Learning*.

```
π0_arr = π_star * L0_arr / (π_star * L0_arr + 1 - π_star)
π1_arr = π_star * L1_arr / (π_star * L1_arr + 1 - π_star)
```

```
fig, axs = plt.subplots(1, 2, figsize=(14, 4))



axs[0].plot(np.arange(1, π0_arr.shape[1]+1), np.mean(π0_arr, 0), label='f0 generates')
axs[0].plot(np.arange(1, π1_arr.shape[1]+1), 1 - np.mean(π1_arr, 0), label='f1␣
↪generates')
axs[0].set_xlabel('t')
axs[0].set_ylabel(r'$E(\pi_t)$ or ($1 - E(\pi_t)$)')
axs[0].set_title('Expectation of beliefs after drawing t observations')
axs[0].legend()

axs[1].plot(np.arange(1, π0_arr.shape[1]+1), np.var(π0_arr, 0), label='f0 generates')
axs[1].plot(np.arange(1, π1_arr.shape[1]+1), np.var(π1_arr, 0), label='f1 generates')
axs[1].set_xlabel('t')
axs[1].set_ylabel(r'var($\pi_t$)')
axs[1].set_title('Variance of beliefs after drawing t observations')
axs[1].legend()
```

(continues on next page)

(continued from previous page)

```
plt.show()
```

The above figures compare averages and variances of updated Bayesian posteriors after t draws.

The left graph compares $E_{f_0}(\pi_t)$ to $1 - E_{f_1}(\pi_t)$: they lie on top of each other.

The martingale property of π_t implies this outcome.

Under the Bayesian's subjective distribution, which mixes f_0 and f_1 with weights π_0 and $1 - \pi_0$, π_t is a martingale with mean π_0.

Therefore $\pi_0 E_{f_0}(\pi_t) + (1 - \pi_0) E_{f_1}(\pi_t) = \pi_0$ for every t.

With $\pi_0 = 1/2$, this identity becomes $E_{f_0}(\pi_t) = 1 - E_{f_1}(\pi_t)$.

The two simulated curves differ only by Monte Carlo error.

The right graph shows that the variance of π_t is lower under f_1 when t is small.

An asymmetry in Kullback-Leibler divergences explains why the Bayesian decision maker waits longer to decide when f_1 generates the data.

Statistical Divergence Measures describes Kullback-Leibler divergence.

Under f_0, $\log L_t$ rises on average by $KL(f_0 \| f_1) = E_{f_0}[\log(f_0(z)/f_1(z))]$ per draw.

Under f_1, $\log L_t$ falls on average by $KL(f_1 \| f_0) = E_{f_1}[\log(f_1(z)/f_0(z))]$ per draw.

With $\pi_0 = 1/2$, the Bayesian stops when $\log L_t$ leaves the interval $(\log L_B, \log L_A)$, where $L_A = A/(1-A)$ and $L_B = B/(1-B)$.

Wald's approximation to the expected number of draws ignores the amount by which $\log L_t$ overshoots a threshold:

$$E_{f_1}[N] \approx \frac{\Pr_{f_1}\{\text{accept } f_1\} \log L_B + \Pr_{f_1}\{\text{accept } f_0\} \log L_A}{-KL(f_1 \| f_0)}$$

and similarly under f_0.

```
def KL(f, g):
    "KL(f || g), the integral of f log(f/g) over [0, 1]."
    integrand = lambda z: f(z) * np.log(f(z) / g(z))
    return quad(integrand, 0, 1)[0]

KL_01 = KL(wf.f0, wf.f1)
KL_10 = KL(wf.f1, wf.f0)

LA = (1 - π_star) * A / (π_star * (1 - A))
```

(continues on next page)

(continued from previous page)

```
LB = (1 - π_star) * B / (π_star * (1 - B))

p0 = correctness0.mean()    # probability of accepting f0 under f0
p1 = correctness1.mean()    # probability of accepting f1 under f1

EN0_wald = (p0 * np.log(LA) + (1 - p0) * np.log(LB)) / KL_01
EN1_wald = (p1 * np.log(LB) + (1 - p1) * np.log(LA)) / (-KL_10)

print(f"KL(f0||f1) = {KL_01:.3f},  KL(f1||f0) = {KL_10:.3f}")
print(f"log L_A = {np.log(LA):.2f},  log L_B = {np.log(LB):.2f}")
print(f"E_f0[N]: Wald approximation {EN0_wald:.1f}, simulation {time_arr0.mean():.1f}
 ↪")
print(f"E_f1[N]: Wald approximation {EN1_wald:.1f}, simulation {time_arr1.mean():.1f}
 ↪")

# Average overshoot of log L_A under f0 and of log L_B under f1
logL0_stop = np.log(L0_arr[np.arange(N), time_arr0 - 1])
logL1_stop = np.log(L1_arr[np.arange(N), time_arr1 - 1])
print(f"mean overshoot: {np.mean(logL0_stop[correctness0] - np.log(LA)):.2f} "
      f"under f0, {np.mean(np.log(LB) - logL1_stop[correctness1]):.2f} under f1")
```

```
KL(f0||f1) = 0.759,  KL(f1||f0) = 0.344
log L_A = 2.84,  log L_B = -2.94
E_f0[N]: Wald approximation 3.4, simulation 6.0
E_f1[N]: Wald approximation 8.3, simulation 9.1
mean overshoot: 1.98 under f0, 0.31 under f1
```

The divergence $KL(f_0 \| f_1) \approx 0.759$ is more than twice $KL(f_1 \| f_0) \approx 0.344$.

The thresholds $\log L_A \approx 2.84$ and $\log L_B \approx -2.94$ lie about equally far from zero.

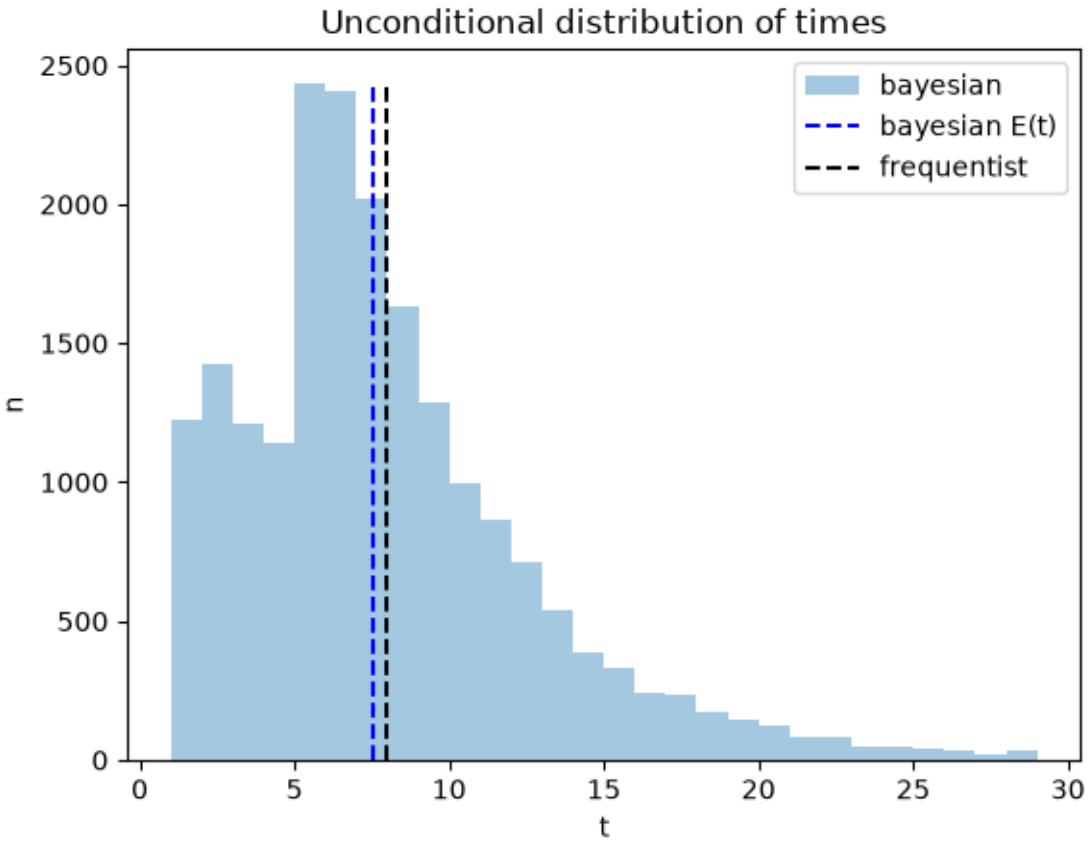
Under f_1, $\log L_t$ drifts toward $\log L_B$ at less than half the speed at which it drifts toward $\log L_A$ under f_0.

Wald's approximation gives $E_{f_1}[N] \approx 8.3$, close to the simulated 9.1.

It gives $E_{f_0}[N] \approx 3.4$, far below the simulated 6.0.

Under f_0, draws of z near zero make $\log(f_0(z)/f_1(z))$ very large, so $\log L_t$ overshoots $\log L_A$ by about 2 on average; under f_1, $\log L_t$ overshoots $\log L_B$ by about 0.3.

The code below plots outcomes of constructing an unconditional distribution by simply pooling the simulated data across the two possible distributions f_0 and f_1.



The pooled distribution describes a sense in which on average the Bayesian decides earlier, an outcome that seems at least partly to confirm the Navy Captain's hunch.

The pooled mean time to decide is 7.54 draws, against $t_{\text{optimal}} = 8$.

```
n = plt.hist(time_arr_u, bins=range(1, 30), alpha=0.4, label='bayesian')[0]
plt.vlines(np.mean(time_arr_u), 0, n.max(), linestyle='--',
           color='b', label='bayesian E(t)')
plt.vlines(t_optimal, 0, n.max(), linestyle='--', color='k', label='frequentist')
plt.legend()

plt.xlabel('t')
plt.ylabel('n')
plt.title('Unconditional distribution of times')

plt.show()
```

34.8 Probability of Making Correct Decision

Now we use simulations to compute the fractions of samples in which the Bayesian and the frequentist Neyman-Pearson decision rules decide correctly.

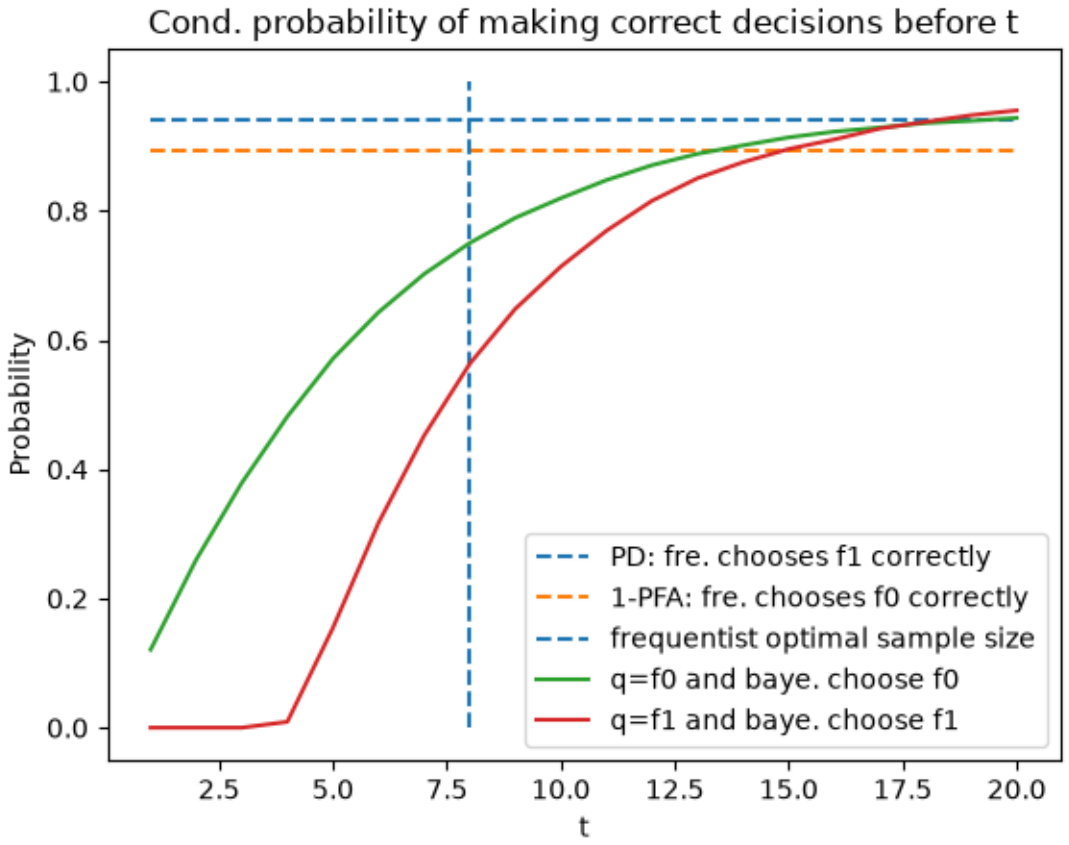
For the frequentist Neyman-Pearson rule, the probability of making the correct decision under f_1 is the optimal probability of detection given t that we defined earlier, and similarly it equals 1 minus the optimal probability of a false alarm under f_0.

Below we plot these two probabilities for the frequentist rule, along with the conditional probabilities that the Bayesian rule decides before t *and* that the decision is correct.

```
# optimal PFA and PD of frequentist with optimal sample size
V, PFA, PD = V_fre_t(t_optimal, L0_arr, L1_arr, π_star, wf)
```

```
plt.plot([1, 20], [PD, PD], linestyle='--', label='PD: fre. chooses f1 correctly')
plt.plot([1, 20], [1-PFA, 1-PFA], linestyle='--', label='1-PFA: fre. chooses f0␣
↪correctly')
plt.vlines(t_optimal, 0, 1, linestyle='--', label='frequentist optimal sample size')

T_arr = np.arange(1, 21)
plt.plot(T_arr, [np.mean(correctness0 & (time_arr0 <= t)) for t in T_arr],
         label='q=f0 and baye. choose f0')
plt.plot(T_arr, [np.mean(correctness1 & (time_arr1 <= t)) for t in T_arr],
         label='q=f1 and baye. choose f1')
```



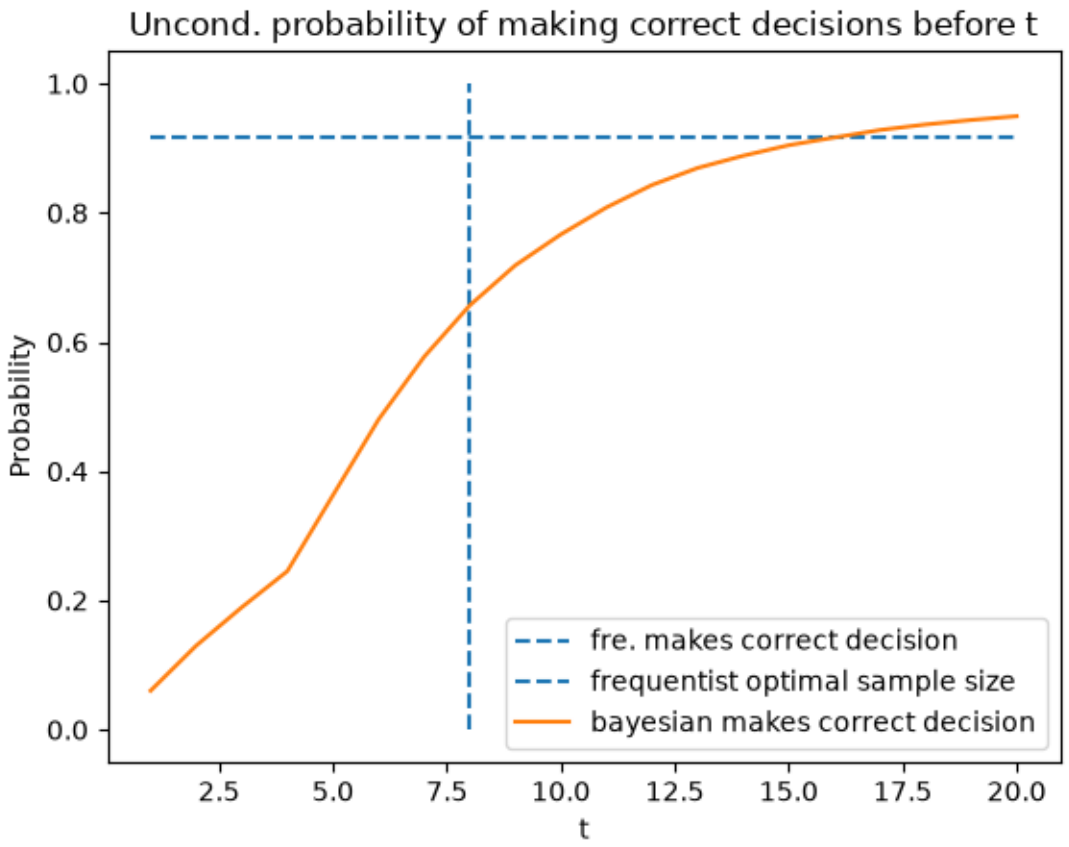
(continues on next page)

(continued from previous page)

```
plt.legend(loc=4)

plt.xlabel('t')
plt.ylabel('Probability')
plt.title('Cond. probability of making correct decisions before t')

plt.show()
```



By averaging using π^*, we also plot the unconditional distribution.

```
plt.plot([1, 20], [(PD + 1 - PFA) / 2, (PD + 1 - PFA) / 2],
         linestyle='--', label='fre. makes correct decision')
plt.vlines(t_optimal, 0, 1, linestyle='--', label='frequentist optimal sample size')

plt.plot(T_arr, [np.mean(correctness_u & (time_arr_u <= t)) for t in T_arr],
         label="bayesian makes correct decision")
plt.legend()

plt.xlabel('t')
plt.ylabel('Probability')
plt.title('Uncond. probability of making correct decisions before t')

plt.show()
```

The simulated times to decide and probabilities of correct decisions give a second estimate of the Bayesian's expected loss.

This estimate uses the same simulated paths that we used for the frequentist rule.

```
V0_sim = wf.c * time_arr0.mean() + wf.L1 * (1 - correctness0.mean())
V1_sim = wf.c * time_arr1.mean() + wf.L0 * (1 - correctness1.mean())
V_baye_sim = π_star * V0_sim + (1 - π_star) * V1_sim

V_fre_sim = wf.c * t_optimal + V

print(f"Bayesian rule:     {V_baye_sim:.2f}")
print(f"fixed-sample rule: {V_fre_sim:.2f}")
```

```
Bayesian rule:     12.27
fixed-sample rule: 18.33
```

The simulated expected loss of the Bayesian rule, 12.27, exceeds the value 11.36 that `V_q` delivered.

The gap comes from Monte Carlo error in the 1,000 draws `wf.z0` and `wf.z1` that `V_q` uses to approximate expectations.

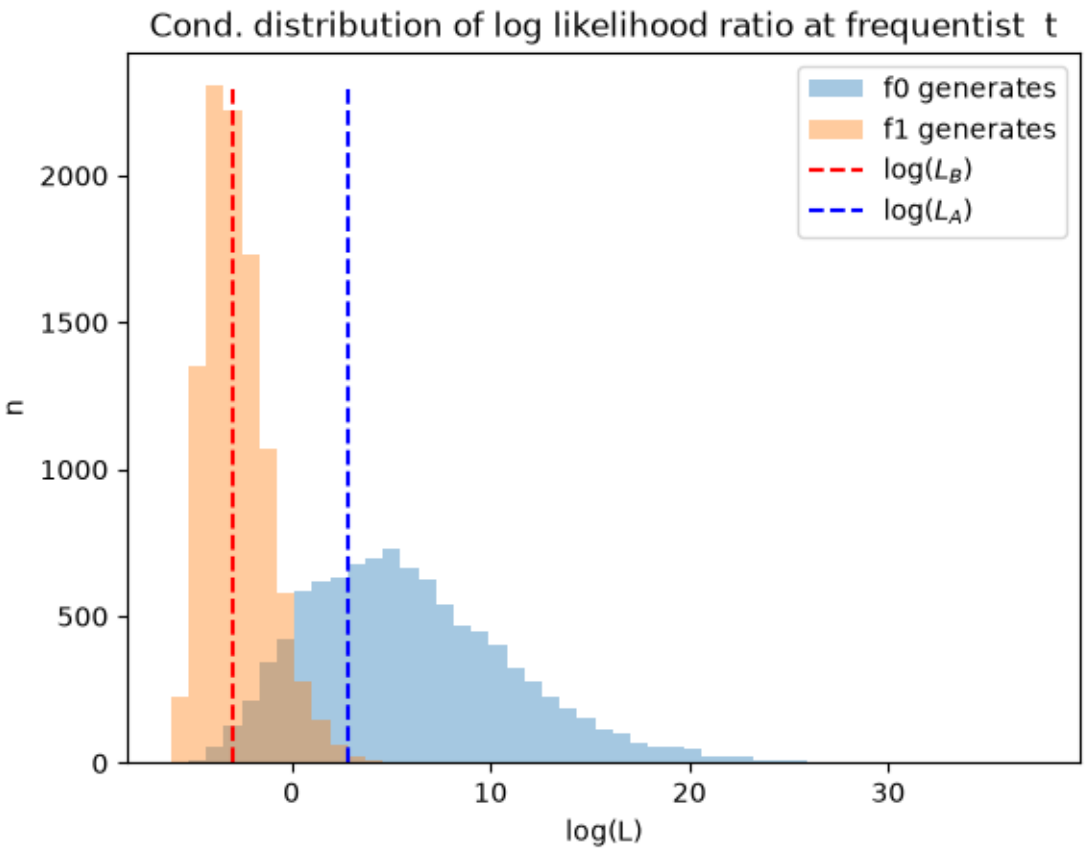
Both values lie far below the fixed-sample loss of 18.33.

34.9 Distribution of Likelihood Ratios at Neyman-Pearson's t

Next we use simulations to construct distributions of likelihood ratios after t draws.

To serve as useful reference points, we also show the likelihood ratios L_A and L_B that correspond to the Bayesian cutoffs A and B.

In order to exhibit the distribution more clearly, we report logarithms of likelihood ratios.



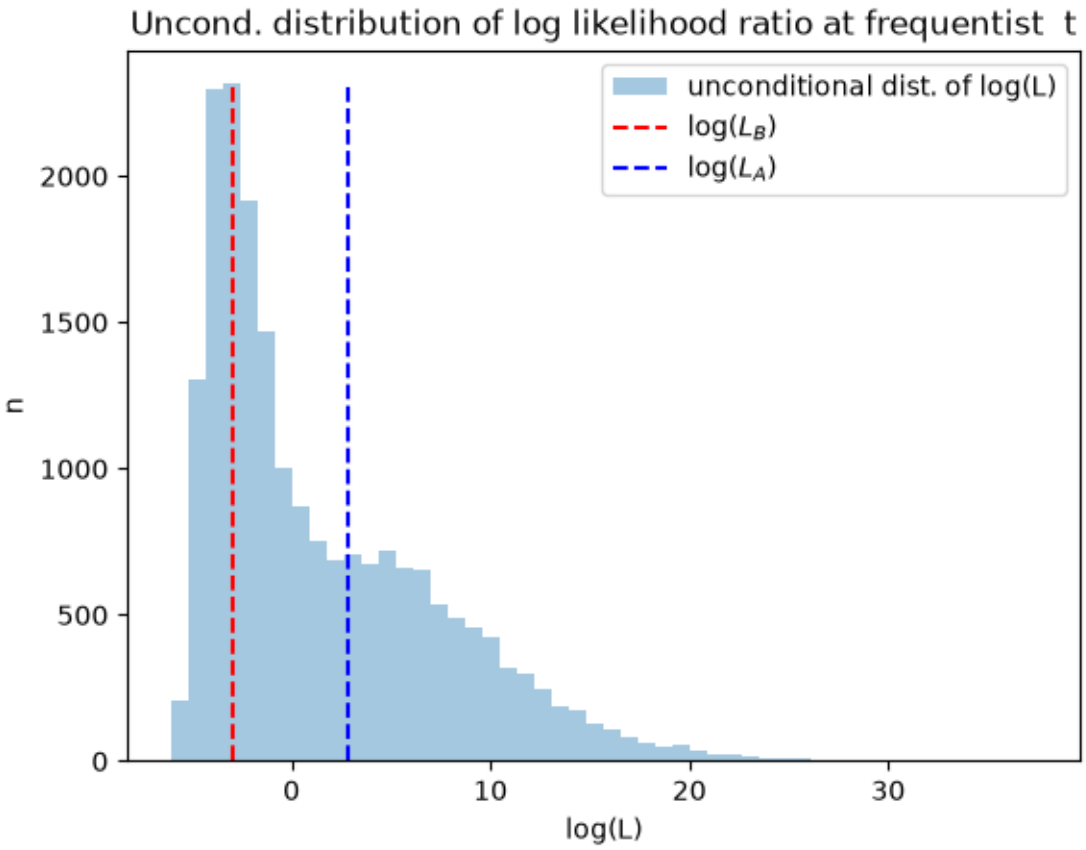
The graphs below reports two distributions, one conditional on f_0 generating the data, the other conditional on f_1 generating the data.

```
L_min = min(L0_arr[:, t_idx].min(), L1_arr[:, t_idx].min())
L_max = max(L0_arr[:, t_idx].max(), L1_arr[:, t_idx].max())
bin_range = np.linspace(np.log(L_min), np.log(L_max), 50)
n0 = plt.hist(np.log(L0_arr[:, t_idx]), bins=bin_range, alpha=0.4, label='f0 generates
 ↪')[0]
n1 = plt.hist(np.log(L1_arr[:, t_idx]), bins=bin_range, alpha=0.4, label='f1 generates
 ↪')[0]

plt.vlines(np.log(LB), 0, max(n0.max(), n1.max()), linestyle='--', color='r', label=
 ↪'log($L_B$)')
plt.vlines(np.log(LA), 0, max(n0.max(), n1.max()), linestyle='--', color='b', label=
 ↪'log($L_A$)')
plt.legend()

plt.xlabel('log(L)')
plt.ylabel('n')
plt.title('Cond. distribution of log likelihood ratio at frequentist  t')

plt.show()
```



The next graph plots the unconditional distribution of log L at the frequentist t, constructed by pooling the two conditional distributions.

With $\pi^* = 0.5$, pooling equal numbers of paths from f_0 and f_1 weights them by π^* and $1 - \pi^*$.

```
n = plt.hist(np.log(np.concatenate([L0_arr[:, t_idx], L1_arr[:, t_idx]])),
             bins=50, alpha=0.4, label='unconditional dist. of log(L)')[0]
plt.vlines(np.log(LB), 0, n.max(), linestyle='--', color='r', label='log($L_B$)')
plt.vlines(np.log(LA), 0, n.max(), linestyle='--', color='b', label='log($L_A$)')
plt.legend()

plt.xlabel('log(L)')
plt.ylabel('n')
plt.title('Uncond. distribution of log likelihood ratio at frequentist  t')

plt.show()
```

34.10 Exercises

Exercise 34.10.1

Fix a sample size t and regard the expected loss (34.1) as a function of the cutoff d.

1. Show that $d^* = (1-\pi^*)\,\bar{L}_0 / \left(\pi^* \bar{L}_1\right)$ minimizes (34.1) for every t. Hint: write PFA and $1-PD$ as integrals over samples z^t and minimize the integrand at each z^t.
2. Let π_t be the posterior probability of f_0 after t draws from a prior π^*. Show that the rule "decide f_1 if $L(z^t) < d^*$" chooses the decision with the smaller posterior expected loss. Explain why this makes the frequentist rule of this lecture a Bayes rule with a sample size fixed in advance.
3. For the 20 values of π^* in `π_star_arr` and $t = 1, \ldots, 20$, compare the simulated loss `V_fre_d_t` at d^* with its minimum over a fine grid of values of d. Do the same for the loss attained by a Nelder-Mead search over d that starts at $d = 1$.

Solution

Write $f_i(z^t) = f_i(z_1) \cdots f_i(z_t)$.

The rule rejects H_0 on the set $R_d = \{z^t : L(z^t) < d\}$.

Then

$$PFA = \int_{R_d} f_0(z^t)\, dz^t, \qquad 1 - PD = \int_{R_d^c} f_1(z^t)\, dz^t$$

and the loss terms of (34.1) that depend on d equal

$$\int \left[\mathbf{1}\{z^t \in R_d\}\, \pi^* \bar{L}_1 f_0(z^t) + \mathbf{1}\{z^t \notin R_d\}\, (1-\pi^*) \bar{L}_0 f_1(z^t) \right] dz^t.$$

The integrand is smallest at each z^t if z^t belongs to R_d whenever $\pi^* \bar{L}_1 f_0(z^t) < (1-\pi^*) \bar{L}_0 f_1(z^t)$ and to its complement otherwise.

Dividing by $\pi^* \bar{L}_1 f_1(z^t)$ turns this condition into $L(z^t) < d^*$.

The set R_{d^*} minimizes the integrand at every z^t, so no other rejection region does better for any t.

Bayes' law gives the posterior

$$\pi_t = \frac{\pi^* L(z^t)}{\pi^* L(z^t) + 1 - \pi^*}.$$

Deciding f_1 has posterior expected loss $\pi_t \bar{L}_1$; deciding f_0 has posterior expected loss $(1-\pi_t)\bar{L}_0$.

The inequality $\pi_t \bar{L}_1 < (1-\pi_t)\bar{L}_0$ is equivalent to $\pi^* L(z^t) \bar{L}_1 < (1-\pi^*)\bar{L}_0$, which is $L(z^t) < d^*$.

After t draws, the frequentist rule with $d = d^*$ therefore takes the action that a Bayesian with prior π^* would take.

Minimizing $\bar{V}_{fre}(t, d^*)$ over t then chooses the best sample size before any data arrive.

The Bayesian sequential rule differs only in letting the data decide when to stop.

Here is the numerical check.

```
from scipy.optimize import minimize

d_grid = np.exp(np.linspace(-10, 10, 4001))

def V_grid_min(t, π_s):
    "Minimum over d_grid of the simulated loss V_fre_d_t."
    n = L0_arr.shape[0]
    PFA = np.searchsorted(np.sort(L0_arr[:, t-1]), d_grid) / n    # Pr{L < d | f0}
    PD = np.searchsorted(np.sort(L1_arr[:, t-1]), d_grid) / n     # Pr{L < d | f1}
    return np.min(π_s * PFA * wf.L1 + (1 - π_s) * (1 - PD) * wf.L0)

gap_closed, gap_nm = [], []
for π_s in π_star_arr:
    for t in range(1, 21):
        V_min = V_grid_min(t, π_s)
        V_closed = V_fre_d_t(d_star(π_s, wf), t, L0_arr, L1_arr, π_s, wf)
        res = minimize(V_fre_d_t, 1, args=(t, L0_arr, L1_arr, π_s, wf),
                       method='Nelder-Mead')
        gap_closed.append(V_closed - V_min)
        gap_nm.append(res.fun - V_min)

gap_closed, gap_nm = np.array(gap_closed), np.array(gap_nm)
print(f"closed form: largest excess over grid minimum {gap_closed.max():.3f}")
print(f"Nelder-Mead: largest excess over grid minimum {gap_nm.max():.3f}, "
      f"cases with excess > 0.5: {np.sum(gap_nm > 0.5)} of {gap_nm.size}")
```

```
closed form: largest excess over grid minimum 0.245
Nelder-Mead: largest excess over grid minimum 0.685, cases with excess > 0.5: 2␣
↪of 400
```

The closed form comes within 0.25 of the grid minimum in all 400 cases.

The grid minimum lies below the loss at d^* because it fits d to the simulated sample; d^* minimizes the population loss.

Nelder-Mead treats the step function `V_fre_d_t` as if it were smooth and can stop on a flat step.

Here it stops more than 0.5 above the grid minimum in 2 of the 400 cases and 0.69 above it in the worst case.

Exercise 34.10.2

A frequentist can test the Navy Captain's hunch without a prior.

Set $\pi^* = 0.5$ and take the error probabilities of the best fixed-sample rule: $\alpha = PFA$ and $\beta = 1 - PD$ at t_{optimal}.

Wald's sequential probability ratio test with targets (α, β) uses the thresholds $a(\alpha, \beta) = (1-\beta)/\alpha$ and $b(\alpha, \beta) = \beta/(1-\alpha)$ of *A Problem that Stumped Milton Friedman*.

That lecture applies them to the likelihood ratio $f_1/f_0 = 1/L$.

In terms of our $L_t = L(z^t)$, the test is

- accept f_0 if $L_t \geq A_L \equiv 1/b(\alpha, \beta) = (1-\alpha)/\beta$
- accept f_1 if $L_t \leq B_L \equiv 1/a(\alpha, \beta) = \alpha/(1-\beta)$
- draw another z if $B_L < L_t < A_L$

Simulate the test on the paths `L0_arr` and `L1_arr`.

Report its realized error probabilities, $E_{f_0}[N]$, and $E_{f_1}[N]$, and compare them with t_{optimal}.

Solution

With $\pi_0 = 1/2$, $\pi_t = L_t/(1+L_t)$.

Wald's test is therefore the rule in `check_results` with $\pi_0 = 1/2$ and probability cutoffs $A_L/(1+A_L)$ and $B_L/(1+B_L)$.

```
V_t, PFA_t, PD_t = V_fre_t(t_optimal, L0_arr, L1_arr, 0.5, wf)
α, β = PFA_t, 1 - PD_t

A_L = (1 - α) / β
B_L = α / (1 - β)

n0, accept0 = check_results(L0_arr, A_L / (1 + A_L), B_L / (1 + B_L), 0, 0.5)
n1, accept1 = check_results(L1_arr, A_L / (1 + A_L), B_L / (1 + B_L), 1, 0.5)

print(f"targets:   α = {α:.3f}, β = {β:.3f}")
print(f"realized:  α = {1 - accept0.mean():.3f}, β = {1 - accept1.mean():.3f}")
print(f"E_f0[N] = {n0.mean():.2f},  E_f1[N] = {n1.mean():.2f},  "
      f"t_optimal = {t_optimal}")
print("paths with no decision by T:", np.sum(n0 > T) + np.sum(n1 > T))
```

```
targets:   α = 0.108, β = 0.059
realized:  α = 0.087, β = 0.019
E_f0[N] = 5.42,  E_f1[N] = 6.84,  t_optimal = 8
paths with no decision by T: 0
```

Wald's test meets both targets.

Its realized error probabilities, 0.087 and 0.019, lie below $\alpha = 0.108$ and $\beta = 0.059$.

It draws 5.42 observations on average under f_0 and 6.84 under f_1, against $t_{\text{optimal}} = 8$ for the fixed-sample rule.

The sequential test has smaller error probabilities and fewer expected draws under both hypotheses, so it dominates the Navy's rule without any appeal to a prior.

Wald and Wolfowitz [1948] proved that no test whose error probabilities are no larger than those of a sequential probability ratio test has a smaller expected number of draws under either hypothesis.

Exercise 34.10.3

This exercise measures the value of sequential sampling.

Evaluate both rules on the simulated paths `L0_arr` and `L1_arr`, so that both use the same random numbers.

1. Set $\pi^* = 0.5$. For a grid of sampling costs c between 0.25 and 14, compute $\bar{V}_{fre}$ and $\bar{V}_{Bayes}$ and plot $\bar{V}_{fre} - \bar{V}_{Bayes}$ against c. For each c, solve the Bayesian's problem again to get new cutoffs A and B. Let the fixed-sample rule choose $t = 0$, which means deciding without data at expected loss $\min\{\pi^* \bar{L}_1, (1-\pi^*)\bar{L}_0\}$.
2. Set $c = 1.25$ and $\pi^* = 0.5$, and let the Bayesian start from a prior $\pi_0 \neq \pi^*$. Plot $\bar{V}_{fre} - \bar{V}_{Bayes}(\pi_0)$ against π_0. Do the same when the fixed-sample rule chooses (t, d) with π_0 in place of π^*.

Solution

The function below computes the expected loss of the Bayesian rule with cutoffs (B, A) and prior π_0 when nature selects f_0 with probability π^*.

A Bayesian whose prior lies outside (B, A) decides without data.

```
def V_baye_sim(A, B, π0, π_star, wf):

    if π0 >= A:
        return (1 - π_star) * wf.L0
    if π0 <= B:
        return π_star * wf.L1

    t0, c0 = check_results(L0_arr, A, B, 0, π0)
    t1, c1 = check_results(L1_arr, A, B, 1, π0)
    assert max(t0.max(), t1.max()) <= T      # every path decides by T

    V0 = wf.c * t0.mean() + wf.L1 * (1 - c0.mean())
    V1 = wf.c * t1.mean() + wf.L0 * (1 - c1.mean())

    return π_star * V0 + (1 - π_star) * V1
```

The misclassification losses of the fixed-sample rule do not depend on c, so we compute them once.

```
π_star = 0.5
t_grid = np.arange(1, T+1)
loss_t = np.array([V_fre_t(t, L0_arr, L1_arr, π_star, wf)[0] for t in t_grid])
loss_0 = min(π_star * wf.L1, (1 - π_star) * wf.L0)    # decide with t = 0

c_grid = np.array([0.25, 0.5, 1, 1.5, 2, 2.5, 3, 4, 6, 8, 10, 14])
V_fre_c = np.empty_like(c_grid)
```

```
V_baye_c = np.empty_like(c_grid)

for i, c in enumerate(c_grid):
    seed_numba(1234)
    wf_c = WaldFriedman(c=c)
    B_c, A_c = find_cutoff_rule(wf_c, solve_model(wf_c))

    V_fre_c[i] = min(loss_0, (c * t_grid + loss_t).min())

```

The gap rises from 2.82 at $c = 0.25$ to 6.77 at $c = 2.5$ and falls to 0.12 at $c = 14$.

When draws are cheap, both rules take many draws and rarely err.

When draws are expensive, both rules take about one draw.

At intermediate costs, the sequential rule stops early after informative draws, while the fixed-sample rule pays for draws that it does not need.

For the second part, `compute_V_fre` with π_0 in place of π^* gives the fixed-sample rule that a decision maker with prior π_0 would choose.

We evaluate that rule's error probabilities with the weights π^* and $1 - \pi^*$.

```

[19.64  6.93  8.15  7.15  6.62  6.12  6.17  6.08  6.06  6.03  6.07  6.07
  6.13  6.51  6.92 35.09 32.29]
```

A Bayesian with a wrong prior still beats the correctly designed fixed-sample rule for $0.15 \leq \pi_0 \leq 0.85$.

At $\pi_0 = 0.1$ and $\pi_0 = 0.9$, the Bayesian starts close to a cutoff and often accepts the wrong distribution.

When the fixed-sample rule uses the same wrong prior, the sequential rule wins at every π_0 on the grid.

35.1 Overview

This lecture studies the merging-of-opinions theorem of Blackwell and Dubins [1962].

The theorem asks a simple question:

> If two agents hold different prior beliefs about a stochastic process but observe the same stream of data indefinitely, will their probability assessments eventually converge?

The answer is yes under an absolute-continuity condition.

If $Q \ll P$ (that is, P dominates Q), then the conditional distributions under P and Q over the entire future path merge in total variation, Q-almost surely.

If in addition $P \ll Q$ (so that $P \sim Q$), then the same conclusion holds under both agents' probabilities.

This result connects to several other ideas:

- Bayesian consistency: posterior predictions approach the truth when the prior lies in the right absolute-continuity class (*Likelihood Ratio Processes and Bayesian Learning*).
- Agreement results: Aumann [1976] studies agents with a common prior and private information; Blackwell–Dubins studies agents with different priors and common information.
- Kakutani's dichotomy: for product measures, equivalence versus singularity can be read from a Hellinger criterion.

We develop the theory in discrete time and then sketch the continuous-time analogue.

Throughout, we use the Beta–Bernoulli model as a running example.

Two agents observe the same stream of coin flips but start from different priors over the coin's bias.

Let us start with some imports.

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.stats import beta as beta_dist, binom, betabinom, norm
from scipy.special import betaln, beta as beta_fn, polygamma
```

35.2 Probability measures on sequence spaces

35.2.1 The sequence space and its filtration

Let $(S, \mathcal{S})$ be a standard Borel space (i.e., a measurable space isomorphic to a Borel subset of a complete separable metric space), called the signal space.

The standard Borel assumption guarantees the existence of regular conditional distributions, which the theorem requires.

Set $\Omega = S^{\mathbb{N}}$, the set of all infinite sequences $\omega = (x_1, x_2, \ldots)$ with $x_n \in S$, equipped with the product σ-algebra $\mathcal{F} = \mathcal{S}^{\otimes\mathbb{N}}$.

For each $n \geq 1$, define the *finite-horizon* σ-algebra

$$\mathcal{F}_n = \sigma(x_1, \ldots, x_n),$$

and set $\mathcal{F}_0 = \{\emptyset, \Omega\}$, so $\mathcal{F}_0 \subseteq \mathcal{F}_1 \subseteq \mathcal{F}_2 \subseteq \cdots \subseteq \mathcal{F}$.

Define $\mathcal{F}_\infty = \sigma\big(\bigcup_{n\geq 1} \mathcal{F}_n\big)$, the σ-algebra of events that can eventually be learned.

Cylinder sets $\{x_1 \in A_1, \ldots, x_n \in A_n\}$ generate the product σ-algebra and belong to $\bigcup_n \mathcal{F}_n$, so $\mathcal{F}_\infty = \mathcal{F}$.

The σ-algebra $\mathcal{F}_\infty$ differs from the **tail σ-algebra** $\mathcal{T} = \bigcap_{n\geq 1} \sigma(x_n, x_{n+1}, \ldots)$, whose events, such as $\{x_n \in A \text{ for infinitely many } n\}$, do not depend on any finite stretch of data.

The collection $\{\mathcal{F}_n\}_{n\geq 1}$ is the **natural filtration** generated by the observation process; $\mathcal{F}_n$ encodes everything that can be learned from the first n data points.

Let P and Q denote two probability measures on $(\Omega, \mathcal{F})$.

Write $P_n = P|_{\mathcal{F}_n}$ and $Q_n = Q|_{\mathcal{F}_n}$ for their restrictions to the history up to time n.

35.2.2 Absolute continuity

Definition 35.2.1 (Absolute Continuity)

P is **absolutely continuous** with respect to Q, written $P \ll Q$, if $Q(A) = 0$ implies $P(A) = 0$ for every $A \in \mathcal{F}$.

They are **mutually absolutely continuous**, or **equivalent**, written $P \sim Q$, if both $P \ll Q$ and $Q \ll P$.

P is **locally absolutely continuous** with respect to Q if $P_n \ll Q_n$ for every $n \geq 1$.

Global absolute continuity $P \ll Q$ implies local absolute continuity, but not conversely.

Mutual absolute continuity means the two agents agree on which events are *possible*.

They can disagree about probabilities, but neither agent rules out an event the other deems possible.

35.2.3 Total variation distance

Definition 35.2.2 (Total Variation Distance)

For two probability measures μ and ν on $(E, \mathcal{E})$,

$$\|\mu - \nu\|_{\text{TV}} = \sup_{A \in \mathcal{E}} |\mu(A) - \nu(A)| = \frac{1}{2} \int_E \left| \frac{d\mu}{d\lambda} - \frac{d\nu}{d\lambda} \right| d\lambda,$$

where λ is any **dominating measure**, meaning $\mu \ll \lambda$ and $\nu \ll \lambda$ (for example, $\lambda = \mu + \nu$).

The distance $\|\mu - \nu\|_{\text{TV}}$ lies in $[0, 1]$; it equals 0 if and only if $\mu = \nu$ and 1 if and only if $\mu \perp \nu$ (mutual singularity).

When $\mu \ll \nu$ with $f = d\mu/d\nu$,

$$\|\mu - \nu\|_{\text{TV}} = \mathbb{E}_\nu[(f-1)^+] = 1 - \mathbb{E}_\nu[\min(f, 1)].$$

Exercise 35.2.1

Show the identity above.

Hint: Start from $\|\mu - \nu\|_{\text{TV}} = \frac{1}{2}\,\mathbb{E}_\nu[|f-1|]$ (which follows from taking ν as the dominating measure) and use the fact that $\mathbb{E}_\nu[f] = 1$.

Solution

Since $\mu \ll \nu$, we can use ν as the dominating measure, so $d\mu/d\nu = f$ and $d\nu/d\nu = 1$, giving

$$\|\mu - \nu\|_{\text{TV}} = \tfrac{1}{2}\,\mathbb{E}_\nu[|f-1|].$$

Write $|f-1| = (f-1)^+ + (1-f)^+$.

Since μ is a probability measure, $\mathbb{E}_\nu[f] = 1$, so the two parts contribute equally: $\mathbb{E}_\nu[(f-1)^+] = \mathbb{E}_\nu[(1-f)^+]$.

Therefore $\frac{1}{2}\,\mathbb{E}_\nu[|f-1|] = \mathbb{E}_\nu[(f-1)^+]$.

Next, note that $(f-1)^+ = f - \min(f,1)$, so $\mathbb{E}_\nu[(f-1)^+] = \mathbb{E}_\nu[f] - \mathbb{E}_\nu[\min(f,1)] = 1 - \mathbb{E}_\nu[\min(f,1)]$.

Total variation is one of the strongest standard notions of distance between probability measures.

If two measures are close in total variation, then their probabilities of every event are close.

35.2.4 The merging question

The Blackwell–Dubins theorem studies the conditional distribution of the *future* given the *past*.

At time n, after observing $(x_1, \dots, x_n)$, each agent forms a conditional distribution over all future events:

$$P(\cdot \mid \mathcal{F}_n)(\omega), \qquad Q(\cdot \mid \mathcal{F}_n)(\omega).$$

These are probability measures on the whole future path, not just the next observation.

The merging question asks whether

$$d_n \;:=\; \big\| P(\cdot \mid \mathcal{F}_n) - Q(\cdot \mid \mathcal{F}_n) \big\|_{\mathrm{TV}} \;\longrightarrow\; 0$$

almost surely as $n \to \infty$.

At $n = 0$ the conditioning is trivial and $d_0 = \|P - Q\|_{\mathrm{TV}}$.

35.3 The likelihood-ratio martingale

Our main tool is the Radon–Nikodym derivative process.

35.3.1 The likelihood ratio

Since $Q \ll P$ implies $Q_n \ll P_n$ for every n, the Radon–Nikodym theorem guarantees the existence of the likelihood ratio

$$Z_n = \frac{dQ_n}{dP_n}, \qquad Z_n \geq 0 \;\; P\text{-a.s.}, \qquad \mathbb{E}_P[Z_n] = 1.$$

The key structural property is that global absolute continuity $Q \ll P$ implies the existence of an overall Radon–Nikodym derivative $Z = dQ/dP$ on all of $(\Omega, \mathcal{F})$, and

$$Z_n = \mathbb{E}_P[Z \mid \mathcal{F}_n] \qquad P\text{-a.s.}$$

That is, $\{Z_n, \mathcal{F}_n\}_{n \geq 0}$ is a non-negative, uniformly integrable P-martingale with $Z_0 = 1$.

Throughout the lecture, Z and Z_n denote densities of Q with respect to P.

Posterior probabilities are martingales of the same kind; *Blackwell's Theorem on Comparing Experiments* uses that property to compare experiments.

Lemma 35.3.1 (Martingale Convergence)

The likelihood-ratio process $\{Z_n\}$ satisfies:

1. $Z_n \to Z_\infty$ P-almost surely as $n \to \infty$.
2. $Z_\infty = \mathbb{E}_P[Z \mid \mathcal{F}_\infty] = Z$ P-a.s.
3. $Z_n \to Z_\infty$ in $L^1(P)$: $\mathbb{E}_P[|Z_n - Z_\infty|] \to 0$.

Proof sketch. Non-negativity and the martingale property give boundedness in $L^1(P)$.

Then almost-sure convergence follows from Doob's martingale convergence theorem [Doob, 1953].

Uniform integrability (which follows from $Z \in L^1(P)$ via the conditional Jensen inequality) upgrades this to $L^1(P)$ convergence.

Lévy's upward theorem identifies the limit as $\mathbb{E}_P[Z \mid \mathcal{F}_\infty]$, which equals Z because $\mathcal{F}_\infty = \mathcal{F}$. □

From here on we write Z_∞ for $Z = dQ/dP$.

35.3.2 Connecting conditional measures to the likelihood ratio

The following identity connects the likelihood ratio to the conditional distributions.

On the set $\{Z_n > 0\}$, the Radon–Nikodym derivative of $Q(\cdot \mid \mathcal{F}_n)$ with respect to $P(\cdot \mid \mathcal{F}_n)$ is

$$\frac{d\,Q(\cdot \mid \mathcal{F}_n)}{d\,P(\cdot \mid \mathcal{F}_n)} = \frac{Z_\infty}{Z_n} \qquad P\text{-a.s. on } \{Z_n > 0\}.$$

This is the abstract Bayes formula $Q(A \mid \mathcal{F}_n) = \mathbb{E}_P[Z_\infty \mathbf{1}_A \mid \mathcal{F}_n] / \mathbb{E}_P[Z_\infty \mid \mathcal{F}_n]$.

The set $\{Z_n > 0\}$ has Q-probability one, because $Q(Z_n = 0) = \mathbb{E}_P[Z_n \mathbf{1}\{Z_n = 0\}] = 0$.

Applying the total-variation formula with $f = Z_\infty / Z_n$ then gives

$$d_n = \mathbb{E}_{P(\cdot \mid \mathcal{F}_n)}\left[\left(\frac{Z_\infty}{Z_n} - 1\right)^+\right] = 1 - \mathbb{E}_{P(\cdot \mid \mathcal{F}_n)}\left[\min\left(\frac{Z_\infty}{Z_n},\, 1\right)\right].$$

Because Z_n is $\mathcal{F}_n$-measurable, the same quantity is a ratio of conditional expectations:

$$d_n = \frac{\mathbb{E}_P[(Z_\infty - Z_n)^+ \mid \mathcal{F}_n]}{Z_n} = \frac{\mathbb{E}_P[|Z_\infty - Z_n| \mid \mathcal{F}_n]}{2 Z_n} \qquad Q\text{-a.s.} \tag{35.1}$$

The second equality holds because $\mathbb{E}_P[Z_\infty - Z_n \mid \mathcal{F}_n] = 0$, so the positive and negative parts of $Z_\infty - Z_n$ have equal conditional means.

Multiplying through by Z_n and taking the P-expectation (then using $\mathbb{E}_P[Z_n\, g] = \mathbb{E}_Q[g]$ for non-negative $\mathcal{F}_n$-measurable g):

$$2\,\mathbb{E}_Q[d_n] \;=\; \mathbb{E}_P[|Z_\infty - Z_n|].$$

So the $L^1(P)$ convergence of the martingale gives $\mathbb{E}_Q[d_n] \to 0$, and its rate governs how fast $\mathbb{E}_Q[d_n]$ goes to zero.

35.4 The Blackwell–Dubins theorem

Theorem 35.4.1 (Blackwell–Dubins (1962))

Let P and Q be probability measures on $(\Omega, \mathcal{F})$ with $Q \ll P$.

Define

$$d_n = \left\| P(\cdot \mid \mathcal{F}_n) - Q(\cdot \mid \mathcal{F}_n) \right\|_{\text{TV}}.$$

Then $d_n \to 0$ Q-almost surely.

The identity $\mathbb{E}_Q[d_n] = \frac{1}{2}\,\mathbb{E}_P[|Z_\infty - Z_n|] \to 0$ gives convergence in Q-probability.

The proof of almost-sure convergence has three steps.

Step 1. A formula for d_n.

Equation (35.1) writes d_n as the ratio of $\mathbb{E}_P[|Z_\infty - Z_n| \,|\, \mathcal{F}_n]$ to $2Z_n$, Q-a.s.

Step 2. The denominator converges to a positive limit.

By *Lemma 35.3.1*, $Z_n \to Z_\infty$ P-a.s., hence Q-a.s. because $Q \ll P$.

The limit is positive Q-a.s., because $Q(Z_\infty = 0) = \mathbb{E}_P[Z_\infty \mathbf{1}\{Z_\infty = 0\}] = 0$.

Step 3. The numerator converges to zero.

Fix $M > 0$ and split $Z_\infty = U + V$, where $U = \min(Z_\infty, M)$ and $V = (Z_\infty - M)^+$.

Let $U_n = \mathbb{E}_P[U \mid \mathcal{F}_n]$ and $V_n = \mathbb{E}_P[V \mid \mathcal{F}_n]$, so $Z_n = U_n + V_n$.

The triangle inequality gives $|Z_\infty - Z_n| \le |U - U_n| + V + V_n$, and conditioning on $\mathcal{F}_n$ gives

$$\mathbb{E}_P[|Z_\infty - Z_n| \,|\, \mathcal{F}_n] \le \mathbb{E}_P[|U - U_n| \,|\, \mathcal{F}_n] + 2V_n.$$

Lévy's upward theorem gives $V_n \to V$ P-a.s.

For the bounded part, fix m and let $W_m = \sup_{k \ge m} |U - U_k| \le 2M$.

For $n \ge m$, $\mathbb{E}_P[|U - U_n| \,|\, \mathcal{F}_n] \le \mathbb{E}_P[W_m \mid \mathcal{F}_n]$, and Lévy's upward theorem sends the right side to W_m as $n \to \infty$.

Lévy's upward theorem also gives $U_k \to U$ P-a.s., so $W_m \to 0$ as $m \to \infty$.

Combining these limits,

$$\limsup_{n \to \infty} \mathbb{E}_P[|Z_\infty - Z_n| \,|\, \mathcal{F}_n] \le 2\,(Z_\infty - M)^+ \qquad P\text{-a.s.}$$

for every M.

Letting $M \to \infty$ through the integers sends the right side to zero, because Z_∞ is finite.

So the numerator converges to zero P-a.s., hence Q-a.s.

Steps 1–3 give $d_n \to 0$ Q-a.s. □

The argument for the bounded part U is Hunt's lemma.

The proof uses no monotonicity of $\{d_n\}$; a *later section* shows that $\{d_n\}$ need not be a supermartingale.

Remark 35.4.1 (One-Sided vs. Mutual Absolute Continuity)

The theorem requires only $Q \ll P$, not $P \ll Q$.

One-sided absolute continuity $Q \ll P$ gives merging Q-almost surely.

Since $Q \ll P$ means every P-null set is also Q-null, Q-a.s. convergence does *not* automatically imply P-a.s. convergence.

To conclude that $d_n \to 0$ under *both* agents' measures, one needs mutual absolute continuity $P \sim Q$.

With $P \ll Q$ added, the proof can be run with the roles of P and Q swapped, yielding $d_n \to 0$ P-a.s. as well.

Remark 35.4.2 (Sharpness)

Absolute continuity matters.

When P and Q are singular, merging can fail completely.

Suppose $P \perp Q$ and $P_n \sim Q_n$ for every n.

Take $S \in \mathcal{F}$ with $P(S) = 1$ and $Q(S) = 0$.

Then $P(S \mid \mathcal{F}_n) = 1$ P-a.s. and $Q(S \mid \mathcal{F}_n) = 0$ Q-a.s.

The events $\{P(S \mid \mathcal{F}_n) = 1\}$ and $\{Q(S \mid \mathcal{F}_n) = 0\}$ belong to $\mathcal{F}_n$, so local equivalence makes each hold both P-a.s. and Q-a.s.

Hence $d_n \geq |P(S \mid \mathcal{F}_n) - Q(S \mid \mathcal{F}_n)| = 1$ for every n, under both measures.

The point-mass example below has $d_n = 1$ for every n.

For product measures, Kakutani's theorem later gives a sharp equivalence-versus-singularity dichotomy.

35.5 The Beta–Bernoulli model

Before turning to Python, we introduce the main example used throughout the simulations.

35.5.1 Model

Suppose the data stream $(x_1, x_2, ...)$ consists of IID Bernoulli draws with unknown probability $p^* \in (0, 1)$.

Agent i has a Beta prior:

$$p \sim \text{Beta}(\alpha_i, \beta_i), \qquad i = 1, 2.$$

After observing n draws with k successes, Bayes' rule yields the posterior

$$p \mid x^n \ \sim \ \text{Beta}(\alpha_i + k, \ \beta_i + n - k),$$

and the one-step-ahead predictive probability is

$$\hat{p}_i^n = \mathbb{E}[p \mid x^n] = \frac{\alpha_i + k}{\alpha_i + \beta_i + n}.$$

By the strong law of large numbers, $k/n \to p^*$ almost surely, so both $\hat{p}_1^n$ and $\hat{p}_2^n$ converge to p^* regardless of the agents' initial priors (α_i, β_i).

35.5.2 The marginal likelihood and likelihood ratio

For each fixed value of $p \in (0,1)$, let P_p denote the IID Bernoulli(p) probability law on infinite sequences.

Agent i does not know p.

Instead, agent i places the prior density π_i on p, which induces a probability measure P_i on data sequences via

$$P_i(A) = \int_0^1 P_p(A)\,\pi_i(p)\,dp \qquad \text{for every event } A.$$

So P_i is the agent's marginal probability measure over histories after averaging over uncertainty about p.

In particular, if x^n is an exact observed history with k successes, then $P_i(x^n)$ means the probability that agent i assigns to that history under this mixture measure.

To compute it, start from the Beta density

$$\pi_i(p) = \frac{p^{\alpha_i - 1}(1-p)^{\beta_i - 1}}{B(\alpha_i, \beta_i)}, \qquad 0 < p < 1.$$

Given p, the probability of that ordered history is $p^k(1-p)^{n-k}$.

Therefore

$$\begin{aligned} P_i(x^n) &= \int_0^1 p^k (1-p)^{n-k} \pi_i(p)\,dp \\ &= \frac{1}{B(\alpha_i, \beta_i)} \int_0^1 p^{\alpha_i + k - 1}(1-p)^{\beta_i + n - k - 1}\,dp \\ &= \frac{B(\alpha_i + k,\ \beta_i + n - k)}{B(\alpha_i,\ \beta_i)}. \end{aligned}$$

where $B(a,b) = \Gamma(a)\Gamma(b)/\Gamma(a+b)$ is the beta function.

This expression is the probability of the ordered history x^n.

It depends on the data only through the count k, so histories with the same number of successes receive the same probability.

The likelihood ratio at time n is therefore

$$Z_n = \frac{P_{1,n}(x^n)}{P_{2,n}(x^n)} = \frac{B(\alpha_2,\ \beta_2)}{B(\alpha_1,\ \beta_1)} \cdot \frac{B(\alpha_1 + k,\ \beta_1 + n - k)}{B(\alpha_2 + k,\ \beta_2 + n - k)}.$$

In the notation of the theorem, $Q = P_1$ and $P = P_2$.

The process $\{Z_n\}$ is a martingale under P_2 (agent 2's probability) and converges almost surely to a finite positive limit Z_∞, reflecting the fact that $P_1 \sim P_2$ for any Beta priors with positive parameters.

The limit has a closed form.

Let $\bar{p} = \lim_n k_n/n$, which exists P_i-a.s. because, conditional on p, the strong law of large numbers applies.

Then

$$Z_\infty = \frac{dP_1}{dP_2} = \frac{\pi_1(\bar{p})}{\pi_2(\bar{p})}.$$

Exercise 35.12.3 asks for a derivation.

For the priors Beta$(1,8)$ and Beta$(8,1)$ used below, $\pi_1(p) = 8(1-p)^7$ and $\pi_2(p) = 8p^7$, so

$$\log Z_\infty = 7 \log \frac{1-\bar{p}}{\bar{p}}.$$

35.5.3 The exact Blackwell–Dubins distance

For the Beta–Bernoulli model, there is a clean formula for d_n.

By construction, agent i's conditional distribution of the future sequence $(x_{n+1}, x_{n+2}, \ldots)$ given x^n is a mixture of IID Bernoulli(p) processes, with p drawn from agent i's posterior Beta distribution.

Exchangeability and Bayesian Updating describes de Finetti's theorem, which delivers such a mixture for every exchangeable process; here the mixture holds by construction.

The Bernoulli$(p)^\infty$ measures for different p are mutually singular, and the limiting frequency $\bar{p}$ recovers p.

The map $\omega \mapsto \bar{p}$ sends each agent's conditional distribution of the future to that agent's posterior, so the TV distance between the conditional distributions is at least the TV distance between the posteriors.

Each conditional distribution is the image of a posterior under the Markov kernel $p \mapsto \text{Bernoulli}(p)^\infty$, so the TV distance between the conditional distributions is at most the TV distance between the posteriors.

Therefore

$$d_n = \left\| \text{Beta}(\alpha_1 + k_n,\, \beta_1 + n - k_n) - \text{Beta}(\alpha_2 + k_n,\, \beta_2 + n - k_n) \right\|_{\text{TV}}.$$

Both posteriors concentrate around k_n/n with standard deviations of order $n^{-1/2}$.

Concentration alone does not deliver $d_n \to 0$.

Two distributions with standard deviation s_n have a TV distance that goes to zero only if their means differ by $o(s_n)$.

When $\alpha_1 + \beta_1 = \alpha_2 + \beta_2 = 9$, as below, the posterior means differ by $\delta_n = (\alpha_2 - \alpha_1)/(n+9) = 7/(n+9)$, which is $O(1/n)$.

Both posterior standard deviations are approximately $s_n = \sqrt{\hat{p}_n(1-\hat{p}_n)/n}$, where $\hat{p}_n = k_n/n$.

Approximating both posteriors by normal distributions with common standard deviation s_n and means δ_n apart gives

$$d_n \approx 2\,\Phi\left(\frac{\delta_n}{2s_n}\right) - 1 \approx \frac{7}{\sqrt{2\pi n\,\hat{p}_n(1-\hat{p}_n)}},$$

where Φ is the standard normal CDF.

At $\hat{p}_n = 0.65$ the right side is $5.85/\sqrt{n}$.

The section on the rate of merging checks this approximation.

When $\alpha_1 + \beta_1 = \alpha_2 + \beta_2$, the ratio of the two posterior densities is proportional to $((1-p)/p)^{\beta_1 - \beta_2}$, which is monotone in p.

The two densities cross once, at a point x^*, and $d_n = |F_1(x^*) - F_2(x^*)|$, where F_i is agent i's posterior CDF.

The following code implements the Beta–Bernoulli updating, predictive probabilities, TV distance, and likelihood-ratio computations described above.

```
def beta_bernoulli_update(data, a0, b0):
    """

```

35.5.4 Simulation

We choose two agents with very different beliefs about the bias of a coin.

- Agent 1 (skeptic): prior Beta$(1, 8)$, so $\hat{p}_1^0 = 1/9 \approx 0.11$.
- Agent 2 (optimist): prior Beta$(8, 1)$, so $\hat{p}_2^0 = 8/9 \approx 0.89$.

Both priors are supported on all of $(0, 1)$, so $P_1 \sim P_2$.

Blackwell–Dubins guarantees merging on P_1-almost every path and on P_2-almost every path.

The figure below follows one path generated by a coin with fixed probability of heads $p^* = 0.65$.

The law $P_{0.65}$ of such a path is singular with respect to P_1 and P_2: the event $\{k_n/n \to 0.65\}$ has $P_{0.65}$-probability one and P_i-probability zero.

Blackwell–Dubins therefore says nothing about this path.

Merging at a fixed p^* follows from the Bernstein–von Mises theorem.

Under P_{p^*}, each agent's posterior is close in total variation to the normal distribution with mean k_n/n and variance $p^*(1-p^*)/n$, so the two posteriors are close to each other.

The normal approximation above makes this concrete.

The next subsection draws p from agent 1's prior on each path, which puts us in the setting of the theorem.

```
p_true = 0.65
a1, b1 = 1.0, 8.0    # skeptic

p_hat = sim['data'].sum() / n_steps
print(f"k_n/n at n = {n_steps}: {p_hat:.3f}")
print(f"d_n at n = {n_steps}: {sim['tv_beta'][-1]:.3f}")
print(f"log Z_n at n = {n_steps}: {sim['log_Z'][-1]:.2f}")
print(f"7 log((1 - k_n/n) / (k_n/n)): "
      f"{7 * np.log((1 - p_hat) / p_hat):.2f}")
print(f"7 log((1 - p*) / p*): {log_Z_limit:.2f}")
```

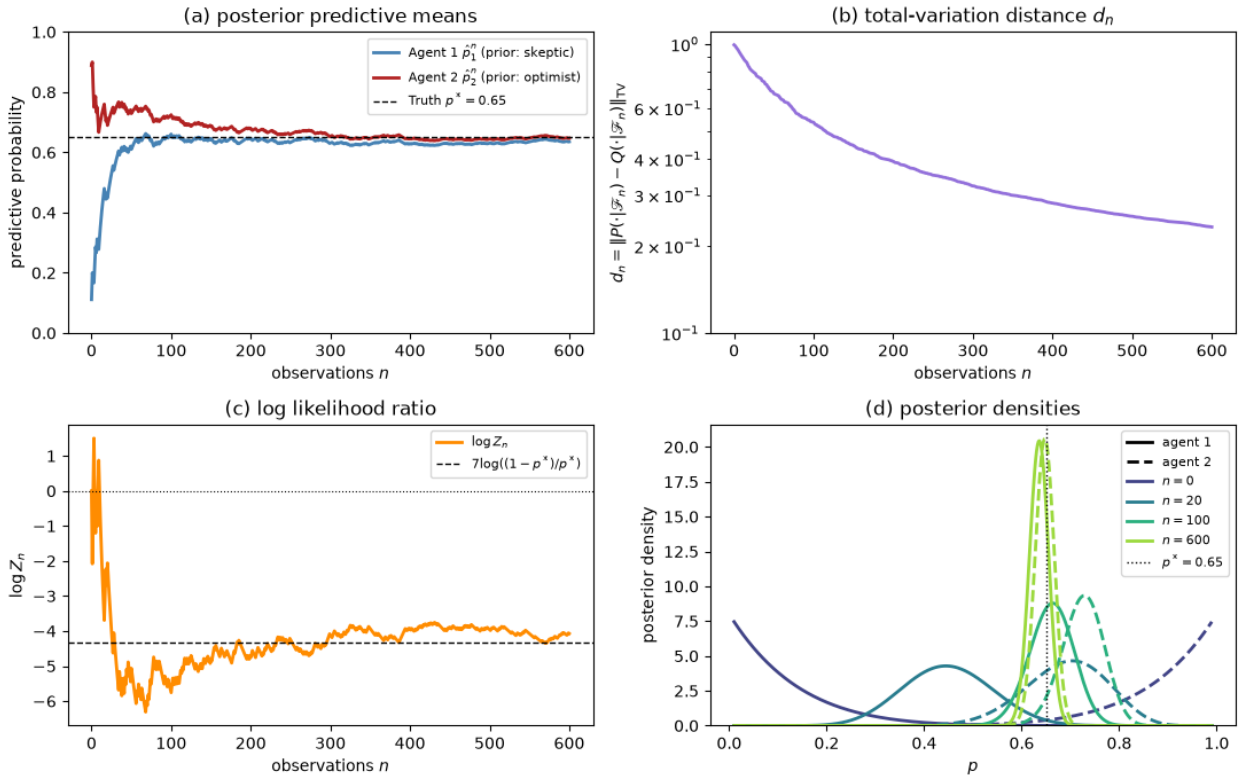

Fig. 35.1: Merging in the Beta–Bernoulli example. The four panels show posterior predictive means, the total-variation distance d_n, the log likelihood ratio $\log Z_n$, and posterior densities at selected horizons.

```
k_n/n at n = 600: 0.643
d_n at n = 600: 0.233
log Z_n at n = 600: -4.07
7 log((1 - k_n/n) / (k_n/n)): -4.13
7 log((1 - p*) / p*): -4.33
```

The four panels show:

- Panel (a): Starting from $\hat{p}_1^0 \approx 0.11$ and $\hat{p}_2^0 \approx 0.89$, both agents' predictive probabilities converge to $p^* = 0.65$.
- Panel (b): The total-variation distance d_n falls from 0.99 to 0.23 at $n = 600$.
- Panel ©: The log likelihood ratio $\log Z_n$ settles near $7 \log((1-p^*)/p^*) = -4.33$, the closed-form limit at $\bar{p} = p^*$. At $n = 600$ the path has $k_n/n = 0.643$, $\log Z_n = -4.07$, and $7 \log((1 - k_n/n)/(k_n/n)) = -4.13$.
- Panel (d): The posterior Beta densities for the two agents start far apart (one near 0, one near 1) and progressively concentrate to the same distribution centred on the truth.

35.5.5 Almost-sure convergence across many paths

To illustrate the almost-sure character of the theorem, we run many independent replications.

Each replication draws p from agent 1's prior $\pi_1 = \text{Beta}(1, 8)$ and then draws $x_1, x_2, \ldots$ IID Bernoulli(p).

Each path is then a draw from P_1.

With $Q = P_1$ and $P = P_2$, the theorem says that $d_n \to 0$ on Q-almost every path.

```
N_paths = 80
n_steps = 2000

rng_p = np.random.default_rng(1234)
p_draws = rng_p.beta(a1, b1, N_paths)     # p drawn from agent 1's prior

tv_all   = np.empty((N_paths, n_steps + 1))
logZ_all = np.empty((N_paths, n_steps + 1))
steps    = np.arange(n_steps + 1)

for i in range(N_paths):
    s = run_simulation(p_draws[i], a1, b1, a2, b2, n_steps, seed=i)
    tv_all[i]   = s['tv_beta']
    logZ_all[i] = s['log_Z']

log_Z_limits = 7 * np.log((1 - p_draws) / p_draws)
norm_p = plt.Normalize(0, p_draws.max())
cmap = plt.cm.viridis

fig, axes = plt.subplots(1, 2, figsize=(11, 4))
ax_tv, ax_log = axes

for i in range(N_paths):
    col = cmap(norm_p(p_draws[i]))
    ax_tv.semilogy(steps, tv_all[i], color=col, lw=0.8, alpha=0.5)
    ax_log.plot(steps, logZ_all[i], color=col, lw=0.8, alpha=0.5)
ax_tv.semilogy(steps, tv_all.mean(axis=0),
               color='black', lw=2, label='mean across paths')
ax_tv.set_xlabel('observations $n$')
ax_tv.set_ylabel(r'$d_n$ (log scale)')
```

(continues on next page)

(continued from previous page)

```
ax_tv.legend()

ax_log.scatter(np.full(N_paths, n_steps), log_Z_limits,
               c=p_draws, cmap=cmap, norm=norm_p, s=12, zorder=3,
               label=r'limit $7 \log((1-p)/p)$')
ax_log.axhline(0, color='gray', lw=0.8, ls=':')
ax_log.set_xlabel('observations $n$')
ax_log.set_ylabel(r'$\log Z_n$')
ax_log.legend()

fig.colorbar(plt.cm.ScalarMappable(norm=norm_p, cmap=cmap),
             ax=axes, label='$p$ drawn from $\\pi_1$')
plt.show()

for n in (500, n_steps):
    print(f"n = {n}: fraction of paths with d_n < 0.30 = "
          f"{np.mean(tv_all[:, n] < 0.30):.2f}, "
          f"mean d_n = {tv_all[:, n].mean():.3f}")
slow = np.argsort(tv_all[:, -1])[-5:]
print(f"p on the five slowest paths: {np.round(p_draws[slow], 4)}")
```

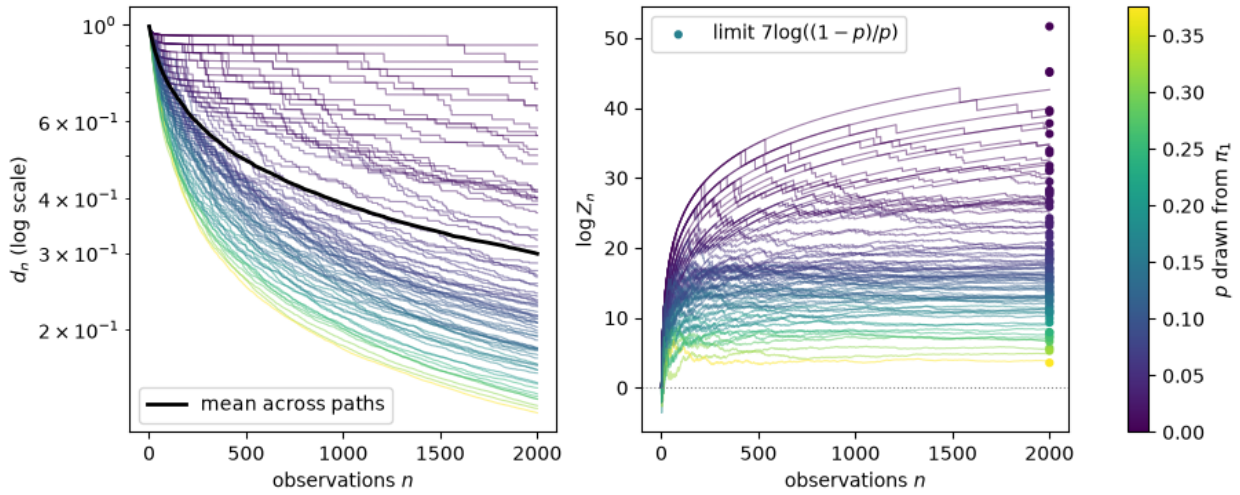

Fig. 35.2: Almost-sure merging across many sample paths drawn from P_1. The left panel plots the total-variation distance and the right panel plots the log likelihood ratio $\log Z_n$. Line colors record the value of p drawn on each path; dots mark the limits $7\log((1-p)/p)$.

```
n = 500: fraction of paths with d_n < 0.30 = 0.14, mean d_n = 0.489
n = 2000: fraction of paths with d_n < 0.30 = 0.68, mean d_n = 0.299
p on the five slowest paths: [0.0036 0.0016 0.0035 0.0006 0.0016]
```

On every path d_{2000} is below d_0, but on many paths d_n falls slowly.

At $n = 500$, 14 percent of paths have $d_n < 0.30$ and the mean of d_n is 0.489; at $n = 2000$ the figures are 68 percent and 0.299.

The slowest paths have p below 0.004.

Agent 2's prior density $8p^7$ is tiny near $p = 0$, so agent 2 needs many observations to move posterior mass there.

These finite-horizon numbers are consistent with the theorem, because almost-sure convergence is an asymptotic state-

ment.

35.5.6 Is d_n a supermartingale?

The proof of the theorem uses no monotonicity of $\{d_n\}$.

In general, $\{d_n\}$ is neither a P-supermartingale nor a Q-supermartingale.

A five-point example shows this.

Let $\Omega = \{1, 2, 3, 4, 5\}$, let P be uniform, and let $Z_\infty = dQ/dP = (0, 1, 1, 1, 2)$.

A first observation reveals whether $\omega \in \{1, 2\}$ or $\omega \in \{3, 4, 5\}$, and a second observation reveals ω.

```
P_pts = np.full(5, 0.2)
Q_pts = np.array([0, 1, 1, 1, 2]) * P_pts
blocks = [[0, 1], [2, 3, 4]]      # cells revealed by the first observation

d_0 = 0.5 * np.abs(P_pts - Q_pts).sum()
E_Q_d1 = E_P_d1 = 0.0
for b in blocks:
    P_b, Q_b = P_pts[b].sum(), Q_pts[b].sum()
    d_1 = 0.5 * np.abs(P_pts[b] / P_b - Q_pts[b] / Q_b).sum()
    E_Q_d1 += Q_b * d_1
    E_P_d1 += P_b * d_1

print(f"d_0 = {d_0:.3f}, E_Q[d_1] = {E_Q_d1:.3f}, E_P[d_1] = {E_P_d1:.3f}")
```

```
d_0 = 0.200, E_Q[d_1] = 0.233, E_P[d_1] = 0.300
```

Here $d_0 = 0.200$, $\mathbb{E}_Q[d_1] = 0.233$, and $\mathbb{E}_P[d_1] = 0.300$.

The first observation raises the expected distance under both measures.

The second observation reveals ω, so $d_2 = 0$.

The identity $2\,\mathbb{E}_Q[d_n] = \mathbb{E}_P[|Z_\infty - Z_n|]$ locates the source of the failure: the L^1 distance between Z_∞ and its conditional expectation given $\mathcal{F}_n$ need not decrease with n.

When $\mathbb{E}_P[Z_\infty^2] < \infty$, the L^2 distance does decrease, because $\mathbb{E}_P[(Z_\infty - Z_n)^2] = \mathbb{E}_P[Z_\infty^2] - \mathbb{E}_P[Z_n^2]$ and $\mathbb{E}_P[Z_n^2]$ is nondecreasing in n.

In the Beta–Bernoulli model with the priors above, the inequality $\mathbb{E}[d_{n+1} \mid \mathcal{F}_n] \le d_n$ holds at every state we check.

The next cell computes $\mathbb{E}_Q[d_{n+1} \mid \mathcal{F}_n] - d_n$ and $\mathbb{E}_P[d_{n+1} \mid \mathcal{F}_n] - d_n$ exactly at every state (n, k_n) with $n < 400$, using each agent's one-step predictive probability.

```
def conditional_increments(n, a1, b1, a2, b2):
    """
    E_Q[d_{n+1} | n, k] - d_n and E_P[d_{n+1} | n, k] - d_n
    for k = 0, ..., n, with Q = P_1 and P = P_2.
    """
    k = np.arange(n + 1)
    d_now  = tv_distance_beta(a1 + k, b1 + n - k, a2 + k, b2 + n - k)
    d_head = tv_distance_beta(a1 + k + 1, b1 + n - k,
                              a2 + k + 1, b2 + n - k)
    d_tail = tv_distance_beta(a1 + k, b1 + n - k + 1,
                              a2 + k, b2 + n - k + 1)
    q1 = (a1 + k) / (a1 + b1 + n)         # agent 1's predictive probability
    q2 = (a2 + k) / (a2 + b2 + n)         # agent 2's predictive probability
```

(continues on next page)

(continued from previous page)

```
    inc_Q = q1 * d_head + (1 - q1) * d_tail - d_now
    inc_P = q2 * d_head + (1 - q2) * d_tail - d_now
    return inc_Q, inc_P

n_check = 400
max_inc_Q = np.empty(n_check)
max_inc_P = np.empty(n_check)
for n in range(n_check):
    inc_Q, inc_P = conditional_increments(n, a1, b1, a2, b2)
    max_inc_Q[n], max_inc_P[n] = inc_Q.max(), inc_P.max()

fig, axes = plt.subplots(1, 2, figsize=(11, 4))

ax = axes[0]
for n, col in zip([20, 100, 399], ['steelblue', 'darkorange', 'firebrick']):
    inc_Q, _ = conditional_increments(n, a1, b1, a2, b2)
    ax.plot(np.arange(n + 1) / n, inc_Q, color=col, lw=2, label=f'$n={n}$')
ax.axhline(0, color='black', lw=0.8, ls='--')
ax.set_xlabel('$k_n / n$')
ax.set_ylabel(r'$\mathbb{E}_Q[d_{n+1} | \mathscr{F}_n] - d_n$')
ax.legend(fontsize=8)

ax = axes[1]
ax.plot(max_inc_Q, color='purple', lw=2, label='under $Q = P_1$')
ax.plot(max_inc_P, color='gray', lw=2, ls='--', label='under $P = P_2$')
ax.axhline(0, color='black', lw=0.8, ls=':')
ax.set_xlabel('observations $n$')
ax.set_ylabel(r'largest increment over $k_n$')
ax.legend(fontsize=8)

plt.tight_layout()
plt.show()

print(f"Largest increment under Q over all states: {max_inc_Q.max():.2e}")
print(f"Largest increment under P over all states: {max_inc_P.max():.2e}")
```

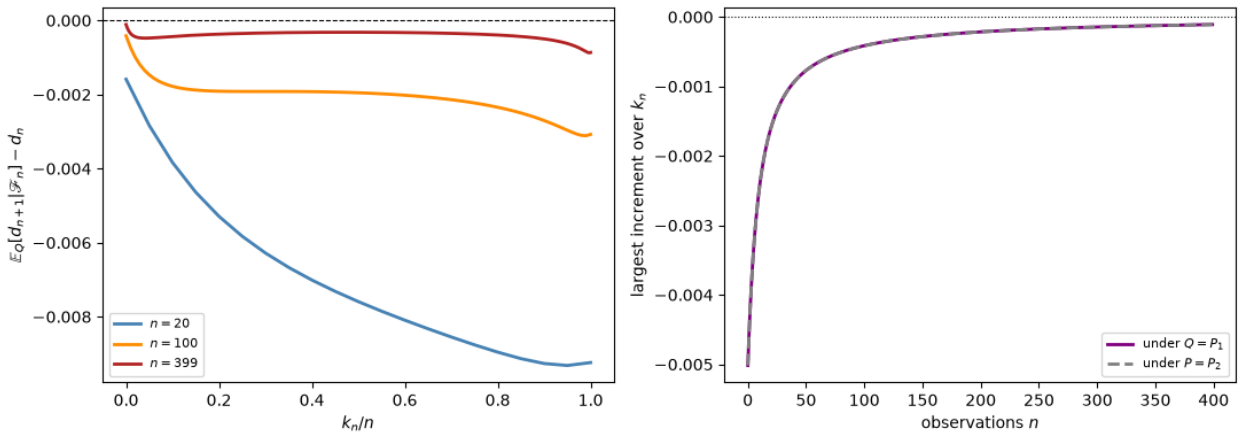

Fig. 35.3: Exact one-step conditional increments of d_n in the Beta–Bernoulli model. The left panel plots $\mathbb{E}_Q[d_{n+1}|\mathcal{F}_n] - d_n$ against k_n/n for selected n. The right panel plots the largest increment over all k_n at each n.

```
Largest increment under Q over all states: -1.10e-04
Largest increment under P over all states: -1.10e-04
```

Every increment is negative, so in this model $\{d_n\}$ behaves as a supermartingale under both P_1 and P_2 over the states we check.

The two curves in the right panel coincide because $\pi_2(p) = \pi_1(1-p)$: exchanging heads and tails exchanges the two agents.

The supermartingale property is specific to the model; the five-point example shows that it fails in general.

35.6 Failure of merging: mutual singularity

What happens when the hypothesis $Q \ll P$ fails?

The singular case is the cleanest counterexample.

35.6.1 Point-mass priors

Suppose both agents hold degenerate (point-mass) priors:

- Agent P: certain that $p = p_P = 0.30$.
- Agent Q: certain that $p = p_Q = 0.75$.

Since P charges only sequences whose empirical frequency converges to 0.30, and Q charges only sequences whose empirical frequency converges to 0.75, the two measures are mutually singular: $P \perp Q$.

The conditional distributions do not update, because both agents are already certain of their model.

For the theorem's object, namely the conditional law of the entire future path,

$$\|P(\cdot \mid \mathcal{F}_n) - Q(\cdot \mid \mathcal{F}_n)\|_{\text{TV}} = \|P - Q\|_{\text{TV}} = 1 \quad \text{for all } n.$$

This equality holds because the infinite-product Bernoulli measures with distinct success probabilities are singular.

If we look only one step ahead, the predictive distance is $|p_P - p_Q| = 0.45$.

That is smaller than one, but it is not the quantity that appears in Blackwell–Dubins.

```
p_P = 0.30
p_Q = 0.75
n_steps = 500

tv_singular_full = np.ones(n_steps + 1)
tv_singular_1step = np.full(n_steps + 1, np.abs(p_P - p_Q))

sim_abs_cont = run_simulation(

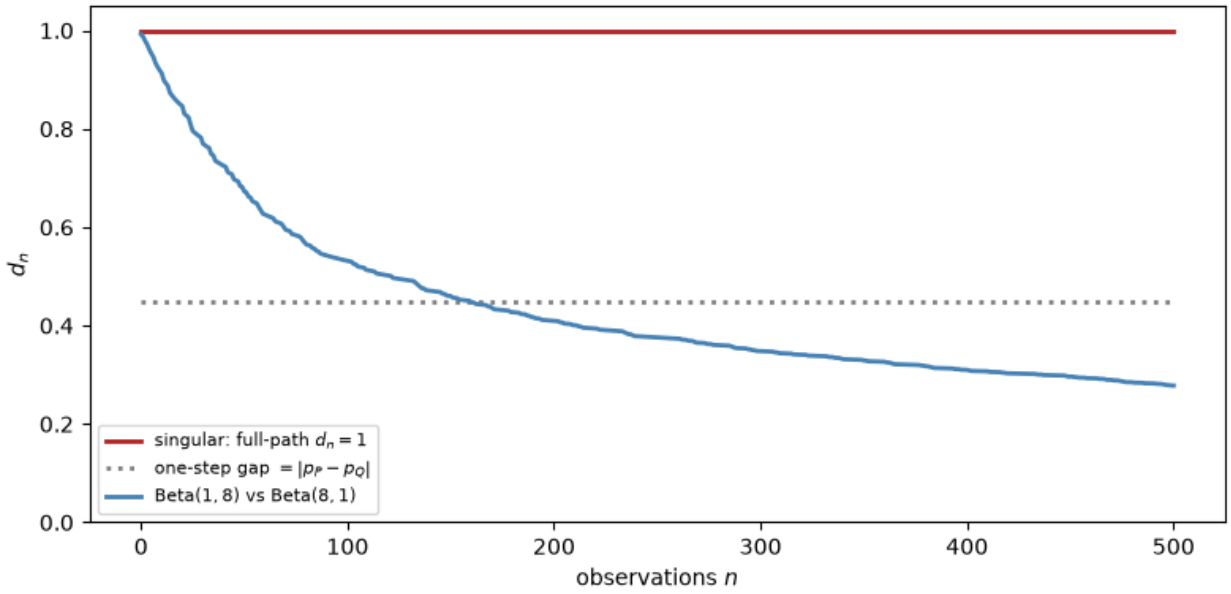

Fig. 35.4: Failure of merging under singular priors. The full future-path distance stays at one, while the one-step predictive gap stays at $|p_P - p_Q|$.

The contrast is sharp.

With mutually absolutely continuous priors, d_n decays to zero on a path generated by a coin with $p = 0.75$.

With singular point-mass priors, the full future-path distance stays at one forever.

More data does not reconcile the agents, because each rules out paths the other assigns positive probability.

35.7 Kakutani's theorem: when does merging hold?

A natural question is: for which product measures does the Blackwell–Dubins hypothesis $Q \ll P$ hold?

For infinite product measures, the answer is given by a classical result of Kakutani [1948].

35.7.1 Hellinger affinities

In this section $P^{(m)}$ and $Q^{(m)}$ denote probability measures on the signal space $(S, \mathcal{S})$, the factors of product measures.

The notation P_n and Q_n keeps its earlier meaning: restrictions of P and Q to $\mathcal{F}_n$.

Definition 35.7.1 (Hellinger Affinity)

For probability measures $P^{(m)}$ and $Q^{(m)}$ on $(S, \mathcal{S})$ with common dominating measure λ, the **Hellinger affinity** is

$$\rho_m = \int_S \sqrt{\frac{dP^{(m)}}{d\lambda} \cdot \frac{dQ^{(m)}}{d\lambda}}\, d\lambda \;\in\; [0, 1].$$

$\rho_m = 1$ if and only if $P^{(m)} = Q^{(m)}$; $\rho_m = 0$ if and only if $P^{(m)} \perp Q^{(m)}$.

The Hellinger affinity is the Bhattacharyya coefficient, the Chernoff coefficient at $\phi = 1/2$ in *Statistical Divergence Measures*.

For two specific one-dimensional families:

- Gaussian: $P^{(m)} = \mathcal{N}(0, 1)$ vs $Q^{(m)} = \mathcal{N}(\mu_m, 1)$:

$$\rho_m^{\text{Gauss}} = \exp\left(-\frac{\mu_m^2}{8}\right).$$

- Bernoulli: $P^{(m)} = \text{Bernoulli}(p)$ vs $Q^{(m)} = \text{Bernoulli}(q)$:

$$\rho_m^{\text{Bern}} = \sqrt{pq} + \sqrt{(1-p)(1-q)}.$$

35.7.2 Kakutani's dichotomy

Theorem 35.7.1 (Kakutani (1948))

Let $P = \bigotimes_{m=1}^{\infty} P^{(m)}$ and $Q = \bigotimes_{m=1}^{\infty} Q^{(m)}$ be infinite product measures whose factors are pairwise equivalent: $P^{(m)} \sim Q^{(m)}$ for every m.

Then either $P \sim Q$ or $P \perp Q$; there is no intermediate case.

Specifically,

$$P \sim Q \quad \Longleftrightarrow \quad \prod_{m=1}^{\infty} \rho_m > 0 \quad \Longleftrightarrow \quad \sum_{m=1}^{\infty} (1 - \rho_m) < \infty.$$

If $\prod_{m=1}^{\infty} \rho_m = 0$, then $P \perp Q$.

Proof idea. A standard proof studies the likelihood-ratio martingale $Z_N = \prod_{m=1}^{N} (dQ^{(m)}/dP^{(m)})$ together with the identity $\mathbb{E}_P[\sqrt{Z_N}] = \prod_{m=1}^{N} \rho_m$.

If the product is positive, $\{\sqrt{Z_N}\}$ is Cauchy in $L^2(P)$, so Z_N converges in $L^1(P)$ and $Q \ll P$; the same argument with P and Q exchanged gives $P \ll Q$.

If the product is zero, Fatou's lemma gives $\mathbb{E}_P[\sqrt{Z_\infty}] = 0$, so $Z_\infty = 0$ P-a.s. and $P \perp Q$.

□

35.7.3 Implication for merging

For IID-type sequences, Kakutani's theorem gives the following picture:

Scenario	$\sum_m (1-\rho_m)$	Conclusion	Merging?
$P^{(m)} = Q^{(m)}$ for all m	0	$P = Q$	Trivially yes
$P^{(m)} \neq Q^{(m)}$ with $\sum_m (1-\rho_m) < \infty$	Finite	$P \sim Q$	Yes; Blackwell–Dubins applies
$P^{(m)} = f \neq g = Q^{(m)}$ for all m	∞	$P \perp Q$	No

The IID case with different fixed marginals is the standard no-merging example.

If two agents assign permanently different distributions to each observation, they end up in disjoint probability worlds.

Likelihood Ratio Processes shows the likelihood ratio process converging to zero when nature permanently draws from one of two fixed densities.

For product measures, the conditional distribution of the future given $\mathcal{F}_n$ does not depend on the past.

So $d_n = \left\| \bigotimes_{m>n} P^{(m)} - \bigotimes_{m>n} Q^{(m)} \right\|_{\text{TV}}$ is deterministic.

Each ρ_m is positive because the factors are equivalent, so dropping finitely many factors does not change whether $\prod_m \rho_m$ is positive.

When $P \perp Q$, the products over $m > n$ are singular, and $d_n = 1$ for every n.

When $P \sim Q$, $d_n \to 0$ by Blackwell–Dubins.

Exercise 35.12.2 computes d_n exactly for Gaussian products.

35.7.4 A Gaussian product-measure example

We illustrate Kakutani's dichotomy with Gaussian product measures.

Take $P = \mathcal{N}(0,1)^{\otimes \mathbb{N}}$ as the reference measure and $Q = \bigotimes_m \mathcal{N}(\mu_m, 1)$ as the alternative.

Then $\log Z_N = \sum_{m=1}^{N} (\mu_m x_m - \mu_m^2/2)$, and the code below draws x_m from $\mathcal{N}(0,1)$, that is, under P.

Three choices of μ_m:

1. $\mu_m = \mu > 0$ constant ($\sum (1-\rho_m) = \infty$) $\Rightarrow P \perp Q$.
2. $\mu_m = c/\sqrt{m}$ ($\sum (1-\rho_m) \approx \sum c^2/(8m) = \infty$) $\Rightarrow P \perp Q$.
3. $\mu_m = c/m$ ($\sum (1-\rho_m) \approx \sum c^2/(8m^2) < \infty$) $\Rightarrow P \sim Q$.

```
N_max  = 2000
ms     = np.arange(1, N_max + 1)
c      = 2.0
N_plot = 400
rng    = np.random.default_rng(0)
```

(continues on next page)

(continued from previous page)

```
cases = [
    (r'$\mu_m = c$ (constant)', np.full(N_max, c)),
    (r'$\mu_m = c/\sqrt{m}$', c / np.sqrt(ms)),
    (r'$\mu_m = c/m$', c / ms),
]
```

With constant drift, $\log Z_N$ drifts to $-\infty$ under P, so $Z_N \to 0$ P-a.s. and $P \perp Q$.

```
label, μ_seq = cases[0]
x = rng.standard_normal(N_plot)
log_Z_inc = μ_seq[:N_plot] * x - μ_seq[:N_plot]**2 / 2
log_Z = np.concatenate([[0], np.cumsum(log_Z_inc)])

fig, ax = plt.subplots(figsize=(8, 3))
ax.plot(np.arange(N_plot + 1), log_Z,
        color='darkorange', lw=2, label=label)
ax.axhline(0, color='black', lw=0.8, ls=':')
ax.set_xlabel('horizon $N$')
ax.set_ylabel(r'$\log Z_N$ under $P$')
ax.legend(fontsize=8)
plt.tight_layout()
plt.show()
```

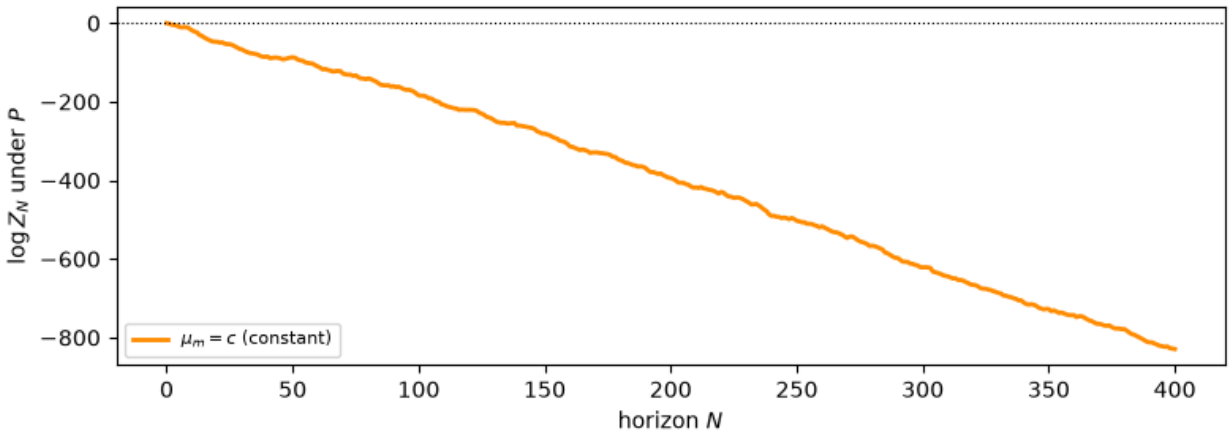

Fig. 35.5: Constant drift $\mu_m = c$: the likelihood ratio collapses ($P \perp Q$).

The $\mu_m = c/\sqrt{m}$ case shows the same qualitative picture: despite the drift vanishing, it does so too slowly.

```
label, μ_seq = cases[1]
x = rng.standard_normal(N_plot)
log_Z_inc = μ_seq[:N_plot] * x - μ_seq[:N_plot]**2 / 2
log_Z = np.concatenate([[0], np.cumsum(log_Z_inc)])

fig, ax = plt.subplots(figsize=(8, 3))
ax.plot(np.arange(N_plot + 1), log_Z,
        color='purple', lw=2, label=label)
ax.axhline(0, color='black', lw=0.8, ls=':')
ax.set_xlabel('horizon $N$')
```

(continues on next page)

(continued from previous page)

```
ax.set_ylabel(r'$\log Z_N$ under $P$')
ax.legend(fontsize=8)
plt.tight_layout()
plt.show()
```

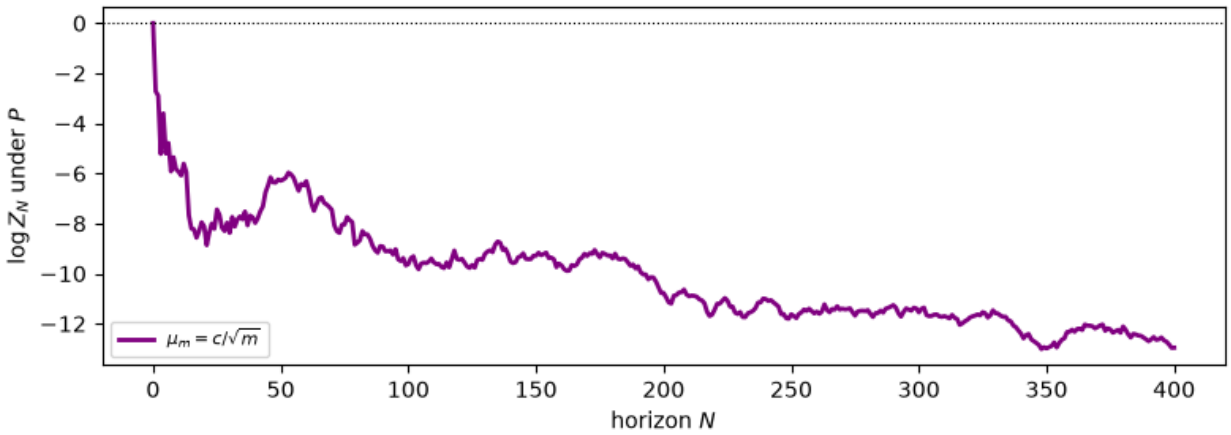

Fig. 35.6: Drift $\mu_m = c/\sqrt{m}$: still singular ($P \perp Q$).

Only with $\mu_m = c/m$ does $\sum(1 - \rho_m) < \infty$ hold, so the likelihood ratio remains nondegenerate and $P \sim Q$.

Blackwell–Dubins applies only in this case.

```
label, μ_seq = cases[2]
x = rng.standard_normal(N_plot)
log_Z_inc = μ_seq[:N_plot] * x - μ_seq[:N_plot]**2 / 2
log_Z = np.concatenate([[0], np.cumsum(log_Z_inc)])

fig, ax = plt.subplots(figsize=(8, 3))
ax.plot(np.arange(N_plot + 1), log_Z,
        color='steelblue', lw=2, label=label)
ax.axhline(0, color='black', lw=0.8, ls=':')
ax.set_xlabel('horizon $N$')
ax.set_ylabel(r'$\log Z_N$ under $P$')
ax.legend(fontsize=8)
plt.tight_layout()
plt.show()
```

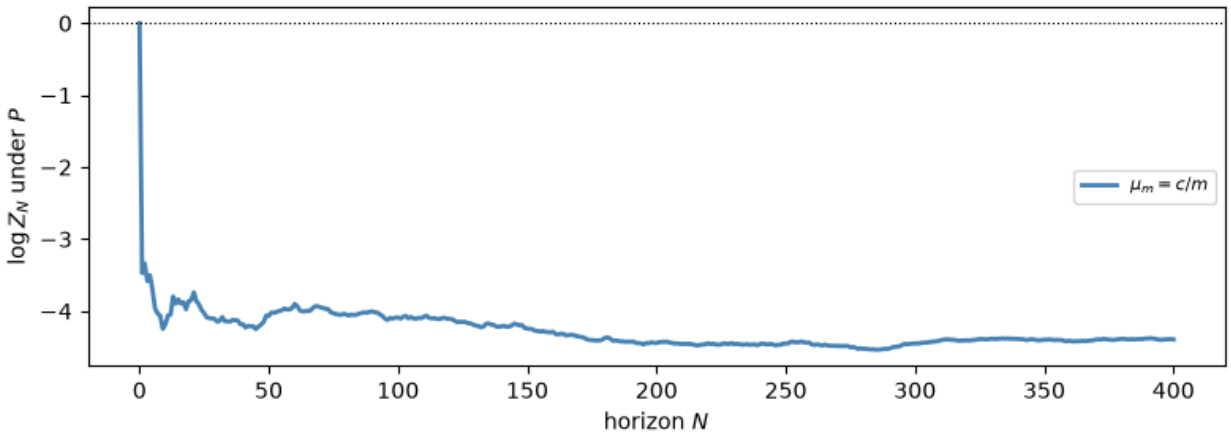

Fig. 35.7: Drift $\mu_m = c/m$: the likelihood ratio stabilises ($P \sim Q$).

35.8 Extension to continuous time

The same logic extends to continuous time.

35.8.1 Girsanov's theorem and the likelihood-ratio process

On the canonical Wiener space with P the Wiener measure (standard Brownian motion W), suppose agent Q believes the process has an additional drift $\theta = \{\theta_s\}_{s \geq 0}$:

$$W_t = \widetilde{W}_t + \int_0^t \theta_s \, ds,$$

where $\widetilde{W}$ is a Q-Brownian motion.

The Girsanov–Cameron–Martin theorem [Girsanov, 1960] gives the likelihood-ratio process $Z_t = dQ_t/dP_t$ as the stochastic exponential

$$Z_t = \exp\left(\int_0^t \theta_s \, dW_s - \frac{1}{2} \int_0^t \theta_s^2 \, ds \right).$$

Z_t is always a non-negative P-local martingale; it is a true martingale if and only if $\mathbb{E}_P[Z_t] = 1$ for all t.

Novikov's condition [Novikov, 1972], $\mathbb{E}_P\left[\exp\left(\frac{1}{2}\int_0^T \theta_s^2 \, ds\right)\right] < \infty$ for all T, is sufficient.

35.8.2 The dichotomy at infinity

A key subtlety on $[0, +\infty)$ is that local absolute continuity does *not* imply global absolute continuity on $\mathcal{F}_\infty$.

Remark 35.8.1 (Infinite-Horizon Subtlety)

Suppose Z_t is a true P-martingale for every finite horizon and let $Z_t \to Z_\infty$ P-a.s.

If $\{Z_t\}$ is uniformly integrable on $[0, \infty)$, then $Q \ll P$ on $\mathcal{F}_\infty$ with $dQ/dP = Z_\infty$.

That is the hypothesis of Blackwell–Dubins, so merging holds Q-a.s.

If in addition $Z_\infty > 0$ P-a.s., then $P \ll Q$ as well, and merging holds P-a.s.

Merging P-a.s. requires only $P \ll Q$, because d_t is symmetric in P and Q and the theorem applies with their roles exchanged.

If uniform integrability fails, then global absolute continuity on $\mathcal{F}_\infty$ can fail.

In many standard examples, including a non-zero constant drift, the measures are in fact singular on $\mathcal{F}_\infty$.

For a deterministic drift θ, the **energy condition**

$$\int_0^\infty \theta_s^2 \, ds < \infty$$

separates the two cases.

If it holds, $\mathbb{E}_P[Z_t^2] = \exp\left(\int_0^t \theta_s^2 \, ds\right)$ is bounded in t, $\{Z_t\}$ is uniformly integrable, $Z_\infty > 0$, and $P \sim Q$ on $\mathcal{F}_\infty$.

If it fails, $\log Z_t \to -\infty$ P-a.s. and $P \perp Q$ on $\mathcal{F}_\infty$.

Informally, $\int_0^\infty \theta_s^2 \, ds$ measures the total amount of information separating the two measures over the infinite horizon.

Under the energy condition, Blackwell–Dubins applies and merging holds under both measures.

When θ is a non-zero constant, the condition fails, the measures are singular on $\mathcal{F}_\infty$, and merging does not occur.

Survival and Long-Run Dynamics under Recursive Preferences studies agents whose beliefs differ from the truth by a constant drift of this kind.

When θ depends on the path of W, $\int_0^\infty \theta_s^2 \, ds$ is a random variable.

In that case $P \sim Q$ on $\mathcal{F}_\infty$ if and only if $\int_0^\infty \theta_s^2 \, ds < \infty$ both P-a.s. and Q-a.s.

Under P, $\log Z_t = \int_0^t \theta_s \, dW_s - \frac{1}{2}\int_0^t \theta_s^2 \, ds$ tends to $-\infty$ on the event $\{\int_0^\infty \theta_s^2 \, ds = \infty\}$.

Under Q, $\log Z_t = \int_0^t \theta_s \, d\widetilde{W}_s + \frac{1}{2}\int_0^t \theta_s^2 \, ds$ tends to $+\infty$ on the same event.

On the complementary event, $\log Z_t$ converges to a finite limit under both measures.

Since $Q \ll P$ on $\mathcal{F}_\infty$ if and only if $Z_\infty < \infty$ Q-a.s., and $P \ll Q$ if and only if $Z_\infty > 0$ P-a.s., the claim follows.

Whenever $Q \ll P$ on $\mathcal{F}_\infty$ is established, the discrete-time proof carries over.

The conditional distance satisfies $d_t = \mathbb{E}_P[|Z_\infty - Z_t| \,|\, \mathcal{F}_t]/(2Z_t)$, $Z_t \to Z_\infty > 0$ Q-a.s., and the truncation argument in Step 3 sends the numerator to zero.

The identity $\mathbb{E}_Q[d_t] = \frac{1}{2}\mathbb{E}_P[|Z_t - Z_\infty|]$ also carries over.

35.9 Applications

35.9.1 Bayesian learning

The most direct application is Bayesian inference.

Suppose data $(x_1, x_2, \ldots)$ are drawn from the true measure Q^*.

An agent holds a prior π over a family $\{Q_\theta : \theta \in \Theta\}$, inducing a marginal $P = \int Q_\theta \, \pi(d\theta)$.

If $Q^* \ll P$ (i.e., the agent's marginal model dominates the truth), then Blackwell–Dubins gives

$$\left\| P(\cdot \mid x_1, \ldots, x_n) - Q^*(\cdot \mid x_1, \ldots, x_n) \right\|_{\mathrm{TV}} \to 0 \quad Q^*\text{-a.s.}$$

This is a strong form of Bayesian consistency: the agent's predictions merge with the truth under the true measure.

A prior assigning positive mass to a neighbourhood of the true parameter typically guarantees *local* absolute continuity $Q_n^* \ll P_n$ for every finite horizon n, but not the global condition $Q^* \ll P$ on $\mathcal{F}_\infty$ that Blackwell–Dubins requires.

For example, in the Beta–Bernoulli model with a non-atomic prior π, the mixture $P = \int \mathrm{Bernoulli}(p)^\infty \, \pi(dp)$ satisfies $Q_n^* \ll P_n$ for every n, yet $Q^* \not\ll P$ globally because the set $\{\lim k_n/n = p^*\}$ has Q^*-measure one but P-measure zero (different Bernoulli product measures are mutually singular).

In an identifiable IID family, the measures Q_θ for distinct θ are mutually singular, so $Q_{\theta^*} \ll P$ if and only if $\pi(\{\theta^*\}) > 0$.

Global absolute continuity therefore holds when π has an atom at θ^*, for example when Θ is finite.

Likelihood Ratio Processes and Bayesian Learning studies an agent whose prior puts positive probability on each of two models, one of which is true; there $Q^* \ll P$.

With a non-atomic prior, the agent's forecasts of the entire future never merge with the truth.

In the Beta–Bernoulli model, the argument that gave the closed form for d_n gives $\|P_i(\cdot \mid \mathcal{F}_n) - P_{p^*}(\cdot \mid \mathcal{F}_n)\|_{\mathrm{TV}} = 1$ for every n, because agent i's posterior has no atom at p^*.

Each agent's one-step-ahead forecast still converges to p^*, and the two agents' forecasts merge with each other.

Doob's consistency theorem [Doob, 1949] states that the posterior concentrates at the true θ for π-almost every θ.

Diaconis and Freedman [1986] study consistency at a fixed parameter value, where Doob's theorem is silent.

They show that in infinite-dimensional models the exceptional π-null set can matter: in a location problem with a Dirichlet-process prior on the error distribution, the posterior can be inconsistent at parameter values in the support of the prior.

In *Incorrect Models*, nature draws IID from a mixture h of densities f and g, while the agent believes that nature drew once and for all from f or from g.

There $P \perp Q^*$, the agent's forecasts stay wrong, and the agent's posterior concentrates on the model closer to h in Kullback–Leibler divergence.

35.9.2 Rational expectations and heterogeneous priors

In macroeconomics, rational-expectations models typically impose a common prior.

Blackwell–Dubins gives a dynamic justification for weaker initial agreement.

If two agents start with equivalent priors and observe the same history, their conditional forecasts eventually agree on every event.

Aumann [1976]'s agreement theorem complements this result.

Aumann's agents share a common prior and see different private information; if their posterior probabilities of an event are common knowledge, the posteriors are equal.

Blackwell and Dubins's agents hold different priors and see the same information.

When merging fails, disagreement persists and has economic consequences.

Heterogeneous Beliefs and Financial Markets studies how wealth moves between agents with different beliefs, including an agent whose prior rules out the true model.

Survival and Long-Run Dynamics under Recursive Preferences studies which agents survive when beliefs differ permanently.

35.9.3 Ergodic Markov chains

For a Markov chain with transition kernel Π and two initial distributions μ and ν, the n-step distributions are $\mu\Pi^n$ and $\nu\Pi^n$.

If Π is ergodic with unique stationary distribution π, both converge to π, so

$$\|\mu\Pi^n - \nu\Pi^n\|_{\mathrm{TV}} \le \|\mu\Pi^n - \pi\|_{\mathrm{TV}} + \|\nu\Pi^n - \pi\|_{\mathrm{TV}} \to 0.$$

This convergence does *not* require absolute continuity: μ and ν can be point masses at different states.

It concerns a different object from Blackwell–Dubins.

The measures $\mu\Pi^n$ and $\nu\Pi^n$ are unconditional distributions of the state at date n, and their convergence says that an ergodic chain forgets its initial condition.

Blackwell–Dubins concerns conditional distributions of the entire future given a common observed history.

Two agents who agree on Π and observe the current state make identical conditional forecasts of the future, whether or not Π is ergodic.

35.10 The rate of merging

Blackwell–Dubins is qualitative.

It tells us that $d_n \to 0$, but not how fast.

The identity

$$\mathbb{E}_Q[d_n] = \tfrac{1}{2}\,\mathbb{E}_P[|Z_n - Z_\infty|]$$

shows that the rate of merging in Q-mean is governed by the $L^1(P)$ convergence rate of the likelihood-ratio martingale.

In regular parametric examples, one often sees $n^{-1/2}$-type behavior.

In the Beta–Bernoulli model, the normal approximation derived earlier gives $d_n \approx 7/\sqrt{2\pi n\,\hat{p}_n(1-\hat{p}_n)}$.

Under a fixed coin P_{p^*}, $\hat{p}_n \to p^*$, so $\mathbb{E}_{P_{p^*}}[d_n] \approx C(p^*)/\sqrt{n}$ with $C(p^*) = 7/\sqrt{2\pi p^*(1-p^*)}$ and $C(0.65) = 5.85$.

Under $Q = P_1$, the coin p is drawn from π_1, and averaging over p gives $\mathbb{E}_Q[d_n] \approx C_Q/\sqrt{n}$ with

$$C_Q = \frac{7}{\sqrt{2\pi}}\,\mathbb{E}_{\pi_1}\left[(p(1-p))^{-1/2}\right] = \frac{7}{\sqrt{2\pi}}\,\frac{B(1/2,\,15/2)}{B(1,\,8)} = 14.7.$$

The next cell computes both expectations exactly by summing d_n over the number of successes k_n, which is binomial under P_{p^*} and beta-binomial under $Q = P_1$.

```
def expected_d(n):
    """Exact E_{P_{p*}}[d_n] and E_Q[d_n], with Q = P_1."""
    k = np.arange(n + 1)
    d = tv_distance_beta(a1 + k, b1 + n - k, a2 + k, b2 + n - k)
    return binom.pmf(k, n, p_true) @ d, betabinom.pmf(k, n, a1, b1) @ d

n_grid = np.unique(np.logspace(0, 4, 60).astype(int))
mean_fixed, mean_Q = np.array([expected_d(n) for n in n_grid]).T

C_fixed = 7 / np.sqrt(2 * np.pi * p_true * (1 - p_true))
C_Q = 7 / np.sqrt(2 * np.pi) * beta_fn(0.5, 7.5) / beta_fn(a1, b1)
```

(continues on next page)

          f"normal approx = {2 * norm.cdf(δ / (2 * s)) - 1:.3f}, "
          f"C/sqrt(n) = {C_fixed / np.sqrt(n):.3f} | "
          f"E_Q[d_n] / (C_Q/sqrt(n)) = {e_Q / (C_Q / np.sqrt(n)):.2f}")

late = n_grid >= 1000
for name, m in (("P_0.65", mean_fixed), ("Q", mean_Q)):
    slope = np.polyfit(np.log(n_grid[late]), np.log(m[late]), 1)[0]
    print(f"log-log slope under {name}, 1000 <= n <= 10^4: {slope:.2f}")
```

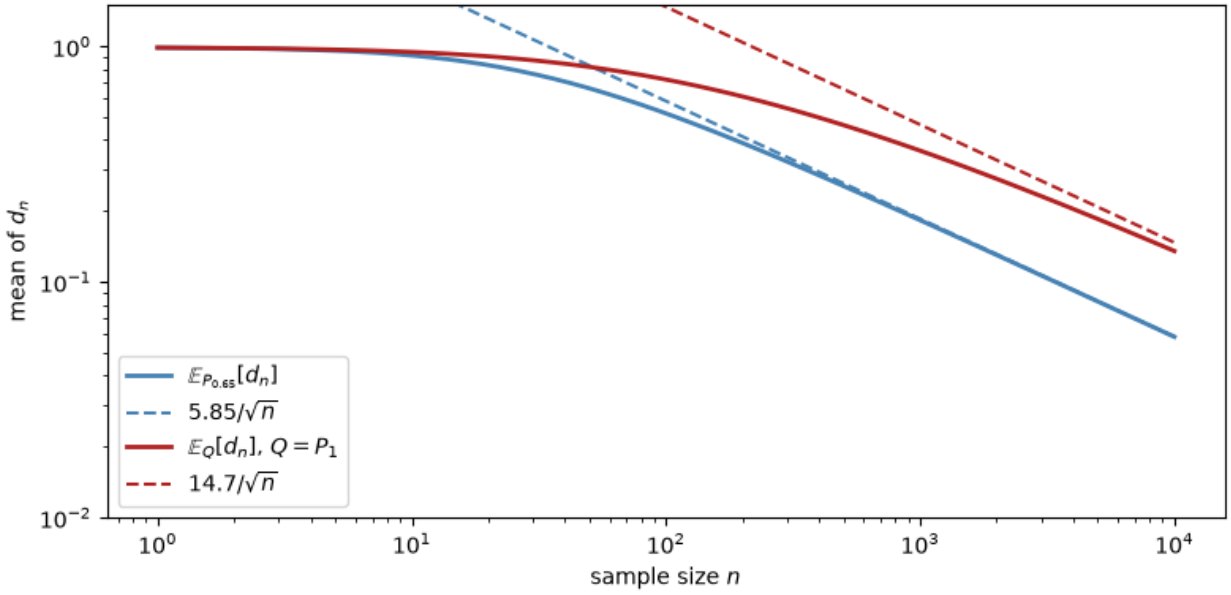

Fig. 35.8: Exact means of d_n in the Beta–Bernoulli model under a fixed coin $P_{0.65}$ and under $Q = P_1$. Dashed lines are the normal approximations $C/\sqrt{n}$.

```
n =    100: E_P0.65[d_n] = 0.519, normal approx = 0.499, C/sqrt(n) = 0.585 | E_Q[d_
 ↪n] / (C_Q/sqrt(n)) = 0.49
n =    500: E_P0.65[d_n] = 0.255, normal approx = 0.253, C/sqrt(n) = 0.262 | E_Q[d_
 ↪n] / (C_Q/sqrt(n)) = 0.70
n =   1000: E_P0.65[d_n] = 0.183, normal approx = 0.182, C/sqrt(n) = 0.185 | E_Q[d_
 ↪n] / (C_Q/sqrt(n)) = 0.78
n =  10000: E_P0.65[d_n] = 0.058, normal approx = 0.058, C/sqrt(n) = 0.059 | E_Q[d_
 ↪n] / (C_Q/sqrt(n)) = 0.92
log-log slope under P_0.65, 1000 <= n <= 10^4: -0.50
log-log slope under Q, 1000 <= n <= 10^4: -0.43
```

Under $P_{0.65}$, the exact mean approaches $5.85/\sqrt{n}$ from below.

At $n = 500$, the exact mean is 0.255, the normal approximation $2\Phi(\delta_n/(2s_n)) - 1$ at $\hat{p}_n = 0.65$ is 0.253, and $5.85/\sqrt{n}$ is 0.262.

The fitted log-log slope over $1000 \le n \le 10^4$ is -0.50.

Under Q, the approach to $14.7/\sqrt{n}$ is slow.

The ratio of $\mathbb{E}_Q[d_n]$ to $14.7/\sqrt{n}$ is 0.70 at $n = 500$ and 0.92 at $n = 10^4$, and the fitted slope over $1000 \le n \le 10^4$ is -0.43.

The prior π_1 puts much of its mass near $p = 0$, where the normal approximation needs np to be large.

35.11 Summary and extensions

The logical flow underlying the Blackwell–Dubins theorem is:

$$Q \ll P \implies Z = \frac{dQ}{dP} \in L^1(P) \implies Z_n = \mathbb{E}_P[Z \,|\, \mathcal{F}_n] \to Z \text{ and } \mathbb{E}_P[|Z - Z_n| \,|\, \mathcal{F}_n] \to 0 \;\; P\text{-a.s.} \implies d_n = \frac{\mathbb{E}_P[|Z - Z_n| \,|\, \mathcal{F}_n]}{2Z_n} \xrightarrow{Q\text{-a}}$$

Takeaways:

1. One-sided absolute continuity $Q \ll P$ gives merging Q-almost surely. For merging under *both* measures, one needs mutual absolute continuity $P \sim Q$.
2. The likelihood-ratio martingale $Z_n = \mathbb{E}_P[Z|\mathcal{F}_n]$ drives the result: in $d_n = \mathbb{E}_P[|Z - Z_n| \,|\, \mathcal{F}_n]/(2Z_n)$, the numerator converges to zero and Z_n converges to $Z > 0$, Q-a.s.
3. More data can only increase the ability to distinguish two hypotheses: $\|P_n - Q_n\|_{\text{TV}}$ on $\mathcal{F}_n$ is nondecreasing in n. The conditional distance d_n need not decrease, even in expectation. It converges to zero when $Q \ll P$.
4. For infinite product measures, Kakutani's theorem gives a sharp equivalence-versus-singularity dichotomy: either $P \sim Q$ (when $\sum_m (1 - \rho_m) < \infty$) or $P \perp Q$ (when the sum diverges), with no intermediate case.
5. When $P \sim Q$, Blackwell–Dubins applies and merging occurs under both measures; when $P \perp Q$ and $P_n \sim Q_n$ for every n, $d_n = 1$ for every n and disagreement persists forever.

35.11.1 Applications in economics

Some influential applications and extensions are:

- [Kalai and Lehrer, 1993]: repeated-game learning drives play toward Nash behavior when priors are absolutely continuous with respect to the truth.
- [Kalai and Lehrer, 1993]: subjective and objective equilibria coincide asymptotically under the same condition.
- [Kalai and Lehrer, 1994]: weak and strong notions of merging are introduced for environments where full total-variation convergence is too strong.
- [Kalai *et al.*, 1999]: merging is linked to calibrated forecasting.
- [Jackson *et al.*, 1999]: de Finetti-style representations are connected to Bayesian learning and posterior convergence.
- [Jackson and Kalai, 1999]: social learning erodes reputational effects that rely on persistent disagreement across cohorts.
- [Sandroni, 1998]: near-absolute-continuity conditions are shown to suffice for Nash-type convergence in repeated games.
- [Miller and Sanchirico, 1999]: gives an alternative proof and an economic interpretation of persistent disagreement in terms of mutually favorable bets.
- [Lehrer and Smorodinsky, 1996]: studies broader compatibility notions beyond Blackwell–Dubins absolute continuity.
- [Lehrer and Smorodinsky, 1996]: surveys merging and learning in repeated strategic environments.
- [Nyarko, 1994]: relates Bayesian learning under absolute continuity to convergence toward correlated equilibrium.
- [Pomatto *et al.*, 2014]: extends the theorem to finitely additive probabilities and connects merging to test manipulability.
- [Acemoglu *et al.*, 2016]: shows how disagreement can persist when agents are uncertain about the signal structure itself.

35.12 Exercises

Exercise 35.12.1

Let agent 1's prior be $\pi_1 = \text{Unif}(0, \frac{1}{2})$ and agent 2's prior be $\pi_2 = \text{Unif}(0, 1)$, and let $P_i = \int_0^1 P_p \, \pi_i(p) \, dp$ as in the Beta–Bernoulli section.

1. Show that $P_1 \ll P_2$ but that $P_2 \ll P_1$ fails.
2. Show that $d_n = \Pr_2(p > \frac{1}{2} \mid x^n)$, agent 2's posterior probability that $p > \frac{1}{2}$.
3. Draw paths from P_2: draw p from π_2, then draw $x_1, x_2, \ldots$ IID Bernoulli(p). Compute and plot d_n along each path, and verify that $d_n \to 0$ on paths with $p < \frac{1}{2}$ and $d_n \to 1$ on paths with $p > \frac{1}{2}$.
4. Reconcile part 3 with the Blackwell–Dubins theorem.

Hint: For part 2, agent 1's posterior is agent 2's posterior conditioned on $p < \frac{1}{2}$.

Solution

Part 1.

The density of π_1 is $2 \cdot \mathbf{1}\{p < \frac{1}{2}\} \leq 2\pi_2(p)$, so $P_1(A) \leq 2P_2(A)$ for every event A, and $P_1 \ll P_2$.

Let $\bar{p} = \limsup_n k_n/n$.

The event $\{\bar{p} > \frac{1}{2}\}$ has P_2-probability $\frac{1}{2}$ and P_1-probability zero, so $P_2 \ll P_1$ fails.

Exercise 35.12.3 gives $dP_1/dP_2 = \pi_1(\bar{p})/\pi_2(\bar{p}) = 2 \cdot \mathbf{1}\{\bar{p} < \frac{1}{2}\}$.

Part 2.

Agent 2's posterior after x^n is $\mu_n = \text{Beta}(k_n + 1, n - k_n + 1)$.

Agent 1's posterior has density proportional to $p^{k_n}(1-p)^{n-k_n}\mathbf{1}\{p < \frac{1}{2}\}$, so it equals $\mu_n(\cdot \mid A)$ with $A = (0, \frac{1}{2})$.

For a probability measure μ, an event A with $\mu(A) > 0$, and any event B,

$$\mu(B \mid A) - \mu(B) = \mu(B \cap A)\left(\frac{1}{\mu(A)} - 1\right) - \mu(B \cap A^c),$$

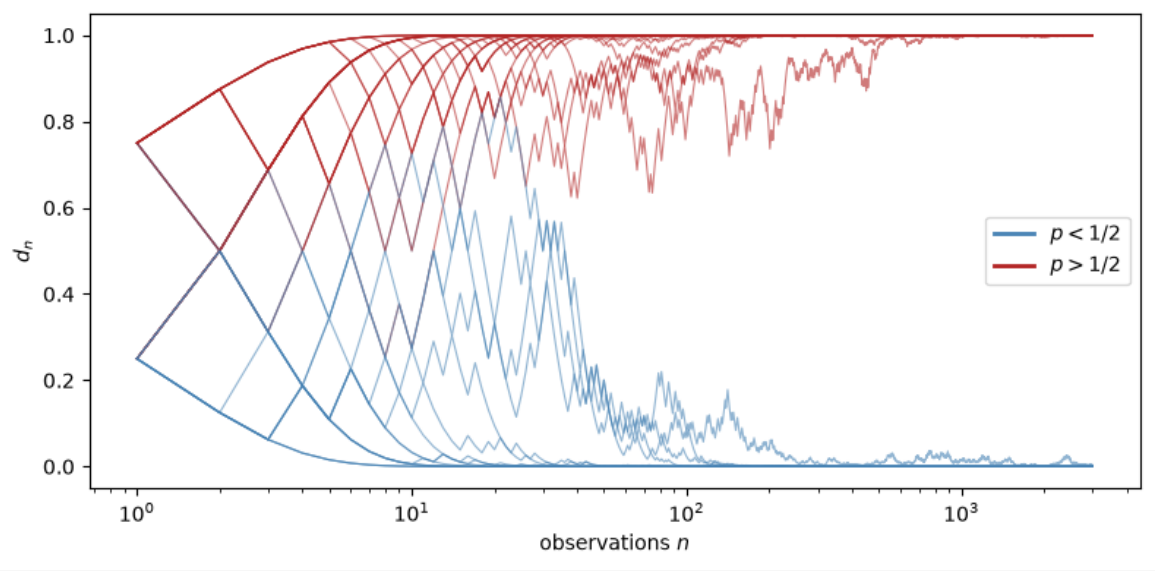
which lies between $-\mu(A^c)$ and $\mu(A^c)$, with the upper bound attained at $B = A$.

Hence $\|\mu(\cdot \mid A) - \mu\|_{\text{TV}} = \mu(A^c)$.

The argument in the Beta–Bernoulli section equates d_n with the TV distance between the two agents' posteriors, so

$$d_n = \mu_n((\tfrac{1}{2}, 1)) = 1 - F_{\text{Beta}(k_n+1,\, n-k_n+1)}(\tfrac{1}{2}).$$

Because $\bar{p} = p$ P_2-a.s., $d_n = P_2(\bar{p} > \frac{1}{2} \mid \mathcal{F}_n)$.



So $\{d_n\}$ is a P_2-martingale, and Lévy's upward theorem gives $d_n \to \mathbf{1}\{\bar{p} > \frac{1}{2}\}$ P_2-a.s.

Part 3.

```
n_steps_ex = 3000
N_paths_ex = 40
rng_ex = np.random.default_rng(0)
p_paths = rng_ex.uniform(0, 1, N_paths_ex)      # p drawn from π_2
steps_ex = np.arange(n_steps_ex + 1)

fig, ax = plt.subplots(figsize=(8, 4))
d_final = np.empty(N_paths_ex)
for i, p in enumerate(p_paths):
    x = rng_ex.binomial(1, p, n_steps_ex)
    k = np.concatenate([[0], np.cumsum(x)])
    d = beta_dist.sf(0.5, k + 1, steps_ex - k + 1)    # Pr_2(p > 1/2 | x^n)
    d_final[i] = d[-1]
    ax.semilogx(steps_ex[1:], d[1:], lw=0.8, alpha=0.6,
                color='firebrick' if p > 0.5 else 'steelblue')
ax.set_xlabel('observations $n$')
ax.set_ylabel('$d_n$')
ax.legend(handles=[
    Line2D([0], [0], color='steelblue', lw=2, label=r'$p < 1/2$'),
    Line2D([0], [0], color='firebrick', lw=2, label=r'$p > 1/2$'),
])
plt.tight_layout()
plt.show()

err = np.abs(d_final - (p_paths > 0.5))
print(f"largest |d_n - 1{{p > 1/2}}| at n = {n_steps_ex}: {err.max():.4f}, "
      f"on the path with p = {p_paths[err.argmax()]:.3f}")
```

```
largest |d_n - 1{p > 1/2}| at n = 3000: 0.0034, on the path with p = 0.486
```

Every path ends near $\mathbf{1}\{p > \frac{1}{2}\}$; the paths that converge slowly have p near $\frac{1}{2}$.

Part 4.

With $Q = P_1$ and $P = P_2$, the hypothesis $Q \ll P$ holds, and the theorem gives $d_n \to 0$ P_1-a.s.

Because $dP_1/dP_2 = 2 \cdot \mathbf{1}\{\bar{p} < \frac{1}{2}\}$, P_1 is P_2 conditioned on $\{\bar{p} < \frac{1}{2}\}$.

So the theorem's conclusion is $d_n \to 0$ P_2-a.s. on $\{\bar{p} < \frac{1}{2}\}$.

The theorem is silent on $\{\bar{p} > \frac{1}{2}\}$, an event with P_2-probability $\frac{1}{2}$ and P_1-probability zero.

There $d_n \to 1$: agent 1's prior rules out $p > \frac{1}{2}$, and no data move agent 1's posterior mass above $\frac{1}{2}$.

Exercise 35.12.2

Let $P = \mathcal{N}(0,1)^{\otimes\mathbb{N}}$ and $Q = \bigotimes_m \mathcal{N}(\mu_m, 1)$, as in the Gaussian product-measure example, and let $\sigma_n^2 = \sum_{m>n} \mu_m^2$.

1. Show that $d_n = 2\Phi(\sigma_n/2) - 1$, with $d_n = 1$ when $\sigma_n = \infty$.
2. For $\mu_m = c/m$, show that $d_n \approx c/\sqrt{2\pi n}$ for large n. Compare the exact and approximate values at $n = 100$ with $c = 2$.
3. For $\mu_m = c/\sqrt{m}$, show that $d_n = 1$ for every n, while the distance between the two agents' one-step-ahead forecasts, $\|\mathcal{N}(0,1) - \mathcal{N}(\mu_{n+1}, 1)\|_{\mathrm{TV}}$, converges to zero.

Kalai and Lehrer [1994] call convergence of forecasts over every fixed finite horizon **weak merging** and convergence of d_n **strong merging**.

Part 3 gives weak merging without strong merging.

Solution

Part 1.

For product measures, the future is independent of the past, so d_n is the TV distance between $\bigotimes_{m>n} \mathcal{N}(0,1)$ and $\bigotimes_{m>n} \mathcal{N}(\mu_m, 1)$.

Suppose $\sigma_n < \infty$.

Then $\sum_{m>n}(1-\rho_m) \leq \sum_{m>n} \mu_m^2/8 < \infty$, so the two tail products are equivalent, and their likelihood ratio is

$$L = \exp\left(S - \tfrac{1}{2}\sigma_n^2\right), \qquad S = \sum_{m>n} \mu_m x_m.$$

Under P, $S \sim \mathcal{N}(0, \sigma_n^2)$; under Q, $S \sim \mathcal{N}(\sigma_n^2, \sigma_n^2)$.

Because L is a function of S, the TV distance between the tail products equals the TV distance between the two laws of S.

Those two normal densities cross at $\sigma_n^2/2$, so

$$d_n = \Phi\left(\frac{\sigma_n}{2}\right) - \Phi\left(-\frac{\sigma_n}{2}\right) = 2\Phi\left(\frac{\sigma_n}{2}\right) - 1.$$

Suppose $\sigma_n = \infty$.

If $\mu_m \not\to 0$, the terms $1-\rho_m = 1 - e^{-\mu_m^2/8}$ do not vanish; if $\mu_m \to 0$, then $1-\rho_m \geq \mu_m^2/16$ for large m.

Either way $\sum_{m>n}(1-\rho_m) = \infty$, Kakutani's theorem makes the tail products singular, and $d_n = 1$.

Part 2.

For $\mu_m = c/m$, $\sigma_n^2 = c^2 \sum_{m>n} m^{-2}$, and $1/(n+1) \leq \sum_{m>n} m^{-2} \leq 1/n$.

So $\sigma_n \approx c/\sqrt{n}$, and $2\Phi(x) - 1 \approx x\sqrt{2/\pi}$ for small x gives $d_n \approx c/\sqrt{2\pi n}$.

The tail sum $\sum_{m>n} m^{-2}$ is the trigamma function $\psi'(n+1)$, which `polygamma(1, n + 1)` computes.

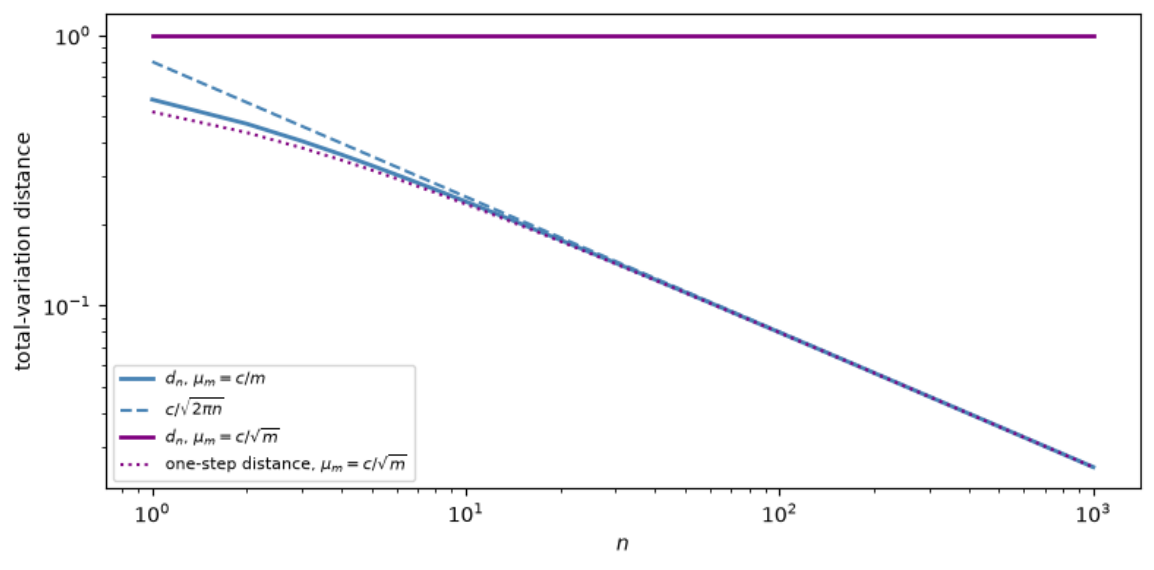
Part 3.

For $\mu_m = c/\sqrt{m}$, $\sum_{m>n} c^2/m = \infty$ for every n, so $d_n = 1$.

The one-step forecast distance is $2\Phi(c/(2\sqrt{n+1})) - 1 \to 0$.

For any fixed k, the distance between the two agents' forecasts of $(x_{n+1}, \ldots, x_{n+k})$ is $2\Phi(\frac{1}{2}(\sum_{m=n+1}^{n+k} c^2/m)^{1/2}) - 1 \leq 2\Phi(c\sqrt{k}/(2\sqrt{n+1})) - 1 \to 0$.

The agents' forecasts of any fixed number of future observations merge, but their forecasts of the entire future never do.



```
c = 2.0
n_vals = np.arange(1, 1001)

σ_inv_m = c * np.sqrt(polygamma(1, n_vals + 1))      # μ_m = c/m
d_inv_m = 2 * norm.cdf(σ_inv_m / 2) - 1
d_inv_m_approx = c / np.sqrt(2 * np.pi * n_vals)
one_step_sqrt = 2 * norm.cdf(c / (2 * np.sqrt(n_vals + 1))) - 1    # μ_m = c/√m

fig, ax = plt.subplots(figsize=(8, 4))
ax.loglog(n_vals, d_inv_m, color='steelblue', lw=2,
          label=r'$d_n$, $\mu_m = c/m$')
ax.loglog(n_vals, d_inv_m_approx, color='steelblue', lw=1.5, ls='--',
          label=r'$c/\sqrt{2\pi n}$')
ax.loglog(n_vals, np.ones_like(n_vals, dtype=float), color='purple',
          lw=2, label=r'$d_n$, $\mu_m = c/\sqrt{m}$')
ax.loglog(n_vals, one_step_sqrt, color='purple', lw=1.5, ls=':',
```

```
          label=r'one-step distance, $\mu_m = c/\sqrt{m}$')
ax.set_xlabel('$n$')
ax.set_ylabel('total-variation distance')
ax.legend(fontsize=8)
plt.tight_layout()
plt.show()

n = 100
print(f"n = {n}: exact d_n = {d_inv_m[n - 1]:.4f}, "
      f"approximation = {d_inv_m_approx[n - 1]:.4f}")
```

```
n = 100: exact d_n = 0.0795, approximation = 0.0798
```

At $n = 100$ with $c = 2$, the exact distance is 0.0795 and the approximation is 0.0798.

The one-step distance for $\mu_m = c/\sqrt{m}$ nearly coincides with d_n for $\mu_m = c/m$, because $\mu_{n+1}^2 = c^2/(n+1)$ and $c^2 \sum_{m>n} m^{-2}$ are both close to c^2/n.

Exercise 35.12.3

Let π_1 and π_2 be prior densities on $(0,1)$ with $\pi_2 > 0$ wherever $\pi_1 > 0$, let $P_i = \int_0^1 P_p \, \pi_i(p)\, dp$, and let $\bar{p} = \limsup_n k_n/n$.

1. Show that $dP_1/dP_2 = \pi_1(\bar{p})/\pi_2(\bar{p})$ on $\mathcal{F}$, so that $Z_\infty = \pi_1(\bar{p})/\pi_2(\bar{p})$.
2. For the priors $\mathrm{Beta}(1,8)$ and $\mathrm{Beta}(8,1)$, simulate several paths from P_2. Compare $\log Z_n$ at large n with $7\log((1-\hat{p}_n)/\hat{p}_n)$, where $\hat{p}_n = k_n/n$, and with $7\log((1-p)/p)$, where p is the coin drawn on that path.

Solution

Part 1.

Under P_p, the strong law of large numbers gives $\bar{p} = p$ almost surely.

Set $\pi_1/\pi_2 = 0$ where $\pi_2 = 0$.

For every $A \in \mathcal{F}$,

$$P_1(A) = \int_0^1 P_p(A)\,\pi_1(p)\,dp = \int_0^1 \mathbb{E}_{P_p}[\mathbf{1}_A]\,\frac{\pi_1(p)}{\pi_2(p)}\,\pi_2(p)\,dp$$
$$= \int_0^1 \mathbb{E}_{P_p}\left[\mathbf{1}_A\,\frac{\pi_1(\bar{p})}{\pi_2(\bar{p})}\right]\pi_2(p)\,dp = \mathbb{E}_{P_2}\left[\mathbf{1}_A\,\frac{\pi_1(\bar{p})}{\pi_2(\bar{p})}\right].$$

The second equality uses $\pi_2 > 0$ wherever $\pi_1 > 0$.

The third replaces p with $\bar{p}$, which equals p P_p-a.s.

So $\pi_1(\bar{p})/\pi_2(\bar{p})$ is a density of P_1 with respect to P_2 on $\mathcal{F}$, and *Lemma 35.3.1* gives $Z_\infty = \pi_1(\bar{p})/\pi_2(\bar{p})$.

A Laplace approximation explains the convergence of Z_n.

The ratio $Z_n = \int_0^1 p^{k_n}(1-p)^{n-k_n}\pi_1(p)\,dp \,/\, \int_0^1 p^{k_n}(1-p)^{n-k_n}\pi_2(p)\,dp$ weights both priors by a likelihood that concentrates near $\hat{p}_n$, so $Z_n \approx \pi_1(\hat{p}_n)/\pi_2(\hat{p}_n)$.

Part 2.

```
n_ex = 20_000
rng_z = np.random.default_rng(5)

print(f"{'p':>6} {'p_hat':>7} {'log Z_n':>9} "
      f"{'gap to p_hat formula':>21} {'gap to p formula':>17}")
for j in range(6):
    p = rng_z.beta(a2, b2)                      # p drawn from π_2
    data = rng_z.binomial(1, p, n_ex)
    log_Z_n = log_likelihood_ratio(data, a1, b1, a2, b2)[-1]
    p_hat = data.mean()
    gap_hat = log_Z_n - 7 * np.log((1 - p_hat) / p_hat)
    gap_true = log_Z_n - 7 * np.log((1 - p) / p)
    print(f"{p:6.3f} {p_hat:7.4f} {log_Z_n:9.3f} "
          f"{gap_hat:21.3f} {gap_true:17.3f}")
```

```
     p   p_hat   log Z_n  gap to p_hat formula  gap to p formula
 0.813  0.8105   -10.169                 0.006             0.113
 0.918  0.9191   -16.996                 0.016            -0.057
 0.877  0.8740   -13.545                 0.009             0.211
 0.917  0.9141   -16.534                 0.015             0.254
 0.856  0.8536   -12.334                 0.008             0.118
 0.986  0.9862   -29.811                 0.099             0.199
```

At $n = 20{,}000$, $\log Z_n$ differs from $7\log((1-\hat{p}_n)/\hat{p}_n)$ by at most 0.10 across these paths.

That gap is the $O(1/n)$ error of the Laplace approximation, and it is largest on the path with p closest to one, where the derivatives of $\log(\pi_1/\pi_2)$ are large.

The gap between $\log Z_n$ and $7\log((1-p)/p)$ reaches 0.25, because $\hat{p}_n$ differs from p by $O(n^{-1/2})$; that gap vanishes as $\hat{p}_n \to p$.

On the path in the first figure of the lecture, $\log Z_{600} = -4.07$ and $7\log((1-\hat{p}_{600})/\hat{p}_{600}) = -4.13$.

36.1 Overview

This lecture studies the theory of long-run survival in Borovička [2020].

The classical **market selection hypothesis** says that agents with less accurate beliefs are driven out of the market in the long run.

Sandroni [2000] and Blume and Easley [2006] established this result for economies with separable expected-utility preferences and aggregate endowment bounded above and away from zero.

Borovička shows that the conclusion can fail under Epstein-Zin recursive preferences.

With recursive preferences, agents with distorted beliefs can survive and can even dominate.

The key mechanism is that recursive preferences separate risk aversion from the intertemporal elasticity of substitution.

Three channels matter for survival:

1. The *risk premium channel* rewards the more optimistic agent for holding more of the risky asset.
2. The *speculative volatility channel* penalizes aggressive positions through log-return volatility.
3. The *saving channel* changes consumption and saving decisions when the IES differs from one.

Under separable preferences, risk aversion equals the inverse of the IES, and that restriction ties the three channels together.

Their sum then depends only on the relative entropies of the two agents' beliefs, and the agent with more accurate beliefs dominates.

Under recursive preferences, the comparison of risk aversion γ with the inverse IES ρ determines which long-run outcomes can occur.

Both agents can survive only if $\gamma > \rho$, which means that agents prefer early resolution of uncertainty.

Each agent can dominate with positive probability only if $\gamma < \rho$.

An IES above one strengthens the saving channel of an optimistic agent, but coexistence does not require it.

Note

The paper builds on the continuous-time recursive utility formulation of Duffie and Epstein [1992], using the planner's problem approach of Dumas *et al.* [2000].

Important foundations for the market selection hypothesis were laid by De Long *et al.* [1991] and Blume and Easley [1992].

We start with some imports.

```
import numpy as np
import matplotlib.pyplot as plt
from math import erf, sqrt
from scipy.optimize import brentq
```

36.2 Environment

The economy contains two infinitely lived agents, indexed by $n \in \{1, 2\}$.

The agents have identical recursive preferences but different beliefs about aggregate endowment growth.

We write Borovička's belief distortions u^n as ω^n.

36.2.1 Aggregate endowment

Under the true probability measure P, aggregate endowment satisfies

$$d \log Y_t = \mu_Y dt + \sigma_Y dW_t, \quad Y_0 > 0 \tag{36.1}$$

where W is a standard Brownian motion, μ_Y is the drift, and $\sigma_Y > 0$ is the volatility.

36.2.2 Heterogeneous beliefs

Agent n believes that the drift is $\mu_Y + \omega^n \sigma_Y$ instead of μ_Y.

The parameter ω^n measures optimism when $\omega^n > 0$ and pessimism when $\omega^n < 0$.

Agent n's subjective probability measure Q^n is defined by the Radon–Nikodym derivative

$$M_t^n = \left. \frac{dQ^n}{dP} \right|_t = \exp\left(-\frac{1}{2} |\omega^n|^2 t + \omega^n W_t \right) \tag{36.2}$$

M^n is a likelihood ratio process, a continuous-time counterpart of the processes studied in *Likelihood Ratio Processes*.

Under Q^n, the process $W_t^n = W_t - \omega^n t$ is a Brownian motion, and agent n perceives

$$d \log Y_t = (\mu_Y + \omega^n \sigma_Y) dt + \sigma_Y dW_t^n.$$

An agent with $\omega^n > 0$ is optimistic about endowment growth, while an agent with $\omega^n < 0$ is pessimistic.

Beliefs are dogmatic: agent n never revises ω^n as she observes Y.

For each finite t, Q^n and P are equivalent on $\mathcal{F}_t$.

Under P, $\log M_t^n$ has constant drift $-\frac{1}{2}(\omega^n)^2$, so $M_t^n \to 0$ P-almost surely when $\omega^n \neq 0$, and Q^n and P are mutually singular on $\mathcal{F}_\infty$.

The Blackwell–Dubins theorem in *Merging of Opinions: The Blackwell–Dubins Theorem* requires absolute continuity on $\mathcal{F}_\infty$, so it does not apply here.

An agent with $\omega^n \neq 0$ never comes to agree with P, and agents with $\omega^1 \neq \omega^2$ never come to agree with each other.

Market selection replaces merging: the open question is whether the market eliminates the agent whose beliefs are wrong.

36.2.3 Recursive preferences

Both agents have Epstein-Zin recursive preferences.

We use $\gamma > 0$ for relative risk aversion, $\rho > 0$ for the inverse of the IES, and $\beta > 0$ for the time-preference rate.

The Duffie-Epstein-Zin felicity function is

$$F(C, \nu) = \beta \frac{C^{1-\gamma}}{1-\gamma} \cdot \left(\frac{(1-\gamma) - (1-\rho)\nu/\beta}{\rho - \gamma} \right)^{(\gamma-\rho)/(1-\rho)} \tag{36.3}$$

where ν is the endogenous discount rate.

Note

In discrete time, Epstein-Zin preferences aggregate current consumption with a certainty equivalent of future utility via a CES aggregator (see Doubts or Variability?).

In continuous time there is no "next-period V_{t+1}," so Duffie and Epstein [1992] recast the recursion as a felicity function $F(C, \nu)$ that depends on the agent's own continuation-value rate ν.

The two formulations encode the same separation of risk aversion γ from the inverse IES ρ.

When $\gamma = \rho$, preferences reduce to the standard separable CRRA case.

36.3 Planner's problem

Following Dumas *et al.* [2000], we study equilibrium allocations through a social planner's problem.

The planner chooses consumption shares z^1 and $z^2 = 1 - z^1$ and discount-rate processes ν^n for the two agents.

36.3.1 Modified discount factors

It is convenient to absorb belief distortions into the modified discount factors $\tilde{\lambda}^n = \lambda^n M^n$, where M^n is the Radon-Nikodym derivative (36.2).

These processes satisfy

$$d \log \tilde{\lambda}_t^n = -\left(\nu_t^n + \frac{1}{2}(\omega^n)^2\right) dt + \omega^n dW_t. \tag{36.4}$$

Exercise 36.3.1

Derive (36.4).

Hint: Use $\log \tilde{\lambda}^n = \log \lambda^n + \log M^n$. The Pareto weight λ^n evolves as $d \log \lambda_t^n = -\nu_t^n \, dt$, and $\log M_t^n$ is given by (36.2).

Solution

From the definition $\tilde{\lambda}^n = \lambda^n M^n$, we have

$$\log \tilde{\lambda}_t^n = \log \lambda_t^n + \log M_t^n.$$

The Pareto weight satisfies $d \log \lambda_t^n = -\nu_t^n \, dt$.

From (36.2), $\log M_t^n = -\frac{1}{2}|\omega^n|^2 t + \omega^n W_t$, so

$$d \log M_t^n = -\tfrac{1}{2}(\omega^n)^2 \, dt + \omega^n \, dW_t.$$

Adding the two:

$$d \log \tilde{\lambda}_t^n = -\nu_t^n \, dt - \tfrac{1}{2}(\omega^n)^2 \, dt + \omega^n \, dW_t = -\left(\nu_t^n + \tfrac{1}{2}(\omega^n)^2\right) dt + \omega^n \, dW_t.$$

36.3.2 State variable: Pareto share

The key state variable is the Pareto share of agent 1:

$$\upsilon = \frac{\tilde{\lambda}^1}{\tilde{\lambda}^1 + \tilde{\lambda}^2} \in (0,1) \tag{36.5}$$

It captures the relative weight of agent 1 in the planner's allocation.

Define the log-odds ratio $\vartheta = \log(\upsilon/(1-\upsilon))$.

Its dynamics are

$$d\vartheta_t = \underbrace{\left[\nu_t^2 + \frac{1}{2}(\omega^2)^2 - \nu_t^1 - \frac{1}{2}(\omega^1)^2\right]}_{m_\vartheta(\upsilon_t)} dt + (\omega^1 - \omega^2) dW_t \tag{36.6}$$

The drift $m_\vartheta(\upsilon)$ determines the long-run behavior of the Pareto share.

Exercise 36.3.2

Derive (36.6) from (36.4) and the definition $\vartheta = \log(\upsilon/(1-\upsilon))$.

Hint: First show that $\vartheta = \log\tilde{\lambda}^1 - \log\tilde{\lambda}^2$, then subtract the two SDEs.

Solution

Since $\upsilon = \tilde{\lambda}^1/(\tilde{\lambda}^1 + \tilde{\lambda}^2)$, we have $1 - \upsilon = \tilde{\lambda}^2/(\tilde{\lambda}^1 + \tilde{\lambda}^2)$, so

$$\vartheta = \log\frac{\upsilon}{1-\upsilon} = \log\tilde{\lambda}^1 - \log\tilde{\lambda}^2.$$

From (36.4), the two log-discount-factor SDEs are

$$d\log\tilde{\lambda}_t^1 = -\left(\nu_t^1 + \tfrac{1}{2}(\omega^1)^2\right)dt + \omega^1 dW_t,$$

$$d\log\tilde{\lambda}_t^2 = -\left(\nu_t^2 + \tfrac{1}{2}(\omega^2)^2\right)dt + \omega^2 dW_t.$$

Subtracting the second from the first:

$$d\vartheta_t = \left[\nu_t^2 + \tfrac{1}{2}(\omega^2)^2 - \nu_t^1 - \tfrac{1}{2}(\omega^1)^2\right]dt + (\omega^1 - \omega^2)dW_t.$$

36.3.3 HJB equation

Homotheticity reduces the planner's problem to a nonlinear ODE in the single state variable υ.

Because each agent's utility is homogeneous of degree $1-\gamma$ in consumption, the planner's value function is homogeneous of degree one in the weights $(\tilde{\lambda}^1, \tilde{\lambda}^2)$ and of degree $1-\gamma$ in Y.

It factors as $J(\tilde{\lambda}, Y) = (\tilde{\lambda}^1 + \tilde{\lambda}^2)Y^{1-\gamma}\tilde{J}(\upsilon)$, eliminating Y as a state variable.

From discrete to continuous time

In discrete time, a planner maximizes a weighted sum of agents' utilities by choosing allocations at each date.

The Bellman equation is

$$\tilde{J}(\upsilon) = \max_{z^1, z^2} \left\{ \upsilon\, u(z^1) + (1-\upsilon)\, u(z^2) + \delta\, \mathbb{E}\left[\tilde{J}(\upsilon')\right] \right\}.$$

Here $\delta \in (0,1)$ is a one-period discount factor; elsewhere in this lecture β is a continuous-time rate of time preference.

In continuous time, the period length shrinks to dt.

The "flow payoff" over $[t, t+dt)$ becomes $\left[\upsilon F(z^1,\nu^1) + (1-\upsilon)F(z^2,\nu^2)\right] dt$, where F is the Duffie-Epstein-Zin felicity (36.3).

The expected change in the value function over dt is captured by the **infinitesimal generator** $\mathcal{L}$.

For a diffusion $d\upsilon = m\, dt + s\, dW$, Itô's lemma gives

$$\mathcal{L}\tilde{J}(\upsilon) = m(\upsilon)\, \tilde{J}'(\upsilon) + \tfrac{1}{2} s(\upsilon)^2\, \tilde{J}''(\upsilon),$$

where m and s are the drift and diffusion of the Pareto share.

This is the continuous-time analogue of $\delta\, \mathbb{E}[\tilde{J}(\upsilon')] - \tilde{J}(\upsilon)$: it measures how the value function drifts and fluctuates as υ evolves.

Setting flow payoff plus expected capital gain equal to zero gives the schematic HJB equation:

$$0 = \sup_{(z^1, z^2, \nu^1, \nu^2)} \left\{ \upsilon F(z^1,\nu^1) + (1-\upsilon)F(z^2,\nu^2) + \mathcal{L}\tilde{J}(\upsilon) \right\} \tag{36.7}$$

subject to $z^1 + z^2 \leq 1$.

Exact reduced ODE

Proposition 2.3 of Borovička [2020] gives the exact HJB equation after substituting the homogeneity reduction $J(\tilde{\lambda}, Y) = (\tilde{\lambda}^1 + \tilde{\lambda}^2) Y^{1-\gamma} \tilde{J}(\upsilon)$ and the dynamics of υ and Y:

$$\begin{aligned} 0 = \sup_{(z^1, z^2, \nu^1, \nu^2)} & \; \upsilon\, F(z^1,\nu^1) + (1-\upsilon)\, F(z^2,\nu^2) \\ & + \left[-\upsilon\nu^1 - (1-\upsilon)\nu^2 + (\upsilon\omega^1 + (1-\upsilon)\omega^2)(1-\gamma)\sigma_Y + (1-\gamma)\mu_Y + \tfrac{1}{2}(1-\gamma)^2\sigma_Y^2 \right] \tilde{J}(\upsilon) \\ & + \upsilon(1-\upsilon)\left[\nu^2 - \nu^1 + (\omega^1 - \omega^2)(1-\gamma)\sigma_Y \right] \tilde{J}'(\upsilon) \\ & + \tfrac{1}{2}\upsilon^2 (1-\upsilon)^2 (\omega^1 - \omega^2)^2\, \tilde{J}''(\upsilon) \end{aligned} \tag{36.8}$$

subject to $z^1 + z^2 \leq 1$.

The first line is the flow payoff from the two agents' felicity functions.

The second line multiplies $\tilde{J}(\upsilon)$ by a term that combines the agents' discount rates, belief-weighted endowment drift, and a variance correction – these arise from absorbing the $Y^{1-\gamma}$ factor via Itô's lemma.

The third line multiplies $\tilde{J}'(\upsilon)$ by the drift of the Pareto share, which depends on the difference in discount rates and the belief-weighted response to endowment risk.

The fourth line multiplies $\tilde{J}''(\upsilon)$ by the squared diffusion of the Pareto share.

The boundary conditions are $\tilde{J}(0) = \tilde{V}^2$ and $\tilde{J}(1) = \tilde{V}^1$, where $\tilde{V}^n$ is the continuation value in the homogeneous economy populated by agent n alone.

This is the continuous-time counterpart of the discrete-time planner's problem in Blume and Easley [2006] (see also *Heterogeneous Beliefs and Financial Markets*).

36.4 Survival conditions

The central result characterizes survival by the boundary behavior of $m_\vartheta(\upsilon)$.

Proposition 36.4.1

Define the following repelling conditions (i) and (ii) and their attracting counterparts (i') and (ii'):

$$\text{(i)} \lim_{\upsilon \searrow 0} m_\vartheta(\upsilon) > 0, \qquad \text{(i')} \lim_{\upsilon \searrow 0} m_\vartheta(\upsilon) < 0$$

$$\text{(ii)} \lim_{\upsilon \nearrow 1} m_\vartheta(\upsilon) < 0, \qquad \text{(ii')} \lim_{\upsilon \nearrow 1} m_\vartheta(\upsilon) > 0$$

Then:

(a) If (i) and (ii) hold, both agents survive under P.

(b) If (i) and (ii') hold, agent 1 dominates in the long run under P.

© If (i') and (ii) hold, agent 2 dominates in the long run under P.

(d) If (i') and (ii') hold, each agent dominates with strictly positive probability.

The proof uses the Feller classification of boundary behavior for diffusions, as in Karlin and Taylor [1981].

Condition (i) says that when agent 1 is close to extinction, there is a force pushing her share back up.

Condition (ii) says that when agent 1 is close to absorbing the whole economy, there is a force pushing her share back down.

When both forces are present, the Pareto share is recurrent and both agents survive.

36.5 Wealth dynamics decomposition

We now rewrite the survival conditions from *Proposition 36.4.1* in terms of equilibrium wealth dynamics.

Agent 1 survives near extinction if and only if her wealth grows faster than agent 2's when she is negligibly small.

When $\upsilon \searrow 0$, prices are set entirely by agent 2, as if the economy were homogeneous.

Agent 1 is a price-taker in agent 2's economy.

Let $m_A^n(\upsilon)$ denote the expected log growth rate of agent n's wealth A^n, so that $d \log A_t^n = m_A^n(\upsilon_t)dt + \sigma_A^n(\upsilon_t)dW_t$.

Proposition 3.3 of Borovička [2020] links the boundary drifts of the log-odds ratio to these growth rates:

$$\lim_{\upsilon \to \bar{\upsilon}} \gamma^{-1} m_\vartheta(\upsilon) = \lim_{\upsilon \to \bar{\upsilon}} [m_A^1(\upsilon) - m_A^2(\upsilon)], \qquad \bar{\upsilon} \in \{0, 1\}. \tag{36.9}$$

Let R^n denote the cumulative return index of agent n's portfolio, with $d \log R_t^n = m_R^n(\upsilon_t)dt + \sigma_R^n(\upsilon_t)dW_t$.

Thus m_R^n is the expected *log* return on agent n's portfolio, and $m_R^n + \frac{1}{2}(\sigma_R^n)^2$ is its expected arithmetic return.

Let $(y^n)^{-1}$ denote agent n's consumption-wealth ratio.

The difference in wealth growth rates decomposes into two channels:

$$\lim_{\upsilon \searrow 0} [m_A^1(\upsilon) - m_A^2(\upsilon)] = \underbrace{\lim_{\upsilon \searrow 0} [m_R^1(\upsilon) - m_R^2(\upsilon)]}_{\text{portfolio returns}} + \underbrace{\lim_{\upsilon \searrow 0} [(y^2(\upsilon))^{-1} - (y^1(\upsilon))^{-1}]}_{\text{consumption-wealth ratios}} \tag{36.10}$$

The first term measures how much faster agent 1's portfolio grows.

The second measures how much less agent 1 consumes out of wealth – a lower consumption-wealth ratio means more saving and faster wealth accumulation.

When this total difference is positive, condition (i) holds and agent 1 survives near extinction.

When it is negative, the boundary $\upsilon = 0$ attracts.

Agent 1 then becomes extinct almost surely if condition (ii) also holds (case ©), and with strictly positive probability if condition (ii') holds (case (d)).

Exercise 36.5.1

Derive (36.10).

Let A^n denote agent n's wealth and C^n her consumption.

Let R^n be the cumulative return index of her portfolio, with $d \log R^n = m_R^n \, dt + \sigma_R^n \, dW$, so that m_R^n is her expected log portfolio return.

The budget constraint is $dA^n = A^n \, dR^n / R^n - C^n dt$.

Define the consumption-wealth ratio $(y^n)^{-1} = C^n / A^n$.

Show that $d \log A^n = (m_R^n - (y^n)^{-1}) \, dt + \sigma_R^n \, dW$, so the difference in expected log wealth growth is $m_A^1 - m_A^2 = (m_R^1 - m_R^2) + [(y^2)^{-1} - (y^1)^{-1}]$.

Solution

By Itô's lemma applied to $R^n = \exp(\log R^n)$, the instantaneous return is

$$\frac{dR^n}{R^n} = \left(m_R^n + \tfrac{1}{2}(\sigma_R^n)^2\right) dt + \sigma_R^n \, dW.$$

Dividing the budget constraint by A^n:

$$\frac{dA^n}{A^n} = \left(m_R^n + \tfrac{1}{2}(\sigma_R^n)^2 - (y^n)^{-1}\right) dt + \sigma_R^n \, dW.$$

By Itô's lemma, $d \log A^n = \frac{dA^n}{A^n} - \frac{1}{2}\left(\frac{dA^n}{A^n}\right)^2$, and $(dA^n / A^n)^2 = (\sigma_R^n)^2 dt$.

Then

$$d \log A^n = (m_R^n - (y^n)^{-1}) \, dt + \sigma_R^n \, dW,$$

so $m_A^n = m_R^n - (y^n)^{-1}$.

Taking the difference for agents 1 and 2 gives

$$m_A^1 - m_A^2 = (m_R^1 - m_R^2) + \left[(y^2)^{-1} - (y^1)^{-1}\right],$$

and passing to the limit $\upsilon \searrow 0$ gives (36.10).

36.5.1 Portfolio returns

At the boundary $\upsilon \searrow 0$, the difference in expected log portfolio returns is

$$\lim_{\upsilon \searrow 0}[m_R^1 - m_R^2] = \underbrace{\frac{\omega^1 - \omega^2}{\gamma\sigma_Y}}_{\text{difference in risky shares}} \cdot \underbrace{(\gamma\sigma_Y^2 - \omega^2\sigma_Y)}_{\text{risk premium}} - \underbrace{\frac{\omega^1 - \omega^2}{\gamma}\left(\sigma_Y + \frac{\omega^1 - \omega^2}{2\gamma}\right)}_{\text{volatility term}} \tag{36.11}$$

An optimistic agent ($\omega^1 > \omega^2$) overweights the risky asset by $(\omega^1 - \omega^2)/(\gamma\sigma_Y)$ relative to agent 2 and earns the equity risk premium on that extra exposure.

The subtracted *volatility penalty* reflects the cost of holding a more extreme portfolio: higher variance of log returns drags down expected log wealth growth.

This term depends on risk aversion γ but not on the IES, because portfolio choice is determined by risk aversion alone.

Exercise 36.5.2

Derive (36.11).

At the boundary $\upsilon \searrow 0$, agent n's optimal risky-asset share is $\pi^n = 1 + (\omega^n - \omega^2)/(\gamma\sigma_Y)$ (see (36.15)).

Let r denote the risk-free rate and $\bar{\mu}_R = r + \gamma\sigma_Y^2 - \omega^2\sigma_Y$ the expected arithmetic return on the risky asset under P.

(Using (36.13) and (36.14), $\bar{\mu}_R$ equals the expected capital gain $\mu_Y + \frac{1}{2}\sigma_Y^2$ plus the dividend yield $(y(0))^{-1}$.)

The continuously rebalanced portfolio has expected log return $m_R^n = r + \pi^n(\bar{\mu}_R - r) - \frac{1}{2}(\pi^n)^2\sigma_Y^2$.

Compute $m_R^1 - m_R^2$ and simplify.

Solution

Using $m_R^n = r + \pi^n(\bar{\mu}_R - r) - \frac{1}{2}(\pi^n)^2\sigma_Y^2$, the difference is

$$m_R^1 - m_R^2 = (\pi^1 - \pi^2)(\bar{\mu}_R - r) - \tfrac{1}{2}[(\pi^1)^2 - (\pi^2)^2]\sigma_Y^2.$$

The difference in risky shares is $\pi^1 - \pi^2 = (\omega^1 - \omega^2)/(\gamma\sigma_Y)$.

The arithmetic equity premium is $\bar{\mu}_R - r = \gamma\sigma_Y^2 - \omega^2\sigma_Y$, so:

$$(\pi^1 - \pi^2)(\bar{\mu}_R - r) = \frac{\omega^1 - \omega^2}{\gamma\sigma_Y} \cdot (\gamma\sigma_Y^2 - \omega^2\sigma_Y).$$

For the volatility term, write $(\pi^1)^2 - (\pi^2)^2 = (\pi^1 - \pi^2)(\pi^1 + \pi^2)$ and use $\pi^2 = 1$, so $\pi^1 + \pi^2 = 2 + (\omega^1 - \omega^2)/(\gamma\sigma_Y)$.

After simplification:

$$\tfrac{1}{2}[(\pi^1)^2 - (\pi^2)^2]\sigma_Y^2 = \frac{\omega^1 - \omega^2}{\gamma}\left(\sigma_Y + \frac{\omega^1 - \omega^2}{2\gamma}\right).$$

Combining the two pieces gives (36.11).

36.5.2 Consumption-wealth ratios

The difference in consumption-wealth ratios at the boundary is

$$\lim_{\upsilon \searrow 0}[(y^2)^{-1} - (y^1)^{-1}] = \frac{1-\rho}{\rho}\left[(\omega^1 - \omega^2)\sigma_Y + \frac{(\omega^1 - \omega^2)^2}{2\gamma}\right] \tag{36.12}$$

The term in brackets is the gap between the *subjective* certainty-equivalent returns that the two agents expect to earn on their optimal portfolios.

Under her own beliefs Q^n, agent n perceives the Sharpe ratio $\lambda^n = \gamma\sigma_Y + \omega^n - \omega^2$ on the risky asset.

Her optimal portfolio earns the certainty-equivalent return $r + (\lambda^n)^2/(2\gamma)$, and the term in brackets equals $[(\lambda^1)^2 - (\lambda^2)^2]/(2\gamma)$.

The bracket also equals half the gap between the agents' subjective expected arithmetic portfolio returns.

The factor $(1-\rho)/\rho$ translates this perceived return advantage into a saving response.

- When IES > 1 ($\rho < 1$), the factor is positive: a higher perceived return makes the agent save more, because the substitution effect dominates the income effect.
- When IES < 1 ($\rho > 1$), the factor is negative: the income effect dominates and the agent saves less, working against survival.
- When IES $= 1$ ($\rho = 1$), the two effects cancel and the saving channel vanishes entirely.

This is the channel through which recursive preferences alter survival outcomes by separating γ from ρ.

Exercise 36.5.3

Derive (36.12).

At the boundary $\upsilon \searrow 0$, both agents take as given the risk-free rate r and a risky asset with volatility σ_Y and expected excess return $\gamma\sigma_Y^2 - \omega^2\sigma_Y$ under P.

1. Show that under Q^n agent n perceives the Sharpe ratio $\lambda^n = \gamma\sigma_Y + \omega^n - \omega^2$. A portfolio with risky share π has subjective certainty-equivalent return $r + \pi\sigma_Y\lambda^n - \frac{1}{2}\gamma\pi^2\sigma_Y^2$. Show that the optimal share reproduces (36.15) and that the maximized certainty-equivalent return is $\mathrm{CE}^n = r + (\lambda^n)^2/(2\gamma)$.
2. Let $c^n = (y^n)^{-1}$ and let $\mu_V^n = \mathrm{CE}^n - c^n$ be the subjective certainty-equivalent growth rate of agent n's wealth, which is also that of her consumption. Use the Hamilton-Jacobi-Bellman equation of an Epstein-Zin investor facing constant investment opportunities to show that $c^n = \beta - (1-\rho)\mu_V^n$, and hence $\mu_V^n = (\mathrm{CE}^n - \beta)/\rho$.
3. Show that $\mu_V^2 = \mu_Y + \omega^2\sigma_Y + \frac{1}{2}(1-\gamma)\sigma_Y^2$, so that c^2 reproduces (36.14).
4. Deduce (36.12).

Hint: For step 2, use the normalized Duffie-Epstein aggregator

$$f(C,V) = \frac{\beta}{1-\rho}(1-\gamma)V\left[\left(\frac{C}{((1-\gamma)V)^{1/(1-\gamma)}}\right)^{1-\rho} - 1\right]$$

and guess $V(A) = (\kappa A)^{1-\gamma}/(1-\gamma)$ for a constant $\kappa > 0$.

Solution

Step 1. Under Q^n, $dW = dW^n + \omega^n dt$.

The risky asset's instantaneous return, $(r + \gamma\sigma_Y^2 - \omega^2\sigma_Y)dt + \sigma_Y dW$, becomes $(r + \gamma\sigma_Y^2 - \omega^2\sigma_Y + \omega^n\sigma_Y)dt + \sigma_Y dW^n$.

Its subjective Sharpe ratio is therefore $\lambda^n = \gamma\sigma_Y + \omega^n - \omega^2$.

The certainty-equivalent return $r + \pi\sigma_Y\lambda^n - \frac{1}{2}\gamma\pi^2\sigma_Y^2$ is maximized at $\pi^n = \lambda^n/(\gamma\sigma_Y) = 1 + (\omega^n - \omega^2)/(\gamma\sigma_Y)$, which is (36.15).

The maximized value is $\text{CE}^n = r + (\lambda^n)^2/(2\gamma)$.

Step 2. Under Q^n, wealth satisfies $dA = A\left[(r + \pi\sigma_Y\lambda^n - c)dt + \pi\sigma_Y dW^n\right]$.

With $V(A) = (\kappa A)^{1-\gamma}/(1-\gamma)$, we have $((1-\gamma)V)^{1/(1-\gamma)} = \kappa A$ and the HJB equation is

$$0 = \max_{c,\pi}\left\{f(cA, V(A)) + V'(A)A(r + \pi\sigma_Y\lambda^n - c) + \tfrac{1}{2}V''(A)A^2\pi^2\sigma_Y^2\right\}.$$

Dividing by $(\kappa A)^{1-\gamma}$ gives

$$0 = \max_{c,\pi}\left\{\frac{\beta}{1-\rho}\left[\left(\frac{c}{\kappa}\right)^{1-\rho} - 1\right] + r + \pi\sigma_Y\lambda^n - c - \tfrac{1}{2}\gamma\pi^2\sigma_Y^2\right\}.$$

The first-order condition for c is $\beta(c/\kappa)^{-\rho}/\kappa = 1$, which implies $(c/\kappa)^{1-\rho} = c/\beta$.

Substituting this and the optimal π into the HJB equation gives

$$0 = \frac{c^n - \beta}{1-\rho} + \text{CE}^n - c^n,$$

which rearranges to $c^n = \beta - (1-\rho)(\text{CE}^n - c^n) = \beta - (1-\rho)\mu_V^n$.

Solving the same equation for c^n gives $\rho c^n = \beta - (1-\rho)\text{CE}^n$, so $\mu_V^n = \text{CE}^n - c^n = (\text{CE}^n - \beta)/\rho$.

The quantity μ_V^n is the subjective certainty-equivalent growth rate of wealth.

Under Q^n, $d\log A$ has drift $r + \pi\sigma_Y\lambda^n - c - \frac{1}{2}\pi^2\sigma_Y^2$ and volatility $\pi\sigma_Y$.

Adding the risk adjustment $\frac{1}{2}(1-\gamma)\pi^2\sigma_Y^2$ and evaluating at π^n gives $\text{CE}^n - c^n$.

Step 3. For agent 2, $\lambda^2 = \gamma\sigma_Y$, so $\text{CE}^2 = r + \frac{1}{2}\gamma\sigma_Y^2$.

Substituting (36.13) gives $\text{CE}^2 = \beta + \rho\left(\mu_Y + \omega^2\sigma_Y + \frac{1}{2}(1-\gamma)\sigma_Y^2\right)$, so $\mu_V^2 = \mu_Y + \omega^2\sigma_Y + \frac{1}{2}(1-\gamma)\sigma_Y^2$.

Then $c^2 = \beta - (1-\rho)\mu_V^2$ is (36.14).

Step 4. Taking differences,

$$(y^2)^{-1} - (y^1)^{-1} = c^2 - c^1 = (1-\rho)(\mu_V^1 - \mu_V^2) = \frac{1-\rho}{\rho}\left(\text{CE}^1 - \text{CE}^2\right).$$

Since $\lambda^1 - \lambda^2 = \omega^1 - \omega^2$ and $\lambda^1 + \lambda^2 = 2\gamma\sigma_Y + \omega^1 - \omega^2$,

$$\text{CE}^1 - \text{CE}^2 = \frac{(\lambda^1)^2 - (\lambda^2)^2}{2\gamma} = (\omega^1 - \omega^2)\sigma_Y + \frac{(\omega^1 - \omega^2)^2}{2\gamma},$$

which gives (36.12).

The factor $1/\rho$ reflects feedback from consumption to wealth growth: c^n depends on μ_V^n, and $\mu_V^n = \text{CE}^n - c^n$ depends on c^n.

Here is a numerical check at $\gamma = 5$, $\rho = 0.67$, $\omega^1 = 0.25$, $\omega^2 = 0$, $\sigma_Y = 0.02$, $\mu_Y = 0.02$, and $\beta = 0.05$.

36.5.3 Two comparative statics

Survival depends on γ, ρ, and the signal-to-noise ratios ω^1/σ_Y and ω^2/σ_Y, not on ω^1, ω^2, and σ_Y separately.

The survival conditions do not depend on β or μ_Y, which affect the level of consumption and prices but not relative wealth dynamics at the boundary.

    )
```

The case $v \nearrow 1$ is symmetric.

Swapping the agents' labels turns ϑ into $-\vartheta$, so $\lim_{v \nearrow 1} m_\vartheta(v)$ equals `-boundary_drift(ω_2, ω_1, y, ρ, σ_y)`.

36.5.4 Risk aversion versus the IES

The two boundary drifts satisfy a simple identity.

Proposition 36.5.1

$$\lim_{v \searrow 0} m_\vartheta(v) - \lim_{v \nearrow 1} m_\vartheta(v) = (\omega^1 - \omega^2)^2 \left(\frac{1}{\rho} - \frac{1}{\gamma} \right).$$

To derive it, let $\Delta = \omega^1 - \omega^2$.

Combining (36.9), (36.10), (36.11), and (36.12) gives

$$\lim_{v \searrow 0} m_\vartheta(v) = \Delta(\gamma \sigma_Y - \omega^2) - \Delta \sigma_Y - \frac{\Delta^2}{2\gamma} + \frac{1-\rho}{\rho} \left(\gamma \Delta \sigma_Y + \frac{\Delta^2}{2} \right).$$

At $v \nearrow 1$ the roles of the agents are reversed, which replaces Δ by $-\Delta$, ω^2 by ω^1, and m_ϑ by $-m_\vartheta$:

$$\lim_{v \nearrow 1} m_\vartheta(v) = -\left[-\Delta(\gamma \sigma_Y - \omega^1) + \Delta \sigma_Y - \frac{\Delta^2}{2\gamma} + \frac{1-\rho}{\rho} \left(-\gamma \Delta \sigma_Y + \frac{\Delta^2}{2} \right) \right].$$

In the difference, the terms linear in σ_Y cancel.

The risk premium terms add to $\Delta(\omega^1 - \omega^2) = \Delta^2$, the volatility terms add to $-\Delta^2/\gamma$, and the saving terms add to $\Delta^2(1-\rho)/\rho$.

The sum is $\Delta^2(1/\rho - 1/\gamma)$.

The identity sorts the (γ, ρ) plane:

- Outcome (a), coexistence, requires $\lim_{v \searrow 0} m_\vartheta > 0 > \lim_{v \nearrow 1} m_\vartheta$, so it requires $\gamma > \rho$.
- Outcome (d), in which each agent dominates with positive probability, requires the reverse inequalities, so it requires $\gamma < \rho$.
- On the diagonal $\gamma = \rho$ the two boundary drifts are equal, so when $|\omega^1| \neq |\omega^2|$ exactly one agent dominates.
- Outcomes (b) and © can occur on either side of the diagonal.

Epstein-Zin agents prefer early resolution of uncertainty when $\gamma > \rho$ [Epstein and Zin, 1989, Kreps and Porteus, 1978].

Both agents can survive only in economies populated by agents with that preference.

Borovička [2020] notes that the coexistence region in the top-left panel of his Figure 2 lies where $\gamma > \rho$; *Proposition 36.5.1* shows that this holds for all belief distortions and all σ_Y.

Neither the IES alone nor risk aversion alone settles the question.

An IES above one is not sufficient for coexistence, because $\gamma < \rho < 1$ rules it out.

An IES above one is not necessary either, as the next section shows.

Exercise 36.5.4

1. Carry out the algebra behind *Proposition 36.5.1*, starting from (36.11) and (36.12).
2. Show that when $\gamma = \rho$ both boundary drifts equal $\frac{1}{2}\left[(\omega^2)^2 - (\omega^1)^2\right]$.
3. Use `boundary_drift` to verify the identity at 10,000 randomly drawn parameter vectors $(\omega^1, \omega^2, \gamma, \rho, \sigma_Y)$.

Solution

Part 1. Multiplying (36.11) by γ gives

$$\gamma \lim_{\upsilon \searrow 0}[m_R^1 - m_R^2] = \frac{\Delta}{\sigma_Y}(\gamma\sigma_Y^2 - \omega^2\sigma_Y) - \Delta\left(\sigma_Y + \frac{\Delta}{2\gamma}\right) = \Delta(\gamma\sigma_Y - \omega^2) - \Delta\sigma_Y - \frac{\Delta^2}{2\gamma}.$$

Multiplying (36.12) by γ gives $\frac{1-\rho}{\rho}\left(\gamma\Delta\sigma_Y + \frac{\Delta^2}{2}\right)$.

Their sum is $\lim_{\upsilon \searrow 0} m_\vartheta$ by (36.9) and (36.10).

At $\upsilon \nearrow 1$, agent 2 is the negligible agent and agent 1 sets prices.

Applying the same formulas with the labels swapped gives $\gamma \lim_{\upsilon \nearrow 1}[m_A^2 - m_A^1]$, which equals $-\lim_{\upsilon \nearrow 1} m_\vartheta$.

Swapping labels replaces Δ by $-\Delta$ and ω^2 by ω^1, so

$$-\lim_{\upsilon \nearrow 1} m_\vartheta = -\Delta(\gamma\sigma_Y - \omega^1) + \Delta\sigma_Y - \frac{\Delta^2}{2\gamma} + \frac{1-\rho}{\rho}\left(-\gamma\Delta\sigma_Y + \frac{\Delta^2}{2}\right).$$

Adding the two expressions term by term:

$$\Delta(\omega^1 - \omega^2) - \frac{\Delta^2}{\gamma} + \frac{1-\rho}{\rho}\Delta^2 = \Delta^2\left(1 - \frac{1}{\gamma} + \frac{1}{\rho} - 1\right) = \Delta^2\left(\frac{1}{\rho} - \frac{1}{\gamma}\right).$$

Part 2. Setting $\rho = \gamma$, the saving term becomes $(1-\gamma)\Delta\sigma_Y + (1-\gamma)\Delta^2/(2\gamma)$.

Adding it to the portfolio term, the terms in σ_Y and in $\Delta^2/(2\gamma)$ cancel and leave

$$\lim_{\upsilon \searrow 0} m_\vartheta = -\Delta\omega^2 - \frac{\Delta^2}{2} = -\frac{(\omega^1 - \omega^2)(\omega^1 + \omega^2)}{2} = \frac{1}{2}\left[(\omega^2)^2 - (\omega^1)^2\right].$$

By Part 1, the drift at $\upsilon \nearrow 1$ is the same.

When $\gamma = \rho$ the saving term is not zero unless $\rho = 1$; the three channels net to a constant that does not depend on γ or σ_Y.

Part 3.

```

36.6 Survival regions

A central contribution of Borovička [2020] is the characterization of survival regions in the (γ, ρ) plane.

Under separable preferences, $\gamma = \rho$, the agent with more accurate beliefs always dominates.

Under recursive preferences, all four outcomes in *Proposition 36.4.1* can occur.

Figure 2 in the paper studies the case where agent 2 has correct beliefs, so $\omega^2 = 0$.

The next cell follows that figure.

For the limiting panel $|\omega^1|/\sigma_Y \to \infty$ we use the limits of $m_\vartheta(0+)/(\omega^1)^2$ and $m_\vartheta(1-)/(\omega^1)^2$, which Exercise 36.6.1 derives.

```
def limit_boundary_drifts(γ, ρ):
    """
    Limits of m_ϑ(0+) / (ω^1)^2 and m_ϑ(1-) / (ω^1)^2
    as |ω^1| / σ_y -> ∞, with ω^2 = 0.
    """
    m_0 = (γ - (1 + γ) * ρ) / (2 * γ * ρ)
    m_1 = ((1 - γ) * ρ - γ) / (2 * γ * ρ)
    return m_0, m_1
```

Each panel plots two curves in the (γ, ρ) plane for a different value of agent 1's belief distortion ω^1 (agent 2 has correct beliefs, $\omega^2 = 0$).

- The dashed curve (blue) is where the boundary drift at $\upsilon = 0$ equals zero – condition (i) in *Proposition 36.4.1*.
- The solid curve (red) is where the boundary drift at $\upsilon = 1$ equals zero – condition (ii).

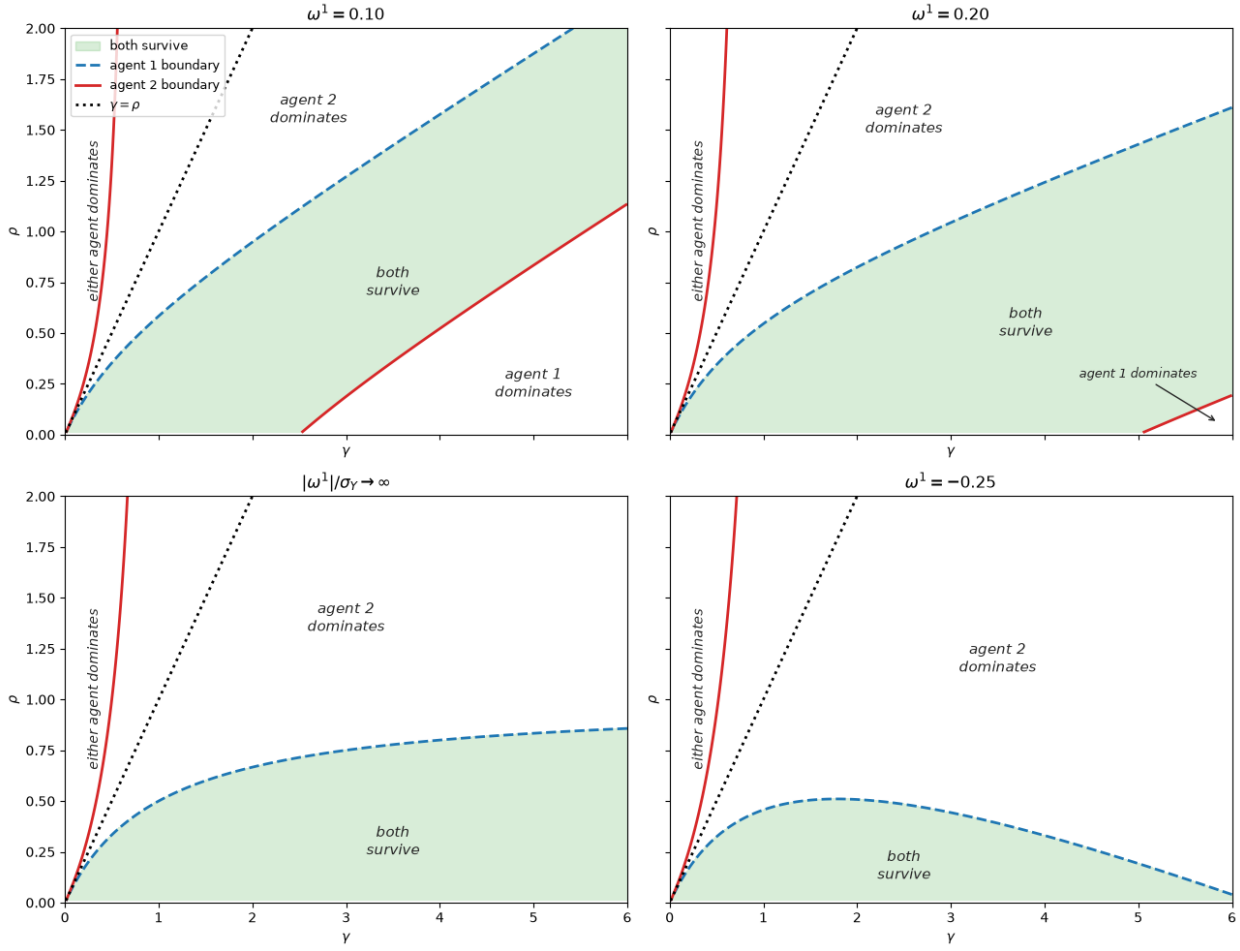

Fig. 36.1: Survival regions corresponding to Figure 2 in Borovička (2020)

- The shaded region is where both agents survive.
- The dotted diagonal $\gamma = \rho$ is the separable CRRA case, along which the agent with more accurate beliefs always dominates.

The next cell reports the share of the plotted window occupied by each outcome, the share of the coexistence region with $\rho > 1$ (IES < 1), and the largest ρ in the coexistence region.

grid points with coexistence and ρ ≥ γ, or with outcome (d) and ρ ≤ γ: 0
```

Every shaded region lies below the diagonal, and every region where either agent can dominate lies above it, as *Proposition 36.5.1* requires.

Moderate optimism ($\omega^1 = 0.10$) produces a wide coexistence region that extends across most of the γ range.

Coexistence does not require IES > 1: 42 percent of the shaded area in this panel has $\rho > 1$, including the point $\gamma = 5$, $\rho = 1.5$.

Stronger optimism ($\omega^1 = 0.20$) rotates both curves clockwise.

The agent 1 curve falls, so agent 2 dominates in a larger part of the plane above it.

The lower branch of the agent 2 curve meets the axis $\rho = 0$ at $\gamma = \omega^1/(2\sigma_Y)$, which is 2.5 when $\omega^1 = 0.10$ and 5 when $\omega^1 = 0.20$.

At that value of γ, the two agents' subjective certainty-equivalent returns at the boundary $v = 1$ are equal, and the saving channel changes sign there.

Agent 1 therefore dominates only in a sliver at the bottom right of the $\omega^1 = 0.20$ panel, and the coexistence region grows from 44 to 49 percent of the plotted window.

In the limit $|\omega^1|/\sigma_Y \to \infty$ (bottom-left), the boundary curves are $\rho = \gamma/(1+\gamma)$ and, for $\gamma < 1$, $\rho = \gamma/(1-\gamma)$ (see Exercise 36.6.1).

Both agents survive exactly when $\rho < \gamma/(1+\gamma)$, the region below the agent 1 curve.

That curve rises toward $\rho = 1$ as γ grows, so in this limit coexistence requires IES > 1.

The agent 2 curve separates outcome © from outcome (d), and agent 1 never dominates.

Pessimistic distortions ($\omega^1 = -0.25$, bottom-right) can also survive, but only in a much narrower part of the parameter space: 17 percent of the plotted window, all of it with $\rho < 0.51$.

The coexistence region ends at $\gamma = |\omega^1|/(2\sigma_Y) = 6.25$, just beyond the plotted range.

For larger γ her short position is too small, $\pi^1 > -1$, for her subjective certainty-equivalent return to exceed agent 2's.

With IES > 1 the saving channel then works against her, and with IES < 1 it is too weak to offset her portfolio losses.

Exercise 36.6.1

Let $\omega^2 = 0$.

1. Show that, holding γ and ρ fixed, $m_\vartheta(0+)/(\omega^1)^2$ and $m_\vartheta(1-)/(\omega^1)^2$ depend on ω^1 and σ_Y only through σ_Y/ω^1, and that as $\sigma_Y/\omega^1 \to 0$ they converge to the expressions in `limit_boundary_drifts`.
2. Deduce that the boundary curves in the limit are $\rho = \gamma/(1+\gamma)$ and, for $\gamma < 1$, $\rho = \gamma/(1-\gamma)$. Classify the four outcomes in the limit and show that agent 1 never dominates.
3. Verify numerically that the zero curve of `boundary_drift` at $\upsilon = 0$ converges to $\rho = \gamma/(1+\gamma)$ as ω^1/σ_Y grows.

Hint: $m_\vartheta(0+)$ is affine in $1/\rho$, so for each γ its zero can be computed in closed form.

Solution

Part 1. Let $\Delta = \omega^1$ and $s = \sigma_Y/\omega^1$.

From the expression for $\lim_{\upsilon \searrow 0} m_\vartheta$ in the derivation of *Proposition 36.5.1*, with $\omega^2 = 0$,

$$\frac{m_\vartheta(0+)}{\Delta^2} = (\gamma - 1)s - \frac{1}{2\gamma} + \frac{1-\rho}{\rho}\left(\gamma s + \frac{1}{2}\right) \longrightarrow \frac{\gamma - (1+\gamma)\rho}{2\gamma\rho}.$$

Similarly,

$$\frac{m_\vartheta(1-)}{\Delta^2} = (\gamma - 1)s - 1 + \frac{1}{2\gamma} + \frac{1-\rho}{\rho}\left(\gamma s - \frac{1}{2}\right) \longrightarrow \frac{(1-\gamma)\rho - \gamma}{2\gamma\rho}.$$

The difference of the two limits is $(\gamma - \rho)/(\gamma\rho) = 1/\rho - 1/\gamma$, as *Proposition 36.5.1* requires.

Part 2. The first limit is positive if and only if $\rho < \gamma/(1+\gamma)$.

The second limit is negative if and only if $(1-\gamma)\rho < \gamma$.

That inequality holds for every $\rho > 0$ when $\gamma \geq 1$, and holds if and only if $\rho < \gamma/(1-\gamma)$ when $\gamma < 1$.

Since $\gamma/(1+\gamma) < \gamma/(1-\gamma)$ for $\gamma \in (0,1)$, condition (i) implies condition (ii).

Hence:

- (a) both survive if and only if $\rho < \gamma/(1+\gamma)$;
- (b) agent 1 dominates nowhere, because (i) and (ii') cannot hold together;
- © agent 2 dominates if $\rho > \gamma/(1+\gamma)$ and either $\gamma \geq 1$ or $\rho < \gamma/(1-\gamma)$;
- (d) either agent dominates if $\gamma < 1$ and $\rho > \gamma/(1-\gamma)$.

Part 3. Write $m_\vartheta(0+) = \gamma\,[P + (1/\rho - 1)S]$, where P is the portfolio-return difference and S is the bracket in (36.12).

The drift vanishes at $1/\rho = 1 - P/S$, so $\rho = S/(S-P)$.

```
def lower_zero_curve(ω_1, ω_2, σ_y, γ):

)
print(f"the total crosses zero at γ = {γ_star:.3f}")
```

```
the total crosses zero at γ = 1.465
```

This figure decomposes the wealth-growth differential $\lim_{\upsilon \searrow 0}[m_A^1 - m_A^2] = \lim_{\upsilon \searrow 0} m_\vartheta/\gamma$ into three terms for an optimistic agent ($\omega^1 = 0.25, \omega^2 = 0$) with IES $= 1/\rho \approx 1.49$ and $\sigma_Y = 0.02$.

- The risk premium term (blue) is positive throughout because the optimistic agent overweights the risky asset and earns the equity premium.
- The volatility term (red dashed) is negative and large at low γ, reflecting the cost of holding a volatile portfolio.
- The saving term (green dash-dot) is positive when IES > 1 because the optimistic agent perceives a high return on wealth and saves more aggressively.
- The total (black) crosses zero at $\gamma \approx 1.47$; below that value the volatility penalty dominates, condition (i) fails, and the boundary $\upsilon = 0$ attracts.

36.8 Varying the IES

The sign of the saving term is pinned down by the IES.

```
fig, axes = plt.subplots(1, 3, figsize=(16, 4.5), sharey=True)

ω_1 = 0.25
ω_2 = 0.0
σ_y = 0.02
y_grid = np.linspace(0.5, 25.0, 300)

ies_values = [0.5, 1.0, 1.5]

for idx, ies in enumerate(ies_values):
    ρ = 1.0 / ies
    risk_term, vol_term, save_term, total = decompose_survival(
        ω_1, ω_2, y_grid, ρ, σ_y
    )

    ax = axes[idx]

    ax.axhline(0, color="gray", lw=1)
    ax.set_title(f"IES = {ies:.1f}", fontsize=12)
    ax.set_xlabel(r"risk aversion $\gamma$")
    ax.set_ylabel("contribution")

axes[0].legend(fontsize=9)
plt.tight_layout()
plt.show()

for ies in ies_values:
    y_star = brentq(
        lambda y: decompose_survival(ω_1, ω_2, y, 1 / ies, σ_y)[3], 0.5, 25.0
    )
    print(f"IES = {ies:.1f}: the total crosses zero at y = {y_star:.2f}")
```

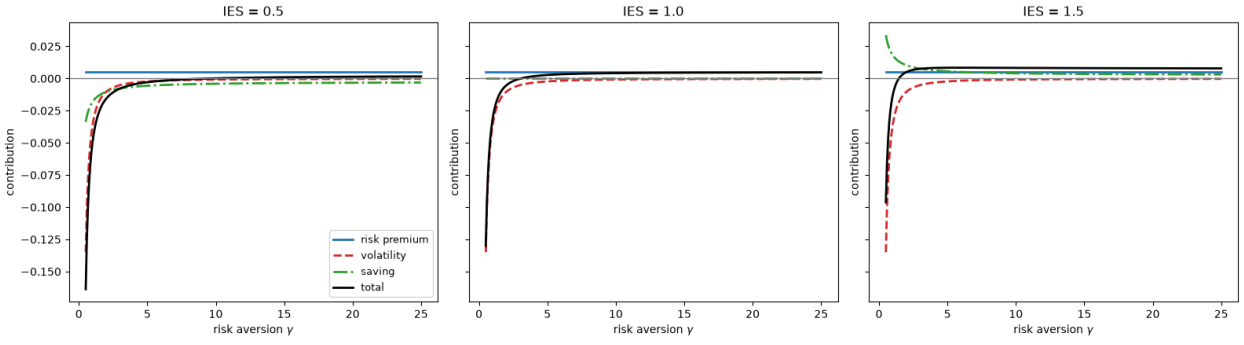

Fig. 36.2: Boundary decomposition for different IES values

```
IES = 0.5: the total crosses zero at y = 9.56
IES = 1.0: the total crosses zero at y = 3.05
IES = 1.5: the total crosses zero at y = 1.45
```

Each panel shows the same three-term decomposition as the previous figure, but now for three different values of the IES ($\omega^1 = 0.25$, $\omega^2 = 0$, $\sigma_Y = 0.02$).

- Left panel (IES $= 0.5$): the saving term is negative, so the optimistic agent actually saves less, working against survival. The risk premium term still makes the total positive for $\gamma > 9.56$, so condition (i) holds with IES below one.
- Center panel (IES $= 1.0$): the saving term vanishes entirely, so only the portfolio return and volatility channels remain.
  - This eliminates the saving channel but does not by itself reproduce the full separable CRRA benchmark, which requires $\gamma = \rho$ (i.e., IES $= 1/\gamma$), not merely $\rho = 1$.
- Right panel (IES $= 1.5$): the saving term is positive and shifts the total drift upward, expanding the range of γ values for which the optimistic agent survives.

The zero crossing moves from $\gamma = 9.56$ to 3.05 to 1.45 as the IES rises from 0.5 to 1 to 1.5.

36.9 Asymptotic results

Borovička derives several useful asymptotic results.

1. As $\gamma \searrow 0$, each agent dominates with strictly positive probability.
2. As $\gamma \nearrow \infty$, the relatively more optimistic agent dominates.
3. As $\rho \searrow 0$, the relatively more optimistic agent always survives.
   - The relatively more pessimistic agent can also survive when risk aversion is sufficiently low.
4. As $\rho \nearrow \infty$, a nondegenerate long-run equilibrium cannot exist.

The next figure illustrates the first result by plotting both boundary drifts as γ becomes small.

```
ω_1 = 0.25
ω_2 = 0.0
ρ = 0.67
σ_y = 0.02
γ_grid = np.linspace(0.05, 5.0, 300)

drift_at_0 = np.array([boundary_drift(ω_1, ω_2, γ, ρ, σ_y) for γ in γ_grid])
drift_at_1 = np.array([-boundary_drift(ω_2, ω_1, γ, ρ, σ_y) for γ in γ_grid])

```

This figure plots the two boundary drifts as a function of γ ($\omega^1 = 0.25$, $\omega^2 = 0$, IES ≈ 1.49).

- The solid blue curve is the drift m_ϑ at $\upsilon \to 0$ (agent 1 near extinction); coexistence requires this to be positive (condition (i)).

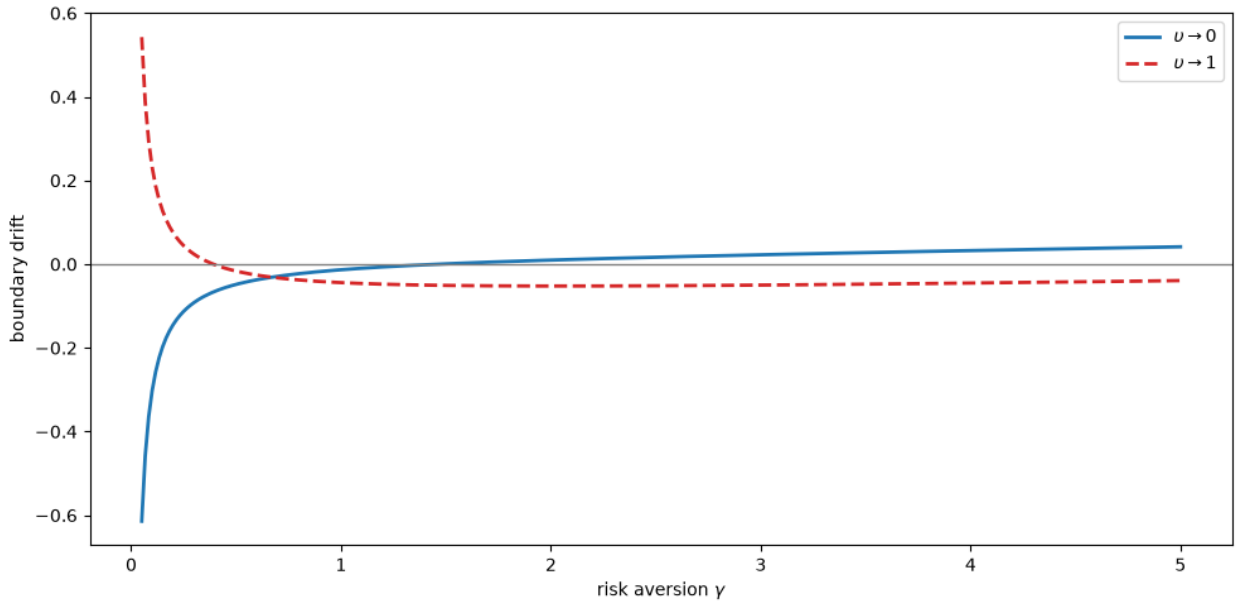

Fig. 36.3: Boundary drifts for small risk aversion

- The dashed red curve is the drift m_ϑ at $\upsilon \to 1$ (agent 2 near extinction); coexistence requires this to be negative (condition (ii)).

The figure illustrates asymptotic result 1.

For small γ, the blue curve is negative and the red curve is positive.

Both boundaries are attracting: near $\upsilon = 0$ the negative drift pulls υ toward 0, and near $\upsilon = 1$ the positive drift pushes υ toward 1.

This is outcome (d) in *Proposition 36.4.1*: neither boundary is repelling, so whichever agent happens to get ahead early will dominate, with each agent having strictly positive probability of dominance depending on the realized Brownian path.

The red curve crosses zero first, at $\gamma \approx 0.39$, while the blue curve is still negative.

For γ between about 0.39 and 1.47, the boundary $\upsilon = 1$ repels and the boundary $\upsilon = 0$ attracts, so agent 2 dominates – outcome ©.

The two curves cross each other at $\gamma = \rho = 0.67$, as *Proposition 36.5.1* requires; their common value there is $-\frac{1}{2}(\omega^1)^2 = -0.03125$.

The blue curve crosses zero at $\gamma \approx 1.47$.

Beyond that point both boundaries repel and both agents survive – outcome (a).

Outside the plotted range, the red curve crosses zero again at $\gamma \approx 10.7$, and for larger γ agent 1 dominates – outcome (b), in line with asymptotic result 2.

Exercise 36.9.1

Take the parameters of Fig. 36.3: $\omega^1 = 0.25$, $\omega^2 = 0$, $\rho = 0.67$, $\sigma_Y = 0.02$.

1. Show that $2\gamma \lim_{\upsilon \searrow 0} m_\vartheta$ and $2\gamma \lim_{\upsilon \nearrow 1} m_\vartheta$ are quadratic polynomials in γ, and use them to find every $\gamma > 0$ at which a boundary drift changes sign.
2. Confirm the roots with `boundary_drift`.

3. Label the outcome of *Proposition 36.4.1* on each interval between consecutive roots.

Solution

Let $\Delta = \omega^1, \omega^2 = 0$, and $k = (1-\rho)/\rho$.

Multiplying the two boundary drifts from the derivation of *Proposition 36.5.1* by 2γ gives

$$2\gamma \lim_{\upsilon \searrow 0} m_\vartheta = \frac{2\Delta\sigma_Y}{\rho}\gamma^2 + \left(k\Delta^2 - 2\Delta\sigma_Y\right)\gamma - \Delta^2,$$

$$2\gamma \lim_{\upsilon \nearrow 1} m_\vartheta = \frac{2\Delta\sigma_Y}{\rho}\gamma^2 - \left(2\Delta\sigma_Y + \frac{1+\rho}{\rho}\Delta^2\right)\gamma + \Delta^2.$$

When $\Delta > 0$, the first quadratic has one positive root because its constant term is negative.

The second has two positive roots when its discriminant is positive, because its constant term and its leading coefficient are both positive.

```
ω_1, ω_2, ρ, σ_y = 0.25, 0.0, 0.67, 0.02
Δ, k = ω_1 - ω_2, (1 - ρ) / ρ

roots_0 = np.roots([2 * Δ * σ_y / ρ, k * Δ**2 - 2 * Δ * σ_y, -Δ**2])
roots_1 = np.roots([2 * Δ * σ_y / ρ,
                    -(2 * Δ * σ_y + (1 + ρ) / ρ * Δ**2), Δ**2])
roots_0 = np.sort(roots_0[roots_0 > 0])
roots_1 = np.sort(roots_1[roots_1 > 0])

m_0 = lambda γ: boundary_drift(ω_1, ω_2, γ, ρ, σ_y)
m_1 = lambda γ: -boundary_drift(ω_2, ω_1, γ, ρ, σ_y)

print("roots of m_ϑ(0+):", roots_0, " check:", [m_0(g) for g in roots_0])
print("roots of m_ϑ(1-):", roots_1, " check:", [m_1(g) for g in roots_1])

outcome = {(True, True): "(a) both survive",
           (True, False): "(b) agent 1 dominates",
           (False, True): "(c) agent 2 dominates",
           (False, False): "(d) either agent dominates"}

cuts = np.concatenate(([0.0], np.sort(np.concatenate((roots_0, roots_1))),
                       [np.inf]))
for lo, hi in zip(cuts[:-1], cuts[1:]):
    γ_mid = 0.5 * (lo + hi) if np.isfinite(hi) else 2 * lo
    print(f"γ in ({lo:6.3f}, {hi:6.3f}):  "
          f"{outcome[(m_0(γ_mid) > 0, m_1(γ_mid) < 0)]}")
```

```
roots of m_ϑ(0+): [1.46529206]  check: [np.float64(5.0837530595323925e-18)]
roots of m_ϑ(1-): [ 0.39074321 10.71675679]  check: [np.float64(-2.
↪4401931409719703e-17), np.float64(-6.971478593011729e-18)]
γ in ( 0.000,  0.391):  (d) either agent dominates
γ in ( 0.391,  1.465):  (c) agent 2 dominates
γ in ( 1.465, 10.717):  (a) both survive
γ in (10.717,    inf):  (b) agent 1 dominates
```

The outcomes run from (d) to © to (a) to (b) as γ rises, consistent with asymptotic results 1 and 2.

36.10 The separable case

When $\gamma = \rho$, the model collapses to the separable CRRA benchmark.

Blume and Easley [2006] study this benchmark in discrete time; *Heterogeneous Beliefs and Financial Markets* presents their analysis.

The two agents' discount rates ν^1 and ν^2 then coincide, and the log-odds process (36.6) becomes

$$d\vartheta_t = \frac{1}{2}\left[(\omega^2)^2 - (\omega^1)^2\right] dt + (\omega^1 - \omega^2) dW_t.$$

Its drift is the common value of the two boundary drifts in *Proposition 36.5.1* when $\gamma = \rho$ (see Exercise 36.5.4).

The drift is constant and depends only on the relative entropy of the two belief distortions.

Under P, the relative entropy of P with respect to Q^n on $\mathcal{F}_t$ is $E^P[-\log M_t^n] = \frac{1}{2}(\omega^n)^2 t$, the Kullback–Leibler divergence described in *Kullback–Leibler divergence*.

The drift of ϑ is the difference between the growth rates of the two agents' relative entropies.

The agent with the smaller $|\omega^n|$ dominates under P.

If the two agents have equal magnitudes of belief distortions, neither becomes extinct almost surely, but no nondegenerate stationary wealth distribution exists.

  2000                             1.00           0.987
```

This figure simulates 50 sample paths of the Pareto share υ_t under separable CRRA preferences ($\gamma = \rho$) with $\omega^1 = 0.10$ and $\omega^2 = 0$.

Agent 2 has correct beliefs, so ϑ has drift $-\frac{1}{2}(\omega^1)^2 = -0.005$ and $\upsilon_t \to 0$ almost surely.

Agent 1 is driven to extinction – the classical market-selection result of Blume and Easley [2006].

Selection is slow.

The volatility of ϑ is 0.1, so at $t = 200$ the mean of ϑ_t, -1, is smaller in magnitude than its standard deviation, 1.41.

The table compares the share of the 50 simulated paths with $\upsilon_t < 1/2$ with the probability $P(\vartheta_t < 0) = \Phi(0.05\sqrt{t})$, where Φ is the standard normal distribution function.

About three quarters of the paths have $\upsilon_t < 1/2$ at $t = 200$; nearly all do by $t = 2000$.

36.11 Asset pricing implications

As one agent becomes negligible, current prices converge to those of the homogeneous economy populated by the large agent.

When agent 2 is the large agent, Proposition 5.1 in Borovička [2020] implies

$$\lim_{\upsilon \searrow 0} r(\upsilon) = \beta + \rho \left(\mu_Y + \omega^2 \sigma_Y + \frac{1}{2}(1-\gamma)\sigma_Y^2 \right) - \frac{1}{2}\gamma\sigma_Y^2 \tag{36.13}$$

and

$$\lim_{\upsilon \searrow 0} y(\upsilon) = \left[\beta - (1-\rho) \left(\mu_Y + \omega^2 \sigma_Y + \frac{1}{2}(1-\gamma)\sigma_Y^2 \right) \right]^{-1}. \tag{36.14}$$

The aggregate wealth dynamics also converge to those of the homogeneous economy:

$$\lim_{\upsilon \searrow 0} m_A(\upsilon) = \mu_Y, \qquad \lim_{\upsilon \searrow 0} \sigma_A(\upsilon) = \sigma_Y.$$

Proposition 5.3 then gives the negligible agent's own consumption-saving and portfolio choices.

Her consumption-wealth ratio converges to

$$\lim_{\upsilon \searrow 0} (y^1(\upsilon))^{-1} = (y(0))^{-1} - \frac{1-\rho}{\rho} \left[(\omega^1 - \omega^2)\sigma_Y + \frac{(\omega^1 - \omega^2)^2}{2\gamma} \right].$$

The small agent's risky-asset share converges to

$$\lim_{\upsilon \searrow 0} \pi^1(\upsilon) = 1 + \frac{\omega^1 - \omega^2}{\gamma \sigma_Y}. \tag{36.15}$$

Hence optimism implies leverage, while sufficiently strong pessimism implies shorting.

```
ω_2 = 0.0
σ_y = 0.02
ω_grid = np.linspace(-0.5, 1.0, 300)

fig, ax = plt.subplots(figsize=(10, 5))

for γ in [2, 5, 10, 20]:
    π_1 = 1 + (ω_grid - ω_2) / (γ * σ_y)
    ax.plot(ω_grid, π_1, lw=2, label=rf"$\gamma = {γ}$")

ax.axhline(1.0, color="gray", linestyle=":", lw=1)
ax.axhline(0.0, color="gray", linestyle=":", lw=1)
ax.axvline(0.0, color="gray", linestyle=":", lw=1)
ax.set_xlabel(r"belief distortion $\omega^1$")
ax.set_ylabel(r"risky share $\pi^1$")
ax.legend()
plt.tight_layout()
plt.show()
```

This figure plots the limiting risky-asset share π^1 of the negligible agent as a function of her belief distortion ω^1 ($\omega^2 = 0$, $\sigma_Y = 0.02$), for four levels of risk aversion.

At $\omega^1 = 0$ the agent agrees with agent 2 and holds the market portfolio ($\pi^1 = 1$).

Optimism ($\omega^1 > 0$) leads to leverage ($\pi^1 > 1$), while sufficient pessimism ($\omega^1 < 0$) leads to shorting ($\pi^1 < 0$).

Higher risk aversion compresses these deviations toward one.

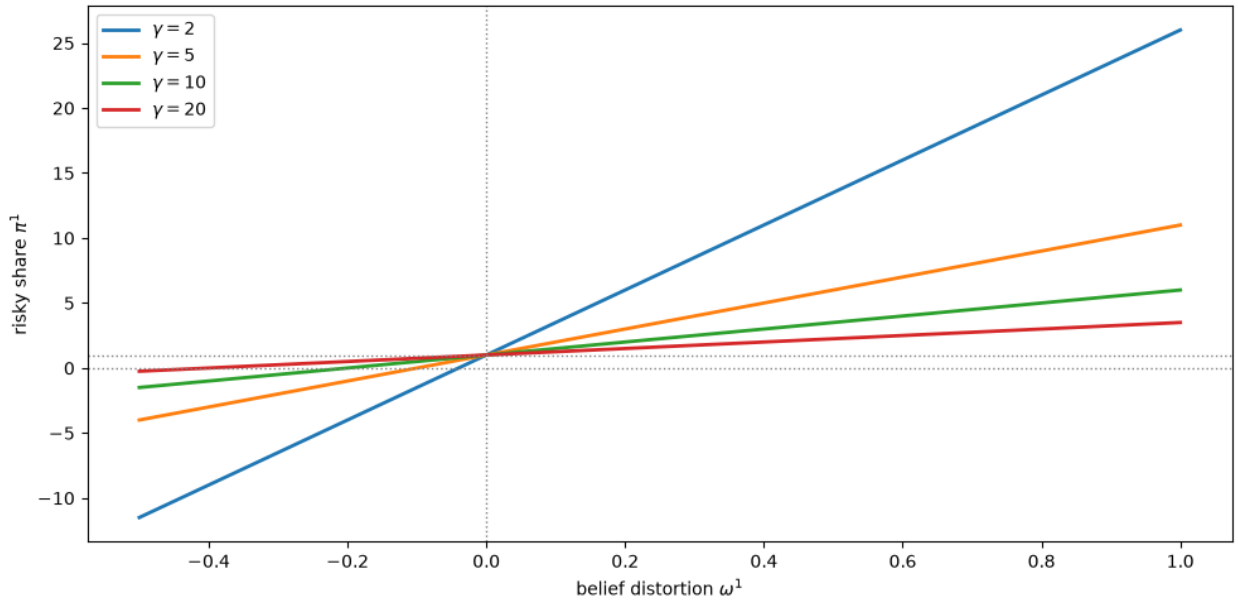

Fig. 36.5: Limiting risky-asset shares of the small agent

36.12 Optimistic and pessimistic distortions

Optimistic and pessimistic beliefs affect survival asymmetrically.

An optimistic agent benefits from the risk premium term and, when IES > 1, from the saving term as well.

A pessimistic agent holds less of the risky asset than agent 2, who holds the market portfolio, $\pi^2 = 1$.

With $\omega^2 = 0$, the portfolio that maximizes the expected log return under P has risky share γ.

When $\gamma \geq 1$, a smaller risky share moves the pessimist away from that portfolio, so she earns a lower expected log return than agent 2.

She can then survive only if the saving effect is strong enough to offset that loss.

With IES > 1 the saving term helps her only when she holds a large short position, $\pi^1 < -1$; with IES < 1 it helps her only when $-1 < \pi^1 < 1$.

When $\gamma < 1$, the market portfolio is more leveraged than the portfolio that maximizes the expected log return.

A mildly pessimistic agent with $2\gamma - 1 < \pi^1 < 1$ then earns a higher expected log return than agent 2 without help from the saving channel.

For example, with $\rho = 1$, $\gamma = 0.5$, $\sigma_Y = 0.02$, and $\omega^1 = -0.005$, both boundary drifts are positive and the pessimist dominates.

```
print(f"m_0(0+) = {boundary_drift(-0.005, 0.0, 0.5, 1.0, 0.02):.2e}, "
      f"m_0(1-) = {-boundary_drift(0.0, -0.005, 0.5, 1.0, 0.02):.2e}")
```

```
m_0(0+) = 2.50e-05, m_0(1-) = 5.00e-05
```

```
fig, axes = plt.subplots(1, 2, figsize=(14, 5), sharey=True)

σ_y = 0.02
```

(continues on next page)

(continued from previous page)

```

print("ω¹ = -1.0: the curve changes sign at y =", np.round(roots, 2))
```

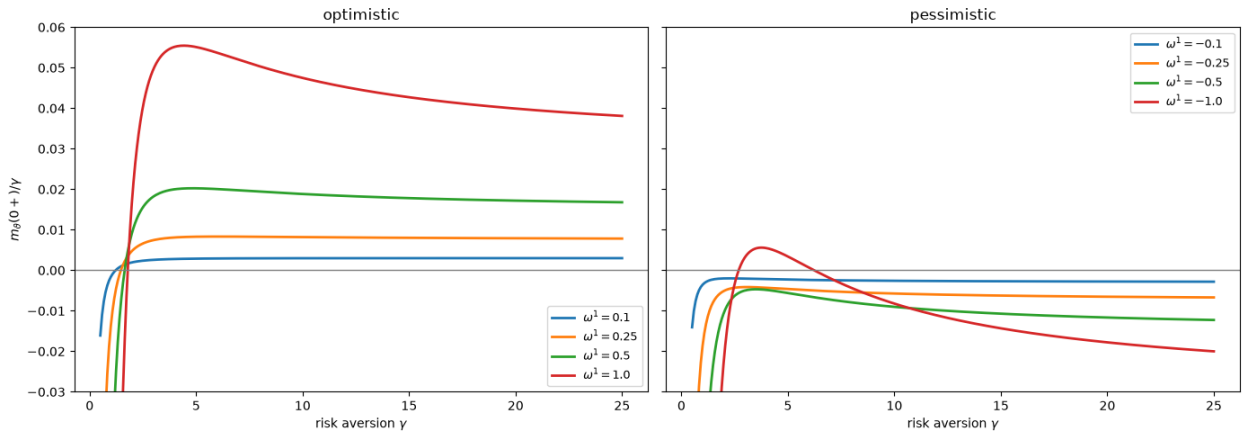

Fig. 36.6: Wealth-growth differential at the boundary for optimistic and pessimistic distortions

```
ω¹ = -1.0: the curve changes sign at y = [2.69 6.23]
```

Both panels plot the wealth-growth differential $\lim_{\upsilon \searrow 0}[m_A^1 - m_A^2] = \lim_{\upsilon \searrow 0} m_\vartheta/\gamma$ as a function of γ (IES ≈ 1.49, $\omega^2 = 0$).

We clip the vertical axis; every curve falls steeply as $\gamma \to 0$.

Where the curve is positive, agent 1 survives near extinction.

- Left panel (optimistic agent): larger ω^1 means a bigger bet on the risky asset, so the volatility penalty dominates at low γ but the drift turns positive once γ is large enough.
- Right panel (pessimistic agent): the curves for $\omega^1 = -0.1, -0.25, -0.5$ are negative throughout. Only the most pessimistic agent, $\omega^1 = -1$, survives near extinction, for γ between about 2.69 and 6.23. There she shorts the risky asset heavily ($\pi^1 < -1$), expects a high return on her position, and saves enough to offset her portfolio losses.

36.13 Long-run consumption distribution

When both agents survive, the Pareto share keeps moving across the whole interval $(0, 1)$.

The next simulation is only a toy approximation.

It interpolates the drift between its two boundary values, so it illustrates the recurrence logic without solving the full equilibrium ODE.

```
def simulate_pareto_share_toy(ω_1, ω_2, γ, ρ, σ_y, T, dt, n_paths=20, seed=42):

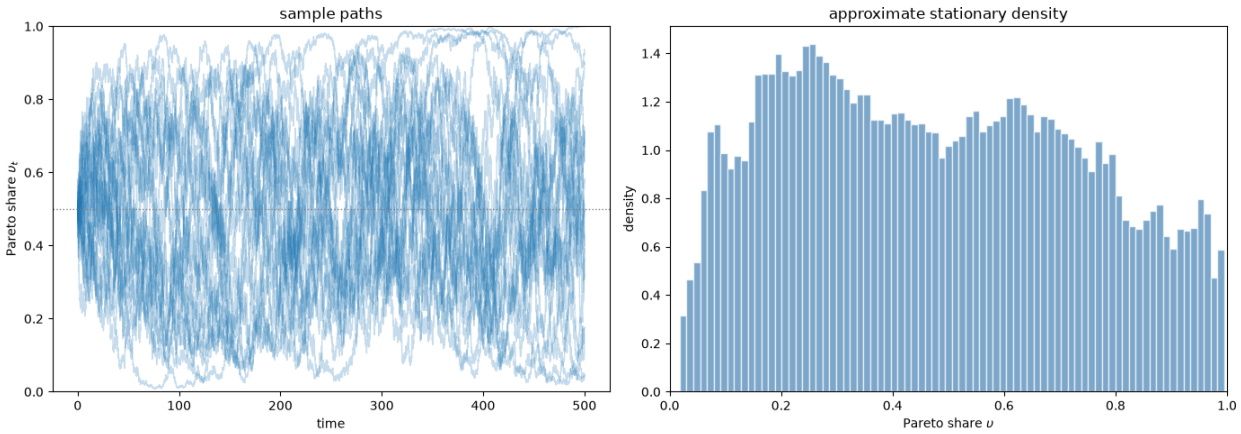

Fig. 36.7: A toy stationary Pareto-share simulation

The left panel shows 50 sample paths of the Pareto share υ_t under parameters inside the coexistence region ($\omega^1 = 0.25$, $\omega^2 = 0$, $\gamma = 5$, IES ≈ 1.49).

Unlike the separable case in Fig. 36.4, the paths do not drift to zero – they repeatedly visit a wide range of values, bouncing between the two repelling boundaries.

The right panel approximates the stationary density by pooling the second half of longer simulations.

The interior mode is consistent with neither agent being driven to extinction.

However, this toy interpolation only illustrates the recurrence logic; it does not reproduce the quantitative stationary consumption-share density in Figure 4 of Borovička [2020], which requires solving the full interior equilibrium ODE.

36.14 Summary

Recursive preferences weaken the classical market-selection result.

The portfolio return channel still rewards more optimistic beliefs.

The volatility channel still penalizes aggressive positions.

The saving channel rewards an agent who expects a high return on her portfolio when IES > 1 and penalizes her when IES < 1.

The two boundary drifts differ by $(\omega^1 - \omega^2)^2(1/\rho - 1/\gamma)$.

Both agents can survive only when $\gamma > \rho$, which means that agents prefer early resolution of uncertainty.

Each agent can dominate with positive probability only when $\gamma < \rho$.

Coexistence does not require IES > 1: with $\omega^1 = 0.10$, $\omega^2 = 0$, and $\sigma_Y = 0.02$, both agents survive at $\gamma = 5$, $\rho = 1.5$.

Recursive-preference economies with $\gamma > \rho$ can support stationary long-run wealth distributions with persistent heterogeneity in beliefs and portfolio positions.

37.1 Overview

Earlier lectures in this section asked *which* statistical experiment a decision maker should prefer.

Blackwell's Theorem on Comparing Experiments gave the classic answer: experiment μ is at least as informative as experiment ν when *every* Bayesian decision maker attains weakly higher expected utility with μ.

This lecture asks a different question.

Suppose somebody *owns* the data and wants to sell it.

What should she sell, and at what price?

We study Bergemann *et al.* [2018], who analyze a monopolist data seller facing a buyer who already has some private information of his own.

The buyer's private information is exactly what he would like to hide, because it determines his willingness to pay.

So the seller screens by offering a *menu* of statistical experiments, degrading the information sold to some buyers in order to charge more to others.

The central finding is that degrading information is not simply a matter of adding noise.

Blackwell's order is a *partial* order, so two experiments can be ranked differently by different decision makers.

The seller exploits precisely those incomparable pairs: information has a **vertical** dimension, its quality, and a **horizontal** dimension, its position.

That horizontal dimension has no counterpart in ordinary monopoly screening over quality or quantity, and it is what allows the seller to extract rents that would otherwise be impossible to reach.

Along the way we will

- compute the value of an arbitrary experiment to an arbitrary belief type,
- verify numerically that Blackwell's order fails to rank the experiments the seller wants to use,
- solve the two-type screening problem by brute force and check it against the paper's closed forms,
- solve the continuum-of-types problem as a **linear program**, which reproduces the paper's ironing and pooling results without any need to implement ironing by hand.

Let's start with imports.

```
import matplotlib.pyplot as plt
import numpy as np
from scipy import stats
from scipy.optimize import linprog

plt.rcParams['figure.figsize'] = (10, 5)
np.set_printoptions(precision=4, suppress=True)
```

37.2 The decision problem

A data buyer must choose an action a from a finite set A without knowing the state ω, which lives in a finite set Ω.

We work throughout with the **matching** case in which the buyer wants his action to match the state,

$$u(\omega_i, a_j) = \mathbb{1}[i = j] \cdot u_i, \tag{37.1}$$

so that matching state ω_i pays $u_i > 0$ and any mismatch pays zero.

From here on we take two states and two actions, $\Omega = \{\omega_1, \omega_2\}$ and $A = \{a_1, a_2\}$, which is the case Bergemann *et al.* [2018] solve completely.

The buyer's **type** is his interim belief

$$\theta = \Pr[\omega = \omega_1] \in [0, 1],$$

which is private information.

The seller knows only the distribution F from which θ is drawn.

Without extra information the buyer picks the better of two constant actions, so his reservation utility is

$$u(\theta) = \max\{\theta u_1,\ (1-\theta) u_2\}. \tag{37.2}$$

The type that is *least* sure what to do is the one where the two terms are equal,

$$\theta^* = \frac{u_2}{u_1 + u_2}. \tag{37.3}$$

Types above θ^* would choose a_1 on their own, types below would choose a_2.

Note

The buyer's belief θ can be generated from a common prior together with a privately observed signal, exactly as in *Likelihood Ratio Processes and Bayesian Learning* and *Exchangeability and Bayesian Updating*.

A buyer with a very precise private signal has θ near 0 or 1; a buyer who has learned nothing sits at the common prior, which equals θ^* only by coincidence.

A "high type" in this lecture is a buyer whose belief lies near θ^*, and he is willing to pay the most.

When the common prior equals θ^*, high types are the badly informed buyers.

37.3 Experiments and their value

A statistical experiment is a stochastic matrix mapping states into signals.

With two states and two actions it suffices to consider two signals, and we write

$$E = \begin{pmatrix} \pi_1 & 1-\pi_1 \\ 1-\pi_2 & \pi_2 \end{pmatrix}, \tag{37.4}$$

where row i gives the signal distribution in state ω_i.

Thus $\pi_1 = \Pr[s_1 \mid \omega_1]$ and $\pi_2 = \Pr[s_2 \mid \omega_2]$.

We adopt the normalization $\pi_1 + \pi_2 \geq 1$, which just says that signal s_1 is relatively more likely in state ω_1 than in state ω_2.

The **fully informative** experiment $\overline{E}$ has $\pi_1 = \pi_2 = 1$.

After seeing signal s_k the buyer picks the action with the highest expected payoff, so his gross value is obtained by summing the best he can do signal by signal.

Subtracting his reservation utility (37.2) gives the **net value of information**

$$V(E,\theta) = \max\{\theta\pi_1 u_1,\ (1-\theta)(1-\pi_2)u_2\} + \max\{\theta(1-\pi_1)u_1,\ (1-\theta)\pi_2 u_2\} - \max\{\theta u_1,\ (1-\theta)u_2\}. \tag{37.5}$$

```
def value(pi1, pi2, theta, u1=1.0, u2=1.0):
    """Net value of experiment (pi1, pi2) to a buyer with belief theta."""
    theta = np.asarray(theta, dtype=float)
    s1 = np.maximum(theta * pi1 * u1, (1 - theta) * (1 - pi2) * u2)
    s2 = np.maximum(theta * (1 - pi1) * u1, (1 - theta) * pi2 * u2)
    return s1 + s2 - np.maximum(theta * u1, (1 - theta) * u2)
```

If the buyer simply obeys the recommendation implicit in each signal, taking a_1 after s_1 and a_2 after s_2, the value collapses to

$$V(E,\theta) = \max\{\theta\pi_1 u_1 + (1-\theta)\pi_2 u_2 - \max\{\theta u_1, (1-\theta)u_2\},\ 0\}, \tag{37.6}$$

which is the expression the paper works with.

```
def value_obedient(pi1, pi2, theta, u1=1.0, u2=1.0):
    """Value when the buyer follows the recommendation, or ignores the signal."""
    theta = np.asarray(theta, dtype=float)
    return np.maximum(theta * pi1 * u1 + (1 - theta) * pi2 * u2
                      - np.maximum(theta * u1, (1 - theta) * u2), 0.0)
```

The two expressions agree exactly under the normalization $\pi_1 + \pi_2 \geq 1$ and can differ sharply without it, which is what the normalization is for.

```
grid = np.linspace(0, 1, 2001)
worst_ok = worst_bad = 0.0
for p1 in np.linspace(0, 1, 51):
    for p2 in np.linspace(0, 1, 51):
        gap = np.abs(value(p1, p2, grid) - value_obedient(p1, p2, grid)).max()
        if p1 + p2 >= 1:
            worst_ok = max(worst_ok, gap)
        else:
            worst_bad = max(worst_bad, gap)

print(f'largest gap where pi1 + pi2 >= 1:  {worst_ok:.2e}')
print(f'largest gap where pi1 + pi2 <  1:  {worst_bad:.4f}')
```

```
largest gap where pi1 + pi2 >= 1:  1.11e-16
largest gap where pi1 + pi2 <  1:  0.5000
```

Under the normalization, reversing the recommendation, taking a_2 after s_1 and a_1 after s_2, is dominated by ignoring the signal, so every type either obeys or ignores.

That is why the two formulas coincide for every θ, including types who misreport and buy an experiment designed for somebody else.

We use the general form (37.5) from here on because it does not rely on the normalization.

Here is the value of information as a function of the buyer's type.

```
theta = np.linspace(0, 1, 1001)

fig, axes = plt.subplots(1, 2, figsize=(11, 4))
for ax, (p1, p2), ttl in zip(
        axes, [(1.0, 1.0), (0.5, 1.0)],
        [r'fully informative $(\pi_1,\pi_2)=(1,1)$',
         r'partially informative $(\pi_1,\pi_2)=(1/2,1)$']):
    ax.plot(theta, value(p1, p2, theta), lw=2)
    ax.axvline(0.5, color='0.6', ls='--', lw=1)
    ax.set(xlabel=r'$\theta$', ylabel=r'$V(E,\theta)$', title=ttl)
fig.suptitle('Value of information, $u_1 = u_2 = 1$')
fig.tight_layout()
plt.show()
```

Three features of these pictures drive everything that follows.

The value is **piecewise linear** in θ, because types are probabilities and expected utilities are linear in probabilities.

The value is **highest at** θ^* and falls to zero at $\theta \in \{0, 1\}$: the buyer who already knows the state will pay nothing, and the buyer who knows least will pay most.

The partially informative experiment in the right panel is worth **nothing at all** to types above $2/3$, even though it is worth a great deal to types just below $1/2$.

That last property is the seller's main tool.

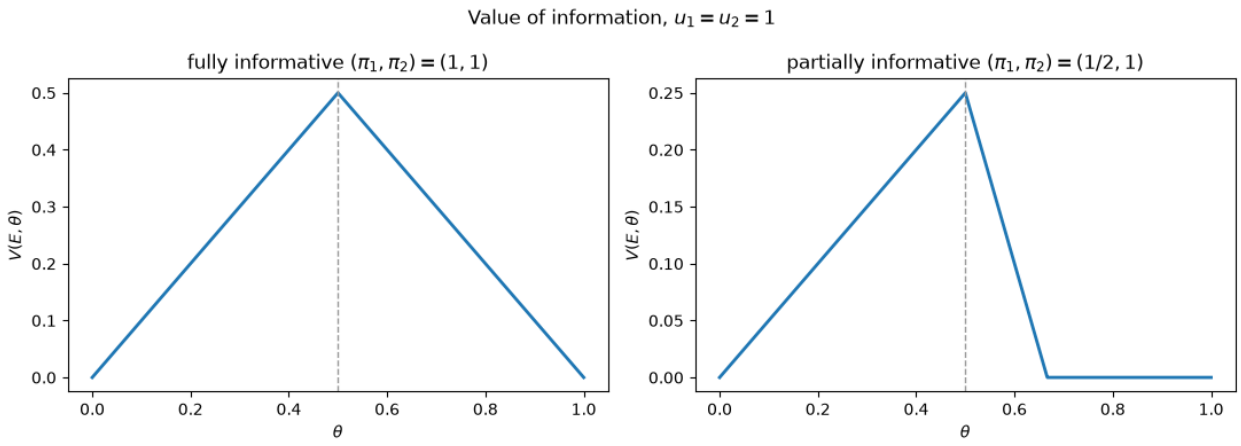

Fig. 37.1: Value of full and partial information

37.4 Blackwell's order is only partial

Blackwell's Theorem on Comparing Experiments establishes that experiment E is at least as informative as E' in Blackwell's sense exactly when E' is a **garbling** of E.

In the notation of *Definition 30.2.1*, with $\mu = E$ and $\nu = E'$, there is a Markov matrix Q with

$$E' = EQ. \tag{37.7}$$

When E is invertible this is easy to check: solve $Q = E^{-1}E'$ and ask whether every entry of Q is nonnegative.

The rows of Q sum to one automatically: $EQ\mathbf{1} = E'\mathbf{1} = \mathbf{1} = E\mathbf{1}$, and E is invertible, so $Q\mathbf{1} = \mathbf{1}$.

```
def experiment(pi1, pi2):
    return np.array([[pi1, 1 - pi1], [1 - pi2, pi2]])

def garbling(E, Ep, tol=1e-9):
    """Return Q with Ep = E @ Q if Ep is a garbling of E, else None."""
    if abs(np.linalg.det(E)) < tol:
        return None
    Q = np.linalg.solve(E, Ep)           # rows of Q sum to one automatically
    if (Q > -tol).all():
        return Q
    return None

pairs = [((1, 1), (0.8, 1)), ((1, 1), (1, 0.8)),
         ((0.9, 0.9), (0.8, 0.8)),
         ((0.8, 1), (1, 0.8)), ((1, 0.8), (0.8, 1))]
for a, b in pairs:
    ok = garbling(experiment(*a), experiment(*b)) is not None
    print(f'  is {b} a garbling of {a}?  {"yes" if ok else "no"}')
```

```
  is (0.8, 1) a garbling of (1, 1)?  yes
  is (1, 0.8) a garbling of (1, 1)?  yes
  is (0.8, 0.8) a garbling of (0.9, 0.9)?  yes
  is (1, 0.8) a garbling of (0.8, 1)?  no
  is (0.8, 1) a garbling of (1, 0.8)?  no
```

The fully informative experiment garbles into everything, and $(0.9, 0.9)$ garbles into the uniformly noisier $(0.8, 0.8)$.

Those are the **vertical** comparisons, and Blackwell's theorem says every type agrees about them.

But $(0.8, 1)$ and $(1, 0.8)$ garble into each other in neither direction.

Blackwell's order simply does not rank them, and that means different types are free to rank them differently.

```
va, vb = value(0.8, 1, theta), value(1, 0.8, theta)

fig, ax = plt.subplots()
ax.plot(theta, va, lw=2, label=r'$E_a = (0.8, 1)$')
ax.plot(theta, vb, lw=2, label=r'$E_b = (1, 0.8)$')
ax.fill_between(theta, va, vb, where=va > vb, alpha=0.15, color='C0')
ax.fill_between(theta, va, vb, where=vb > va, alpha=0.15, color='C1')
ax.axvline(0.5, color='0.4', ls='--', lw=1)
ax.set(xlabel=r'$\theta$', ylabel=r'$V(E,\theta)$',
       title='Types below $1/2$ prefer $E_a$, types above prefer $E_b$')
ax.legend()
fig.tight_layout()
plt.show()

for t in [0.2, 0.35, 0.65, 0.8]:
    pref = 'E_a' if value(0.8, 1, t) > value(1, 0.8, t) else 'E_b'
    print(f'  theta = {t}:  V(E_a) = {value(0.8, 1, t):.4f},'
          f'  V(E_b) = {value(1, 0.8, t):.4f}   prefers {pref}')
```

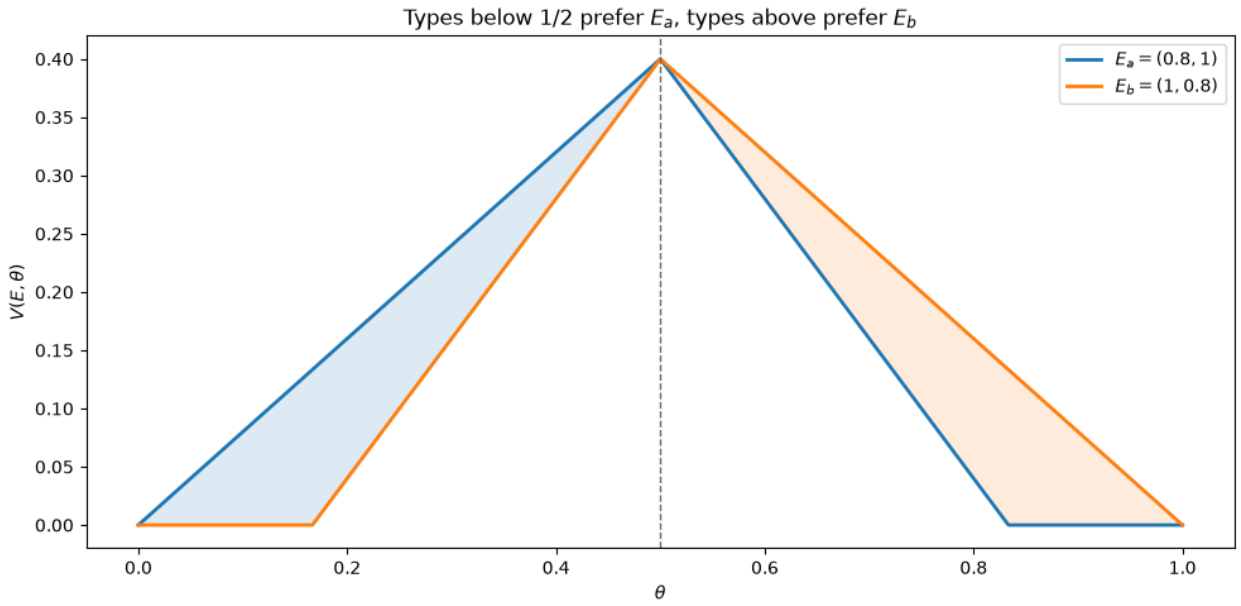

Fig. 37.2: Two experiments that Blackwell's order does not rank

```
theta = 0.2:  V(E_a) = 0.1600,  V(E_b) = 0.0400   prefers E_a
theta = 0.35:  V(E_a) = 0.2800,  V(E_b) = 0.2200   prefers E_a
theta = 0.65:  V(E_a) = 0.2200,  V(E_b) = 0.2800   prefers E_b
theta = 0.8:  V(E_a) = 0.0400,  V(E_b) = 0.1600   prefers E_b
```

Signal s_1 of E_a occurs only in state ω_1, so it rules out ω_2; signal s_2 of E_b occurs only in state ω_2, so it rules out ω_1.

A buyer who leans toward ω_1 takes a_1 on his own and switches to a_2 only on strong evidence for ω_2.

E_b supplies conclusive evidence for ω_2, so he values E_b.

A buyer who leans toward ω_2 values E_a for the same reason.

This is the **horizontal** dimension of information.

In ordinary nonlinear pricing over quality or quantity, all types agree on the ranking of products and the seller can only move up and down a single ladder.

Here the seller has a second dial, and turning it lets her hand one type something that is worthless to another.

37.5 The seller's problem

The seller commits to a menu $\{E(\theta), t(\theta)\}$ assigning an experiment and a price to each reported type.

Payments cannot be made contingent on the state, the signal, or the buyer's action, so the value of an experiment to a buyer is determined by his belief alone.

Writing $V(\theta) = V(E(\theta), \theta) - t(\theta)$ for the buyer's rent, the seller solves

$$\max_{\{E(\theta),\, t(\theta)\}} \int t(\theta)\, dF(\theta) \tag{37.8}$$

subject to incentive compatibility and individual rationality,

$$V(\theta) \geq V(E(\theta'), \theta) - t(\theta') \;\; \forall \theta, \theta', \qquad V(\theta) \geq 0 \;\; \forall \theta. \tag{37.9}$$

Bergemann *et al.* [2018] establish structural results that every menu we compute confirms.

Proposition 37.5.1

1. The fully informative experiment $\overline{E}$ is part of an optimal menu.
2. Every experiment in any optimal menu is **nondispersed**, meaning $\pi_{ij} = 0$ for some $i \neq j$.
3. In the matching case every experiment in any optimal menu is **concentrated**, meaning $\pi_{ii} = 1$ for some i.

Part 3 says that in our binary setting every experiment on the menu has $\pi_1 = 1$ or $\pi_2 = 1$.

With two states and two signals, a zero off-diagonal entry forces a one on the diagonal of the same row, so "nondispersed" and "concentrated" coincide.

An optimal experiment keeps one signal that perfectly reveals one state; the other signal is noisy.

37.6 Two types

Take two types θ^L and θ^H, with θ^H the *high value* type in the sense that he values the fully informative experiment more,

$$V(\overline{E}, \theta^H) \geq V(\overline{E}, \theta^L).$$

With $u_1 = u_2$ this says $|\theta^H - 1/2| \leq |\theta^L - 1/2|$, so the high type is the one who is *less* well informed to begin with.

Let $\gamma = \Pr[\theta = \theta^H]$.

The types are **congruent** if $\theta^* < \theta^H < \theta^L$, so both would take the same action without extra information, and **noncongruent** if $\theta^L < \theta^* < \theta^H$.

An optimal menu has the familiar shape: the high type buys $\overline{E}$, the low type's participation constraint binds, and the high type's incentive constraint binds.

Those three facts pin down both prices once the low type's experiment is chosen.

To search over *all* low-type experiments we also need prices for experiments that the high type values less than the low type does.

For those, the price that makes the high type's incentive constraint bind exceeds his value of $\overline{E}$, so his participation constraint binds instead.

The function below charges the high type the smaller of the two prices.

```
def two_type_revenue(pi1, pi2, tL, tH, gamma, u1=1.0, u2=1.0):
    """Revenue when the high type buys E_bar and the low type buys (pi1, pi2)."""
    VbarH, VbarL = value(1, 1, tH, u1, u2), value(1, 1, tL, u1, u2)
    VL_L, VL_H = value(pi1, pi2, tL, u1, u2), value(pi1, pi2, tH, u1, u2)
    t_low = VL_L                                    # low type's IR binds
    t_high = min(VbarH - VL_H + t_low,              # high type's IC
                 VbarH)                             # high type's IR
    if VbarL - t_high > 1e-12:                      # low type must not deviate
        return -np.inf
    return gamma * t_high + (1 - gamma) * t_low
```

37.6.1 Noncongruent types

Set $\theta^L = 1/5$ and $\theta^H = 7/10$ with $u_1 = u_2 = 1$, so that $\theta^* = 1/2$ lies between them.

Because the two types would take *different* actions on their own, the seller can build an experiment that is valuable to one and worthless to the other.

Choosing $\pi_2 = 1$ and

$$\pi_1' = \frac{u_1\theta^H - u_2(1-\theta^H)}{u_1\theta^H} \tag{37.10}$$

leaves the high type exactly indifferent between his two actions after signal s_2, so the experiment is worth nothing to him while the low type values it strictly.

That is feasible but not optimal.

The seller does better by making the high type's incentive constraint bind instead, which gives

$$\pi_1'' = \frac{u_1\theta^H - u_2(1-\theta^H)}{u_1(\theta^H - \theta^L)}. \tag{37.11}$$

```
tL, tH, u1, u2 = 0.2, 0.7, 1.0, 1.0
pi1_zero = (u1 * tH - u2 * (1 - tH)) / (u1 * tH)
pi1_opt = (u1 * tH - u2 * (1 - tH)) / (u1 * (tH - tL))

print(f'zero-value-to-high experiment   pi1 = {pi1_zero:.4f}  (= 4/7)')
print(f'binding-IC experiment            pi1 = {pi1_opt:.4f}  (= 4/5)')
print(f'\n  V(E_zero, theta_H) = {value(pi1_zero, 1, tH):.4f}')
print(f'  V(E_opt,  theta_L) = {value(pi1_opt, 1, tL):.4f}'
      f'    V(E_opt, theta_H) = {value(pi1_opt, 1, tH):.4f}')
```

```
zero-value-to-high experiment   pi1 = 0.5714   (= 4/7)
binding-IC experiment           pi1 = 0.8000   (= 4/5)

  V(E_zero, theta_H) = 0.0000
  V(E_opt,  theta_L) = 0.1600    V(E_opt, theta_H) = 0.1600
```

The second experiment gives *both* types the same net value of information, 0.16.

The seller charges the low type 0.16 for it and charges the high type his full value of $\overline{E}$.

The high type's incentive constraint binds, and so do both participation constraints.

The seller extracts the entire surplus from both types; the only cost of screening is the distortion of the low type's experiment.

```
fig, axes = plt.subplots(1, 2, figsize=(12, 4.2))
for ax, p1, ttl in zip(axes, [pi1_zero, pi1_opt],
                       ['suboptimal menu: partial experiment worth zero to $\\theta^H$
↪',
                        'optimal menu: high type indifferent between the two items']):
    t_hi = value(1, 1, tH)                                    # price of E_bar
    t_lo = value(p1, 1, tL)                                   # price of partial item
    ax.plot(theta, value(1, 1, theta) - t_hi, lw=2, label='fully informative')
    ax.plot(theta, value(p1, 1, theta) - t_lo, lw=2, ls='--',
            label=f'partial, $\\pi_1={p1:.3f}$')
    ax.axhline(0, color='0.3', lw=1)
    for t, nm in [(tL, r'$\theta^L$'), (tH, r'$\theta^H$')]:
        ax.axvline(t, color='0.7', ls=':', lw=1)
        ax.annotate(nm, (t, ax.get_ylim()[0]), fontsize=9)
    ax.set(xlabel=r'$\theta$', ylabel=r'$V - t$', title=ttl, ylim=(-0.35, 0.25))
    ax.legend(fontsize=8, loc='upper left')
fig.tight_layout()
plt.show()
```

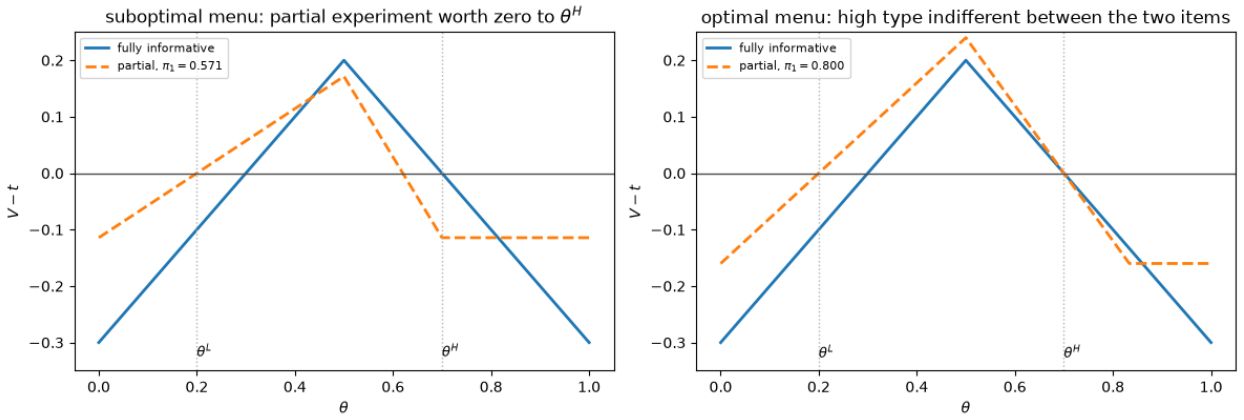

Fig. 37.3: Net value of the two menus as a function of the buyer's type

In the left panel the high type's net value of the fully informative experiment lies strictly above his net value of the partial one, so his incentive constraint is slack and the seller is leaving money on the table.

In the right panel the two curves meet exactly at θ^H.

Now we check the closed form (37.11) against a brute-force search over *all* experiments.

```
def brute_force(tL, tH, gamma, n=301, u1=1.0, u2=1.0):
    """Search over all (pi1, pi2) for the best low-type experiment."""
    g = np.linspace(0, 1, n)
    best, arg = -np.inf, None
    for p1 in g:
        for p2 in g:
            if p1 + p2 < 1:
                continue
            r = two_type_revenue(p1, p2, tL, tH, gamma, u1, u2)
            if r > best:
                best, arg = r, (p1, p2)
    return best, arg

print(f'{"gamma":>7s}{"brute force":>13s}{"argmax":>18s}'
      f'{"closed form":>14s}{"E_bar to both":>15s}')
for gamma in [0.10, 0.25, 0.30, 0.50, 0.90]:
    best, arg = brute_force(tL, tH, gamma)
    closed = two_type_revenue(pi1_opt, 1.0, tL, tH, gamma)
    both = two_type_revenue(1.0, 1.0, tL, tH, gamma)
    print(f'{gamma:7.2f}{best:13.5f}   ({arg[0]:.3f}, {arg[1]:.3f})'
          f'{closed:14.5f}{both:15.5f}')
print(f'\nthe paper: discriminate iff gamma > theta_L / theta_H = {tL / tH:.4f}')
```

```
  gamma  brute force            argmax   closed form  E_bar to both
   0.10      0.20000   (1.000, 1.000)       0.17400        0.20000
   0.25      0.20000   (1.000, 1.000)       0.19500        0.20000
   0.30      0.20200   (0.800, 1.000)       0.20200        0.20000
   0.50      0.23000   (0.800, 1.000)       0.23000        0.20000
   0.90      0.28600   (0.800, 1.000)       0.28600        0.20000

the paper: discriminate iff gamma > theta_L / theta_H = 0.2857
```

The brute-force optimum sits at $(\pi_1, \pi_2) = (0.8, 1)$ whenever discrimination pays, matching (37.11) exactly, and at $(1, 1)$ otherwise.

The switch happens right at $\gamma = \theta^L/\theta^H$.

When low types are common the seller prefers to sell everyone the fully informative experiment cheaply; when high types are common she prefers to protect the high price by degrading what the low type gets.

Note also that both experiments in the optimal menu have $\pi_2 = 1$, confirming part 3 of *Proposition 37.5.1*.

37.7 A continuum of types

Now let θ be distributed on $[0, 1]$ with density f and distribution F.

The key simplification is that the value of a *concentrated* experiment depends on (π_1, π_2) only through the scalar

$$q = \pi_1 u_1 - \pi_2 u_2 \in [-u_2,\ u_1], \tag{37.12}$$

which Bergemann *et al.* [2018] call the **differential informativeness** of the experiment.

By part 3 of *Proposition 37.5.1*, restricting the seller to concentrated experiments loses nothing.

For other experiments q does not determine the value: with $u_1 = u_2 = 1$, the experiments $(0.8, 0.8)$, $(0.9, 0.9)$ and $(1, 1)$ all have $q = 0$, but at $\theta = 1/2$ they are worth 0.3, 0.4 and 0.5.

In terms of q the value becomes

$$V(q,\theta) = \max\{\theta q + u_2 + \min\{u_1 - u_2 - q,\ 0\} - \max\{\theta u_1,\ (1-\theta)u_2\},\ 0\}. \tag{37.13}$$

The fully informative experiment is $q = u_1 - u_2$.

The two endpoints $q = -u_2$ and $q = u_1$ are the experiments in which one signal occurs with probability one in both states, so they convey nothing.

```
def value_q(q, theta, u1=1.0, u2=1.0):
    """Value of the experiment with differential informativeness q."""
    theta = np.asarray(theta, dtype=float)
    gross = theta * q + u2 + np.minimum(u1 - u2 - q, 0.0)
    return np.maximum(gross - np.maximum(theta * u1, (1 - theta) * u2), 0.0)

def q_to_experiment(q, u1=1.0, u2=1.0):
    """Recover (pi1, pi2) from q using pi1 = 1 or pi2 = 1."""
    return (1.0, (u1 - q) / u2) if q >= u1 - u2 else ((q + u2) / u1, 1.0)

for q in [-1.0, -0.5, 0.0, 0.5, 1.0]:
    p1, p2 = q_to_experiment(q)
    print(f'  q = {q:+.2f}  ->  (pi1, pi2) = ({p1:.3f}, {p2:.3f}),'
          f'   max value over types = {value_q(q, theta).max():.4f}')
```

```
  q = -1.00  ->  (pi1, pi2) = (0.000, 1.000),   max value over types = 0.0000
  q = -0.50  ->  (pi1, pi2) = (0.500, 1.000),   max value over types = 0.2500
  q = +0.00  ->  (pi1, pi2) = (1.000, 1.000),   max value over types = 0.5000
  q = +0.50  ->  (pi1, pi2) = (1.000, 0.500),   max value over types = 0.2500
  q = +1.00  ->  (pi1, pi2) = (1.000, 0.000),   max value over types = 0.0000
```

A menu is now a function $q(\theta)$, and incentive compatibility requires it to be non-decreasing.

Types who think ω_1 is more likely want experiments with higher q, which deliver sharper evidence about the state they consider *less* likely.

There is a second, less familiar restriction.

Because information is worthless to types $\theta \in \{0, 1\}$, applying the envelope theorem separately on $[0, \theta^*]$ and $[\theta^*, 1]$ and matching the two expressions for the rent of the pivotal type θ^* forces

$$\int_0^1 q(\theta)\, d\theta = u_1 - u_2. \tag{37.14}$$

Note that this integral is taken with respect to $d\theta$, not $dF(\theta)$.

With those two constraints, the seller's problem reduces to

$$\max_{q(\cdot)} \int_0^1 \Big[(\theta f(\theta) + F(\theta))q(\theta) + \min\big\{(u_1 - u_2 - q(\theta))f(\theta),\ 0\big\}\Big] d\theta \tag{37.15}$$

subject to q non-decreasing and (37.14).

37.7.1 Solving it as a linear program

The integrand of (37.15) is **concave and piecewise linear** in q, since $\min\{(d-q)f, 0\} = -f\max\{q-d, 0\}$ with $d = u_1 - u_2$ and $f \geq 0$.

Maximizing a concave piecewise-linear objective subject to linear constraints is a linear program.

Introducing $z(\theta) \geq \max\{q(\theta) - d,\ 0\}$ and discretizing θ on a grid gives

$$\max_{q,z} \sum_n w_n \Big[(\theta_n f_n + F_n) q_n - f_n z_n\Big]$$

subject to $z_n \geq q_n - d$, $z_n \geq 0$, $q_{n+1} \geq q_n$, $-u_2 \leq q_n \leq u_1$, and $\sum_n w_n q_n = d$.

```
def solve_menu(theta, f, u1=1.0, u2=1.0):
    """Solve the seller's problem on a grid of types by linear programming."""
    N = len(theta)
    dth = theta[1] - theta[0]
    f = f / (np.sum(f) * dth)                                  # density on the grid
    F = np.cumsum(f) * dth
    w = np.full(N, dth)
    d = u1 - u2

    c = np.concatenate([-(theta * f + F) * w, f * w])          # linprog minimizes
    A_ub = np.hstack([np.eye(N), -np.eye(N)])                  # q - z <= d
    b_ub = np.full(N, d)
    D = np.zeros((N - 1, 2 * N))                               # q_n - q_{n+1} <= 0
    rows = np.arange(N - 1)
    D[rows, rows], D[rows, rows + 1] = 1.0, -1.0
    A_ub = np.vstack([A_ub, D])
    b_ub = np.concatenate([b_ub, np.zeros(N - 1)])
    A_eq = np.concatenate([w, np.zeros(N)])[None, :]           # integral constraint
    bounds = [(-u2, u1)] * N + [(0, None)] * N

    res = linprog(c, A_ub=A_ub, b_ub=b_ub, A_eq=A_eq, b_eq=np.array([d]),
                  bounds=bounds, method='highs')
    return res.x[:N], res
```

The linear program handles the monotonicity constraint automatically.

This matters, because the alternative is to implement Myerson's **ironing** procedure by hand: form the virtual values

$$\phi^-(\theta) = \theta f(\theta) + F(\theta), \qquad \phi^+(\theta) = (\theta - 1) f(\theta) + F(\theta), \tag{37.16}$$

replace them by the derivatives of the convex hulls of their integrals, and then find the multiplier on (37.14) (see Myerson [1981] and Toikka [2011]).

Denote the ironed virtual values by $\bar{\phi}^-$ and $\bar{\phi}^+$.

Bergemann *et al.* [2018] show that a menu q^* is optimal if and only if it satisfies (37.14), it is constant on every interval where the relevant ironed virtual value is constant, and for some multiplier $\lambda^* > 0$ and every θ, $q^*(\theta)$ maximizes

$$\bar{\phi}^-(\theta)\min\{q, d\} + \bar{\phi}^+(\theta)\max\{0, q - d\} - \lambda^* q \tag{37.17}$$

over $q \in [-u_2, u_1]$.

Where $\bar{\phi}^+(\theta) \leq \bar{\phi}^-(\theta)$, the maximizer is $q^* = -u_2$ if $\bar{\phi}^-(\theta) < \lambda^*$, $q^* = d$ if $\bar{\phi}^+(\theta) < \lambda^* < \bar{\phi}^-(\theta)$, and $q^* = u_1$ if $\bar{\phi}^+(\theta) > \lambda^*$.

The linear program does all of that implicitly.

The multiplier λ^* on (37.14) is the dual value of the equality constraint, `-res.eqlin.marginals[0]`; the sign flips because `linprog` minimizes minus revenue.

We also want the prices, which follow from the requirement that a buyer at the boundary between two items be indifferent between them.

```
def menu_items(theta, q, u1=1.0, u2=1.0, tol=1e-4, min_width=0.01):
    """Distinct items in the menu, with the interval of types served and the price.

    Values of q taken on a negligible set of types are transition artifacts of the
    grid, not items on the menu, so we drop them.
    """
    qr = np.round(q / tol) * tol
    vals = [v for v in np.unique(qr)
            if theta[qr == v].max() - theta[qr == v].min() >= min_width]
    items = sorted([(v, theta[qr == v].min(), theta[qr == v].max()) for v in vals],
                   key=lambda x: x[1])
    out, prev_v, prev_t = [], None, 0.0
    for v, lo, hi in items:
        if value_q(v, theta, u1, u2).max() < 1e-9:      # uninformative item
            price = 0.0
        elif prev_v is None:
            price = 0.0
        else:
            price = float(value_q(v, lo, u1, u2)
                          - value_q(prev_v, lo, u1, u2) + prev_t)
        out.append((v, lo, hi, price))
        prev_v, prev_t = v, price
    return out
```

37.7.2 Uniformly distributed types

With $u_1 = u_2 = 1$ and θ uniform, the virtual values are $\phi^-(\theta) = 2\theta$ and $\phi^+(\theta) = 2\theta - 1$.

Both are strictly increasing, so no ironing is required and the optimal menu should contain a single informative item.

```
N = 2001
theta_g = np.linspace(0, 1, N)
q_unif, res = solve_menu(theta_g, np.ones(N))

print('LP status:', res.message)
print('distinct values of q:', np.unique(np.round(q_unif, 4)))
for v, lo, hi, p in menu_items(theta_g, q_unif):
    p1, p2 = q_to_experiment(v)
    print(f'   q = {v:+.4f}  (pi1, pi2) = ({p1:.3f}, {p2:.3f})'
          f'   types [{lo:.3f}, {hi:.3f}]   price {p:.4f}')
```

```
LP status: Optimization terminated successfully. (HiGHS Status 7: Optimal)
distinct values of q: [-1. -0.  1.]
   q = -1.0000  (pi1, pi2) = (0.000, 1.000)   types [0.000, 0.249]   price 0.0000
   q = -0.0000  (pi1, pi2) = (1.000, 1.000)   types [0.250, 0.750]   price 0.2500
   q = +1.0000  (pi1, pi2) = (1.000, 0.000)   types [0.751, 1.000]   price 0.0000
```

The seller offers the fully informative experiment to the middle range of types at a single price and nothing to anyone else.

The cutoffs and the price match the analytic solution of Bergemann *et al.* [2018] exactly: full information to $\theta \in [1/4, 3/4]$ at a price of $1/4$.

This is the "no-haggling" outcome of Riley and Zeckhauser [1983] adapted to information.

```
fig, axes = plt.subplots(1, 2, figsize=(12, 4))
axes[0].plot(theta_g, 2 * theta_g, lw=2, label=r'$\phi^-(\theta) = 2\theta$')
axes[0].plot(theta_g, 2 * theta_g - 1, lw=2, label=r'$\phi^+(\theta) = 2\theta - 1$')

plt.show()
```

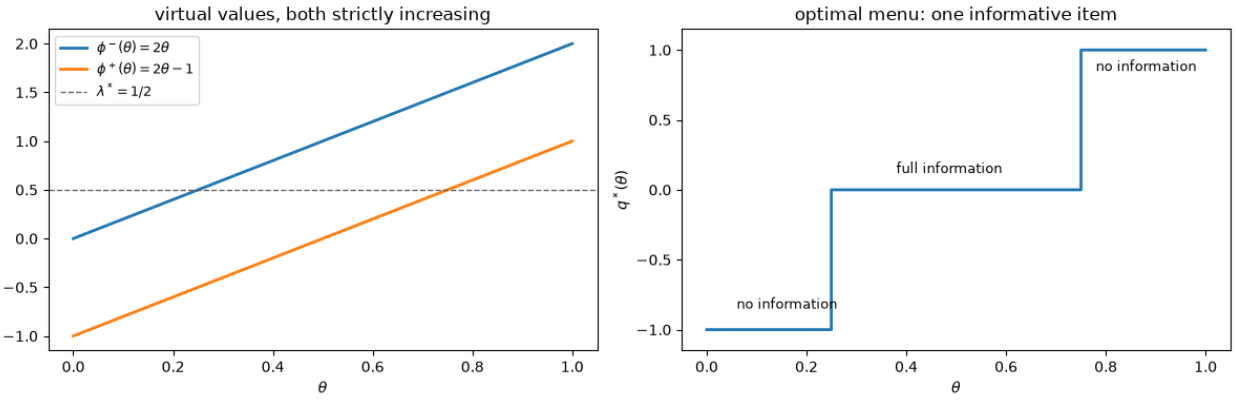

Fig. 37.4: Optimal menu with uniformly distributed types

37.7.3 Bimodal types and the case for versioning

Corollary 1 of Bergemann *et al.* [2018] says that a second experiment is offered only when the virtual values require ironing.

Differentiating (37.16) gives

$$\phi^{-\prime}(\theta) = 2f(\theta) + \theta f'(\theta), \qquad \phi^{+\prime}(\theta) = 2f(\theta) - (1-\theta)f'(\theta). \tag{37.18}$$

So ϕ^- is increasing if and only if $\theta^2 f(\theta)$ is increasing, and ϕ^+ is increasing if and only if $(1-\theta)^2 f(\theta)$ is decreasing.

Regularity fails where the density falls faster than θ^{-2} or rises faster than $(1-\theta)^{-2}$, that is, where the density is steep.

Bergemann *et al.* [2018] remark informally that ironing becomes necessary when most buyers are well informed ex ante, with most types close to 0 or 1.

That remark needs qualification.

For a Beta(a, b) density both virtual values are increasing if and only if $a \leq 1$ and $b \leq 1$ (Exercise 37.9.4), so U-shaped Beta populations of well-informed buyers are regular and are offered a single item.

Steep clusters of beliefs are irregular whether they sit near the ends of $[0, 1]$ or in its interior, and Exercise 37.9.4 exhibits a well-informed population of that kind that is offered two items.

Irregularity is necessary for a second item but not sufficient.

Beta$(30, 30)$ is irregular, but it is symmetric about $1/2$, and with $u_1 = u_2$ Corollary 1 of Bergemann *et al.* [2018] then delivers a single item.

We follow the paper and take an equal mixture of Beta$(8, 30)$ and Beta$(60, 30)$.

Each component concentrates beliefs in a narrow range, so the mixture has two steep clusters, near $\theta \approx 0.2$ and $\theta \approx 0.67$.

```
f_bimodal = (0.5 * stats.beta(8, 30).pdf(theta_g)
             + 0.5 * stats.beta(60, 30).pdf(theta_g))

def falling_intervals(theta, phi, min_width=0.01):
    """Intervals of types on which phi decreases."""
    down = np.concatenate([[0], (np.diff(phi) < 0).astype(int), [0]])
    edges = np.flatnonzero(np.diff(down))
    return [(theta[a], theta[b]) for a, b in zip(edges[::2], edges[1::2])
            if theta[b] - theta[a] >= min_width]

dth = theta_g[1] - theta_g[0]
F_bi = np.cumsum(f_bimodal) * dth
for name, phi in [('phi-', theta_g * f_bimodal + F_bi),
                  ('phi+', (theta_g - 1) * f_bimodal + F_bi)]:
    print(f'{name} decreases on',
          ', '.join(f'[{a:.3f}, {b:.3f}]'
                    for a, b in falling_intervals(theta_g, phi)))

q_bi, res_bi = solve_menu(theta_g, f_bimodal)

print('\nLP status:', res_bi.message)
print('distinct values of q:', np.unique(np.round(q_bi, 3)))
print(f'multiplier lambda* = {-res_bi.eqlin.marginals[0]:.4f}')
print()
for v, lo, hi, p in menu_items(theta_g, q_bi):
    p1, p2 = q_to_experiment(v)
    label = 'no information' if abs(p) < 1e-9 else (
        'full information' if abs(v) < 1e-6 else 'partial information')
    print(f'   q = {v:+.4f}  (pi1, pi2) = ({p1:.3f}, {p2:.3f})'
          f'   types [{lo:.3f}, {hi:.3f}]   price {p:.4f}   {label}')
```

```
phi- decreases on [0.237, 0.472], [0.678, 0.955]
phi+ decreases on [0.000, 0.184], [0.475, 0.655]

LP status: Optimization terminated successfully. (HiGHS Status 7: Optimal)

↪ no information
```

ϕ^- decreases on the upper flank of each cluster, where the density falls steeply; ϕ^+ decreases on the lower flank of each cluster, where it rises steeply.

Both virtual values require ironing.

Now the menu contains **two** informative items, in line with *Proposition 37.5.1* and with the result of Bergemann *et al.* [2018] that some optimal menu contains at most two.

The partial item has $\pi_2 = 1$, so signal s_1 occurs only in state ω_1 and perfectly reveals it, while signal s_2 leaves the buyer uncertain.

Types $\theta \in [0.175, 0.550]$ buy it.

That interval contains $\theta^* = 1/2$, the type least sure what to do, who values information most.

The type indifferent between the two informative items is $\theta \approx 0.55$.

Selling $\overline{E}$ to θ^* would require a further distortion of the partial item and a lower price for it, and that would cost revenue from the many types near $\theta \approx 0.2$.

The partial item lets the seller charge a high price for $\overline{E}$ to the large mass of buyers near $\theta \approx 0.7$.

```
items = menu_items(theta_g, q_bi)

fig, axes = plt.subplots(1, 2, figsize=(12, 4))
axes[0].plot(theta_g, f_bimodal, lw=2, color='C2')
axes[0].fill_between(theta_g, f_bimodal, alpha=0.2, color='C2')
axes[0].set(xlabel=r'$\theta$', ylabel='density',
            title='beliefs packed into two steep clusters')

axes[1].step(theta_g, q_bi, lw=2, where='mid')
axes[1].set(xlabel=r'$\theta$', ylabel=r'$q^*(\theta)$', ylim=(-1.15, 1.15),
            title='optimal menu: two informative items')
for v, lo, hi, p in items:
    if p > 1e-9:
        axes[1].annotate(f'price {p:.3f}', ((lo + hi) / 2, v + 0.12),
                         ha='center', fontsize=9)
fig.tight_layout()
plt.show()
```

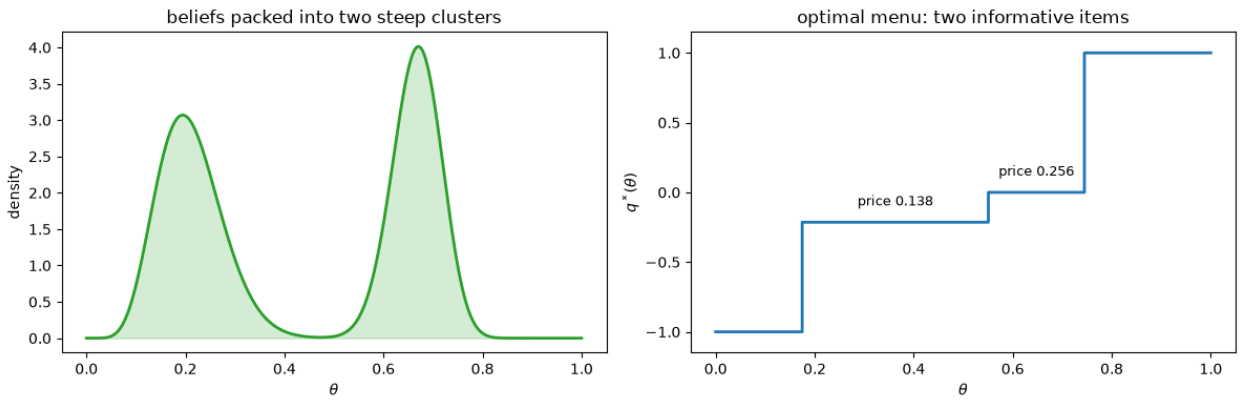

Fig. 37.5: Bimodal type density and the resulting two-item menu

We can see directly why the seller bothers.

Every type values $\overline{E}$ at least as much as any other experiment, so the best single-item menu sells $\overline{E}$ at a posted price p.

With $u_1 = u_2 = 1$, $V(\overline{E}, \theta) = \min\{\theta, 1-\theta\}$, so types $\theta \in [p, 1-p]$ buy and revenue is $p\,[F(1-p) - F(p)]$.

```
def revenue(theta, q, f, u1=1.0, u2=1.0):
    """Expected revenue from the menu q under density f."""
    dth = theta[1] - theta[0]
    price = np.zeros_like(theta)
    for v, lo, hi, p in menu_items(theta, q, u1, u2):
        price[(theta >= lo) & (theta <= hi)] = p
    return np.sum(price * f) * dth / (np.sum(f) * dth)

def F_mix(x):
    """Distribution function of the bimodal mixture."""
    return 0.5 * stats.beta(8, 30).cdf(x) + 0.5 * stats.beta(60, 30).cdf(x)

p_post = np.linspace(0, 0.5, 5001)
rev_post = p_post * (F_mix(1 - p_post) - F_mix(p_post))
k = rev_post.argmax()
rev_two = revenue(theta_g, q_bi, f_bimodal)

print(f'revenue, optimal two-item menu      {rev_two:.4f}')
print(f'revenue, best posted price for E_bar {rev_post[k]:.4f}'
      f'   at p = {p_post[k]:.3f}')
print(f'gain from versioning                {100 * (rev_two / rev_post[k] - 1):.1f}%')
```

```
revenue, optimal two-item menu      0.1675
revenue, best posted price for E_bar 0.1547   at p = 0.223
gain from versioning                8.3%
```

Adding the partial item raises revenue by about 8 percent over the best posted price for full information.

The partial experiment is not a noisier version of the same product; it is a *differently positioned* one, cheap enough for the well-informed types and useless enough to the ill-informed ones that it does not undercut the high price.

37.8 Concluding remarks

Blackwell's theorem tells us when *all* decision makers agree that one experiment beats another.

Read as a design principle, its real content is the size of the set where it is silent.

Bergemann *et al.* [2018] show that a monopolist selling data lives in that set, since screening by belief requires products that different types rank differently.

Two lessons carry beyond the model.

First, optimal degradation of information is structured rather than random: every experiment on the menu has a signal that perfectly reveals one state.

Bergemann *et al.* [2018] conclude that no product on an optimal menu should add unbiased noise to the seller's data, unless buyers compete with each other downstream or the data must be anonymized.

Second, versioning requires virtual values that must be ironed, and steep densities of beliefs produce them.

How well informed the buyers are does not settle the matter: a U-shaped Beta population of well-informed buyers is offered a single item, while steep clusters of beliefs, near the ends of $[0, 1]$ or in its interior, can be offered two.

Selling information to imperfectly informed buyers has a long history.

Admati and Pfleiderer [1986] study a seller facing a continuum of *ex ante identical* traders who then trade a common-value asset, and find that the seller wants to supply noisy and *idiosyncratic* information, so that each trader retains a local monopoly on what he knows.

Their traders compete downstream, so the first lesson does not apply to them.

The heterogeneity there is created by the seller; here it is the buyer's own prior information, and that is what turns the problem into one of screening.

Bergemann and Bonatti [2015] study a single data provider who sets a price per "cookie", a record on an individual consumer, and an advertiser with no private information who chooses which cookies to buy.

A useful contrast is Kamenica and Gentzkow [2011], where a sender also commits to an information structure but has no monetary transfers and cares directly about the receiver's action; here the seller cares only about revenue and cannot condition payments on the state, the signal, or the buyer's action.

Readers who want the statistical background can return to *Blackwell's Theorem on Comparing Experiments* for the equivalence between the economic, sufficiency, and uncertainty-reduction criteria, to *Likelihood Ratio Processes and Bayesian Learning* for how private signals generate the interim beliefs that are the buyer types here, and to *Information and Market Equilibrium* for what happens when information is transmitted by prices rather than sold directly.

Incentives for Information Transfer studies a related screening problem without prices: a planner offers an informed agent a menu of lotteries over her own actions.

37.9 Exercises

Exercise 37.9.1

This exercise studies the **congruent** case, in which both types would take the same action without extra information.

Set $u_1 = u_2 = 1$, $\theta^L = 0.9$ and $\theta^H = 0.7$, so that $\theta^* = 1/2 < \theta^H < \theta^L$.

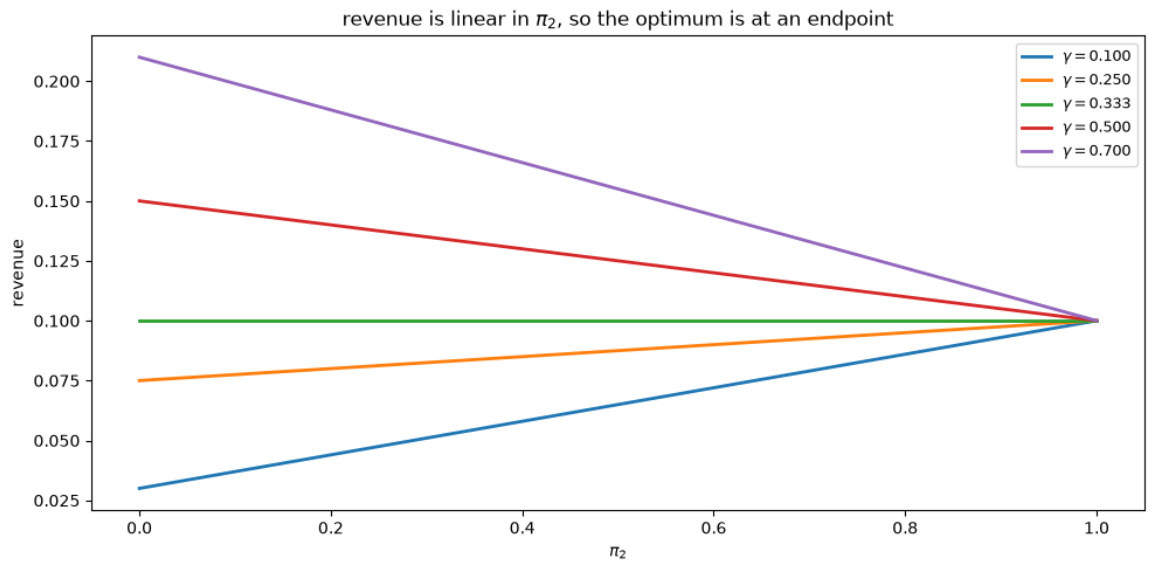
Because both types would choose a_1 on their own, the seller has no reason to degrade what the low type learns about ω_1, so set $\pi_1 = 1$ and treat π_2 as the only choice variable.

1. Plot the seller's revenue against $\pi_2 \in [0, 1]$ for several values of γ, and confirm that it is *linear*.
2. Conclude that the optimum is always at an endpoint, so the low type receives either full information or none.
3. Bergemann *et al.* [2018] show that the low type receives the fully informative experiment if and only if $\gamma \leq (1 - \theta^L)/(1 - \theta^H)$.

   Locate the switch point numerically by bisection and compare.

Why is the answer extremal here, when the noncongruent case in the lecture produced an interior $\pi_1 = 4/5$?

Solution



Here is one solution:

```
tL_c, tH_c = 0.9, 0.7
p2_grid = np.linspace(0, 1, 401)

fig, ax = plt.subplots()
for gamma in [0.1, 0.25, 1/3, 0.5, 0.7]:
    r = np.array([two_type_revenue(1.0, p2, tL_c, tH_c, gamma) for p2 in p2_grid])
```

```
    dev = np.abs(r - np.interp(p2_grid, [0, 1], [r[0], r[-1]])).max()
    ax.plot(p2_grid, r, lw=2, label=rf'$\gamma = {gamma:.3f}$')
    print(f'gamma = {gamma:.3f}:  revenue at pi2=0 is {r[0]:.5f}, '
          f'at pi2=1 is {r[-1]:.5f},  deviation from linear {dev:.1e}')
ax.set(xlabel=r'$\pi_2$', ylabel='revenue',
       title='revenue is linear in $\pi_2$, so the optimum is at an endpoint')
ax.legend(fontsize=9)
fig.tight_layout()
plt.show()
```

for _ in range(60):
    mid = (lo + hi) / 2
    if two_type_revenue(1, 1, tL_c, tH_c, mid) >= two_type_revenue(1, 0, tL_c, tH_
 ↪c, mid):
        lo = mid
    else:
        hi = mid

print(f'numerical switch point            gamma = {lo:.6f}')
print(f'(1 - theta_L) / (1 - theta_H)           = {(1 - tL_c) / (1 - tH_c):.6f}')
```

```
numerical switch point            gamma = 0.333333
(1 - theta_L) / (1 - theta_H)           = 0.333333
```

Revenue is linear in π_2 to machine precision, so the optimum is always at $\pi_2 \in \{0, 1\}$, and the switch occurs exactly at $\gamma = 1/3$ as predicted.

The reason for the extremal answer is that with congruent beliefs both types would choose a_1 anyway, so the only

question is how much the seller reveals about ω_2.

Both types then value the experiment through the same term $(1-\theta)\pi_2 u_2$, which is why the objective and constraints are linear in the single variable π_2 and why the no-haggling logic of Riley and Zeckhauser [1983] applies.

With noncongruent beliefs the two types take different actions on their own, the kink in the value function lies between them, and the seller can position an experiment so that it is worth much to one type and little to the other.

That possibility is what makes an interior distortion optimal.

Exercise 37.9.2

Corollary 1 of Bergemann *et al.* [2018] states that the optimal menu contains a single item whenever both virtual values (37.16) are strictly increasing, and that for uniformly distributed types this holds **irrespective of the payoffs** (u_1, u_2).

1. Verify this by solving the seller's problem with uniform types for several asymmetric payoff pairs, for instance $(u_1, u_2) \in \{(1,1), (2,1), (1,3), (5,1)\}$.
2. For each case report θ^*, the interval of types served, and the price.
3. Confirm that the fully informative experiment is always the item offered, as *Proposition 37.5.1* requires.
4. Use (37.17) and (37.14) to show analytically that the multiplier is $\lambda^* = \theta^*$, that types $\theta \in [\theta^*/2,\ (1+\theta^*)/2]$ are served, and that the price is $u_1 u_2/(2(u_1+u_2))$.

   Print these values next to the ones from the linear program.

Solution

Here is one solution:

```
print(f'{"u1":>3s}{"u2":>3s}{"theta*":>8s}{"q":>6s}{"":3s}'
      f'{"served (LP)":<16s}{"served (theory)":<17s}'

every menu contains exactly one informative item, and it is the fully␣
↪informative one
```

The virtual values for a uniform density are $\phi^-(\theta) = 2\theta$ and $\phi^+(\theta) = 2\theta - 1$ whatever the payoffs, because u_1 and u_2 enter the seller's problem only through $d = u_1 - u_2$ and the bounds on q, not through f or F.

Both are strictly increasing, so no ironing is needed and a single item is optimal.

The payoffs do move θ^* and hence which types are served and at what price, but they never make versioning worthwhile under a uniform density.

For the analytic benchmark, no ironing is needed, so (37.17) gives $q^* = -u_2$ for $\theta < \lambda^*/2$, $q^* = u_1 - u_2$ for $\lambda^*/2 < \theta < (1+\lambda^*)/2$, and $q^* = u_1$ for $\theta > (1+\lambda^*)/2$.

Substituting into (37.14) gives

$$-u_2 \frac{\lambda^*}{2} + (u_1 - u_2)\frac{1}{2} + u_1 \frac{1-\lambda^*}{2} = u_1 - u_2,$$

so $\lambda^*(u_1 + u_2) = u_2$ and $\lambda^* = \theta^*$.

The lowest type served, $\theta^*/2$, is indifferent between $\overline{E}$ and nothing.

For $\theta \le \theta^*$ we have $V(\overline{E}, \theta) = \theta u_1$, so the price is $u_1\theta^*/2 = u_1 u_2/(2(u_1+u_2))$.

The highest type served, $(1+\theta^*)/2$, values $\overline{E}$ at $(1-\theta)u_2 = u_1 u_2/(2(u_1+u_2))$, the same price.

The linear program matches all three objects up to the discretization of the type grid.

Exercise 37.9.3

This exercise connects the lecture back to *Blackwell's Theorem on Comparing Experiments*.

Blackwell's theorem says that if E' is a garbling of E then *every* decision maker weakly prefers E.

1. Draw many random pairs of binary experiments with $\pi_1 + \pi_2 \ge 1$.
2. For each pair, use `garbling` to decide whether one is a garbling of the other, and separately compute whether one dominates the other in value at every type.

   Because $V(E, \theta)$ is piecewise linear in θ, it suffices to compare the two values at $\theta \in \{0, 1\}$ and at the types where either value function has a kink.
3. Confirm that garbling implies unanimous preference, and report what fraction of random pairs Blackwell's order fails to rank.
4. Among the unranked pairs, verify that some types prefer one experiment and some the other.
5. Explain why, for two-state experiments, the pairs that Blackwell's order leaves unranked should be exactly the

pairs on which types disagree.

What goes wrong if dominance is checked only on a finite grid of types?

Solution

Here is one solution:

```
def kinks(pi1, pi2, u1=1.0, u2=1.0):
    """Endpoints and types at which V(E, theta) can change slope."""
    k = [0.0, 1.0, u2 / (u1 + u2)]
    for a, b in [(pi1 * u1, (1 - pi2) * u2), ((1 - pi1) * u1, pi2 * u2)]:
        if a + b > 0:
            k.append(b / (a + b))        # indifference after one of the signals
    return np.array(k)

rng = np.random.default_rng(0)
grid_t = np.linspace(0.001, 0.999, 999)

n_pairs, n_garble, n_unranked, violations = 4000, 0, 0, 0
n_disagree, n_disagree_grid, n_unanimous_unranked = 0, 0, 0
for _ in range(n_pairs):
    (a1, a2), (b1, b2) = rng.uniform(0, 1, 2), rng.uniform(0, 1, 2)
    if a1 + a2 < 1 or b1 + b2 < 1:
        continue
    Ea, Eb = experiment(a1, a2), experiment(b1, b2)
    t = np.concatenate([kinks(a1, a2), kinks(b1, b2)])
    va, vb = value(a1, a2, t), value(b1, b2, t)
    va_g, vb_g = value(a1, a2, grid_t), value(b1, b2, grid_t)

pairs unranked by Blackwell           318
  of which types disagree (kinks)     318
  of which types disagree (grid)      317
```

Blackwell's theorem is never violated: whenever one experiment garbles into the other, every type prefers the garbling source.

The converse also holds in every draw: whenever all types rank two experiments the same way, one is a garbling of the other.

A large share of random pairs is left unranked, and for every one of them some types prefer one experiment and some the other.

That unranked region is exactly the room the data seller needs.

If Blackwell's order were complete, every buyer would agree on the ranking of all information products, the seller's problem would collapse to standard nonlinear pricing over a single quality index, and the horizontal screening described in this lecture would be impossible.

The match between garbling and unanimous preference is exact for two-state experiments.

Fix a reference prior $c \in (0,1)$ and let x denote the posterior probability of ω_1 that a signal induces under c.

The gross value of E to type θ with $u_1 = u_2 = 1$ equals the expectation, under c, of the convex function $k_\theta(x) = \max\{\theta x/c,\ (1-\theta)(1-x)/(1-c)\}$, which has a single kink.

As θ ranges over $(0,1)$, the kink ranges over $(0,1)$.

Every convex function on $[0,1]$ is an affine function plus a nonnegative mixture of such one-kink functions, and the affine part has the same expectation under every experiment.

By *Theorem 30.5.1*, E' is a garbling of E if and only if $V(E,\theta) \geq V(E',\theta)$ for every θ.

A check on a finite grid of types can miss a disagreement confined to a short interval between grid points.

The grid of 999 types does so once in the draws above.

Evaluating at kinks is exact, because the difference of two piecewise-linear functions attains its maximum and minimum at kinks or endpoints.

Exercise 37.9.4

This exercise characterizes the type densities for which the virtual values (37.16) need no ironing.

1. Use (37.18) to show that on $(0,1)$, ϕ^- is strictly increasing if and only if $\theta^2 f(\theta)$ is strictly increasing, and ϕ^+ is strictly increasing if and only if $(1-\theta)^2 f(\theta)$ is strictly decreasing.
2. Deduce that for a Beta(a,b) density both virtual values are strictly increasing if and only if $a \leq 1$ and $b \leq 1$.
3. Confirm the condition numerically on a grid of (a,b) pairs.
4. Use `solve_menu` to show that the U-shaped densities Beta$(0.5,0.5)$, Beta$(0.3,0.3)$ and Beta$(0.5,0.8)$ are offered a single item, that the irregular Beta$(30,30)$ is also offered a single item, and that the irregular Beta$(60,30)$ is offered two informative items.

5. Show that an equal mixture of Beta$(2, 60)$ and Beta$(40, 4)$, a population in which most buyers are well informed, is irregular and is offered two informative items.

Solution

Here is one solution.

For $\theta \in (0, 1)$,

$$\frac{d}{d\theta}[\theta^2 f(\theta)] = \theta[2f(\theta) + \theta f'(\theta)] = \theta\,\phi^{-\prime}(\theta), \qquad \frac{d}{d\theta}[(1-\theta)^2 f(\theta)] = -(1-\theta)\,\phi^{+\prime}(\theta).$$

So $\phi^{-\prime}$ has the sign of the derivative of $\theta^2 f$, and $\phi^{+\prime}$ has the sign opposite to the derivative of $(1-\theta)^2 f$.

For $f(\theta) \propto \theta^{a-1}(1-\theta)^{b-1}$,

$$\frac{d}{d\theta}\log[\theta^2 f(\theta)] = \frac{a+1}{\theta} - \frac{b-1}{1-\theta}, \qquad \frac{d}{d\theta}\log[(1-\theta)^2 f(\theta)] = \frac{a-1}{\theta} - \frac{b+1}{1-\theta}.$$

The first expression is positive on all of $(0, 1)$ if and only if $b \leq 1$, since for $b > 1$ it diverges to $-\infty$ as $\theta \to 1$.

The second is negative on all of $(0, 1)$ if and only if $a \leq 1$, since for $a > 1$ it diverges to $+\infty$ as $\theta \to 0$.

```
th_in = theta_g[1:-1]                    # Beta densities can be infinite at 0 and 1

```

The numerical check agrees with the condition $a \leq 1, b \leq 1$ at every pair.

The three U-shaped densities are regular and are offered only $\overline{E}$.

Beta$(30, 30)$ is irregular but symmetric about $\theta^* = 1/2$, and it is also offered only $\overline{E}$.

The steep, asymmetric Beta$(60, 30)$ is offered a partial item with $q < 0$ as well as $\overline{E}$.

The mixture of Beta$(2, 60)$ and Beta$(40, 4)$ puts more of its mass within 0.15 of 0 or 1 than any of the U-shaped densities.

Its two clusters are steep, it is irregular, and it is offered two informative items.

Both kinds of population consist mostly of well-informed buyers; the steepness of the density separates them.

Exercise 37.9.5

This exercise irons the virtual values of the bimodal example by hand and checks the menu that the linear program found.

Set $u_1 = u_2 = 1$, so that $d = 0$, and use the density `f_bimodal`.

1. Compute $\Phi^{\pm}(\theta) = \int_0^\theta \phi^{\pm}(x)\,dx$ on the grid, their greatest convex minorants, and the ironed virtual values $\bar{\phi}^{\pm}$ as the slopes of the minorants.
2. By (37.17), types with $\bar{\phi}^- < \lambda^*$ get $q = -1$, types with $\bar{\phi}^+ < \lambda^* < \bar{\phi}^-$ get $q = 0$, types with $\bar{\phi}^+ > \lambda^*$ get $q = 1$, and types on an interval where $\bar{\phi}^- = \lambda^*$ share a common $q_m \in [-1, 0]$.

   Find λ^* and q_m from the integral constraint (37.14).
3. Compare λ^*, q_m, the interval of types who buy the partial item, and the cutoff above which types buy nothing

with the solution of the linear program.

4. Plot $\phi^{\pm}$, $\bar{\phi}^{\pm}$ and λ^*.

Solution

Here is one solution.

```
def ironed(theta, phi):
    """Slopes of the greatest convex minorant of the integral of phi."""

```

The multiplier is the level at which the integral of q jumps across zero.

Just below λ^* the pooled types get $q = 0$ and the integral is positive; just above λ^* they get $q = -1$ and the integral is negative.

On the pooled interval $[\theta_a, \theta_b]$ the integral constraint reads $-\theta_a + q_m(\theta_b - \theta_a) + (1 - \theta_c) = 0$, which gives $q_m = (\theta_a - (1 - \theta_c))/(\theta_b - \theta_a)$.

The pooled interval is the interval on which ironing flattens ϕ^- at the level λ^*.

Its upper end, $\theta \approx 0.55$, is the type indifferent between the partial item and $\overline{E}$.

The hand calculation and the linear program agree up to the grid spacing.

38.1 Overview

In *The Design and Price of Information* a monopolist *owned* information and sold it.

This lecture studies a market in which nobody sells information and everybody produces it.

We follow Bergemann and Välimäki [1997], who study a duopoly in which an established firm competes on price with a firm selling a new product of unknown quality.

Buyers learn what the new product is worth only by using it, and the aggregate record of their experience is public.

So every purchase of the new product is simultaneously a consumption decision and an experiment, and its informational value spills over to everyone.

Both sides of the market learn from the same public record, which is what "two-sided learning" means here: buyers and sellers hold identical beliefs at every date, and no asymmetric information ever arises.

Three results organize the lecture.

First, both firms *want* more information, but only the new firm's sales produce it.

That asymmetry softens price competition: the established firm prices less aggressively than it would in a one-shot game, and the entrant captures a larger market share early on.

Second, equilibrium experimentation is **excessive** when beliefs are pessimistic and **insufficient** when they are optimistic, with a single crossing in between.

Third, the noise-free diffusion path of a successful new product is **S-shaped**, matching a long empirical tradition, and its inflection occurs at a belief we can pin down exactly.

Note

The connection to the rest of this section runs through the *value of information*.

Blackwell's Theorem on Comparing Experiments shows that a more informative experiment spreads the posterior in the convex order.

A single decision maker's value is a maximum of functions that are linear in the belief, so it is convex, and every decision maker weakly gains from a more informative experiment.

A player's equilibrium value in a game need not be convex, because the other players' strategies also move with the belief.

Here beliefs are a martingale and experimentation controls how fast they spread, so each firm's gain from experimentation is governed by the convexity of its equilibrium value function.

Both equilibrium value functions are convex.

The belief itself is driven by a log-likelihood-ratio process of the kind studied in *Likelihood Ratio Processes*, now run in continuous time.

Let's start with imports.

```
import matplotlib.pyplot as plt
import numpy as np

plt.rcParams['figure.figsize'] = (10, 5)
np.set_printoptions(precision=4, suppress=True)
```

38.2 The market

Buyers are distributed uniformly on $[0, 1]$ and each demands one unit per instant.

The established product delivers value

$$s_n = s + nh \tag{38.1}$$

to buyer n, and the new product delivers

$$\mu_n = \mu + (1 - n)h. \tag{38.2}$$

The parameter $h > 0$ measures horizontal differentiation, so buyers near $n = 0$ are naturally drawn to the new product and buyers near $n = 1$ to the established one.

This is the standard Hotelling structure, with one twist: the vertical quality μ of the new product is **unknown** and can take one of two values,

$$\mu \in \{\mu_L, \mu_H\}, \qquad 0 < s - h < \mu_L < s < \mu_H < s + h. \tag{38.3}$$

The inner inequalities say the new product may be better or worse than the established one.

The outer inequalities say that under full information both firms would retain a positive share of the market, so the innovation is not drastic.

Marginal cost is zero for both firms.

If the new firm serves the buyers in $[0, n]$, the average flow value delivered by each product is

$$\bar{\mu}(n) = \mu + \frac{(2-n)h}{2}, \qquad \bar{s}(n) = s + \frac{(1+n)h}{2}, \tag{38.4}$$

so total surplus per unit of time is $n\bar{\mu}(n) + (1-n)\bar{s}(n)$.

Writing $\mu(\alpha)$ for the expected quality under belief $\alpha = \Pr[\mu = \mu_H]$, a little algebra puts the flow surplus in a convenient quadratic form,

$$F(n, \alpha) = s + \frac{h}{2} + n(\mu(\alpha) - s + h) - n^2 h. \tag{38.5}$$

```
class Market:
    """The duopoly of Bergemann and Valimaki (1997)."""

    def __init__(self, s=4.0, h=1.0, mu_L=3.1, mu_H=4.9, sigma=1.0):
        self.s, self.h = s, h
        self.mu_L, self.mu_H, self.sigma = mu_L, mu_H, sigma
        assert 0 < s - h < mu_L < s < mu_H < s + h, 'condition (4) fails'

    def mu(self, a):
        """Expected quality of the new product under belief a."""
        return (1 - a) * self.mu_L + a * self.mu_H

    def flow_surplus(self, n, a):
        return (self.s + self.h / 2 + n * (self.mu(a) - self.s + self.h)
                - n ** 2 * self.h)
```

38.3 Two-sided learning

A buyer's individual experience is a noisy draw on μ, and since each buyer has measure zero, only the *aggregate* record matters.

When a fraction n of buyers uses the new product, the cumulative market outcome X evolves as

$$dX = n\mu\, dt + \sigma\sqrt{n}\, dB, \tag{38.6}$$

so both the drift and the variance scale with the size of the experiment n.

Everyone observes X, so beliefs stay common.

Since μ takes only two values, the belief $\alpha_t = \Pr[\mu = \mu_H \mid \mathcal{F}_t]$ is a sufficient statistic.

Proposition 38.3.1 (Posterior belief)

The belief α_t is a martingale with zero drift and instantaneous variance

$$n\Sigma^2(\alpha) = n\left[\frac{\alpha(1-\alpha)(\mu_H - \mu_L)}{\sigma}\right]^2. \tag{38.7}$$

This is the standard filtering result for a two-point prior observed through a diffusion; see Liptser and Shiryaev [1977].

Likelihood Ratio Processes and Bayesian Learning and *A Bayesian Formulation of Friedman and Wald's Problem* study the same two-point learning problem in discrete time.

Two features of (38.7) drive everything.

The variance is **linear in** n, so information arrives in proportion to the size of the experiment, and only the new firm's sales generate it.

The variance is proportional to $\alpha^2(1-\alpha)^2$, so learning is fastest when beliefs are most diffuse and grinds to a halt as α approaches 0 or 1.

38.3.1 Learning as a likelihood ratio process

It is worth seeing where (38.7) comes from, because the mechanism is the one studied in *Likelihood Ratio Processes*, transplanted to continuous time.

Over a short interval of length Δ the increment ΔX is normal with mean $n\mu\Delta$ and variance $\sigma^2 n\Delta$ under either hypothesis, so the increment to the **log likelihood ratio** is

$$\Delta\ell = \log\frac{f_H(\Delta X)}{f_L(\Delta X)} = \frac{(\mu_H-\mu_L)\,\Delta X - \frac{1}{2}n\Delta(\mu_H^2-\mu_L^2)}{\sigma^2}. \tag{38.8}$$

Beliefs then follow from Bayes' rule in its log-odds form, exactly as in *Likelihood Ratio Processes and Bayesian Learning*,

$$\log\frac{\alpha_{t+\Delta}}{1-\alpha_{t+\Delta}} = \log\frac{\alpha_t}{1-\alpha_t} + \Delta\ell. \tag{38.9}$$

We implement (38.8) and (38.9) directly, which gives an *exact* Bayesian update at each step rather than a discretization of a stochastic differential equation.

```
def simulate_beliefs(mkt, alpha0, T, dt, mu_true, rng, policy):
    """Simulate beliefs by exact Bayesian updating of the log odds.

    `mu_true` holds the true quality for each path, so the paths run in parallel.
    Returns an array of shape (number of paths, number of steps + 1).
    """
    mu_true = np.atleast_1d(np.asarray(mu_true, dtype=float))
    M, steps = len(mu_true), int(T / dt)
    a = np.empty((M, steps + 1))
    a[:, 0] = alpha0
    ell = np.full(M, np.log(alpha0 / (1 - alpha0)))
    dmu, half = mkt.mu_H - mkt.mu_L, (mkt.mu_H ** 2 - mkt.mu_L ** 2) / 2
    for k in range(steps):
        n = policy(a[:, k])
        dX = n * mu_true * dt + mkt.sigma * np.sqrt(n * dt) * rng.standard_normal(M)
        ell += (dmu * dX - n * dt * half) / mkt.sigma ** 2
        a[:, k + 1] = 1 / (1 + np.exp(-ell))
    return a
```

Before using it, we check *Proposition 38.3.1* by Monte Carlo.

```
def Sigma2(mkt, a):
    return (a * (1 - a) * (mkt.mu_H - mkt.mu_L) / mkt.sigma) ** 2

mkt = Market()
```

(continues on next page)

(continued from previous page)

```
rng = np.random.default_rng(0)
dt, n_draw = 1e-4, 400_000

print(f'{"alpha":>7s}{"simulated var/dt":>19s}{"formula n*Sigma^2":>20s}'
      f'{"mean/dt (s.e.)":>22s}')
for a0 in [0.2, 0.5, 0.8]:

    print(f'{a0:7.2f}{d.var() / dt:19.6f}{n * Sigma2(mkt, a0):20.6f}'
          f'{d.mean() / dt:14.4f} ({se:.3f})')
```

```
  alpha   simulated var/dt   formula n*Sigma^2        mean/dt (s.e.)
   0.20           0.041586            0.041472        0.0034 (0.032)
   0.50           0.101145            0.101250        0.0606 (0.050)
   0.80           0.041428            0.041472        0.0096 (0.032)
```

The simulated variance matches (38.7), and the mean increment is indistinguishable from zero, confirming that beliefs form a martingale.

38.4 Efficient experimentation

A planner choosing $n(\alpha)$ trades current surplus against the information that sales generate.

Bergemann and Välimäki [1997] avoid the nonlinear differential equations that discounting would produce by working with the **undiscounted** limit, using the strong long-run average criterion of Dutta [1991].

The optimal policies in this limit are the limits of the discounted policies as the discount rate goes to zero, so the intertemporal tradeoff survives.

The Bellman equation becomes

$$\max_{n} \left\{ F(n,\alpha) - v(\alpha) + \tfrac{1}{2} n \Sigma^2(\alpha) V''(\alpha) \right\} = 0, \tag{38.10}$$

where $v(\alpha)$ is the long-run average attainable under full information and the last term is the **value of information**: the size of the experiment n times the speed of learning Σ^2 times the shadow price V''.

Because the belief is a martingale, no first-derivative term appears.

Every policy we consider keeps n bounded away from zero, so information accumulates without bound.

The prior puts positive probability on each of the two possible values of μ, so the truth is absolutely continuous with respect to the prior predictive distribution, and the posterior converges to the truth almost surely; see the discussion of Bayesian learning with a finite parameter space in *Merging of Opinions: The Blackwell–Dubins Theorem*.

Since μ is eventually learned, v is just the linear interpolation of the two full-information values,

$$v(\alpha) = \frac{s + \mu(\alpha) + \frac{3}{2}h}{2} + (1-\alpha)\frac{(\mu_L - s)^2}{4h} + \alpha\frac{(\mu_H - s)^2}{4h}. \tag{38.11}$$

The clever step is that the maximized bracket in (38.10) equals zero, so we may divide through by n without changing the maximizer.

Doing so removes V'' from the first-order condition entirely and leaves

$$\max_n \left\{ \frac{s + \frac{h}{2} - v(\alpha)}{n} - hn \right\} + \text{terms free of } n,$$

whose first-order condition gives the efficient policy in closed form.

Proposition 38.4.1 (Efficient experimentation)

The efficient market share of the new product is

$$n^*(\alpha) = \sqrt{\frac{v(\alpha) - s - \frac{h}{2}}{h}}. \tag{38.12}$$

The myopic planner, who ignores the informational value of sales, instead sets $m^*(\alpha) = \arg\max_n F(n, \alpha)$.

```
def v_social(mkt, a):
    s, h = mkt.s, mkt.h
    return ((s + mkt.mu(a) + 1.5 * h) / 2
            + (1 - a) * (mkt.mu_L - s) ** 2 / (4 * h)
            + a * (mkt.mu_H - s) ** 2 / (4 * h))

def n_star(mkt, a):
    """Efficient share, equation (nstar)."""
    return np.sqrt((v_social(mkt, a) - mkt.s - mkt.h / 2) / mkt.h)

def m_star(mkt, a):
    """Myopically efficient share."""
    return (mkt.mu(a) - mkt.s + mkt.h) / (2 * mkt.h)
```

At $\alpha \in \{0, 1\}$ there is nothing left to learn, so the two must agree, and they do.

```
for a, mu_i in [(0.0, mkt.mu_L), (1.0, mkt.mu_H)]:
    direct = (mu_i - mkt.s + mkt.h) / (2 * mkt.h)
    print(f'alpha = {a}:  n* = {n_star(mkt, a):.6f}   '
          f'full-information share = {direct:.6f}')

A = np.linspace(1e-6, 1 - 1e-6, 4001)          # full grid, for plotting
A_int = np.linspace(0.05, 0.95, 1801)          # strictly interior grid
```

```
alpha = 0.0:  n* = 0.050000   full-information share = 0.050000
alpha = 1.0:  n* = 0.950000   full-information share = 0.950000
```

The planner always experiments **more** than the myopic benchmark.

Let $m_i = (\mu_i - s + h)/(2h)$ be the efficient full-information share when $\mu = \mu_i$, and let E_α average over $i \in \{L, H\}$ with weights $1 - \alpha$ and α.

Substituting m_i into (38.11) gives $v(\alpha) - s - \frac{h}{2} = hE_\alpha[m_i^2]$, so

$$n^*(\alpha) = \sqrt{E_\alpha[m_i^2]} \geq E_\alpha[m_i] = m^*(\alpha)$$

by Jensen's inequality, with strict inequality for $\alpha \in (0,1)$ because $m_L \neq m_H$.

The gap is the intertemporal value of information showing up as extra sales of the new product.

```
def E_alpha(f_L, f_H, a):
    """Average of full-information quantities under belief a."""
    return (1 - a) * f_L + a * f_H

m_L, m_H = [(mu_i - mkt.s + mkt.h) / (2 * mkt.h) for mu_i in (mkt.mu_L, mkt.mu_H)]
print(f'max |n*(alpha)^2 - E[m_i^2]|  '
      f'{np.abs(n_star(mkt, A) ** 2 - E_alpha(m_L ** 2, m_H ** 2, A)).max():.1e}')
print(f'max |m*(alpha) - E[m_i]|      '
      f'{np.abs(m_star(mkt, A) - E_alpha(m_L, m_H, A)).max():.1e}')
print(f'n*(0.5) - m*(0.5) = {float(n_star(mkt, 0.5) - m_star(mkt, 0.5)):.5f}')
```

```
max |n*(alpha)^2 - E[m_i^2]|  1.4e-15
max |m*(alpha) - E[m_i]|      4.4e-16
n*(0.5) - m*(0.5) = 0.17268
```

38.5 Equilibrium

Now let the two firms set prices p_1 and p_2 and let buyers choose.

The marginal buyer n is indifferent when $s + nh - p_1 = \mu(\alpha) + (1-n)h - p_2$, which pins the market share to prices.

Each firm solves a dynamic program in which its own value of information appears, and the same divide-by-n trick removes the second derivatives from the first-order conditions.

Proposition 38.5.1 (Equilibrium)

There is a unique Markov-perfect equilibrium, with

$$p_1(\alpha) = \tfrac{2}{3}(s - \mu(\alpha)) + \sqrt{2h v_2(\alpha)}, \qquad p_2(\alpha) = \tfrac{1}{3}(\mu(\alpha) - s) + h, \tag{38.13}$$

and market share of the new firm

$$n(\alpha) = \sqrt{\frac{v_2(\alpha)}{2h}}, \tag{38.14}$$

where $v_i(\alpha)$ is firm i's full-information long-run average revenue.

```
def v1(mkt, a):
    s, h = mkt.s, mkt.h
    return ((1 - a) * ((s - mkt.mu_L) / 3 + h) ** 2 / (2 * h)
            + a * ((s - mkt.mu_H) / 3 + h) ** 2 / (2 * h))

def v2(mkt, a):
    s, h = mkt.s, mkt.h
    return ((1 - a) * ((mkt.mu_L - s) / 3 + h) ** 2 / (2 * h)
            + a * ((mkt.mu_H - s) / 3 + h) ** 2 / (2 * h))
```

(continues on next page)

(continued from previous page)

```
def n_eq(mkt, a):
    return np.sqrt(v2(mkt, a) / (2 * mkt.h))

def p1(mkt, a):
    return 2 / 3 * (mkt.s - mkt.mu(a)) + np.sqrt(2 * mkt.h * v2(mkt, a))

def p2(mkt, a):
    return (mkt.mu(a) - mkt.s) / 3 + mkt.h

def p1_myopic(mkt, a):
    return (mkt.s - mkt.mu(a)) / 3 + mkt.h

def n_myopic(mkt, a):
    return ((mkt.mu(a) - mkt.s) / 3 + mkt.h) / (2 * mkt.h)
```

Comparing the dynamic equilibrium with the static one played period by period reveals the asymmetry at the heart of the paper.

In the static game at belief α, the share of the new firm is $(\mu(\alpha) - s + h + p_1 - p_2)/(2h)$, and the first-order conditions of the two revenue-maximizing firms form a linear system in (p_1, p_2).

We solve that system directly and compare its solution with the dynamic equilibrium.

```
def static_equilibrium(mkt, a):
    """Prices and share in the one-shot Hotelling game at belief a."""
    d = mkt.mu(a) - mkt.s

```

The new firm's price is *exactly* its myopic price, a knife-edge consequence of the linear preference structure and the

absence of discounting.

The established firm charges *more* than it would in a one-shot game, and so concedes market share.

That is the striking result: the incumbent softens competition, not out of weakness, but because the entrant's sales are the only source of information and the incumbent wants the information.

38.5.1 Who values information more?

The Bellman equations imply that each firm's value of information equals the gap between its expected full-information revenue and its current revenue.

```
voi_1 = v1(mkt, A) - (1 - n_eq(mkt, A)) * p1(mkt, A)
voi_2 = v2(mkt, A) - n_eq(mkt, A) * p2(mkt, A)

print(f'established firm, minimum value of information  {voi_1.min():.3e}')
print(f'new firm, minimum value of information          {voi_2.min():.3e}')
print(f'ratio voi_1 / voi_2:  min {np.min(voi_1 / voi_2):.6f}, '
      f'max {np.max(voi_1 / voi_2):.6f}')
```

```
established firm, minimum value of information  1.800e-07
new firm, minimum value of information          9.000e-08
ratio voi_1 / voi_2:  min 2.000000, max 2.000000
```

Both are positive, so both value functions are convex in the belief.

That is the *Blackwell's Theorem on Comparing Experiments* logic at work: beliefs are a martingale, more experimentation spreads them further, and a firm with a convex value function gains from the spread.

More surprisingly, the ratio is exactly 2 at every belief: the **established** firm values information twice as much as the entrant.

Let n_i be the full-information equilibrium share when $\mu = \mu_i$ and let $\bar{n}(\alpha) = E_\alpha[n_i]$, which equals the static equilibrium share `n_myopic`.

Full-information prices are $p_{1,i} = 2h(1-n_i)$ and $p_{2,i} = 2hn_i$, so $v_2 = 2hE_\alpha[n_i^2] = 2hn^2$ and $v_1 = 2hE_\alpha[(1-n_i)^2] = 2h(1-2\bar{n}+n^2)$.

The entrant charges its static price $p_2 = 2h\bar{n}$, while the incumbent charges $p_1 = 2h(1-\bar{n}) + 2h(n-\bar{n})$, above its static price by $2h(n-\bar{n})$.

Substituting,

$$v_2 - np_2 = 2h\,n(n-\bar{n}), \qquad v_1 - (1-n)p_1 = 4h\,n(n-\bar{n}).$$

Jensen's inequality, $n = \sqrt{E_\alpha[n_i^2]} > E_\alpha[n_i] = \bar{n}$ for $\alpha \in (0,1)$, makes both gaps positive.

```
n_bar = n_myopic(mkt, A)
print(f'max |voi_2 - 2h n (n - n_bar)|  '
      f'{np.abs(voi_2 - 2 * mkt.h * n_eq(mkt, A) * (n_eq(mkt, A) - n_bar)).max():.1e}
↪')
print(f'max |voi_1 - 4h n (n - n_bar)|  '
      f'{np.abs(voi_1 - 4 * mkt.h * n_eq(mkt, A) * (n_eq(mkt, A) - n_bar)).max():.1e}
↪')
```

```
max |voi_2 - 2h n (n - n_bar)|  2.0e-16
max |voi_1 - 4h n (n - n_bar)|  8.6e-16
```

38.6 Too much experimentation, then too little

We can now compare the equilibrium share with the efficient one.

```
gap = n_star(mkt, A) - n_eq(mkt, A)
cross = A[np.argmin(np.abs(gap))]

fig, axes = plt.subplots(1, 2, figsize=(12, 4.2))
axes[0].plot(A, n_star(mkt, A), lw=2, label=r'efficient $n^*(\alpha)$')
axes[0].plot(A, n_eq(mkt, A), lw=2, label=r'equilibrium $n(\alpha)$')
axes[0].plot(A, m_star(mkt, A), lw=1.5, ls='--', color='0.5',
             label=r'myopic planner $m^*(\alpha)$')
axes[0].set(xlabel=r'$\alpha$', ylabel='market share of the new firm',
            title='experimentation policies')
axes[0].legend(fontsize=9)

axes[1].plot(A, gap, lw=2, color='C3')
axes[1].axhline(0, color='0.3', lw=1)
axes[1].axvline(cross, color='0.6', ls=':', lw=1.5)
axes[1].fill_between(A, gap, 0, where=gap < 0, alpha=0.15, color='C3')
axes[1].fill_between(A, gap, 0, where=gap > 0, alpha=0.15, color='C0')
axes[1].annotate('equilibrium\nexperiments too much', (0.05, gap.min() / 2),
                 fontsize=9)
axes[1].annotate('too little', (0.75, gap.max() / 2), fontsize=9)
axes[1].set(xlabel=r'$\alpha$', ylabel=r'$n^*(\alpha) - n(\alpha)$',
            title=f'single crossing at ' + rf'$\alpha = {cross:.3f}$')
fig.tight_layout()
plt.show()

n_L, n_H = n_eq(mkt, 0.0), n_eq(mkt, 1.0)
print(f'n*^2 - n^2 at alpha = 0:  m_L^2 - n_L^2 = {m_L ** 2 - n_L ** 2:+.4f}')
print(f'n*^2 - n^2 at alpha = 1:  m_H^2 - n_H^2 = {m_H ** 2 - n_H ** 2:+.4f}')
```

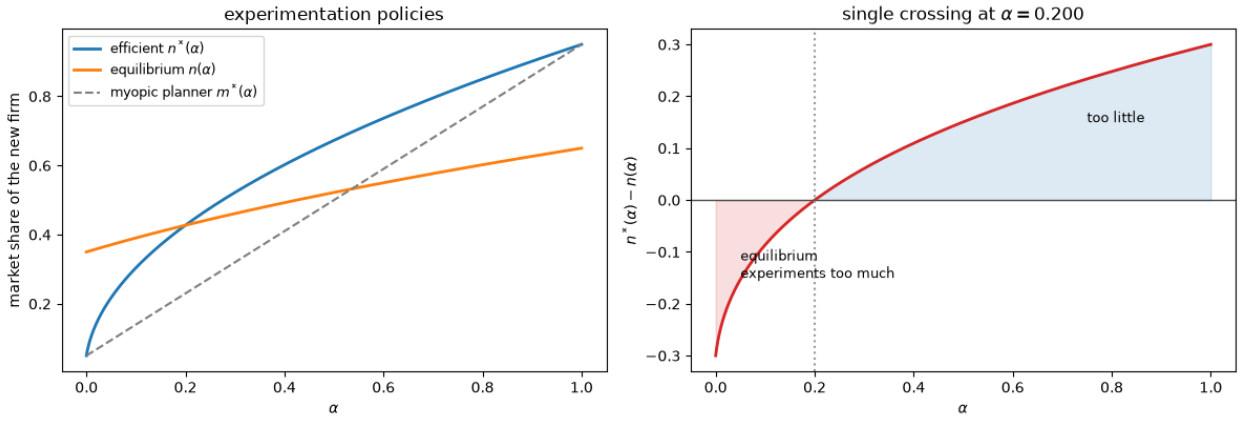

Fig. 38.1: Equilibrium versus efficient experimentation

```
n*^2 - n^2 at alpha = 0:  m_L^2 - n_L^2 = -0.1200
n*^2 - n^2 at alpha = 1:  m_H^2 - n_H^2 = +0.4800
```

The single crossing follows from the affine structure already used.

Both $n^*(\alpha)^2 = E_\alpha[m_i^2]$ and $n(\alpha)^2 = E_\alpha[n_i^2]$ are affine in α, so $n^*(\alpha)^2 - n(\alpha)^2$ is affine and changes sign at most once.

The gap $n^* - n$ has the same sign.

Condition (38.3) makes $m_L < n_L$ and $m_H > n_H$, so the gap is negative at $\alpha = 0$, positive at $\alpha = 1$, and crosses zero exactly once.

The intuition is about who has to cut price to gain a buyer.

At pessimistic beliefs the entrant is small, so attracting one more buyer costs it little in inframarginal revenue, while the incumbent is large and unwilling to defend its share by cutting price on everyone.

The entrant therefore expands aggressively and the market over-experiments.

At optimistic beliefs the positions are reversed, the incumbent fights harder, and experimentation falls short of the efficient level.

38.7 Diffusion over time

So far everything is a function of the state α.

To follow a product over calendar time we need the law of motion of the belief when the product really is good.

Conditional on $\mu = \mu_H$, the belief acquires an upward drift, since the data are generated by μ_H while the market still puts weight $1 - \alpha$ on μ_L,

$$d\alpha = \frac{n(\alpha)(\mu_H - \mu_L)^2 \alpha(1-\alpha)^2}{\sigma^2}\, dt + \frac{(\mu_H - \mu_L)\alpha(1-\alpha)\sqrt{n(\alpha)}}{\sigma}\, dB. \tag{38.15}$$

Equivalently, the log odds $\log(\alpha/(1-\alpha))$ drift up at rate $n(\alpha)(\mu_H - \mu_L)^2/(2\sigma^2)$.

The factor $(\mu_H - \mu_L)^2/(2\sigma^2)$ is the Kullback–Leibler divergence per unit of time between the signal distributions under μ_H and under μ_L (see *Kullback–Leibler divergence*), and $n(\alpha)$ scales it by the size of the experiment; Exercise 38.10.5 derives this drift and uses it to bound the expected time needed to learn.

Following Bergemann and Välimäki [1997], we drop the noise term.

The belief path $\hat{\alpha}(t)$ then solves the ordinary differential equation

$$\frac{d\hat{\alpha}}{dt} = \frac{n(\hat{\alpha})(\mu_H - \mu_L)^2 \hat{\alpha}(1-\hat{\alpha})^2}{\sigma^2}, \qquad \hat{\alpha}(0) = \alpha_0, \tag{38.16}$$

and $\hat{n}(t) = n(\hat{\alpha}(t))$ is the corresponding market share.

Bergemann and Välimäki [1997] call $\hat{\alpha}$ the mean posterior.

Because the drift in (38.15) is nonlinear in α, $\hat{\alpha}(t)$ is not the conditional mean $E[\alpha_t \mid \mu = \mu_H]$, and $\hat{n}(t)$ is not $E[n(\alpha_t) \mid \mu = \mu_H]$.

We call $\hat{\alpha}$ and $\hat{n}$ the noise-free paths.

```
def noise_free_belief_path(mkt, alpha0, T, dt, policy):
    """Euler solution of the noise-free belief equation when mu = mu_H."""
    steps = int(T / dt)
    a = np.empty(steps + 1)
    a[0] = alpha0
    dmu2 = (mkt.mu_H - mkt.mu_L) ** 2 / mkt.sigma ** 2
    for k in range(steps):
        drift = policy(a[k]) * dmu2 * a[k] * (1 - a[k]) ** 2
        a[k + 1] = min(max(a[k] + drift * dt, 1e-12), 1 - 1e-12)
    return a
```

Proposition 38.7.1 (S-shaped diffusion)

Let $\hat{\alpha}(t)$ solve (38.16) with $\alpha_0 \in (0,1)$ and let $\hat{n}(t) = n(\hat{\alpha}(t))$.

The noise-free market share $\hat{n}(t)$ is increasing over time.

Its rate of increase is itself increasing while $\hat{\alpha}(t) < 1/3$ and decreasing thereafter.

The proof uses the affine structure again.

Because $n(\alpha)^2 = n_L^2 + (n_H^2 - n_L^2)\alpha$, the product $n(\alpha)n'(\alpha)$ equals the constant $(n_H^2 - n_L^2)/2$, and

$$\frac{d\hat{n}}{dt} = n'(\hat{\alpha})\frac{d\hat{\alpha}}{dt} = \frac{(n_H^2 - n_L^2)(\mu_H - \mu_L)^2}{2\sigma^2}\,\hat{\alpha}(1-\hat{\alpha})^2.$$

Since $\hat{\alpha}$ increases with t and $\alpha(1-\alpha)^2$ increases in α exactly when $\alpha < 1/3$, the rate $d\hat{n}/dt$ rises until $\hat{\alpha} = 1/3$ and falls thereafter.

The composition of two forces produces the S.

Learning accelerates as beliefs move away from zero, which speeds up the growth of the entrant's share; but the equilibrium share $n(\alpha)$ is concave, so further belief improvements translate into ever smaller share gains.

The S-shape and the inflection at $\hat{\alpha} = 1/3$ are properties of the noise-free path.

Exercise 38.10.4 computes $E[\alpha_t \mid \mu = \mu_H]$ and $E[n_t \mid \mu = \mu_H]$ by Monte Carlo and compares them with $\hat{\alpha}$ and $\hat{n}$.

```
T, dt, alpha0 = 8.0, 1e-3, 0.03
policy = lambda a: n_eq(mkt, a)

a_hat = noise_free_belief_path(mkt, alpha0, T, dt, policy)
t_grid = np.linspace(0, T, len(a_hat))

rng = np.random.default_rng(12)
paths = simulate_beliefs(mkt, alpha0, T, dt, np.full(6, mkt.mu_H), rng, policy)

fig, axes = plt.subplots(1, 2, figsize=(12, 4.2))
for pth in paths:
    axes[0].plot(t_grid, pth, lw=0.7, alpha=0.55, color='C0')
axes[0].plot(t_grid, a_hat, lw=2.5, color='C3', label='noise-free path')
axes[0].axhline(1 / 3, color='0.5', ls=':', lw=1.5)

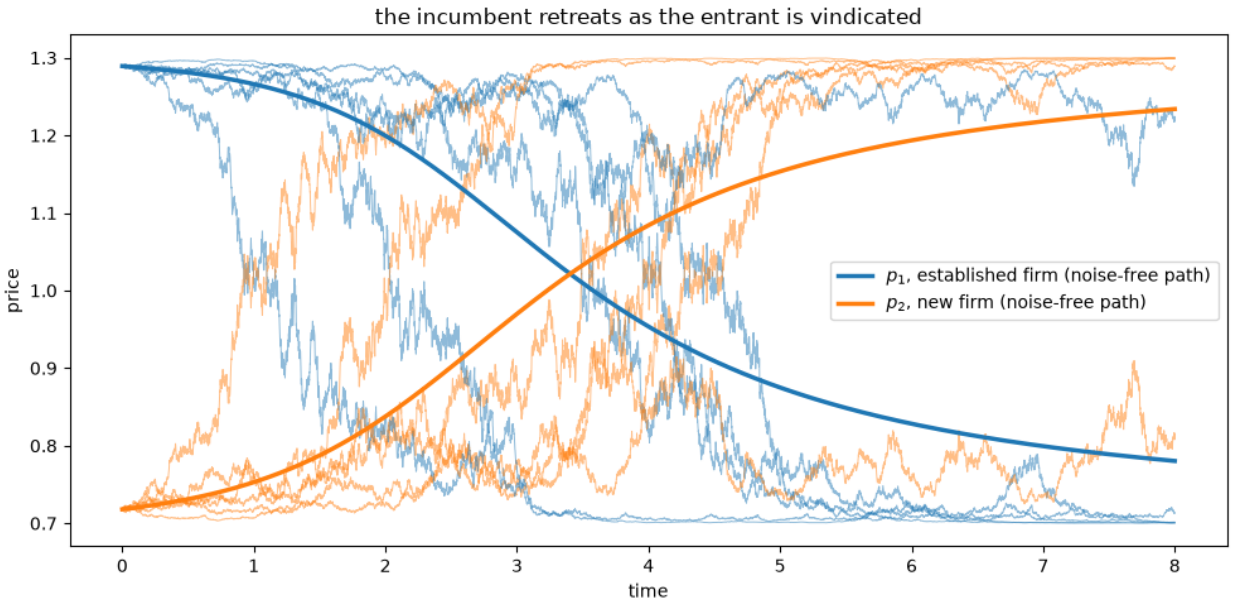

Fig. 38.3: Price paths of the two firms

38.8 Martingale properties

Bergemann and Välimäki [1997] characterize the equilibrium objects probabilistically: the entrant's price is a martingale, the incumbent's price and the entrant's share are supermartingales, and both revenues are submartingales.

Because α is a martingale, each of these follows from the shape of the corresponding function of α, and we can check them all by simulation.

```
rng = np.random.default_rng(3)
a0, M = 0.5, 20_000

# draw the true quality from the prior, one value per path
mu_true = np.where(rng.random(M) < a0, mkt.mu_H, mkt.mu_L)
ends = simulate_beliefs(mkt, a0, 4.0, 2e-3, mu_true, rng, policy)[:, -1]

rows = [
    ('belief', a0, ends.mean(), 'martingale'),
    ('share of new firm', n_eq(mkt, a0), n_eq(mkt, ends).mean(), 'supermartingale'),
    ('price of new firm', p2(mkt, a0), p2(mkt, ends).mean(), 'martingale'),
    ('price of incumbent', p1(mkt, a0), p1(mkt, ends).mean(), 'supermartingale'),
    ('revenue of incumbent', (1 - n_eq(mkt, a0)) * p1(mkt, a0),
     ((1 - n_eq(mkt, ends)) * p1(mkt, ends)).mean(), 'submartingale'),
    ('revenue of new firm', n_eq(mkt, a0) * p2(mkt, a0),
     (n_eq(mkt, ends) * p2(mkt, ends)).mean(), 'submartingale')]

print(f'{"":24s}{"t = 0":>10s}{"E[t = 4]":>11s}{"change":>10s}   prediction')
for name, x0, xT, pred in rows:
    print(f'{name:24s}{x0:10.4f}{xT:11.4f}{xT - x0:+10.4f}   {pred}')
```

```
                         t = 0   E[t = 4]    change   prediction
belief                  0.5000     0.5010   +0.0010   martingale
share of new firm       0.5220     0.5072   -0.0148   supermartingale
```

(continues on next page)

(continued from previous page)

revenue of new firm        0.5220     0.5389   +0.0168   submartingale
```

Every sign comes out as predicted.

The entrant's expected share *falls* over time even though its share rises conditional on the product being good, because the early aggression reflects the value of information rather than confidence in the product.

Both firms expect to earn more later, which is the sense in which they sacrifice current profit to buy information.

38.9 Concluding remarks

Two lectures in this section now feature information whose value is entirely instrumental.

In *The Design and Price of Information* a seller designs and prices experiments, and the interesting economics comes from the fact that Blackwell's order is incomplete.

Here nobody prices information at all, and the interesting economics comes from the fact that only one firm's sales produce it.

Both rest on the same foundation from *Blackwell's Theorem on Comparing Experiments*: more informative experiments spread posterior beliefs in the convex order, and a decision maker whose value is convex in the belief gains from the spread.

A single decision maker's value is always convex in the belief, but an equilibrium value in a game need not be.

The distinctive lesson of Bergemann and Välimäki [1997] is that this convexity is shared by *competitors*.

Because both firms would rather face a market that has sorted out the quality of the new product, uncertainty about vertical quality relaxes price competition much as deterministic differentiation does in Shaked and Sutton [1982].

That is why the incumbent lets the entrant in cheaply at first and why a successful product diffuses along an S-shaped path.

The continuous-time technique used here, and in particular the device of taking the undiscounted limit to keep the Bellman equations tractable, comes from Bolton and Harris [1999], who were the first to study strategic experimentation in continuous time.

A companion paper, Bergemann and Välimäki [2000], studies the same duopoly with a continuum of *identical* consumers.

Homogeneity there rules out market sharing, so the horizontal differentiation that generates the diffusion path in this lecture is absent and the analysis concentrates instead on how informational externalities affect market efficiency.

38.10 Exercises

Exercise 38.10.1

Condition (38.3) requires $|\mu_i - s| < h$ for both quality levels.

1. Show algebraically that this confines the full-information equilibrium share of the new firm to the interval $(1/3, 2/3)$, and hence that $n(\alpha) \in (1/3, 2/3)$ for every belief.
2. Verify this numerically for several admissible (μ_L, μ_H) pairs.

3. Bergemann and Välimäki [1997] draw their diffusion figures with $s = 4$, $h = 1$, $\mu_L = 2$ and $\mu_H = 6$.

   Check whether these satisfy (38.3), compute the equilibrium shares at $\alpha \in \{0, 1\}$, and compute the myopically efficient share m^* at each quality level.

   What goes wrong, and which of the lecture's results still hold?

Solution

Here is one solution:

Under full information with quality μ_i the equilibrium share is $n_i = (\frac{1}{3}(\mu_i - s) + h)/(2h)$.

Condition (38.3) gives $-h < \mu_i - s < h$, so $\frac{1}{3}(\mu_i - s) \in (-h/3, h/3)$ and therefore $n_i \in (\frac{2h/3}{2h}, \frac{4h/3}{2h}) = (1/3, 2/3)$.

Since $n(\alpha)^2$ is a convex combination of n_0^2 and n_1^2, the equilibrium share lies between n_0 and n_1 for every α.

```
for mu_L, mu_H in [(3.1, 4.9), (3.4, 4.6), (3.9, 4.1)]:
    m_ = Market(mu_L=mu_L, mu_H=mu_H)

          f'{(mu_i - paper.s + paper.h) / (2 * paper.h):+.4f}')
```

```
condition (4) needs  s - h < mu_L:  3 < 2?  False
condition (4) needs  mu_H < s + h:  6 < 5?  False

equilibrium shares:  n(0) = 0.1667, n(1) = 0.8333
myopically efficient share at mu_L: -0.5000
myopically efficient share at mu_H: +1.5000
```

The paper's figure parameters violate (38.3) at both ends.

The consequence is that the *efficient* allocation is at a corner: it would assign every buyer to the established product

when $\mu = \mu_L$ and every buyer to the new product when $\mu = \mu_H$, so the interior formula (38.12) no longer applies and the efficiency comparison of *Proposition 38.4.1* breaks down.

Everything about the *equilibrium* survives, because equilibrium shares remain strictly interior at $1/6$ and $5/6$.

That is why those parameters are fine for drawing diffusion paths, which is all the paper uses them for, and why they buy a much more dramatic S-curve than any admissible parameter set could.

Exercise 38.10.2

The lecture found a single belief at which equilibrium experimentation switches from excessive to insufficient.

1. Write a function that locates this crossing point by bisection.
2. Compute it as the quality spread $\mu_H - \mu_L$ widens, holding the midpoint $\frac{1}{2}(\mu_L + \mu_H) = s$ fixed, and again as the horizontal differentiation parameter h varies.
3. Both experiments produce the same numbers whenever the ratio $(\mu_H - \mu_L)/h$ agrees.

   Guess the closed form for the crossing point and check it numerically.
4. Does your formula survive when the quality midpoint is moved away from s?

Solution

Here is one solution:

```
def crossing(mkt, tol=1e-13):
    """Belief at which n*(alpha) = n(alpha), by bisection."""
    lo, hi = 1e-12, 1 - 1e-12
    f = lambda a: n_star(mkt, a) - n_eq(mkt, a)
    if f(lo) > 0 or f(hi) < 0:
        return np.nan
    while hi - lo > tol:
        mid = (lo + hi) / 2
        lo, hi = (mid, hi) if f(mid) < 0 else (lo, mid)
    return (lo + hi) / 2

print('widening the quality spread, midpoint fixed at s = 4, h = 1')
for spread in [0.4, 0.8, 1.2, 1.6, 1.9]:
    m_ = Market(s=4, h=1, mu_L=4 - spread / 2, mu_H=4 + spread / 2)
    print(f'   (mu_H - mu_L)/h = {spread / 1:.3f}:  crossing = {crossing(m_):.6f}')

print('\nvarying horizontal differentiation, mu = (3.4, 4.6)')
for h_ in [0.65, 0.8, 1.0, 1.5, 2.5]:
    m_ = Market(s=4, h=h_, mu_L=3.4, mu_H=4.6)
    print(f'   (mu_H - mu_L)/h = {1.2 / h_:.3f}:  crossing = {crossing(m_):.6f}')
```

```
widening the quality spread, midpoint fixed at s = 4, h = 1
   (mu_H - mu_L)/h = 0.400:  crossing = 0.433333
   (mu_H - mu_L)/h = 0.800:  crossing = 0.366667
   (mu_H - mu_L)/h = 1.200:  crossing = 0.300000
   (mu_H - mu_L)/h = 1.600:  crossing = 0.233333
   (mu_H - mu_L)/h = 1.900:  crossing = 0.183333

varying horizontal differentiation, mu = (3.4, 4.6)
   (mu_H - mu_L)/h = 1.846:  crossing = 0.192308
   (mu_H - mu_L)/h = 1.500:  crossing = 0.250000
   (mu_H - mu_L)/h = 1.200:  crossing = 0.300000
   (mu_H - mu_L)/h = 0.800:  crossing = 0.366667
   (mu_H - mu_L)/h = 0.480:  crossing = 0.420000
```

Sorted by the ratio $(\mu_H - \mu_L)/h$ the two tables line up, which suggests that the crossing point depends on the parameters only through that ratio.

The numbers fall on a straight line with slope $-1/6$ through $1/2$.

```
print(f'{"(mu_H-mu_L)/h":>15s}{"bisection":>12s}{"1/2 - ratio/6":>16s}{"error":>
 ↪12s}')

```

So when the two quality levels straddle s symmetrically, the switch occurs at

$$\alpha^{\text{cross}} = \frac{1}{2} - \frac{\mu_H - \mu_L}{6h},$$

which condition (38.3) keeps strictly inside $(1/6, 1/2)$, since that condition forces $\mu_H - \mu_L < 2h$.

The region of excessive experimentation therefore *shrinks* as the quality spread widens relative to h.

A wider spread means more is at stake in learning, and the efficient policy responds by experimenting a great deal; the equilibrium, driven by each firm's private revenue motive, does not keep up except at the most pessimistic beliefs.

Raising h works in the opposite direction, since strongly attached buyers blunt the price instrument and let the entrant expand more freely than a planner would choose.

The symmetric formula does not survive a move of the midpoint, but a general closed form does.

Let $d_i = (\mu_i - s)/h$.

The efficient and equilibrium full-information shares are $m_i = (1 + d_i)/2$ and $n_i = (1 + d_i/3)/2$, so $m_i^2 - n_i^2 = \varphi(d_i)/9$ with $\varphi(d) = d(3 + 2d)$.

Because $n^*(\alpha)^2 - n(\alpha)^2 = E_\alpha[m_i^2 - n_i^2]$ is affine in α, it vanishes at

$$\alpha^{\text{cross}} = \frac{\varphi(d_L)}{\varphi(d_L) - \varphi(d_H)}.$$

Condition (38.3) gives $d_L \in (-1, 0)$ and $d_H \in (0, 1)$, so $\varphi(d_L) < 0 < \varphi(d_H)$ and $\alpha^{\text{cross}} \in (0, 1)$.

When $d_H = -d_L = (\mu_H - \mu_L)/(2h)$, the formula reduces to $\frac{1}{2} - (\mu_H - \mu_L)/(6h)$.

```
def crossing_formula(mkt):
    φ = lambda d: d * (3 + 2 * d)
    d_L, d_H = (mkt.mu_L - mkt.s) / mkt.h, (mkt.mu_H - mkt.s) / mkt.h
    return φ(d_L) / (φ(d_L) - φ(d_H))

print('moving the quality midpoint away from s, with mu = (3.4, 4.6), h = 1')
for s_ in [3.9, 4.0, 4.1]:
    m_ = Market(s=s_, h=1, mu_L=3.4, mu_H=4.6)
    print(f'   s = {s_}:  bisection = {crossing(m_):.6f}'
          f'   general formula = {crossing_formula(m_):.6f}'
          f'   symmetric formula = {0.5 - 1.2 / 6:.6f}')
```

```
moving the quality midpoint away from s, with mu = (3.4, 4.6), h = 1
   s = 3.9:  bisection = 0.245098   general formula = 0.245098   symmetric␣
↪formula = 0.300000
   s = 4.0:  bisection = 0.300000   general formula = 0.300000   symmetric␣
↪formula = 0.300000
   s = 4.1:  bisection = 0.358974   general formula = 0.358974   symmetric␣
↪formula = 0.300000
```

The general formula matches the bisection at every s; the symmetric formula matches only at $s = 4$.

Exercise 38.10.3

This exercise makes the link with *Blackwell's Theorem on Comparing Experiments* precise.

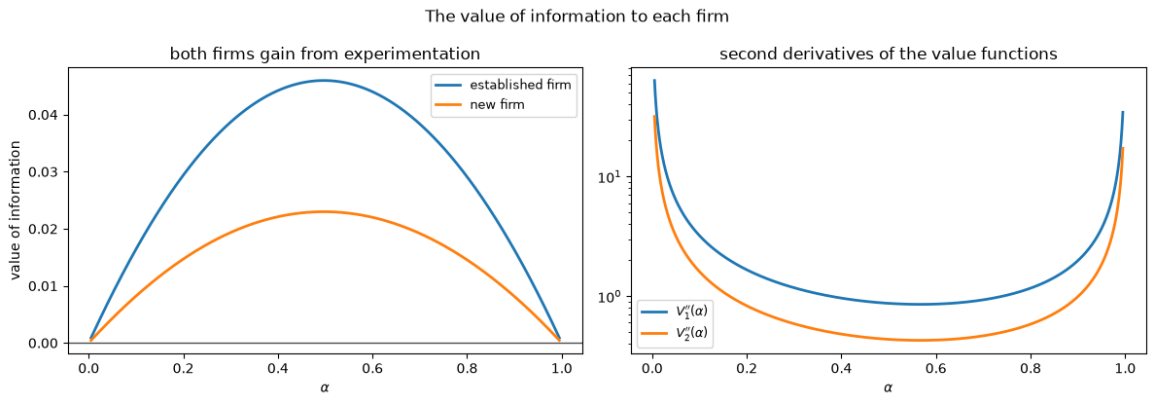
In that lecture, a more informative experiment produces a mean-preserving spread of the posterior, and a decision maker whose value is convex in the belief gains from it.

Here the belief is a martingale and experimentation controls the speed at which it spreads, so the same logic applies to each firm, provided its equilibrium value function is convex.

1. Plot each firm's value of information, $v_i(\alpha)$ minus its current equilibrium revenue, against α.
2. Confirm that both are positive everywhere in the interior and vanish at $\alpha \in \{0, 1\}$, and explain why they must vanish there.
3. The value of information also equals $\frac{1}{2} n(\alpha) \Sigma^2(\alpha) V_i''(\alpha)$.

   Use this to recover $V_i''(\alpha)$ and confirm that both value functions are convex.

Solution



Here is one solution:

```
Ai = np.linspace(0.005, 0.995, 2001)
voi_1 = v1(mkt, Ai) - (1 - n_eq(mkt, Ai)) * p1(mkt, Ai)
voi_2 = v2(mkt, Ai) - n_eq(mkt, Ai) * p2(mkt, Ai)

fig, axes = plt.subplots(1, 2, figsize=(12, 4.2))
axes[0].plot(Ai, voi_1, lw=2, label='established firm')
axes[0].plot(Ai, voi_2, lw=2, label='new firm')
axes[0].axhline(0, color='0.3', lw=1)
axes[0].set(xlabel=r'$\alpha$', ylabel='value of information',
            title='both firms gain from experimentation')
axes[0].legend(fontsize=9)

V1pp = 2 * voi_1 / (n_eq(mkt, Ai) * Sigma2(mkt, Ai))
V2pp = 2 * voi_2 / (n_eq(mkt, Ai) * Sigma2(mkt, Ai))
axes[1].plot(Ai, V1pp, lw=2, label=r"$V_1''(\alpha)$")
axes[1].plot(Ai, V2pp, lw=2, label=r"$V_2''(\alpha)$")
axes[1].set(xlabel=r'$\alpha$', yscale='log',
            title='second derivatives of the value functions')
axes[1].legend(fontsize=9)
fig.suptitle('The value of information to each firm')
fig.tight_layout()
plt.show()
```

```
print(f'minimum value of information, established firm  {voi_1.min():.3e}')
print(f'minimum value of information, new firm          {voi_2.min():.3e}')
print(f'minimum of V1\'\'  {V1pp.min():.4f}    minimum of V2\'\'  {V2pp.min():.4f}
 ↪')
```

```
minimum value of information, established firm  8.957e-04
minimum value of information, new firm          4.479e-04
minimum of V1''  0.8531    minimum of V2''  0.4265
```

Both curves are strictly positive on the interior and both second derivatives are strictly positive, so both value functions are convex.

The value of information vanishes at $\alpha \in \{0, 1\}$ for two reinforcing reasons.

There is nothing left to learn, so the equilibrium coincides with the full-information equilibrium and the revenue gap closes.

And the speed of learning $\Sigma^2(\alpha) \propto \alpha^2(1-\alpha)^2$ vanishes as well, so even a convex value function earns nothing from an experiment that reveals nothing.

The second derivatives do not vanish at the endpoints; they diverge.

Near $\alpha = 0$ the value of information of the new firm is approximately $h(n_H - n_L)^2\alpha$, while $\Sigma^2(\alpha) \approx (\mu_H - \mu_L)^2\alpha^2/\sigma^2$.

Hence $V_2''(\alpha) \approx 2h(n_H - n_L)^2\sigma^2/(n_L(\mu_H - \mu_L)^2\alpha)$, so $\alpha V_2''(\alpha)$ converges to a positive constant, and the same holds for V_1'' and at $\alpha = 1$ with $1 - \alpha$ in place of α.

The shadow value V_i'' of spreading beliefs grows like $1/\alpha$, but the speed Σ^2 at which experimentation spreads them falls like α^2.

Their product, the value of information, therefore vanishes linearly.

```
n_L, n_H = n_eq(mkt, 0.0), n_eq(mkt, 1.0)
limit = 2 * mkt.h * (n_H - n_L) ** 2 * mkt.sigma ** 2 / (

    print(f'alpha = {a:.0e}:  alpha * V2\'\' = {a * V2pp_a:.4f}')
print(f'limit:            {limit:.4f}')
```

```
alpha = 1e-02:  alpha * V2'' = 0.1587
alpha = 1e-03:  alpha * V2'' = 0.1587
alpha = 1e-04:  alpha * V2'' = 0.1587
limit:            0.1587
```

Exercise 38.10.4

Proposition 38.7.1 describes the noise-free path $\hat{\alpha}(t)$, not the conditional mean of the belief.

1. Use `simulate_beliefs` to estimate $E[\alpha_t \mid \mu = \mu_H]$ and $E[n(\alpha_t) \mid \mu = \mu_H]$ for $t \in [0, 8]$, starting from $\alpha_0 = 0.03$, and plot them against $\hat{\alpha}(t)$ and $\hat{n}(t)$.
2. Find the time at which $E[n(\alpha_t) \mid \mu = \mu_H]$ grows fastest and the value of $E[\alpha_t \mid \mu = \mu_H]$ at that time.
3. Explain why the noise-free path runs ahead of the conditional mean.

Hint: Differentiating a Monte Carlo average with respect to time amplifies sampling noise.

Instead use $\frac{d}{dt}E[n(\alpha_t)] = E[\mathcal{G}n(\alpha_t)]$, where $\mathcal{G}n = n' \times \text{drift} + \frac{1}{2}n'' \times \text{variance}$ is the generator of the belief process (38.15) applied to n.

Solution

Here is one solution.

Write $n(\alpha)^2 = n_L^2 + b\alpha$ with $b = n_H^2 - n_L^2$, and let $k = (\mu_H - \mu_L)^2/\sigma^2$.

Then $n' = b/(2n)$ and $n'' = -b^2/(4n^3)$, and the coefficients of (38.15) give

$$\mathcal{G}n(\alpha) = \frac{bk}{2}\,\alpha(1-\alpha)^2\left[1 - \frac{b\alpha}{4n(\alpha)^2}\right].$$

The first term is the rate $d\hat{n}/dt$ along the noise-free path; the second is an Itô correction that comes from the concavity of n.

We simulate 10,000 paths in five batches to save memory.

```
alpha0, T4, dt4 = 0.03, 8.0, 5e-3
n_L, n_H = n_eq(mkt, 0.0), n_eq(mkt, 1.0)
b = n_H ** 2 - n_L ** 2
k2 = (mkt.mu_H - mkt.mu_L) ** 2 / mkt.sigma ** 2

def generator_n(a):
    """Generator of the belief process under mu_H applied to n(alpha)."""
    n = n_eq(mkt, a)
    return 0.5 * b * k2 * a * (1 - a) ** 2 * (1 - b * a / (4 * n ** 2))

   6      0.823     0.562   0.608   0.528
   8      0.890     0.693   0.624   0.565

E[n_t] grows fastest at t = 2.41, where E[alpha_t] = 0.214
its growth rate is within 1% of the maximum for t in [2.02, 2.78]
the belief drift is concave for alpha below 0.72
```

The noise-free path runs well ahead of the conditional mean: at $t = 4$ it puts the belief at 0.64 and the share at 0.561, while the conditional means are about 0.38 and 0.48.

The conditional mean share is also S-shaped.

It grows fastest at about the same date as the noise-free share, near $t = 2.4$, but the conditional mean belief there is about 0.21, not 1/3.

The growth rate of $E[n_t \mid \mu_H]$ is within one percent of its maximum between $t \approx 2.0$ and $t \approx 2.8$, so the date of fastest growth is imprecisely located.

Two forces hold the mean back.

The drift in (38.15) is concave in α for α below about 0.72, so while most paths lie in that region the average drift across paths falls short of the drift at the average belief.

Paths that receive bad news early sink toward $\alpha = 0$, where both the drift and the volatility vanish and learning nearly stops; those paths hold the average down.

Exercise 38.10.5

Let $\ell_t = \log(\alpha_t/(1-\alpha_t))$ and $\kappa = (\mu_H - \mu_L)^2/(2\sigma^2)$.

1. Use (38.6) and (38.8) to show that, conditional on $\mu = \mu_H$,

$$d\ell = \kappa\, n(\alpha)\, dt + \frac{\mu_H - \mu_L}{\sigma}\sqrt{n(\alpha)}\, dB,$$

   and that conditional on $\mu = \mu_L$ the drift is $-\kappa\, n(\alpha)$. Interpret κ as a Kullback–Leibler divergence rate.

2. When $\mu = \mu_H$, let τ be the first time the belief reaches 0.9, starting from $\alpha_0 = 0.03$. Use part 1, the optional stopping theorem, and $n(\alpha) \in (1/3, 2/3)$ to bound $E[\tau]$, and check the bounds by simulation.

3. Repeat conditional on $\mu = \mu_L$. Explain why the expected time for the belief to rise from 0.03 to 0.9 is now infinite, and bound instead the expected time for it to fall from 0.97 to 0.1. Explain why the two simulated expected times differ although the bounds are the same.

Solution

Here is one solution.

Part 1. In continuous time (38.8) becomes $d\ell = [(\mu_H - \mu_L)\, dX - \frac{1}{2} n(\mu_H^2 - \mu_L^2)\, dt]/\sigma^2$.

Conditional on $\mu = \mu_H$, $dX = n\mu_H\, dt + \sigma\sqrt{n}\, dB$, so the drift of ℓ is

$$\frac{n}{\sigma^2}\left[(\mu_H - \mu_L)\mu_H - \tfrac{1}{2}(\mu_H - \mu_L)(\mu_H + \mu_L)\right] = \frac{n(\mu_H - \mu_L)^2}{2\sigma^2} = \kappa n$$

and its diffusion coefficient is $(\mu_H - \mu_L)\sqrt{n}/\sigma$.

Conditional on $\mu = \mu_L$, replacing μ_H by μ_L in the first term of the bracket gives drift $-\kappa n$.

Over an interval of length Δ with $n = 1$, the increment ΔX is $N(\mu_H\Delta, \sigma^2\Delta)$ under μ_H and $N(\mu_L\Delta, \sigma^2\Delta)$ under μ_L.

The Kullback–Leibler divergence between these two distributions, in either direction, is $(\mu_H - \mu_L)^2\Delta/(2\sigma^2) = \kappa\Delta$ (see *Kullback–Leibler divergence*).

So the log odds drift toward the truth at n times the KL divergence rate, the continuous-time version of the link between expected log likelihood ratios and KL divergence in *Likelihood Ratio Processes*.

Part 2. The process $\ell_t - \ell_0 - \kappa \int_0^t n(\alpha_s)\, ds$ is a martingale.

Because $n \geq n_L > 0$, the drift of ℓ is bounded below by a positive constant and $E[\tau] < \infty$, so optional stopping applies.

Because ℓ has continuous paths, $\ell_\tau = \ell^* = \log 9$.

Hence

$$\kappa\, E\left[\int_0^\tau n(\alpha_s)\, ds\right] = \ell^* - \ell_0,$$

and $\frac{1}{3}E[\tau] < E\left[\int_0^\tau n(\alpha_s)\, ds\right] < \frac{2}{3}E[\tau]$ gives

$$\frac{3}{2}\,\frac{\ell^* - \ell_0}{\kappa} < E[\tau] < 3\,\frac{\ell^* - \ell_0}{\kappa}.$$

With the lecture's parameters, n actually stays in $[n_L, n_H] = [0.35, 0.65]$, which tightens the bounds to $(\ell^* - \ell_0)/(\kappa n_H) \leq E[\tau] \leq (\ell^* - \ell_0)/(\kappa n_L)$.

Part 3. Conditional on $\mu = \mu_L$, Itô's lemma and part 1 show that the odds $e^{\ell_t} = \alpha_t/(1-\alpha_t)$ form a martingale: the drift of ℓ, $-\kappa n$, is minus one half of its instantaneous variance, $2\kappa n$.

The odds are the prior odds times a likelihood ratio process of the kind studied in *Likelihood Ratio Processes*.

Stopped when the belief first reaches 0.9, the odds are bounded by 9, and $\ell_t \to -\infty$ on paths that never get there.

Optional stopping gives a probability $(0.03/0.97)/9 \approx 0.0034$ that the belief ever reaches 0.9 from 0.03, so with probability close to one it never does, and the expected hitting time is infinite.

The time for the belief to fall from 0.97 to 0.1 obeys the argument of part 2 applied to $-\ell$, with the same distance $|\ell^* - \ell_0| = \log 9 + \log(0.97/0.03)$, so the bounds are identical.

```
def first_passage_times(mkt, alpha0, alpha_target, mu_true, M, dt, T, rng):

Both simulated means lie inside the bounds.

Optional stopping pins down $E\left[\int_0^\tau n(\alpha_s)\,ds\right]$, the expected cumulative size of the experiment, not $E[\tau]$ itself.

A good product that starts from a pessimistic belief is sold to a small share of buyers, near n_L, while the market learns about it.

A bad product that starts from an optimistic belief is sold to a large share, near n_H.

The market therefore learns faster that a popular product is bad than that an unpopular product is good.

39.1 Overview

Some structural economic models have the following two properties:

- it is possible to compute an equilibrium and simulate it, given a known parameter vector
- it is not possible to write down a likelihood function analytically

We can solve "the direct problem," which maps a parameter vector into a probability distribution of the data.

We cannot use maximum likelihood to solve "the inverse problem," which maps an observed data set into an estimate of the parameter vector.

Researchers with such models turn to the generalized method of moments of Hansen [1982] and compute the moments by simulation [Duffie and Singleton, 1993, McFadden, 1989, Pakes and Pollard, 1989].

They must decide which moments to match.

A. Ronald Gallant and George Tauchen studied this question in Gallant and Tauchen [1996].

They put two models on the table:

- the economist's **structural** model, indexed by a parameter vector ρ, whose likelihood function cannot be written down
- a distinct, descriptive **auxiliary** model, indexed by a parameter vector θ, whose likelihood function can be written down and maximized

The two parameter vectors usually differ in dimension and always differ in meaning.

- ρ specifies the preferences, technologies, constraint sets and other features of the agents inside the structural model. The economist wants to learn ρ.
- θ summarizes the observed data. Its components answer no economic question. The economist estimates θ only as a step toward estimating ρ.

	structural model	auxiliary model
density	$p(y_t \mid x_t, \rho)$	$f(y_t \mid x_t, \theta)$
parameter	$\rho \in \mathbb{R}^{k_\rho}$	$\theta \in \mathbb{R}^{k_\theta}$
interpretation	economic	descriptive
likelihood	unavailable	available
role	object of inference	source of moment conditions

Here x_t collects lagged values of y_t, possibly the whole history.

In the stochastic volatility example below, $\rho = (a, r_w, r_y)$ governs a latent log-volatility process, while $\theta = (\mu, \omega, \alpha, \beta)$ holds the parameters of a GARCH(1,1) model.

No component of θ corresponds to a component of ρ.

Gallant and Tauchen's method uses the **scores** associated with the likelihood function of the auxiliary model as the moment vector for GMM.

They fit θ to the observed data once.

They then choose ρ so that, in data simulated from the structural model, the auxiliary score evaluated at that fitted θ averages as close to zero as possible.

Note

Section *Why the score is the right thing to match* shows that the score moment conditions are the negative gradient of a Kullback-Leibler divergence. *Statistical Divergence Measures* and *Likelihood Ratio Processes* study properties of the KL divergence.

Gallant and Tauchen prove that if the auxiliary model nests the structural model, their estimator is as efficient as maximum likelihood.

They argue that if the auxiliary model closely approximates the distribution of the data, the estimator is nearly as efficient.

Practitioners call their method the **efficient method of moments**, or EMM.

Gallant and Tauchen [2010] surveys the method and its applications.

Let's start with some imports.

```
import numpy as np
import matplotlib.pyplot as plt
from numba import jit
from scipy.optimize import minimize
from scipy.stats import chi2
```

39.2 The estimation problem

A structural model is a sequence of probability densities for an observed process $\{y_t\}$,

$$p(y_t \mid x_t, \rho), \qquad \rho \in \mathcal{R} \subset \mathbb{R}^{k_\rho},$$

where x_t collects whatever the model conditions on, usually lagged values of y_t.

We call ρ the **structural parameter vector**.

Nature generated the observed data $\{\tilde{y}_t, \tilde{x}_t\}_{t=1}^n$ from ρ^0.

Tildes mark observed data and statistics computed from them.

Hats mark simulated data and the final estimator $\hat{\rho}_n$.

We assume two things about the structural model.

Simulation is feasible: given ρ, we can generate a long artificial series $\{\hat{y}_\tau, \hat{x}_\tau\}_{\tau=1}^N$.

The likelihood is unavailable: $\prod_t p(\tilde{y}_t \mid \tilde{x}_t, \rho)$ has no expression that we can evaluate and maximize.

Gallant and Tauchen take a stationary Markov structural model as the leading case.

A single long simulation then suffices to compute any expectation under the model.

Their paper also covers independent cross-sectional data and processes whose laws of motion depend on t.

39.3 The auxiliary model and its score

An auxiliary model is a second sequence of densities for the same observed process,

$$f(y_t \mid x_t, \theta), \qquad \theta \in \Theta \subset \mathbb{R}^{k_\theta}.$$

We call θ the **auxiliary parameter vector**.

Gallant and Tauchen call the auxiliary model the **score generator**.

Two properties make an auxiliary model useful.

Its density has an analytic expression, so we can write down its likelihood and differentiate it.

It describes the data well.

The first property is required.

Consistency requires only that the scores identify ρ, as Exercise 39.15.1 and Exercise 39.15.3 show.

Section *Choosing the score generator* explains what a close fit buys.

A GARCH model of asset returns, a vector autoregression, and a Hermite series expansion of a conditional density all qualify.

The **score** of the auxiliary model is the derivative of its log density with respect to its own parameters,

$$s(y, x, \theta) = \frac{\partial}{\partial \theta} \ln f(y \mid x, \theta).$$

The score is a $k_\theta \times 1$ vector that we can evaluate at any (y, x, θ).

39.4 The estimator

The estimator takes three steps.

Step 1. Projection. Fit the auxiliary model to the observed data by quasi-maximum likelihood,

$$\tilde{\theta}_n = \arg\max_{\theta \in \Theta} \frac{1}{n} \sum_{t=1}^{n} \ln f(\tilde{y}_t \mid \tilde{x}_t, \theta).$$

This step uses the data and the auxiliary model alone, so it happens once, before any structural parameter is estimated.

Step 2. Moments by simulation. Define the moment function $m(\rho, \theta)$ as the expectation *under the structural model* of the auxiliary score,

$$m(\rho, \theta) = \iint s(y, x, \theta)\, p(y \mid x, \rho)\, dy\, p(x \mid \rho)\, dx, \tag{39.1}$$

where $p(x \mid \rho)$ is the stationary density of x_t under the structural model.

A long simulation approximates the double integral at $\theta = \tilde{\theta}_n$,

$$m(\rho, \tilde{\theta}_n) \approx \frac{1}{N} \sum_{\tau=1}^{N} s(\hat{y}_\tau, \hat{x}_\tau, \tilde{\theta}_n) \tag{39.2}$$

The right side of (39.2) averages the auxiliary score over a long simulation from the structural model at ρ.

Each evaluation requires a simulation and no optimization.

Step 3. GMM. Estimate ρ by making the moment vector as close to zero as the GMM metric allows,

$$\hat{\rho}_n = \arg\min_{\rho \in \mathcal{R}} \; m(\rho, \tilde{\theta}_n)^\top \, (\tilde{\mathcal{J}}_n)^{-1} \, m(\rho, \tilde{\theta}_n), \tag{39.3}$$

where

$$\tilde{\mathcal{J}}_n = \frac{1}{n} \sum_{t=1}^{n} s(\tilde{y}_t, \tilde{x}_t, \tilde{\theta}_n)\, s(\tilde{y}_t, \tilde{x}_t, \tilde{\theta}_n)^\top. \tag{39.4}$$

The weighting matrix (39.4) is the outer product of the auxiliary scores at the data.

It estimates $\mathcal{J}^0$, the asymptotic variance of $n^{-1/2} \sum_{t=1}^{n} s(\tilde{y}_t, \tilde{x}_t, \theta^0)$, where θ^0 is the probability limit of $\tilde{\theta}_n$.

It depends on the auxiliary model and the data alone.

The outer product is a valid estimate when the scores are serially uncorrelated.

An auxiliary model that describes the conditional distribution of the data correctly delivers serially uncorrelated scores.

Gaussian quasi-maximum likelihood scores are also serially uncorrelated when the auxiliary model specifies the conditional mean and variance correctly [Bollerslev and Wooldridge, 1992].

Otherwise Gallant and Tauchen recommend a heteroskedasticity and autocorrelation consistent estimate with Parzen weights [Gallant, 1987], and they cite Andrews [1991] for alternatives.

Exercise 39.15.4 shows how far the outer product can understate $\mathcal{J}^0$ when the scores are serially correlated.

A researcher computes either estimate once, before the search over ρ begins.

GMM usually requires a preliminary estimate of the structural parameters to form an efficient weighting matrix, and with either of these estimates that requirement disappears.

The order condition for identification is $k_\theta \geq k_\rho$.

The order condition is necessary but not sufficient, and Exercise 39.15.3 constructs a failure.

39.5 Why the score is the right thing to match

Statistical Divergence Measures shows that maximum likelihood minimizes the cross-entropy of the parametric model relative to the empirical distribution of the data, the sample analogue of the KL divergence from the data-generating distribution to the model.

Step 1 projects the data onto the auxiliary family by minimizing KL divergence.

For each ρ, define the **pseudo-true value**

$$\theta^0(\rho) = \arg\min_{\theta \in \Theta} \; D_{KL}(p(\cdot \mid \rho) \,\|\, f(\cdot \mid \theta)),$$

the point in the auxiliary family closest to the structural model at ρ [White, 1982][1].

The function $\theta^0(\cdot)$ maps structural parameters into auxiliary parameters.

As n grows, $\tilde{\theta}_n$ converges to $\theta^0 = \theta^0(\rho^0)$.

Now differentiate the divergence with respect to θ:

$$\frac{\partial}{\partial \theta} D_{KL}(p(\cdot \mid \rho) \,\|\, f(\cdot \mid \theta)) = \frac{\partial}{\partial \theta} \left[\int p \ln p - \int p \ln f_\theta \right] = -\, m(\rho, \theta) \tag{39.5}$$

The moment function (39.1) is the negative gradient of a Kullback-Leibler divergence.

Setting $m(\rho, \theta) = 0$ states the first-order condition for a KL projection.

The estimator (39.3) searches for the structural parameter whose KL projection onto the auxiliary family lands where the data's projection landed, or as close as the GMM metric allows when $k_\theta > k_\rho$.

This reading explains why the structural model need not nest inside the auxiliary model.

At $\rho = \rho^0$ the structural model generated the data, the two projections coincide, and $m(\rho^0, \theta^0) = 0$.

Exercise 39.15.1 asks you to verify this chain of reasoning.

[1] Here $p(\cdot \mid \rho)$ and $f(\cdot \mid \theta)$ are conditional densities of y_t given x_t. The divergence averages $\int p(y \mid x, \rho) \ln[p(y \mid x, \rho)/f(y \mid x, \theta)]\, dy$ over the stationary density $p(x \mid \rho)$.

39.6 Efficiency

Consistency and asymptotic normality hold under weak regularity conditions,

$$\sqrt{n}\,(\hat{\rho}_n - \rho^0) \to N\Big(0, \big[(M^0)^\top (\mathcal{J}^0)^{-1} M^0\big]^{-1}\Big), \qquad M^0 = \frac{\partial}{\partial \rho^\top} m(\rho^0, \theta^0),$$

which is Theorem 1 of Gallant and Tauchen [1996].

Here $\mathcal{J}^0$ is the variance of the auxiliary score that $\tilde{\mathcal{J}}_n$ in (39.4) estimates.

The formula assumes that the weighting matrix converges to $(\mathcal{J}^0)^{-1}$, as $(\tilde{\mathcal{J}}_n)^{-1}$ does when $\tilde{\mathcal{J}}_n$ estimates $\mathcal{J}^0$ consistently.

With any other limiting weighting matrix W, the asymptotic variance takes the sandwich form

$$\big[(M^0)^\top W M^0\big]^{-1} (M^0)^\top W \, \mathcal{J}^0 \, W M^0 \big[(M^0)^\top W M^0\big]^{-1}.$$

Exercise 39.15.4 uses it.

Gallant and Tauchen assume that N is large enough to make simulation error negligible, so the formula treats m as computed exactly.

A simulation of length N adds independent noise to m and multiplies the asymptotic variance of $\sqrt{n}\,m$, and hence of $\hat{\rho}_n$, by $1 + n/N$.

Gallant and Tauchen say that the structural model is **smoothly embedded** within the auxiliary model when a twice continuously differentiable map g carries structural parameters into auxiliary parameters,

$$p(y \mid x, \rho) = f(y \mid x, g(\rho)) \qquad \text{for every } \rho \text{ near } \rho^0.$$

Smooth embedding says that the auxiliary model nests the structural model.

In general $p(\cdot \mid \rho)$ lies outside the auxiliary family, and no g satisfies this equation.

The function $\theta^0(\rho)$ always exists.

Under smooth embedding $\theta^0(\rho) = g(\rho)$.

Write $G^0 = \partial g(\rho^0)/\partial \rho^\top$.

Their Theorem 2 states that smooth embedding implies

$$\sqrt{n}\,(\hat{\rho}_n - \rho^0) \to N\Big(0, \big[(G^0)^\top \mathcal{J}^0 G^0\big]^{-1}\Big),$$

which is the asymptotic distribution of the maximum likelihood estimator of ρ.

The proof turns on the identity $M^0 = \mathcal{J}^0 G^0$, which converts the GMM variance into the ML variance.

The estimator attains maximum likelihood efficiency without the structural likelihood.

Smooth embedding is a strong assumption, and consistency and asymptotic normality do not require it.

Gallant and Tauchen argue that an auxiliary model that approximates the distribution of the data closely without nesting the structural model delivers an estimator that is nearly fully efficient.

Gallant and Tauchen read this as instruction about how to choose the auxiliary model: make it fit.

39.7 Comparison with matching the auxiliary parameters

Indirect inference names the class of estimators that compare observed and simulated data through an auxiliary model.

Gourieroux *et al.* [1993] and Smith [1993] match the auxiliary parameters.

Gourieroux *et al.* [1993] call $\theta^0(\rho)$ the **binding function**.

Their estimator is

$$\hat{\rho}_{II} = \arg\min_{\rho} \left[\tilde{\theta}_n - \theta^0(\rho)\right]^\top \Omega \left[\tilde{\theta}_n - \theta^0(\rho)\right]$$

for a weighting matrix Ω.

Under smooth embedding $\theta^0 = g$, and the choice $\Omega = \mathcal{J}^0$ yields the minimum chi-square estimator, which is as efficient as maximum likelihood.

The binding function is unavailable whenever the structural likelihood is unavailable, so a practitioner replaces $\theta^0(\rho)$ by the average of auxiliary estimates computed on H simulated data sets.

That replacement is expensive.

Each trial value of ρ requires H separate maximizations of the auxiliary likelihood, one per simulated data set.

The score-based estimator requires exactly one maximization of the auxiliary likelihood, in Step 1, and never repeats it.

With suitably chosen weighting matrices, the parameter-based and score-based estimators are asymptotically equivalent [Gourieroux *et al.*, 1993].

The advantage of matching scores is computational.

Finite-sample behavior can differ.

Duffee and Stanton [2008] study highly persistent Gaussian autoregressions and find that score matching yields confidence intervals that are wider than those of parameter matching yet less likely to cover the true value.

They trace the problem to the large role that the population variance plays in the score moment conditions.

39.8 Choosing the score generator

A model known to describe the data accurately should be the auxiliary model.

Lacking one, Gallant and Tauchen recommend two general purpose families.

The **seminonparametric** or SNP density of Gallant and Nychka [1987] and Gallant and Tauchen [1989] multiplies a Gaussian density by a squared Hermite polynomial whose coefficients depend on lagged values.

Tuning parameters nest an IID Gaussian, a Gaussian VAR, Gaussian ARCH and GARCH, and fully nonlinear nonparametric specifications, so a specification search selects the auxiliary model from the data [Gallant and Tauchen, 2010].

The **neural net** score approximates any nonlinear autoregression, including deterministic chaos.

Both families are series expansions, so adding terms drives the approximation error to zero.

Adding terms also drives the conditional mean of the score toward zero, so the scores approach martingale differences.

The outer product (39.4) then estimates $\mathcal{J}^0$ accurately, and the weighting matrix needs no correction for serial correlation.

A close fit therefore buys two things: near efficiency and a valid outer-product weighting matrix.

Exercise 39.15.4 shows what happens with a score generator that lacks the second.

The number of terms governs a trade-off between bias and variance.

More terms reduce the approximation error of the auxiliary model and raise the sampling variance of $\tilde{\theta}_n$.

Gallant and Tauchen warn against taking too many terms and then claiming that standard asymptotics apply.

39.9 A first example: an AR(1) inside an AR(2)

An example in which we *can* compute the maximum likelihood estimator lets us check Theorem 2.

Take as the structural model a Gaussian first-order autoregression,

$$y_t = \rho_1 y_{t-1} + \sigma \epsilon_t, \qquad \epsilon_t \sim N(0,1),$$

with $\rho = (\rho_1, \sigma)^\top$.

Take as the auxiliary model a Gaussian second-order autoregression,

$$y_t = \theta_1 y_{t-1} + \theta_2 y_{t-2} + \varsigma e_t, \qquad e_t \sim N(0,1),$$

with $\theta = (\theta_1, \theta_2, \varsigma)^\top$.

The AR(2) nests the AR(1) through $g(\rho_1, \sigma) = (\rho_1, 0, \sigma)$, so the structural model is smoothly embedded and $k_\theta = 3$ exceeds $k_\rho = 2$.

The components θ_1 and ρ_1 share an interpretation only because the AR(2) nests the AR(1).

Theorem 2 predicts that our estimator and the maximum likelihood estimator have the same asymptotic distribution, up to the simulation factor $1 + n/N$.

Writing $u_t = y_t - \theta_1 y_{t-1} - \theta_2 y_{t-2}$, the auxiliary score is

$$s(y_t, x_t, \theta) = \begin{bmatrix} u_t y_{t-1}/\varsigma^2 \\ u_t y_{t-2}/\varsigma^2 \\ -1/\varsigma + u_t^2/\varsigma^3 \end{bmatrix}.$$

```
@jit(nopython=True)
def simulate_ar1(ρ1, σ, ε):
    "Simulate the structural AR(1) from a fixed array of shocks ε."
    n = ε.size
    y = np.empty(n)
    y[0] = σ * ε[0] / np.sqrt(1 - ρ1**2)
    for t in range(1, n):
        y[t] = ρ1 * y[t-1] + σ * ε[t]
    return y

def ar2_scores(θ, y):
    "Per-observation scores of the Gaussian AR(2) auxiliary model."
    θ1, θ2, ς = θ
    yt, y1, y2 = y[2:], y[1:-1], y[:-2]
    u = yt - θ1 * y1 - θ2 * y2
    return np.column_stack([u * y1 / ς**2, u * y2 / ς**2, -1/ς + u**2 / ς**3])

def ar2_qmle(y):
    "Quasi-maximum likelihood estimates of the AR(2), available in closed form."
    X = np.column_stack([y[1:-1], y[:-2]])
    b = np.linalg.lstsq(X, y[2:], rcond=None)[0]
    ς = np.sqrt(np.mean((y[2:] - X @ b)**2))
    return np.array([b[0], b[1], ς])
```

Let's generate data from the structural model and compute the conditional maximum likelihood estimator, which for this model is least squares.

```
rng = np.random.default_rng(0)
T, ρ1_0, σ_0 = 1000, 0.8, 1.0
y_data = simulate_ar1(ρ1_0, σ_0, rng.standard_normal(T))

X1 = y_data[:-1]
ρ1_mle = float(X1 @ y_data[1:] / (X1 @ X1))
σ_mle = float(np.sqrt(np.mean((y_data[1:] - ρ1_mle * X1)**2)))
print(f"maximum likelihood:  ρ1 = {ρ1_mle:.4f}   σ = {σ_mle:.4f}")
```

```
maximum likelihood:  ρ1 = 0.8022   σ = 0.9784
```

Step 1 fits the auxiliary model and forms the weighting matrix.

```
θ_tilde = ar2_qmle(y_data)
S = ar2_scores(θ_tilde, y_data)
I_tilde = S.T @ S / S.shape[0]
W = np.linalg.inv(I_tilde)

print(f"auxiliary QMLE: θ1 = {θ_tilde[0]:.4f}, θ2 = {θ_tilde[1]:.4f}, ς = {θ_
↪tilde[2]:.4f}")
```

```
auxiliary QMLE: θ1 = 0.8083, θ2 = -0.0075, ς = 0.9789
```

The estimate of θ_2 sits near zero, as the nesting map g anticipates.

Steps 2 and 3 simulate and minimize.

We draw the shocks ϵ once and reuse them at every trial value of ρ.

We call them **common random numbers**, and a figure below shows their effect on the criterion.

```
N = 20_000
ε_sim = rng.standard_normal(N)      # common random numbers

def moments_ar1(ρ):
    "Expectation under the structural model of the auxiliary score."
    y_sim = simulate_ar1(ρ[0], ρ[1], ε_sim)
    return ar2_scores(θ_tilde, y_sim).mean(axis=0)

def criterion_ar1(ρ):
    if not (abs(ρ[0]) < 0.999 and ρ[1] > 1e-6):
        return 1e10
    m = moments_ar1(ρ)
    return float(m @ W @ m)

res = minimize(criterion_ar1, np.array([0.5, 1.5]), method='Nelder-Mead',
               options=dict(xatol=1e-6, fatol=1e-12, maxiter=2000))

print(f"true values:         ρ1 = {ρ1_0:.4f}   σ = {σ_0:.4f}")
print(f"maximum likelihood:  ρ1 = {ρ1_mle:.4f}   σ = {σ_mle:.4f}")
print(f"score matching:      ρ1 = {res.x[0]:.4f}   σ = {res.x[1]:.4f}")
```

```
true values:         ρ1 = 0.8000   σ = 1.0000
maximum likelihood:  ρ1 = 0.8022   σ = 0.9784
score matching:      ρ1 = 0.8009   σ = 0.9830
```

The two sets of estimates nearly coincide, differing in the third decimal place.

The next figure evaluates the criterion on a grid of ρ_1 values with σ held at its estimate.

One curve uses the common random numbers `ε_sim`, and the other draws fresh shocks at each grid point.

```
rng_fresh = np.random.default_rng(1)
ρ1_grid = np.linspace(0.77, 0.83, 61)
σ_hat = res.x[1]

def criterion_fresh(ρ):
    "The criterion with a fresh draw of shocks at each evaluation."
    y_sim = simulate_ar1(ρ[0], ρ[1], rng_fresh.standard_normal(N))
    m = ar2_scores(θ_tilde, y_sim).mean(axis=0)
    return float(m @ W @ m)

crn = [criterion_ar1(np.array([r1, σ_hat])) for r1 in ρ1_grid]
fresh = [criterion_fresh(np.array([r1, σ_hat])) for r1 in ρ1_grid]

fig, ax = plt.subplots()
ax.plot(ρ1_grid, crn, lw=2, label='common random numbers')
ax.plot(ρ1_grid, fresh, lw=2, label='fresh shocks at each point')
ax.set_xlabel(r'$\rho_1$')
ax.set_ylabel('criterion')
ax.legend()
plt.show()
```

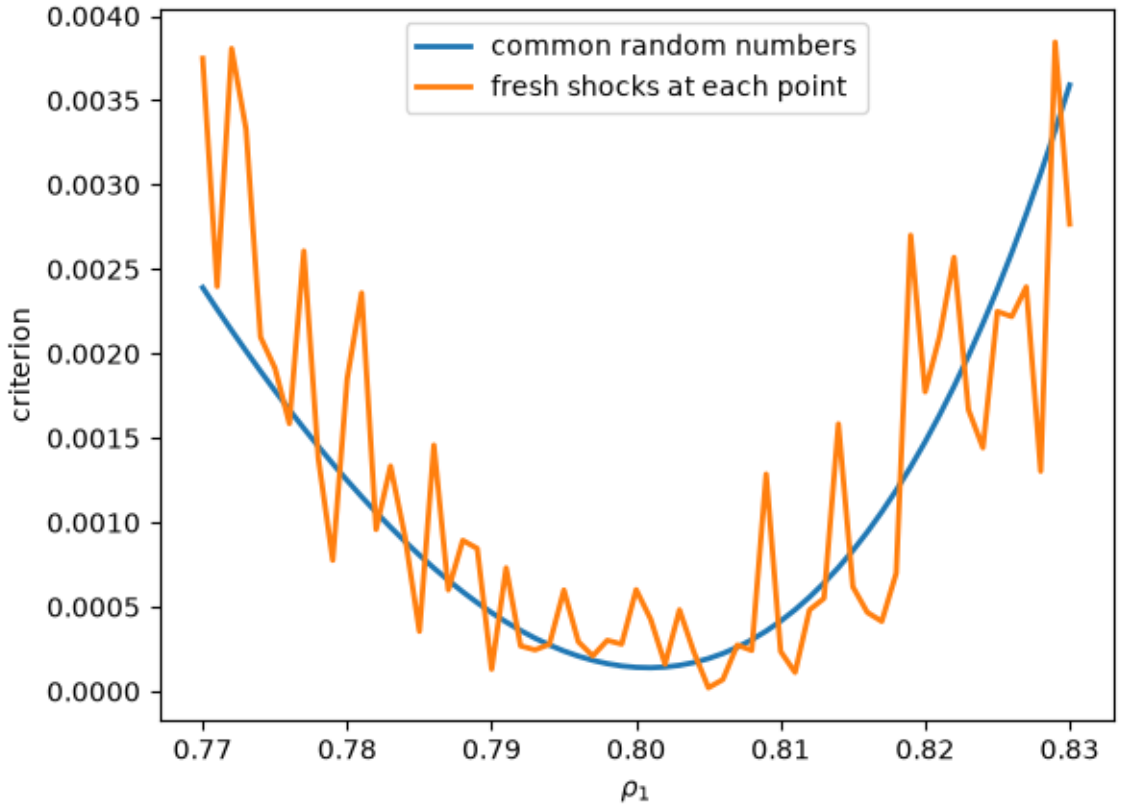

Fig. 39.1: Criterion with common and fresh shocks

Fresh shocks make the criterion jagged, with many local minima.

Common random numbers make it a smooth function of ρ_1 with a single minimum.

The minimized criterion tests the $k_\theta - k_\rho = 1$ overidentifying restriction that the structural model places on the auxiliary model.

Under correct specification, n times the minimized criterion, divided by the simulation factor $1 + n/N$, is asymptotically distributed as $\chi^2(k_\theta - k_\rho)$[2].

The code writes the sample size n as `T`.

```
J = T * criterion_ar1(res.x) / (1 + T / N)
df = 3 - 2
print(f"J = {J:.3f},  χ²({df}) 5% critical value = {chi2.ppf(0.95, df):.3f}")
```

```
J = 0.133,  χ²(1) 5% critical value = 3.841
```

Theorem 1 delivers standard errors.

We compute M^0 by central differences of the simulated moment vector, which common random numbers make smooth in ρ, and we multiply the variance by the simulation factor $1 + n/N$.

For the AR(1), the maximum likelihood standard errors are $\sqrt{(1-\rho_1^2)/n}$ for ρ_1 and $\sigma/\sqrt{2n}$ for σ.

```
def jacobian(moments, ρ, h=1e-4):
    "Central-difference Jacobian of a moment function with respect to ρ."
    cols = []
    for j in range(ρ.size):
        e = np.zeros(ρ.size)
        e[j] = h * max(1.0, abs(ρ[j]))
        cols.append((moments(ρ + e) - moments(ρ - e)) / (2 * e[j]))
    return np.column_stack(cols)

def std_errors(moments, ρ, W, n, N):
    "Asymptotic standard errors from Theorem 1, including the simulation factor."
    M = jacobian(moments, ρ)
    V = np.linalg.inv(M.T @ W @ M) * (1 + n / N) / n
    return np.sqrt(np.diag(V))

se_emm = std_errors(moments_ar1, res.x, W, T, N)
se_mle = np.array([np.sqrt((1 - ρ1_mle**2) / T), σ_mle / np.sqrt(2 * T)])

print(f"{'':20}{'se ρ1':>10}{'se σ':>10}")
print(f"{'maximum likelihood':20}{se_mle[0]:10.4f}{se_mle[1]:10.4f}")
print(f"{'score matching':20}{se_emm[0]:10.4f}{se_emm[1]:10.4f}")

e_data = y_data[1:] - ρ1_mle * y_data[:-1]
kurt_e = ((e_data - e_data.mean())**4).mean() / e_data.var()**2
print(f"\nkurtosis of the residuals = {kurt_e:.2f}")
```

```
                      se ρ1      se σ
maximum likelihood      0.0189    0.0219
score matching          0.0188    0.0241

kurtosis of the residuals = 3.29
```

[2] The factor is 1.05 in the AR(1) example and 1.04 in the stochastic volatility example. It matters when N is not large relative to n.

The two standard errors for ρ_1 agree to three decimal places.

The score matching standard error for σ exceeds the maximum likelihood one by about 10 percent.

The simulation factor $1 + n/N = 1.05$ accounts for about 2.5 percent.

The weighting matrix $\tilde{\mathcal{J}}_n$ accounts for the rest: it estimates the variance of the σ score from the sample fourth moment of the residuals, whose kurtosis is 3.3 in this sample and 3 in the population.

Exercise 39.15.2 asks you to compare the sampling distributions of the two estimators.

39.10 A second example: stochastic volatility

Now we turn to a model whose likelihood function is intractable.

Section 4.2 of Gallant and Tauchen [1996] discusses a stochastic volatility model whose mean equation also contains an intercept and a lagged return.

We drop those two terms and study

$$
\begin{aligned}
y_t &= \exp(w_t)\, r_y\, z_t, \\
w_t &= a\, w_{t-1} + r_w\, \eta_t,
\end{aligned}
$$

with z_t and η_t independent standard normals and $\rho = (a, r_w, r_y)^\top$.

The observed return y_t has a volatility $\exp(w_t) r_y$ driven by a latent autoregression w_t.

Writing the likelihood of $\{y_t\}_{t=1}^n$ requires integrating the latent volatility path out of an n-dimensional integral,

$$
p(y_1, \ldots, y_n \mid \rho) = \int \cdots \int \prod_{t=1}^{n} \phi(y_t; 0, e^{2w_t} r_y^2)\, p(w_1, \ldots, w_n \mid a, r_w)\, dw_1 \cdots dw_n,
$$

which no analytic expression evaluates.

Simulating the model takes two lines of code.

The model generates fat tails and persistent volatility.

Gallant *et al.* [1997] fit the full model and extensions of it to 16,127 daily observations on the Standard and Poor's composite index, using SNP score generators.

Section 4.1 of Gallant and Tauchen [1996] notes that ARCH and GARCH models fit returns data well.

We choose as the auxiliary model a Gaussian GARCH(1,1),

$$
y_t = \mu + u_t, \qquad u_t = \sigma_t \nu_t, \qquad \sigma_t^2 = \omega + \alpha u_{t-1}^2 + \beta \sigma_{t-1}^2,
$$

with $\theta = (\mu, \omega, \alpha, \beta)^\top$ and $\nu_t \sim N(0, 1)$.

The GARCH conditional density depends on the entire past of y_t through the recursion for σ_t^2, so here x_t is the whole history.

Gallant and Tauchen call such a score generator non-Markov.

The structural parameters (a, r_w, r_y) describe a latent log-volatility process; the auxiliary parameters $(\mu, \omega, \alpha, \beta)$ describe a conditional variance recursion in observed returns.

The auxiliary model needs no economic interpretation.

Its credential is a good fit to the data.

We differentiate the GARCH log density numerically.

Numerical differentiation keeps the method general: an auxiliary model need only support evaluation of its log likelihood.

The code fits the GARCH model in the unconstrained coordinates $(\mu, \log\omega, \operatorname{logit}\alpha, \operatorname{logit}\beta)$.

The scores, the weighting matrix, and the moment vector all refer to those coordinates.

The reparameterization changes neither $\hat{\rho}_n$ nor the test statistic.

It multiplies the score by a fixed invertible matrix, and the criterion (39.3) is invariant to that transformation.

```

    return S
```

Section 4.2 reports no parameter values, so we choose our own.

Let's generate a long return series from the structural model.

```
rng = np.random.default_rng(5)
T = 2000
a_0, r_w0, r_y0 = 0.80, 0.20, 0.65
y_sv = simulate_sv(a_0, r_w0, r_y0, rng.standard_normal(T), rng.standard_normal(T))

kurt = ((y_sv - y_sv.mean())**4).mean() / y_sv.var()**2
print(f"standard deviation = {y_sv.std():.3f},  kurtosis = {kurt:.2f}")
```

```
standard deviation = 0.738,  kurtosis = 3.93
```

The population kurtosis of y_t is $3\exp(4r_w^2/(1-a^2)) = 4.7$ at these parameter values, above the Gaussian value of 3.

The sample kurtosis understates it, as sample kurtoses of heavy-tailed series often do.

```
fig, ax = plt.subplots()
ax.plot(y_sv, lw=0.6)
ax.set_xlabel('$t$')
ax.set_ylabel('$y_t$')
plt.show()
```

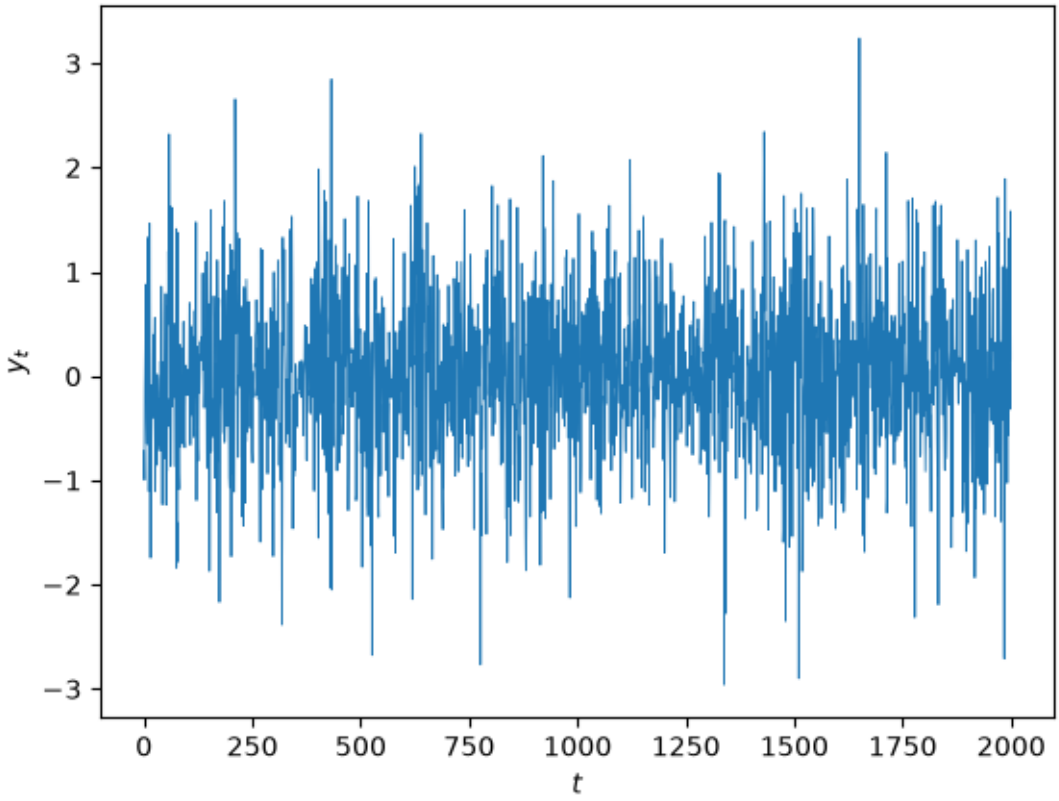

Fig. 39.2: Simulated returns from the SV model

Step 1 fits the GARCH auxiliary model to these data.

```
θ_start = np.array([0.0, np.log(0.05), -2.0, 1.5])
r = minimize(garch_negll, θ_start, args=(y_sv,), method='Nelder-Mead',
```

(continues on next page)

(continued from previous page)

```
            options=dict(maxiter=8000, xatol=1e-8, fatol=1e-8))
θ_sv = r.x
μ_h, ω_h, α_h, β_h = unpack(θ_sv)
print(f"auxiliary GARCH QMLE: μ = {μ_h:.4f}, ω = {ω_h:.4f}, "
      f"α = {α_h:.4f}, β = {β_h:.4f}   (α + β = {α_h + β_h:.4f})")

S_sv = garch_scores(θ_sv, y_sv)
W_sv = np.linalg.inv(S_sv.T @ S_sv / T)
```

```
auxiliary GARCH QMLE: μ = 0.0150, ω = 0.0922, α = 0.1209, β = 0.7127   (α + β = 0.
↪8337)
```

An $\alpha + \beta$ of 0.83 records the persistence of volatility that the auxiliary model reads off the data.

Steps 2 and 3 estimate the three structural parameters.

We search over unconstrained coordinates and reuse one pair of shock arrays throughout.

```
N = 50_000
z_sim, η_sim = rng.standard_normal(N), rng.standard_normal(N)

def moments_sv(ρ):
    y_s = simulate_sv(ρ[0], ρ[1], ρ[2], z_sim, η_sim)
    return garch_scores(θ_sv, y_s).mean(axis=0)

def to_ρ(u):
    "Map unconstrained coordinates to a in (0,1) and r_w, r_y > 0."
    return np.array([1 / (1 + np.exp(-u[0])), np.exp(u[1]), np.exp(u[2])])

def criterion_sv(u):
    if np.max(np.abs(u)) > 25:
        return 1e10
    m = moments_sv(to_ρ(u))
    return float(m @ W_sv @ m)

u_0 = np.array([np.log(0.6 / 0.4), np.log(0.3), np.log(0.5)])
res_sv = minimize(criterion_sv, u_0, method='Nelder-Mead',
                  options=dict(maxiter=400, xatol=1e-4, fatol=1e-10))
ρ_hat = to_ρ(res_sv.x)
```

Theorem 1 delivers standard errors.

```
se_sv = std_errors(moments_sv, ρ_hat, W_sv, T, N)

print(f"{'':17}{'a':>9}{'r_w':>9}{'r_y':>9}")
print(f"{'true values':17}{a_0:9.4f}{r_w0:9.4f}{r_y0:9.4f}")
print(f"{'score matching':17}" + "".join(f"{x:9.4f}" for x in ρ_hat))
print(f"{'standard errors':17}" + "".join(f"{x:9.4f}" for x in se_sv))
```

```
                         a       r_w       r_y
true values         0.8000    0.2000    0.6500
score matching      0.8447    0.1794    0.6700
standard errors     0.0404    0.0372    0.0244
```

The estimator locates all three parameters of a model whose likelihood function we never wrote down.

Each estimate lies within about one standard error of its true value.

The data pin down the scale r_y most precisely.

39.11 Testing the structural model

The auxiliary model has four parameters and the structural model has three, so one overidentifying restriction remains to be tested.

```
J_sv = T * criterion_sv(res_sv.x) / (1 + T / N)
df_sv = 4 - 3
print(f"J = {J_sv:.3f},  χ²({df_sv}) 5% critical value = {chi2.ppf(0.95, df_sv):.3f}")
```

```
J = 0.606,  χ²(1) 5% critical value = 3.841
```

The data give the structural model no trouble, as they should, because the structural model generated them.

A misspecified structural model fares differently.

Let's impose $r_w = 0$, which shuts down stochastic volatility and leaves a Gaussian white noise with one free parameter.

```
def moments_const_vol(v):
    "Moments of the constant volatility model r_w = 0, with v = log r_y; a has no␣
 ↪effect."
    return moments_sv(np.array([0.5, 1e-8, np.exp(v[0])]))

def criterion_const_vol(v):
    m = moments_const_vol(v)
    return float(m @ W_sv @ m)

r_cv = minimize(criterion_const_vol, np.array([0.0]), method='Nelder-Mead',
                options=dict(maxiter=200, xatol=1e-6))
J_cv = T * criterion_const_vol(r_cv.x) / (1 + T / N)
df_cv = 4 - 1
print(f"constant volatility model: J = {J_cv:.1f}, "
      f"χ²({df_cv}) 5% critical value = {chi2.ppf(0.95, df_cv):.3f}")
```

```
constant volatility model: J = 21.0, χ²(3) 5% critical value = 7.815
```

The test rejects the restricted model at the 1% level[3].

Gallant and Tauchen emphasize this second use of the machinery.

An auxiliary model that approximates the data well makes the test powerful against structural model error, and the individual score components say *which* features of the data a rejected model fails to match.

Gallant and Tauchen's **quasi-t-ratios** divide each component of $\sqrt{n}\, m(\hat{\rho}_n, \tilde{\theta}_n)$ by its standard error.

The asymptotic variance of $\sqrt{n}\, m(\hat{\rho}_n, \tilde{\theta}_n)$ is

$$\left(1 + \frac{n}{N}\right)\left[\mathcal{J}^0 - M^0\left((M^0)^\top (\mathcal{J}^0)^{-1} M^0\right)^{-1}(M^0)^\top\right].$$

Estimating ρ removes the variance in the directions that the columns of M^0 span.

The unconstrained coordinates transform each GARCH parameter separately through an increasing function.

[3] The $\chi^2(3)$ critical value is approximate here. Under the constant volatility null, the pseudo-true GARCH value has $\alpha = 0$, on the boundary of the parameter space, and β is then unidentified. In the code's coordinates, logit $\alpha \to -\infty$. Standard asymptotics do not apply. The weighting matrix raises no separate concern: under the null, the GARCH model with $\alpha = 0$ describes the data correctly, so its scores are martingale differences and the outer product is valid. Gallant and Tauchen observe that null hypotheses usually deliver such conditions.

The t-ratios are therefore the same as in the coordinates $(\mu, \omega, \alpha, \beta)$.

```
I_sv = S_sv.T @ S_sv / T
M_cv = jacobian(moments_const_vol, r_cv.x)
V_cv = (I_sv - M_cv @ np.linalg.inv(M_cv.T @ W_sv @ M_cv) @ M_cv.T) * (1 + T / N)
t_cv = np.sqrt(T) * moments_const_vol(r_cv.x) / np.sqrt(np.diag(V_cv))

for name, t in zip(['μ', 'ω', 'α', 'β'], t_cv):
    print(f"{name:>4}: {t:6.2f}")
```

```
   μ:  -0.75
   ω:  -3.04
   α:  -3.95
   β:  -2.79
```

The components for ω, α and β, which govern the conditional variance, carry the rejection.

The μ component does not.

Each negative sign says that, holding the other auxiliary parameters fixed, data from the constant volatility model would pull that parameter below the value that the observed data choose.

The constant volatility model matches the mean of returns and fails to reproduce the dependence of today's variance on yesterday's squared return.

Gallant *et al.* [1997] use the score vector of a rejected stochastic volatility model to diagnose its defects, and they then repair the model by thickening the tails of z_t and lengthening the memory of the volatility equation.

39.12 Applications

Gallant and Tauchen [2010] collects applications of the method to continuous-time models in finance.

Andersen *et al.* [2002] estimate stochastic volatility diffusions for the Standard and Poor's 500 index and reject them, and jump diffusions pass the same tests.

Other applications fit multifactor stochastic volatility models, term structure models of interest rates, and exchange rate models.

Bansal *et al.* [1995] fit a two-country general equilibrium monetary model to high-frequency currency market data, and Gallant and Tauchen [1996] propose fitting a one-sector stochastic growth model to consumption and stock returns.

Empirical auction models form another class of applications.

Game theory delivers the density of the winning bid under independent private values, and that density has a tractable form only for special valuation distributions.

Simulating from it is easy for any valuation distribution, so score matching brings all of the restrictions of the theory to bear.

39.13 Recovering the latent state

Having estimated ρ, a researcher often wants the latent state, such as the volatility path behind a return series.

Reprojection recovers it [Gallant and Tauchen, 2010].

Simulate a long path of states and observables at $\hat{\rho}_n$, calibrate inside the simulation the conditional distribution of the latent state given current and lagged observables, then evaluate those calibrated functions at the observed data.

Reprojection is a simulation-based nonlinear filter.

39.14 Related lectures

Statistical Divergence Measures develops the Kullback-Leibler divergence that appears in (39.5) and shows its link to maximum likelihood.

Likelihood Ratio Processes studies likelihood ratio processes and expresses their drift in terms of two KL divergences, a representation closely related to the projection step of this lecture.

Maximum Likelihood Estimation estimates parameters by maximum likelihood in settings where the likelihood is available.

Estimating Euler Equations by Generalized Method of Moments applies the generalized method of moments to Euler equations of an asset pricing model.

Mean of a Likelihood Ratio Process describes importance sampling, an alternative route to expectations that a model cannot deliver analytically.

39.15 Exercises

Exercise 39.15.1

Let the structural model at ρ have density $p(\cdot \mid \rho)$ and let the auxiliary family be $\{f(\cdot \mid \theta) : \theta \in \Theta\}$.

a. Show that

$$\frac{\partial}{\partial \theta} D_{KL}(p(\cdot \mid \rho) \,\|\, f(\cdot \mid \theta)) = -\, m(\rho, \theta),$$

where $m(\rho, \theta) = \mathbb{E}_{p(\cdot|\rho)}[\partial \ln f(\cdot \mid \theta)/\partial \theta]$.

b. Conclude that the pseudo-true value $\theta^0(\rho)$ satisfies $m(\rho, \theta^0(\rho)) = 0$.

c. Explain why $m(\rho^0, \theta^0) = 0$, and why the structural model does not need to nest inside the auxiliary family for this to hold.

Solution

For part a, write the divergence as

$$D_{KL}(p(\cdot \mid \rho) \,\|\, f(\cdot \mid \theta)) = \int p(y \mid \rho) \ln p(y \mid \rho)\, dy - \int p(y \mid \rho) \ln f(y \mid \theta)\, dy.$$

The first term does not involve θ.

Differentiating the second term under the integral sign gives

$$\frac{\partial}{\partial\theta} D_{KL} = -\int p(y \mid \rho) \frac{\partial}{\partial\theta} \ln f(y \mid \theta)\, dy = -m(\rho, \theta).$$

For part b, the pseudo-true value minimizes the divergence over θ.

An interior minimum sets the gradient to zero, so $m(\rho, \theta^0(\rho)) = 0$.

For part c, nature generated the data from ρ^0, so the quasi-maximum likelihood estimator $\tilde{\theta}_n$ converges to $\theta^0 = \theta^0(\rho^0)$, the KL projection of the true data generating process.

Part b evaluated at $\rho = \rho^0$ then gives $m(\rho^0, \theta^0) = 0$.

Nesting plays no role in this argument.

The pseudo-true value is defined as a projection whether or not the divergence at its minimum is zero, and the divergence is zero only in the nested case.

A misspecified auxiliary model still delivers valid moment conditions.

It costs efficiency.

It preserves consistency.

Exercise 39.15.2

Theorem 2 of Gallant and Tauchen [1996] says that the score matching estimator and the maximum likelihood estimator have the same asymptotic distribution when the structural model is smoothly embedded within the auxiliary model and simulation error is negligible.

Check this claim by Monte Carlo in the AR(1) and AR(2) example.

Generate 60 independent samples of length $T = 500$ from the structural AR(1) with $\rho_1 = 0.8$ and $\sigma = 1$.

For each sample compute both estimators, then compare their means, their standard deviations, and the correlation between them across replications.

Compare the Monte Carlo standard deviations with the asymptotic standard deviations that Theorem 2 delivers.

Solution

```

fig, axes = plt.subplots(1, 2)
for j, name in enumerate([r'$\rho_1$', r'$\sigma$']):
    axes[j].scatter(mle_draws[:, j], emm_draws[:, j], s=18)
    lo = min(mle_draws[:, j].min(), emm_draws[:, j].min())
    hi = max(mle_draws[:, j].max(), emm_draws[:, j].max())
    axes[j].plot([lo, hi], [lo, hi], 'k--', lw=1)
    axes[j].set_xlabel(f'maximum likelihood, {name}')
    axes[j].set_ylabel(f'score matching, {name}')
plt.tight_layout()
plt.show()
```

The two estimators have nearly identical standard deviations.

Both standard deviations are close to the asymptotic values $\sqrt{(1-\rho_1^2)/T}$ and $\sigma/\sqrt{2T}$ that Theorem 2 delivers.

The simulation factor $1 + T/N$ raises the score matching values by about 1 percent.

The correlation between the two estimators across replications sits very close to one, and the scatter plots hug the 45 degree line.

The two estimators are nearly the same random variable in each sample.

The means of the two estimators of ρ_1 differ by about 0.005.

Every replication shares the shock array `ε_mc`, so its simulation error shifts all 60 score matching estimates together.

The next cell repeats the score matching estimates of ρ_1 with three other shock arrays.

```
gap = (emm_draws[:, 0] - mle_draws[:, 0]).mean()
print(f"shock array ε_mc:       mean gap in ρ1 = {gap:7.4f}")
for seed in (100, 101, 102):
    ε_alt = np.random.default_rng(seed).standard_normal(N_mc)
    ρ1_alt = np.array([emm_estimate(y_r, ε_alt)[0] for y_r in samples])
    gap = (ρ1_alt - mle_draws[:, 0]).mean()
    print(f"shock array seed {seed}:  mean gap in ρ1 = {gap:7.4f}")
```

```
shock array ε_mc:       mean gap in ρ1 = -0.0047
shock array seed 100:  mean gap in ρ1 =  0.0013
shock array seed 101:  mean gap in ρ1 =  0.0041
shock array seed 102:  mean gap in ρ1 =  0.0004
```

The gap changes sign across shock arrays, so simulation error accounts for it.

Exercise 39.15.3

The order condition $k_\theta \geq k_\rho$ does not guarantee identification.

Gallant and Tauchen warn that the parameters of the mixing process of a stochastic volatility model need third and fourth moment information, and that the score of a Gaussian vector autoregression will not supply it.

Investigate their warning.

Replace the GARCH auxiliary model of the stochastic volatility example by a Gaussian AR(2), which has $k_\theta = 3$ parameters against $k_\rho = 3$ structural parameters, so the order condition holds.

With $k_\theta = k_\rho$ the model leaves no overidentifying restriction to test.

Minimize the resulting criterion from several different starting values and report the estimates together with the criterion values.

Explain what you find, and say which function of (a, r_w, r_y) the Gaussian AR(2) score does pin down.

Solution

```
θ_ar = ar2_qmle(y_sv)
S_ar = ar2_scores(θ_ar, y_sv)
W_ar = np.linalg.inv(S_ar.T @ S_ar / S_ar.shape[0])

def criterion_ar_score(u):
    if np.max(np.abs(u)) > 25:
        return 1e10
    ρ = to_ρ(u)
    if ρ[1] / np.sqrt(1 - ρ[0]**2) > 1.0:   # keep sd(w) where second moments stay␣
 ↪reliable
        return 1e10
    m = ar2_scores(θ_ar, simulate_sv(ρ[0], ρ[1], ρ[2], z_sim, η_sim)).mean(axis=0)
    return float(m @ W_ar @ m)

def implied_var(ρ):

criterion when the variance of y is badly wrong: 6.95e+01
```

The estimates wander all over the parameter space while the criterion stays near its floor.

A criterion of order 10^{-3} at each of these very different parameter vectors, against a value near 70 when the variance of y is badly wrong, reveals a flat valley in the criterion surface.

In this stochastic volatility model z_t is independent of the volatility path, so y_t is serially uncorrelated, though not independent, at every (a, r_w, r_y).

Write γ_j for the jth autocovariance of y_t under the structural model.

With $\gamma_1 = \gamma_2 = 0$, the three components of the Gaussian AR(2) score have expectations

$$-\frac{\theta_1 \gamma_0}{\varsigma^2}, \qquad -\frac{\theta_2 \gamma_0}{\varsigma^2}, \qquad -\frac{1}{\varsigma} + \frac{(1 + \theta_1^2 + \theta_2^2)\,\gamma_0}{\varsigma^3}.$$

All three depend on ρ only through γ_0, the variance

$$\mathbb{V}(y_t) = r_y^2 \exp\left(\frac{2 r_w^2}{1 - a^2}\right),$$

so one equation must determine three parameters.

In population, any (a, r_w, r_y) holding that expression fixed fits the Gaussian AR(2) score equally well.

The criterion does not fall to zero.

The sample autocorrelations of the data are not exactly zero, so $\tilde{\theta}_1$ and $\tilde{\theta}_2$ are not zero either, and no value of γ_0 sets all three expectations to zero.

In a finite simulation, Monte Carlo error in the simulated autocovariances perturbs the floor of the valley, so the minimized criterion differs a little across rows.

The table bears this out: the implied variances cluster near the variance of the data while the three parameters themselves differ wildly.

The code bounds the standard deviation of the log volatility process, $r_w / \sqrt{1 - a^2}$, which holds the search inside the region where simulated second moments are reliable.

A log volatility with a very large standard deviation makes $\exp(2w_t)$ so heavy tailed that the optimizer can drive the simulated moments to zero by exploiting Monte Carlo error alone.

Fat tails and volatility clustering are fourth moment phenomena, and a Gaussian autoregression records neither.

The GARCH auxiliary model used earlier does record both, through the dependence of its log density on u_t^2 / σ_t^2, and it identifies all three parameters.

Gallant and Tauchen recommend this diagnostic: flat spots in the criterion signal a score generator too small for the structural model.

Exercise 39.15.4

The stochastic volatility example sets $a = 0.8$.

Rerun it with $a = 0.95$, $r_w = 0.2$ and $r_y = 0.65$.

Log volatility then has standard deviation $r_w/\sqrt{1-a^2} = 0.64$, and the population kurtosis of y_t is about 15.5.

a. Compute the first three autocorrelations of each component of the GARCH score at the data.

b. Estimate $\mathcal{J}^0$ two more ways.

First, use Gallant and Tauchen's heteroskedasticity and autocorrelation consistent estimate. It adds to the outer product the sample autocovariances of the score at lags $\tau = 1, \ldots, \ell$, with $\ell = [n^{1/5}]$, weighted by the Parzen kernel $w(\tau/\ell)$, where

$$w(x) = \begin{cases} 1 - 6x^2 + 6x^3 & 0 \le x \le 1/2, \\ 2(1-x)^3 & 1/2 < x \le 1. \end{cases}$$

Second, at the estimate $\hat{\rho}_n$, simulate 300 independent data sets of length n from the structural model, compute $\sqrt{n}$ times the average GARCH score at $\tilde{\theta}_n$ in each, and take the covariance matrix across data sets.

Compare the diagonals of the three estimates.

c. Re-estimate ρ with each estimate of $\mathcal{J}^0$, and compare the Theorem 1 standard errors.

The Theorem 1 formula $\left[M^\top W M\right]^{-1}$ assumes that the weighting matrix W equals $(\mathcal{J}^0)^{-1}$.

For the outer-product and Parzen estimators, also compute the sandwich standard errors

$$\left(1 + \frac{n}{N}\right)\frac{1}{n}(M^\top W M)^{-1} M^\top W \mathcal{J} W M (M^\top W M)^{-1},$$

with the simulated estimate of $\mathcal{J}^0$ in place of $\mathcal{J}$.

d. Explain what you find.

```

The α and β components of the score have autocorrelations between 0.16 and 0.37 at lags 1 to 3.

A Gaussian GARCH model is a misspecified score generator for these data, and its scores are not martingale differences.

The outer product omits the autocovariances that the long-run variance $\mathcal{J}^0$ contains.

The simulated estimate of $\mathcal{J}^0$ is two to four times the outer product for the ω, α and β components.

The Parzen estimate closes less than half of that gap.

With $n = 2000$ its lag truncation is $\ell = 4$, and the Parzen weights at lags 1, 2 and 3 are 0.72, 0.25 and 0.03, so it discards much of the persistent autocovariance.

With the outer product as W, the Theorem 1 formula understates the standard errors of a and r_y by about a third.

The Parzen estimate raises those two standard errors by about a fifth.

The sandwich standard errors of the outer-product and Parzen estimators nearly equal the standard errors of the estimator that uses the simulated estimate of $\mathcal{J}^0$.

The three estimators are almost equally precise, and the estimates barely move.

The damage from a poor weighting matrix falls on the reported precision.

Here the estimator itself loses almost nothing.

The simulated estimate is itself imprecise.

The variance of the GARCH score depends on eighth moments of y_t, and those are enormous at these parameter values.

The simulated estimate also requires a preliminary estimate of ρ, the requirement that the outer product avoided.

Gallant and Tauchen's advice addresses the source of the problem: choose a score generator that fits.

Section *Choosing the score generator* explains why: adding terms to a series expansion pushes its scores toward martingale differences, and then the outer product is valid.

Part V

Linear Programming

CHAPTER

FORTY

OPTIMAL TRANSPORT

40.1 Overview

The **transportation** or **optimal transport** problem is interesting both because of its many applications and because of its important role in the history of economic theory.

In this lecture, we describe the problem, tell how linear programming is a key tool for solving it, and then provide some examples.

We will provide other applications in followup lectures.

Incentives for Information Transfer uses a transport problem with an extra averaging constraint to check whether one statistical experiment is a garbling of another.

The optimal transport problem was studied in early work about linear programming, as summarized for example by [Dorfman *et al.*, 1958]. A modern reference about applications in economics is [Galichon, 2016].

Below, we show how to solve the optimal transport problem using several implementations of linear programming, including, in order,

1. the linprog solver from SciPy,
2. the linprog_simplex solver from QuantEcon and
3. the simplex-based solvers included in the Python Optimal Transport package.

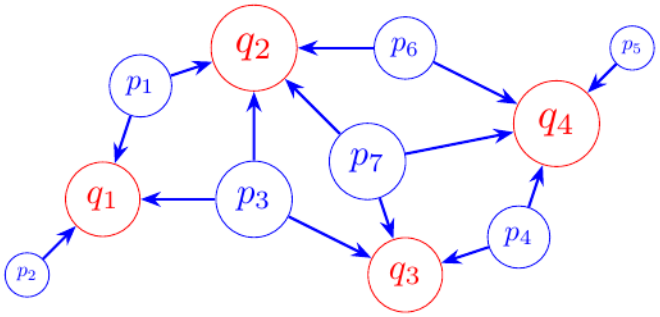
```
!pip install --upgrade quantecon
!pip install --upgrade POT
```

Let's start with some imports.

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.optimize import linprog
from quantecon.optimize.linprog_simplex import linprog_simplex
import ot
from scipy.stats import betabinom
import networkx as nx
```

40.2 The Optimal Transport Problem

Suppose that m factories produce goods that must be sent to n locations.



Let

- x_{ij} denote the quantity shipped from factory i to location j
- c_{ij} denote the cost of shipping one unit from factory i to location j
- p_i denote the capacity of factory i and q_j denote the amount required at location j.
- $i = 1, 2, \ldots, m$ and $j = 1, 2, \ldots, n$.

A planner wants to minimize total transportation costs subject to the following constraints:

- The amount shipped **from** each factory must equal its capacity.
- The amount shipped **to** each location must equal the quantity required there.

The figure below shows one visualization of this idea, when factories and target locations are distributed in the plane.

The size of the vertices in the figure are proportional to

- capacity, for the factories, and
- demand (amount required) for the target locations.

The arrows show one possible transport plan, which respects the constraints stated above.

The planner's problem can be expressed as the following constrained minimization problem:

$$\begin{aligned} \min_{x_{ij}} \ & \sum_{i=1}^{m} \sum_{j=1}^{n} c_{ij} x_{ij} \\ \text{subject to} \ & \sum_{j=1}^{n} x_{ij} = p_i, \quad i = 1, 2, \ldots, m \\ & \sum_{i=1}^{m} x_{ij} = q_j, \quad j = 1, 2, \ldots, n \\ & x_{ij} \geq 0 \end{aligned} \tag{40.1}$$

This is an **optimal transport problem** with

- mn decision variables, namely, the entries x_{ij} and
- $m + n$ constraints.

Summing the q_j's across all j's and the p_i's across all i's indicates that the total capacity of all the factories equals total requirements at all locations:

$$\sum_{j=1}^{n} q_j = \sum_{j=1}^{n} \sum_{i=1}^{m} x_{ij} = \sum_{i=1}^{m} \sum_{j=1}^{n} x_{ij} = \sum_{i=1}^{m} p_i \tag{40.2}$$

The presence of the restrictions in (40.2) will be the source of one redundancy in the complete set of restrictions that we describe below.

More about this later.

40.3 The Linear Programming Approach

In this section we discuss using using standard linear programming solvers to tackle the optimal transport problem.

40.3.1 Vectorizing a Matrix of Decision Variables

A *matrix* of decision variables x_{ij} appears in problem (40.1).

The SciPy function `linprog` expects to see a *vector* of decision variables.

This situation impels us to rewrite our problem in terms of a *vector* of decision variables.

Let

- X, C be $m \times n$ matrices with entries x_{ij}, c_{ij},
- p be m-dimensional vector with entries p_i,
- q be n-dimensional vector with entries q_j.

With $\mathbf{1}_n$ denoting the n-dimensional column vector $(1, 1, \ldots, 1)'$, our problem can now be expressed compactly as:

$$\begin{aligned} \min_X \ & \text{tr}(C'X) \\ \text{subject to } & X\,\mathbf{1}_n = p \\ & X'\,\mathbf{1}_m = q \\ & X \geq 0 \end{aligned}$$

We can convert the matrix X into a vector by stacking all of its columns into a column vector.

Doing this is called **vectorization**, an operation that we denote $\text{vec}(X)$.

Similarly, we convert the matrix C into an mn-dimensional vector $\text{vec}(C)$.

The objective function can be expressed as the inner product between $\text{vec}(C)$ and $\text{vec}(X)$:

$$\text{vec}(C)' \cdot \text{vec}(X).$$

To express the constraints in terms of $\text{vec}(X)$, we use a **Kronecker product** denoted by $\otimes$ and defined as follows.

Suppose A is an $m \times s$ matrix with entries (a_{ij}) and that B is an $n \times t$ matrix.

The **Kronecker product** of A and B is defined, in block matrix form, by

$$A \otimes B = \begin{bmatrix} a_{11}B & a_{12}B & \ldots & a_{1s}B \\ a_{21}B & a_{22}B & \ldots & a_{2s}B \\ & & \vdots & \\ a_{m1}B & a_{m2}B & \ldots & a_{ms}B \end{bmatrix}.$$

$A \otimes B$ is an $mn \times st$ matrix.

It has the property that for any $m \times n$ matrix X

$$\text{vec}(A'XB) = (B' \otimes A')\,\text{vec}(X). \tag{40.3}$$

We can now express our constraints in terms of $\text{vec}(X)$.

Let $A = \mathbf{I}'_m$, $B = \mathbf{1}_n$.

By equation (40.3)

$$X\,\mathbf{1}_n = \text{vec}(X\,\mathbf{1}_n) = \text{vec}(\mathbf{I}_m X\,\mathbf{1}_n) = (\mathbf{1}'_n \otimes \mathbf{I}_m)\,\text{vec}(X).$$

where $\mathbf{I}_m$ denotes the $m \times m$ identity matrix.

Constraint $X\,\mathbf{1}_n = p$ can now be written as:

$$(\mathbf{1}'_n \otimes \mathbf{I}_m)\,\text{vec}(X) = p.$$

Similarly, the constraint $X'\,\mathbf{1}_m = q$ can be rewriten as:

$$(\mathbf{I}_n \otimes \mathbf{1}'_m)\,\text{vec}(X) = q.$$

With $z := \text{vec}(X)$, our problem can now be expressed in terms of an mn-dimensional vector of decision variables:

$$\begin{aligned} \min_z \ & \text{vec}(C)'z \\ \text{subject to } \ & Az = b \\ & z \geq 0 \end{aligned} \tag{40.4}$$

where

$$A = \begin{bmatrix} \mathbf{1}'_n \otimes \mathbf{I}_m \\ \mathbf{I}_n \otimes \mathbf{1}'_m \end{bmatrix} \quad \text{and} \quad b = \begin{bmatrix} p \\ q \end{bmatrix}$$

40.3.2 An Application

We now provide an example that takes the form (40.4) that we'll solve by deploying the function `linprog`.

The table below provides numbers for the requirements vector q, the capacity vector p, and entries c_{ij} of the cost-of-shipping matrix C.

The numbers in the above table tell us to set $m = 3$, $n = 5$, and construct the following objects:

$$p = \begin{bmatrix} 50 \\ 100 \\ 150 \end{bmatrix}, \quad q = \begin{bmatrix} 25 \\ 115 \\ 60 \\ 30 \\ 70 \end{bmatrix} \quad \text{and} \quad C = \begin{bmatrix} 10 & 15 & 20 & 20 & 40 \\ 20 & 40 & 15 & 30 & 30 \\ 30 & 35 & 40 & 55 & 25 \end{bmatrix}.$$

Let's write Python code that sets up the problem and solves it.

```
# Define parameters
m = 3
n = 5

p = np.array([50.0, 100.0, 150.0])
```

(continues on next page)

(continued from previous page)

```
q = np.array([25.0, 115.0, 60.0, 30.0, 70.0])

C = np.array([[10.0, 15.0, 20.0, 20.0, 40.0],
              [20.0, 40.0, 15.0, 30.0, 30.0],
              [30.0, 35.0, 40.0, 55.0, 25.0]])

# Vectorize matrix C
C_vec = C.reshape((m*n, 1), order='F')

# Construct matrix A by Kronecker product
A1 = np.kron(np.ones((1, n)), np.identity(m))
A2 = np.kron(np.identity(n), np.ones((1, m)))
A = np.vstack([A1, A2])

# Construct vector b
b = np.hstack([p, q])

# Solve the primal problem
res = linprog(C_vec, A_eq=A, b_eq=b)

# Print results
print("message:", res.message)
print("nit:", res.nit)
print("fun:", res.fun)
print("z:", res.x)
print("X:", res.x.reshape((m,n), order='F'))
```

```
message: Optimization terminated successfully. (HiGHS Status 7: Optimal)
nit: 8
fun: 7225.0
z: [ 0. 10. 15. 50.  0. 65.  0. 60.  0.  0. 30.  0.  0.  0. 70.]
X: [[ 0. 50.  0.  0.  0.]
 [10.  0. 60. 30.  0.]
 [15. 65.  0.  0. 70.]]
```

Notice how, in the line `C_vec = C.reshape((m*n, 1), order='F')`, we are careful to vectorize using the flag `order='F'`.

This is consistent with converting C into a vector by stacking all of its columns into a column vector.

Here `'F'` stands for "Fortran", and we are using Fortran style column-major order.

(For an alternative approach, using Python's default row-major ordering, see this lecture by Alfred Galichon.)

Interpreting the solver behavior:

Looking at matrix A, we can see that it is rank deficient.

```
np.linalg.matrix_rank(A) < min(A.shape)
```

```
np.True_
```

This indicates that the linear program has been set up to include one or more redundant constraints.

Here, the source of the redundancy is the structure of restrictions (40.2).

Let's explore this further by printing out A and staring at it.

```
A
```

```
array([[1., 0., 0., 1., 0., 0., 1., 0., 0., 1., 0., 0., 1., 0., 0.],
       [0., 1., 0., 0., 1., 0., 0., 1., 0., 0., 1., 0., 0., 1., 0.],
       [0., 0., 1., 0., 0., 1., 0., 0., 1., 0., 0., 1., 0., 0., 1.],
       [1., 1., 1., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0.],
       [0., 0., 0., 1., 1., 1., 0., 0., 0., 0., 0., 0., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 1., 1., 1., 0., 0., 0., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 0., 0., 0., 1., 1., 1., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 1., 1., 1.]])
```

The singularity of A reflects that the first three constraints and the last five constraints both require that "total requirements equal total capacities" expressed in (40.2).

One equality constraint here is redundant.

Fortunately, SciPy's `linprog` function handles the redundant constraints automatically without explicitly warning about rank deficiency.

But we can drop one of the equality constraints, and use only 7 of them.

After doing this, we attain the same minimized cost.

However, we find a different transportation plan.

Though it is a different plan, it attains the same cost!

```
linprog(C_vec, A_eq=A[:-1], b_eq=b[:-1])
```

```

```

Evidently, it is slightly quicker to work with the system that removed a redundant constraint.

Let's drill down and do some more calculations to help us understand whether or not our finding **two** different optimal transport plans reflects our having dropped a redundant equality constraint.

Hint

It will turn out that dropping a redundant equality isn't really what mattered.

To verify our hint, we shall simply use **all** of the original equality constraints (including a redundant one), but we'll just shuffle the order of the constraints.

```
arr = np.arange(m+n)
```

```
sol_found = []
cost = []
rng = np.random.default_rng()

# simulate 1000 times
for i in range(1000):

    rng.shuffle(arr)
    res_shuffle = linprog(C_vec, A_eq=A[arr], b_eq=b[arr])

    # if find a new solution
    sol = tuple(res_shuffle.x)
    if sol not in sol_found:
        sol_found.append(sol)
        cost.append(res_shuffle.fun)
```

```
for i in range(len(sol_found)):
    print(f"transportation plan {i}: ", sol_found[i])
    print(f"     minimized cost {i}: ", cost[i])
```

```
transportation plan 0:  (np.float64(0.0), np.float64(10.0), np.float64(15.0), np.
↪float64(50.0), np.float64(0.0), np.float64(65.0), np.float64(0.0), np.float64(60.
↪0), np.float64(0.0), np.float64(0.0), np.float64(30.0), np.float64(0.0), np.
↪float64(0.0), np.float64(0.0), np.float64(70.0))
    minimized cost 0:  7225.0
```

Ah hah! As you can see, putting constraints in different orders in this case uncovers two optimal transportation plans that achieve the same minimized cost.

These are the same two plans computed earlier.

Next, we show that leaving out the first constraint "accidentally" leads to the initial plan that we computed.

```
linprog(C_vec, A_eq=A[1:], b_eq=b[1:])
```

```
        message: Optimization terminated successfully. (HiGHS Status 7: Optimal)
        success: True
         status: 0
            fun: 7225.0
              x: [ 0.000e+00  1.000e+01 ...  0.000e+00  7.000e+01]
            nit: 8
          lower:  residual: [ 0.000e+00  1.000e+01 ...  0.000e+00
                              7.000e+01]
                 marginals: [ 0.000e+00  0.000e+00 ...  1.500e+01
                              0.000e+00]
          upper:  residual: [       inf        inf ...        inf
```

(continues on next page)

(continued from previous page)

```
                                  inf]
                marginals: [ 0.000e+00  0.000e+00 ...  0.000e+00
                             0.000e+00]
          eqlin:  residual: [ 0.000e+00  0.000e+00  0.000e+00  0.000e+00
                             0.000e+00  0.000e+00  0.000e+00]
                marginals: [ 1.000e+01  2.000e+01  1.000e+01  1.500e+01
                             5.000e+00  2.000e+01  5.000e+00]
        ineqlin:  residual: []
                marginals: []
 mip_node_count: 0
 mip_dual_bound: 0.0
        mip_gap: 0.0
```

Let's compare this transport plan with

```
res.x
```

```
array([ 0., 10., 15., 50.,  0., 65.,  0., 60.,  0.,  0., 30.,  0.,  0.,
        0., 70.])
```

Here the matrix X contains entries x_{ij} that tell amounts shipped **from** factor $i = 1, 2, 3$ **to** location $j = 1, 2, \ldots, 5$.

The vector z evidently equals vec(X).

The minimized cost from the optimal transport plan is given by the fun variable.

40.3.3 Using a Just-in-Time Compiler

We can also solve optimal transportation problems using a powerful tool from QuantEcon, namely, `quantecon.optimize.linprog_simplex`.

While `scipy.optimize.linprog` uses the HiGHS solver by default, `quantecon.optimize.linprog_simplex` implements the simplex algorithm accelerated by using a just-in-time compiler shipped in the `numba` library.

As you will see very soon, by using `quantecon.optimize.linprog_simplex` the time required to solve an optimal transportation problem can be reduced significantly.

```
# construct matrices/vectors for linprog_simplex
c = C.flatten()

# Equality constraints
A_eq = np.zeros((m+n, m*n))
for i in range(m):
    for j in range(n):
        A_eq[i, i*n+j] = 1
        A_eq[m+j, i*n+j] = 1

b_eq = np.hstack([p, q])
```

Since `quantecon.optimize.linprog_simplex` does maximization instead of minimization, we need to put a negative sign before vector `c`.

```
res_qe = linprog_simplex(-c, A_eq=A_eq, b_eq=b_eq)
```

While the two LP solvers use different algorithms (HiGHS vs. simplex), both should find optimal solutions.

The solutions differs since there are multiple optimal solutions, but the objective values are the same

```
np.allclose(-res_qe.fun, res.fun)
```

```
True
```

```
res_qe.x.reshape((m, n), order='C')
```

```
array([[15., 35.,  0.,  0.,  0.],
       [10.,  0., 60., 30.,  0.],
       [ 0., 80.,  0.,  0., 70.]])
```

```
res.x.reshape((m, n), order='F')
```

```
array([[ 0., 50.,  0.,  0.,  0.],
       [10.,  0., 60., 30.,  0.],
       [15., 65.,  0.,  0., 70.]])
```

Let's do a speed comparison between `scipy.optimize.linprog` and `quantecon.optimize.linprog_simplex`.

```
# scipy.optimize.linprog
%time res = linprog(C_vec, A_eq=A[:-1, :], b_eq=b[:-1])
```

```
CPU times: user 2.39 ms, sys: 17 µs, total: 2.41 ms
Wall time: 2.24 ms
```

```
# quantecon.optimize.linprog_simplex
%time out = linprog_simplex(-c, A_eq=A_eq, b_eq=b_eq)
```

```
CPU times: user 57 µs, sys: 3 µs, total: 60 µs
Wall time: 63.4 µs
```

As you can see, the `quantecon.optimize.linprog_simplex` is much faster.

(Note however, that the SciPy version is probably more stable than the QuantEcon version, having been tested more extensively over a longer period of time.)

40.4 The Dual Problem

Let u, v denotes vectors of dual decision variables with entries $(u_i), (v_j)$.

The **dual** to **minimization** problem (40.1) is the **maximization** problem:

$$\max_{u_i, v_j} \sum_{i=1}^{m} p_i u_i + \sum_{j=1}^{n} q_j v_j$$
$$\text{subject to } u_i + v_j \leq c_{ij},\ i = 1, 2, \dots, m;\ j = 1, 2, \dots, n \tag{40.5}$$

The dual problem is also a linear programming problem.

It has $m + n$ dual variables and mn constraints.

Vectors u and v of **values** are attached to the first and the second sets of primal constraits, respectively.

Thus, u is attached to the constraints

- $(\mathbf{1}'_n \otimes \mathbf{I}_m)\,\text{vec}(X) = p$

and v is attached to constraints

- $(\mathbf{I}_n \otimes \mathbf{1}'_m)\,\text{vec}(X) = q$.

Components of the vectors u and v of per unit **values** are **shadow prices** of the quantities appearing on the right sides of those constraints.

We can write the dual problem as

$$\begin{aligned} &\max_{u_i, v_j} pu + qv \\ &\text{subject to } A' \begin{bmatrix} u \\ v \end{bmatrix} = \text{vec}(C) \end{aligned} \tag{40.6}$$

For the same numerical example described above, let's solve the dual problem.

```
# Solve the dual problem
res_dual = linprog(-b, A_ub=A.T, b_ub=C_vec,
                   bounds=[(None, None)]*(m+n))

#Print results
print("message:", res_dual.message)
print("nit:", res_dual.nit)
print("fun:", res_dual.fun)
print("u:", res_dual.x[:m])
print("v:", res_dual.x[-n:])
```

```
message: Optimization terminated successfully. (HiGHS Status 7: Optimal)
nit: 9
fun: -7225.0
u: [-20. -10.   0.]
v: [30. 35. 25. 40. 25.]
```

`quantecon.optimize.linprog_simplex` computes and returns the dual variables alongside the primal solution.

The dual variables (shadow prices) can be extracted directly from the primal solution:

```
# The dual variables are returned by linprog_simplex
print("Dual variables from linprog_simplex:")
print("u:", -res_qe.lambd[:m])
print("v:", -res_qe.lambd[m:])
```

```
Dual variables from linprog_simplex:
u: [-20. -10.  -0.]
v: [30. 35. 25. 40. 25.]
```

We can verify these match the dual solution from SciPy:

```
print("Dual variables from SciPy linprog:")
print("u:", res_dual.x[:m])
print("v:", res_dual.x[-n:])
```

```
Dual variables from SciPy linprog:
u: [-20. -10.   0.]
v: [30. 35. 25. 40. 25.]
```

40.4.1 Interpretation of dual problem

By **strong duality** (please see this lecture Linear Programming), we know that:

$$\sum_{i=1}^{m}\sum_{j=1}^{n} c_{ij}x_{ij} = \sum_{i=1}^{m} p_i u_i + \sum_{j=1}^{n} q_j v_j$$

One unit more capacity in factory i, i.e. p_i, results in u_i more transportation costs.

Thus, u_i describes the cost of shipping one unit **from** factory i.

Call this the ship-out cost of one unit shipped from factory i.

Similarly, v_j is the cost of shipping one unit **to** location j.

Call this the ship-in cost of one unit to location j.

Strong duality implies that total transprotation costs equals total ship-out costs **plus** total ship-in costs.

It is reasonable that, for one unit of a product, ship-out cost u_i **plus** ship-in cost v_j should equal transportation cost c_{ij}.

This equality is assured by **complementary slackness** conditions that state that whenever $x_{ij} > 0$, meaning that there are positive shipments from factory i to location j, it must be true that $u_i + v_j = c_{ij}$.

40.5 The Python Optimal Transport Package

There is an excellent Python package for optimal transport that simplifies some of the steps we took above.

In particular, the package takes care of the vectorization steps before passing the data out to a linear programming routine.

(That said, the discussion provided above on vectorization remains important, since we want to understand what happens under the hood.)

40.5.1 Replicating Previous Results

The following line of code solves the example application discussed above using linear programming.

```
X = ot.emd(p, q, C)
X
```

```
array([[15., 35.,  0.,  0.,  0.],
       [10.,  0., 60., 30.,  0.],
       [ 0., 80.,  0.,  0., 70.]])
```

Sure enough, we have the same solution and the same cost

```
total_cost = np.vdot(X, C)
total_cost
```

```
np.float64(7225.0)
```

Here we use np.vdot for the trace inner product of X and C

40.5.2 A Larger Application

Now let's try using the same package on a slightly larger application.

The application has the same interpretation as above but we will also give each node (i.e., vertex) a location in the plane.

This will allow us to plot the resulting transport plan as edges in a graph.

The following class defines a node by

- its location $(x, y) \in \mathbb{R}^2$,
- its group (factory or location, denoted by `p` or `q`) and
- its mass (e.g., p_i or q_j).

```
class Node:

    def __init__(self, x, y, mass, group, name):

        self.x, self.y = x, y
        self.mass, self.group = mass, group
        self.name = name
```

Next we write a function that repeatedly calls the class above to build instances.

It allocates to the nodes it creates their location, mass, and group.

Locations are assigned randomly.

```
def build_nodes_of_one_type(group='p', n=100, seed=123):

    nodes = []
    rng = np.random.default_rng(seed)

    for i in range(n):

        if group == 'p':
            m = 1/n
            x = rng.uniform(-2, 2)
            y = rng.uniform(-2, 2)
        else:
            m = betabinom.pmf(i, n-1, 2, 2)
            x = 0.6 * rng.uniform(-1.5, 1.5)
            y = 0.6 * rng.uniform(-1.5, 1.5)

        name = group + str(i)
        nodes.append(Node(x, y, m, group, name))

    return nodes
```

Now we build two lists of nodes, each one containing one type (factories or locations)

```
n_p = 32
n_q = 32
p_list = build_nodes_of_one_type(group='p', n=n_p)
q_list = build_nodes_of_one_type(group='q', n=n_q)

p_probs = [p.mass for p in p_list]
q_probs = [q.mass for q in q_list]
```

For the cost matrix C, we use the Euclidean distance between each factory and location.

```
c = np.empty((n_p, n_q))
for i in range(n_p):
    for j in range(n_q):
        x0, y0 = p_list[i].x, p_list[i].y
        x1, y1 = q_list[j].x, q_list[j].y
        c[i, j] = np.sqrt((x0-x1)**2 + (y0-y1)**2)
```

Now we are ready to apply the solver

```
%time pi = ot.emd(p_probs, q_probs, c)
```

```
CPU times: user 540 µs, sys: 24 µs, total: 564 µs
Wall time: 393 µs
```

Finally, let's plot the results using `networkx`.

In the plot below,

- node size is proportional to probability mass
- an edge (arrow) from i to j is drawn when a positive transfer is made from i to j under the optimal transport plan.

```
g = nx.DiGraph()
g.add_nodes_from([p.name for p in p_list])
g.add_nodes_from([q.name for q in q_list])

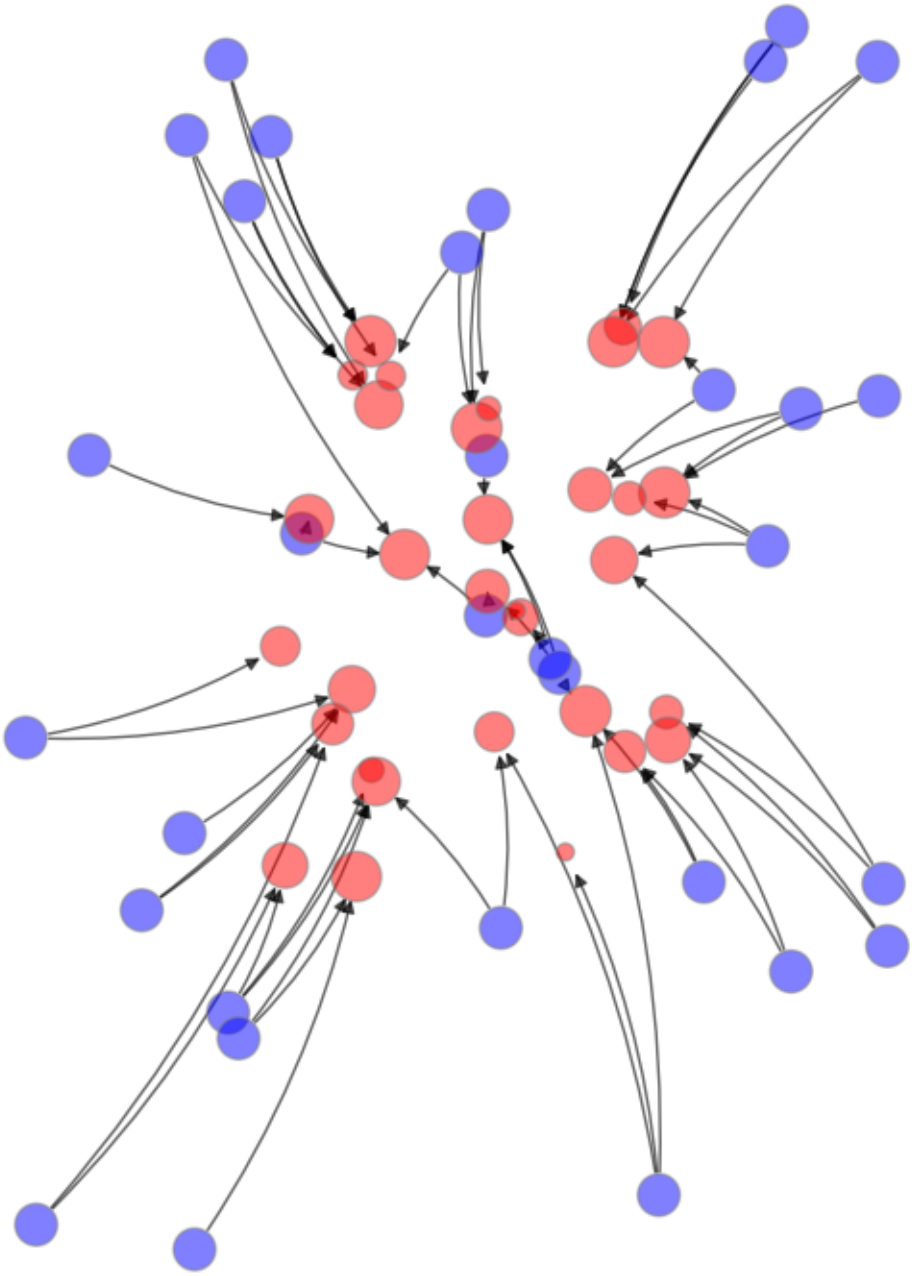
for i in range(n_p):
    for j in range(n_q):
        if pi[i, j] > 0:
            g.add_edge(p_list[i].name, q_list[j].name, weight=pi[i, j])

node_pos_dict={}
for p in p_list:
    node_pos_dict[p.name] = (p.x, p.y)

for q in q_list:
    node_pos_dict[q.name] = (q.x, q.y)

node_color_list = []
node_size_list = []
scale = 8_000
for p in p_list:
    node_color_list.append('blue')
    node_size_list.append(p.mass * scale)
for q in q_list:
    node_color_list.append('red')
    node_size_list.append(q.mass * scale)

fig, ax = plt.subplots(figsize=(7, 10))
plt.axis('off')



nx.draw_networkx_nodes(g,
                       node_pos_dict,
                       node_color=node_color_list,
                       node_size=node_size_list,
                       edgecolors='grey',
```

(continues on next page)

(continued from previous page)

```
                        linewidths=1,
                        alpha=0.5,
                        ax=ax)

nx.draw_networkx_edges(g,
                        node_pos_dict,
                        arrows=True,
                        connectionstyle='arc3,rad=0.1',
                        alpha=0.6)
plt.show()
```

CHAPTER

FORTYONE

VON NEUMANN GROWTH MODEL (AND A GENERALIZATION)

Contents

- *Von Neumann Growth Model (and a Generalization)*
  - *Notation*
  - *Model Ingredients and Assumptions*
  - *Dynamic Interpretation*
  - *Duality*
  - *Interpretation as Two-player Zero-sum Game*

This lecture uses the class `Neumann` to calculate key objects of a linear growth model of John von Neumann [von Neumann, 1937] that was generalized by Kemeny, Morgenstern and Thompson [Kemeny *et al.*, 1956].

Objects of interest are the maximal expansion rate (α), the interest factor (β), the optimal intensities (x), and prices (p).

In addition to watching how the towering mind of John von Neumann formulated an equilibrium model of price and quantity vectors in balanced growth, this lecture shows how fruitfully to employ the following important tools:

- a zero-sum two-player game
- linear programming
- the Perron-Frobenius theorem

We'll begin with some imports:

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.optimize import fsolve, linprog
from textwrap import dedent

np.set_printoptions(precision=2)
```

The code below provides the `Neumann` class

```
class Neumann:

    """
    This class describes the Generalized von Neumann growth model as it was
    discussed in Kemeny et al. (1956, ECTA) and Gale (1960, Chapter 9.5):
```

(continues on next page)

(continued from previous page)

```
    Let:
    n ... number of goods
    m ... number of activities
    A ... input matrix is m-by-n
        a_{i,j} - amount of good j consumed by activity i
    B ... output matrix is m-by-n
        b_{i,j} - amount of good j produced by activity i

    x ... intensity vector (m-vector) with non-negative entries
        x'B - the vector of goods produced
        x'A - the vector of goods consumed
    p ... price vector (n-vector) with non-negative entries
        Bp - the revenue vector for every activity
        Ap - the cost of each activity

    Both A and B have non-negative entries. Moreover, we assume that
    (1) Assumption I (every good which is consumed is also produced):
        for all j, b_{.,j} > 0, i.e. at least one entry is strictly positive
    (2) Assumption II (no free lunch):
        for all i, a_{i,.} > 0, i.e. at least one entry is strictly positive

    Parameters
    ----------
    A : array_like or scalar(float)
        Part of the state transition equation.  It should be `n x n`
    B : array_like or scalar(float)
        Part of the state transition equation.  It should be `n x k`
    """

41.1 Notation

We use the following notation.

0 denotes a vector of zeros.

We call an n-vector **positive** and write $x \gg \mathbf{0}$ if $x_i > 0$ for all $i = 1, 2, \dots, n$.

We call a vector **non-negative** and write $x \geq \mathbf{0}$ if $x_i \geq 0$ for all $i = 1, 2, \dots, n$.

We call a vector **semi-positive** written $x > \mathbf{0}$ if $x \geq \mathbf{0}$ and $x \neq \mathbf{0}$.

For two conformable vectors x and y, $x \gg y$, $x \geq y$ and $x > y$ mean $x - y \gg \mathbf{0}$, $x - y \geq \mathbf{0}$, and $x - y > \mathbf{0}$, respectively.

We let all vectors in this lecture be column vectors; $x^\top$ denotes the transpose of x (i.e., a row vector).

Let ι_n denote a column vector composed of n ones, i.e. $\iota_n = (1, 1, \dots, 1)^\top$.

Let e^i denote a vector (of arbitrary size) containing zeros except for the i th position where it is one.

We denote matrices by capital letters. For an arbitrary matrix A, $a_{i,j}$ represents the entry in its i th row and j th column. $a_{.j}$ and $a_{i.}$ denote the j th column and i th row of A, respectively.

41.2 Model Ingredients and Assumptions

A pair (A, B) of $m \times n$ non-negative matrices defines an economy.

- m is the number of **activities** (or sectors)
- n is the number of **goods** (produced and/or consumed)
- A is called the **input matrix**; $a_{i,j}$ denotes the amount of good j consumed by activity i
- B is called the **output matrix**; $b_{i,j}$ represents the amount of good j produced by activity i

Two key assumptions restrict economy (A, B):

Assumption 41.2.1 (every good that is consumed is also produced)

$$b_{.,j} > \mathbf{0} \quad \forall j = 1, 2, \ldots, n$$

Assumption 41.2.2 (no free lunch)

$$a_{i,.} > \mathbf{0} \quad \forall i = 1, 2, \ldots, m$$

A semi-positive **intensity** m-vector x denotes levels at which activities are operated.

Therefore,

- vector $x^\top A$ gives the total amount of **goods used in production**
- vector $x^\top B$ gives **total outputs**

An economy (A, B) is said to be **productive**, if there exists a non-negative intensity vector $x \geq 0$ such that $x^\top B > x^\top A$.

The semi-positive n-vector p contains prices assigned to the n goods.

The p vector implies **cost** and **revenue** vectors

- the vector Ap tells **costs** of the vector of activities
- the vector Bp tells **revenues** from the vector of activities

Satisfaction of a property of an input-output pair (A, B) called **irreducibility** (or indecomposability) determines whether an economy can be decomposed into multiple "sub-economies".

Definition 41.2.1

For an economy (A, B), the set of goods $S \subset \{1, 2, \ldots, n\}$ is called an **independent subset** if it is possible to produce every good in S without consuming goods from outside S.

Formally, the set S is independent if $\exists T \subset \{1, 2, \ldots, m\}$ (a subset of activities) such that $a_{i,j} = 0$, $\forall i \in T$ and $j \in S^c$ and for all $j \in S$, $\exists i \in T$ for which $b_{i,j} > 0$.

The economy is **irreducible** if there are no proper independent subsets.

We study two examples, both in Chapter 9.6 of Gale [Gale, 1989]

```
# (1) Irreducible (A, B) example: α_0 = β_0
A1 = np.array([[0, 1, 0, 0],
               [1, 0, 0, 1],
               [0, 0, 1, 0]])

B1 = np.array([[1, 0, 0, 0],
               [0, 0, 2, 0],
               [0, 1, 0, 1]])

# (2) Reducible (A, B) example: β_0 < α_0
A2 = np.array([[0, 1, 0, 0, 0, 0],
               [1, 0, 1, 0, 0, 0],
               [0, 0, 0, 1, 0, 0],
               [0, 0, 1, 0, 0, 1],
               [0, 0, 0, 0, 1, 0]])

B2 = np.array([[1, 0, 0, 1, 0, 0],
               [0, 1, 0, 0, 0, 0],
               [0, 0, 1, 0, 0, 0],
               [0, 0, 0, 0, 2, 0],
               [0, 0, 0, 1, 0, 1]])
```

The following code sets up our first Neumann economy or `Neumann` instance

```
n1 = Neumann(A1, B1)
n1
```

```
Generalized von Neumann expanding model:
  - number of goods          : 4
  - number of activities     : 3

Assumptions:
  - AI:  every column of B has a positive entry    : True
  - AII: every row of A has a positive entry       : True
```

Here is a second instance of a Neumann economy

```
n2 = Neumann(A2, B2)
n2
```

```
Generalized von Neumann expanding model:
  - number of goods          : 6
  - number of activities     : 5

Assumptions:
  - AI:  every column of B has a positive entry    : True
  - AII: every row of A has a positive entry       : True
```

41.3 Dynamic Interpretation

Attach a time index t to the preceding objects, regard an economy as a dynamic system, and study sequences

$$\{(A_t, B_t)\}_{t\geq 0}, \qquad \{x_t\}_{t\geq 0}, \qquad \{p_t\}_{t\geq 0}$$

An interesting special case holds the technology process constant and investigates the dynamics of quantities and prices only.

Accordingly, in the rest of this lecture, we assume that $(A_t, B_t) = (A, B)$ for all $t \geq 0$.

A crucial element of the dynamic interpretation involves the timing of production.

We assume that production (consumption of inputs) takes place in period t, while the consequent output materializes in period $t + 1$, i.e., consumption of $x_t^\top A$ in period t results in $x_t^\top B$ amounts of output in period $t + 1$.

These timing conventions imply the following feasibility condition:

$$x_t^\top B \geq x_{t+1}^\top A \qquad \forall t \geq 1$$

which asserts that no more goods can be used today than were produced yesterday.

Accordingly, Ap_t tells the costs of production in period t and Bp_t tells revenues in period $t + 1$.

41.3.1 Balanced Growth

We follow John von Neumann in studying "balanced growth".

Let $./$ denote an elementwise division of one vector by another and let $\alpha > 0$ be a scalar.

Then **balanced growth** is a situation in which

$$x_{t+1}./x_t = \alpha, \quad \forall t \geq 0$$

With balanced growth, the law of motion of x is evidently $x_{t+1} = \alpha x_t$ and so we can rewrite the feasibility constraint as

$$x_t^\top B \geq \alpha x_t^\top A \qquad \forall t$$

In the same spirit, define $\beta \in \mathbb{R}$ as the **interest factor** per unit of time.

We assume that it is always possible to earn a gross return equal to the constant interest factor β by investing "outside the model".

Under this assumption about outside investment opportunities, a no-arbitrage condition gives rise to the following (no profit) restriction on the price sequence:

$$\beta A p_t \geq B p_t \qquad \forall t$$

This says that production cannot yield a return greater than that offered by the outside investment opportunity (here we compare values in period $t + 1$).

The balanced growth assumption allows us to drop time subscripts and conduct an analysis purely in terms of a time-invariant growth rate α and interest factor β.

41.4 Duality

Two problems are connected by a remarkable dual relationship between technological and valuation characteristics of the economy:

Definition 41.4.1

The **technological expansion problem** (TEP) for the economy (A, B) is to find a semi-positive m-vector $x > 0$ and a number $\alpha \in \mathbb{R}$ that satisfy

$$\begin{aligned} \max_{\alpha} \quad & \alpha \\ \text{s.t.} \quad & x^\top B \geq \alpha x^\top A \end{aligned}$$

Theorem 9.3 of David Gale's book [Gale, 1989] asserts that if *Assumption 41.2.1* and *Assumption 41.2.2* are both satisfied, then a maximum value of α exists and that it is positive.

The maximal value is called the *technological expansion rate* and is denoted by α_0. The associated intensity vector x_0 is the *optimal intensity vector*.

Definition 41.4.2

The economic expansion problem (EEP) for (A, B) is to find a semi-positive n-vector $p > 0$ and a number $\beta \in \mathbb{R}$ that satisfy

$$\begin{aligned} \min_{\beta} \quad & \beta \\ \text{s.t.} \quad & Bp \leq \beta Ap \end{aligned}$$

Assumption 41.2.1 and *Assumption 41.2.2* imply existence of a minimum value $\beta_0 > 0$ called the *economic expansion rate*.

The corresponding price vector p_0 is the *optimal price vector*.

Because the criterion functions in the *technological expansion* problem and the *economical expansion problem* are both linearly homogeneous, the optimality of x_0 and p_0 are defined only up to a positive scale factor.

For convenience (and to emphasize a close connection to zero-sum games), we normalize both vectors x_0 and p_0 to have unit length.

A standard duality argument (see Lemma 9.4. in (Gale, 1960) [Gale, 1989]) implies that under *Assumption 41.2.1* and *Assumption 41.2.2*, $\beta_0 \leq \alpha_0$.

But to deduce that $\beta_0 \geq \alpha_0$, *Assumption 41.2.1* and *Assumption 41.2.2* are not sufficient.

Therefore, von Neumann [von Neumann, 1937] went on to prove the following remarkable "duality" result that connects TEP and EEP.

Theorem 41.4.1 (von Neumann)

If the economy (A, B) satisfies *Assumption 41.2.1* and *Assumption 41.2.2*, then there exist (γ^*, x_0, p_0), where $\gamma^* \in [\beta_0, \alpha_0] \subset \mathbb{R}$, $x_0 > 0$ is an m-vector, $p_0 > 0$ is an n-vector, and the following arbitrage conditions hold

$$\begin{aligned} x_0^\top B &\geq \gamma^* x_0^\top A \\ Bp_0 &\leq \gamma^* Ap_0 \\ x_0^\top (B - \gamma^* A)\, p_0 &= 0 \end{aligned}$$

Proof. (Sketch)

Assumption 41.2.1 and *Assumption 41.2.2* imply that there exist (α_0, x_0) and (β_0, p_0) that solve the TEP and EEP, respectively.

If $\gamma^* > \alpha_0$, then by definition of α_0, there cannot exist a semi-positive x that satisfies $x^\top B \geq \gamma^* x^\top A$.

Similarly, if $\gamma^* < \beta_0$, there is no semi-positive p for which $Bp \leq \gamma^* Ap$. Let $\gamma^* \in [\beta_0, \alpha_0]$, then $x_0^\top B \geq \alpha_0 x_0^\top A \geq \gamma^* x_0^\top A$.

Moreover, $Bp_0 \leq \beta_0 Ap_0 \leq \gamma^* Ap_0$. These two inequalities imply $x_0 \left(B - \gamma^* A\right) p_0 = 0$.

Here the constant γ^* is both an expansion factor and an interest factor (not necessarily optimal).

We have already encountered and discussed the first two inequalities that represent feasibility and no-profit conditions.

Moreover, the equality $x_0^\top \left(B - \gamma^* A\right) p_0 = 0$ concisely expresses the requirements that if any good grows at a rate larger than γ^* (i.e., if it is *oversupplied*), then its price must be zero; and that if any activity provides negative profit, it must be unused.

Therefore, the conditions stated in *Theorem 41.4.1* encode all equilibrium conditions.

So *Theorem 41.4.1* essentially states that under *Assumption 41.2.1* and *Assumption 41.2.2* there always exists an equilibrium (γ^*, x_0, p_0) with balanced growth.

Note that *Theorem 41.4.1* is silent about uniqueness of the equilibrium. In fact, it does not rule out (trivial) cases with $x_0^\top B p_0 = 0$ so that nothing of value is produced.

To exclude such uninteresting cases, Kemeny, Morgenstern and Thompson [Kemeny *et al.*, 1956] add an extra requirement

$$x_0^\top B p_0 > 0$$

and call the associated equilibria *economic solutions*.

They show that this extra condition does not affect the existence result, while it significantly reduces the number of (relevant) solutions.

41.5 Interpretation as Two-player Zero-sum Game

To compute the equilibrium (γ^*, x_0, p_0), we follow the algorithm proposed by Hamburger, Thompson and Weil (1967), building on the key insight that an equilibrium (with balanced growth) can be solved as a particular two-player zero-sum game.

First, we introduce some notation.

Consider the $m \times n$ matrix C as a payoff matrix, with the entries representing payoffs from the **minimizing** column player to the **maximizing** row player and assume that the players can use mixed strategies. Thus,

- the row player chooses the m-vector $x > \mathbf{0}$ subject to $\iota_m^\top x = 1$
- the column player chooses the n-vector $p > \mathbf{0}$ subject to $\iota_n^\top p = 1$.

Definition 41.5.1

The $m \times n$ matrix game C has the *solution* $(x^*, p^*, V(C))$ in mixed strategies if

$$(x^*)^\top C e^j \geq V(C) \quad \forall j \in \{1, \dots, n\} \qquad \text{and} \qquad (e^i)^\top C p^* \leq V(C) \quad \forall i \in \{1, \dots, m\}$$

The number $V(C)$ is called the **value** of the game.

From the above definition, it is clear that the value $V(C)$ has two alternative interpretations:

- by playing the appropriate mixed strategy, the maximizing player can assure himself at least $V(C)$ (no matter what the column player chooses)
- by playing the appropriate mixed strategy, the minimizing player can make sure that the maximizing player will not get more than $V(C)$ (irrespective of what is the maximizing player's choice)

A famous theorem of Nash (1951) tells us that there always exists a mixed strategy Nash equilibrium for any *finite* two-player zero-sum game.

Moreover, von Neumann's Minmax Theorem [von Neumann, 1928] implies that

$$V(C) = \max_x \min_p \; x^\top C p = \min_p \max_x \; x^\top C p = (x^*)^\top C p^*$$

41.5.1 Connection with Linear Programming (LP)

Nash equilibria of a finite two-player zero-sum game solve a linear programming problem.

To see this, we introduce the following notation

- For a fixed x, let v be the value of the minimization problem: $v \equiv \min_p x^\top C p = \min_j x^\top C e^j$
- For a fixed p, let u be the value of the maximization problem: $u \equiv \max_x x^\top C p = \max_i (e^i)^\top C p$

Then the *max-min problem* (the game from the maximizing player's point of view) can be written as the *primal* LP

$$\begin{aligned} V(C) = \max \quad & v \\ \text{s.t.} \quad & v \iota_n^\top \leq x^\top C \\ & x \geq \mathbf{0} \\ & \iota_n^\top x = 1 \end{aligned}$$

while the *min-max problem* (the game from the minimizing player's point of view) is the *dual* LP

$$\begin{aligned} V(C) = \min \quad & u \\ \text{s.t.} \quad & u \iota_m \geq C p \\ & p \geq \mathbf{0} \\ & \iota_m^\top p = 1 \end{aligned}$$

Hamburger, Thompson and Weil [Hamburger *et al.*, 1967] view the input-output pair of the economy as payoff matrices of two-player zero-sum games.

Using this interpretation, they restate *Assumption 41.2.1* and *Assumption 41.2.2* as follows

$$V(-A) < 0 \qquad \text{and} \qquad V(B) > 0$$

Proof. (Sketch)

- $\Rightarrow V(B) > 0$ implies $x_0^\top B \gg \mathbf{0}$, where x_0 is a maximizing vector. Since B is non-negative, this requires that each column of B has at least one positive entry, which is *Assumption 41.2.1*.
- $\Leftarrow$ From *Assumption 41.2.1* and the fact that $p > \mathbf{0}$, it follows that $Bp > \mathbf{0}$. This implies that the maximizing player can always choose x so that $x^\top Bp > 0$ so that it must be the case that $V(B) > 0$.

In order to (re)state *Theorem 41.4.1* in terms of a particular two-player zero-sum game, we define a matrix for $\gamma \in \mathbb{R}$

$$M(\gamma) \equiv B - \gamma A$$

For fixed γ, treating $M(\gamma)$ as a matrix game, calculating the solution of the game implies

- If $\gamma > \alpha_0$, then for all $x > 0$, there $\exists j \in \{1, \dots, n\}$, s.t. $[x^\top M(\gamma)]_j < 0$ implying that $V(M(\gamma)) < 0$.
- If $\gamma < \beta_0$, then for all $p > 0$, there $\exists i \in \{1, \dots, m\}$, s.t. $[M(\gamma)p]_i > 0$ implying that $V(M(\gamma)) > 0$.
- If $\gamma \in \{\beta_0, \alpha_0\}$, then (by *Theorem 41.4.1*) the optimal intensity and price vectors x_0 and p_0 satisfy

$$x_0^\top M(\gamma) \geq \mathbf{0}^\top \qquad \text{and} \qquad M(\gamma)p_0 \leq \mathbf{0}$$

That is, $(x_0, p_0, 0)$ is a solution of the game $M(\gamma)$ so that $V\left(M(\beta_0)\right) = V\left(M(\alpha_0)\right) = 0$.

- If $\beta_0 < \alpha_0$ and $\gamma \in (\beta_0, \alpha_0)$, then $V(M(\gamma)) = 0$.

Moreover, if x' is optimal for the maximizing player in $M(\gamma')$ for $\gamma' \in (\beta_0, \alpha_0)$ and p'' is optimal for the minimizing player in $M(\gamma'')$ where $\gamma'' \in (\beta_0, \gamma')$, then $(x', p'', 0)$ is a solution for $M(\gamma)$ $\forall \gamma \in (\gamma'', \gamma')$.

Proof. (Sketch) If x' is optimal for a maximizing player in game $M(\gamma')$, then $(x')^\top M(\gamma') \geq \mathbf{0}^\top$ and so for all $\gamma < \gamma'$.

$$(x')^\top M(\gamma) = (x')^\top M(\gamma') + (x')^\top (\gamma' - \gamma) A \geq \mathbf{0}^\top$$

hence $V(M(\gamma)) \geq 0$. If p'' is optimal for a minimizing player in game $M(\gamma'')$, then $M(\gamma'')p'' \leq \mathbf{0}$ and so for all $\gamma'' < \gamma$

$$M(\gamma)p'' = M(\gamma'') + (\gamma'' - \gamma) A p'' \leq \mathbf{0}$$

hence $V(M(\gamma)) \leq 0$.

It is clear from the above argument that β_0, α_0 are the minimal and maximal γ for which $V(M(\gamma)) = 0$.

Furthermore, Hamburger et al. [Hamburger *et al.*, 1967] show that the function $\gamma \mapsto V(M(\gamma))$ is continuous and nonincreasing in γ.

This suggests an algorithm to compute (α_0, x_0) and (β_0, p_0) for a given input-output pair (A, B).

41.5.2 Algorithm

Hamburger, Thompson and Weil [Hamburger *et al.*, 1967] propose a simple bisection algorithm to find the minimal and maximal roots (i.e. β_0 and α_0) of the function $\gamma \mapsto V(M(\gamma))$.

Step 1

First, notice that we can easily find trivial upper and lower bounds for α_0 and β_0.

- TEP requires that $x^\top (B - \alpha A) \geq \mathbf{0}^\top$ and $x > \mathbf{0}$, so if α is so large that $\max_i \{[(B - \alpha A)\iota_n]_i\} < 0$, then TEP ceases to have a solution.

Accordingly, let **UB** be the α^* that solves $\max_i \{[(B - \alpha^* A)\iota_n]_i\} = 0$.

- Similar to the upper bound, if β is so low that $\min_j \{[\iota_m^\top (B - \beta A)]_j\} > 0$, then the EEP has no solution and so we can define **LB** as the β^* that solves $\min_j \{[\iota_m^\top (B - \beta^* A)]_j\} = 0$.

The *bounds* method calculates these trivial bounds for us

```
n1.bounds()
```

```
(1.0, 2.0)
```

Step 2

Compute α_0 and β_0

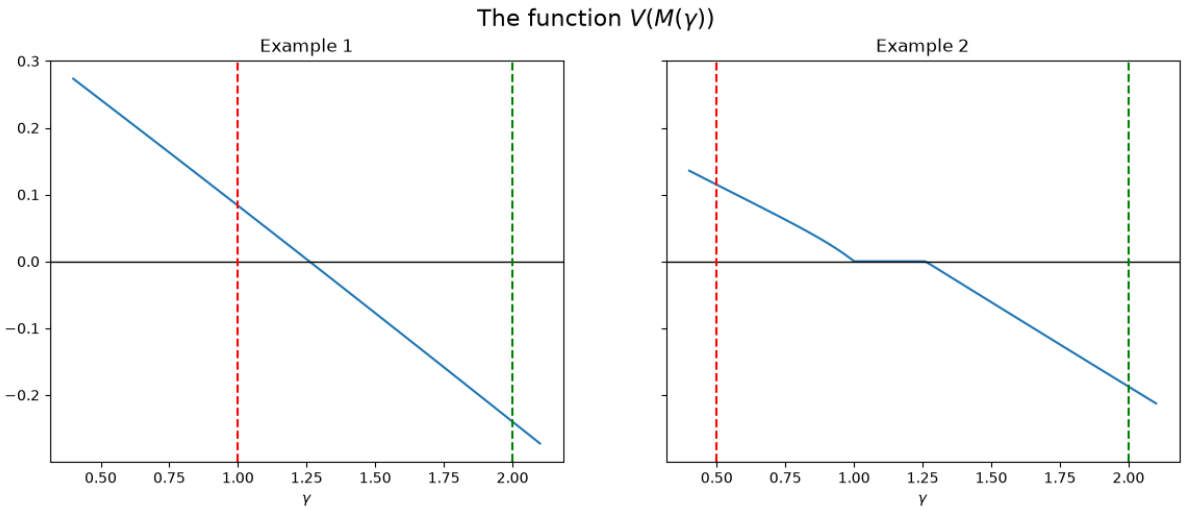
- Finding α_0
  1. Fix $\gamma = \frac{UB+LB}{2}$ and compute the solution of the two-player zero-sum game associated with $M(\gamma)$. We can use either the primal or the dual LP problem.
  2. If $V(M(\gamma)) \geq 0$, then set $LB = \gamma$, otherwise let $UB = \gamma$.
  3. Iterate on 1. and 2. until $|UB - LB| < \epsilon$.
- Finding β_0
  1. Fix $\gamma = \frac{UB+LB}{2}$ and compute the solution of the two-player zero-sum game associated with $M(\gamma)$. We can use either the primal or the dual LP problem.
  2. If $V(M(\gamma)) > 0$, then set $LB = \gamma$, otherwise let $UB = \gamma$.
  3. Iterate on 1. and 2. until $|UB - LB| < \epsilon$.
- *Existence*: Since $V(M(LB)) > 0$ and $V(M(UB)) < 0$ and $V(M(\cdot))$ is a continuous, nonincreasing function, there is at least one $\gamma \in [LB, UB]$, s.t. $V(M(\gamma)) = 0$.

The *zerosum* method calculates the value and optimal strategies associated with a given γ.

```
y = 2

print(f'Value of the game with y = {y}')
print(n1.zerosum(y=y)[0])
print('Intensity vector (from the primal)')
print(n1.zerosum(y=y)[1])
print('Price vector (from the dual)')
print(n1.zerosum(y=y, dual=True)[1])
```

```
Value of the game with γ = 2
-0.24
Intensity vector (from the primal)
[0.32 0.28 0.4 ]
Price vector (from the dual)
[0.4  0.32 0.28 0.  ]
```



```
numb_grid = 100
γ_grid = np.linspace(0.4, 2.1, numb_grid)

value_ex1_grid = np.asarray([n1.zerosum(γ=γ_grid[i])[0]
                             for i in range(numb_grid)])
value_ex2_grid = np.asarray([n2.zerosum(γ=γ_grid[i])[0]
                             for i in range(numb_grid)])

fig, axes = plt.subplots(1, 2, figsize=(14, 5), sharey=True)
fig.suptitle(r'The function $V(M(\gamma))$', fontsize=16)

for ax, grid, N, i in zip(axes, (value_ex1_grid, value_ex2_grid),
                          (n1, n2), (1, 2)):
    ax.plot(γ_grid, grid)
    ax.set(title=f'Example {i}', xlabel=r'$\gamma$')
    ax.axhline(0, c='k', lw=1)
    ax.axvline(N.bounds()[0], c='r', ls='--', label='lower bound')
    ax.axvline(N.bounds()[1], c='g', ls='--', label='upper bound')

plt.show()
```

The *expansion* method implements the bisection algorithm for α_0 (and uses the primal LP problem for x_0)

```
α_0, x, p = n1.expansion()
print(f'α_0 = {α_0}')
print(f'x_0 = {x}')
print(f'The corresponding p from the dual = {p}')
```

```
α_0 = 1.2599210478365421
x_0 = [0.33 0.26 0.41]
The corresponding p from the dual = [0.41 0.33 0.26 0.  ]
```

The *interest* method implements the bisection algorithm for β_0 (and uses the dual LP problem for p_0)

```
β_0, x, p = n1.interest()
print(f'β_0 = {β_0}')
print(f'p_0 = {p}')
print(f'The corresponding x from the primal = {x}')
```

```
β_0 = 1.2599210478365421
p_0 = [0.41 0.33 0.26 0.  ]
The corresponding x from the primal = [0.33 0.26 0.41]
```

Of course, when γ^* is unique, it is irrelevant which one of the two methods we use – both work.

In particular, as will be shown below, in case of an irreducible (A, B) (like in Example 1), the maximal and minimal roots of $V(M(\gamma))$ necessarily coincide implying a "full duality" result, i.e. $\alpha_0 = \beta_0 = \gamma^*$ so that the expansion (and interest) rate γ^* is unique.

41.5.3 Uniqueness and Irreducibility

As an illustration, compute first the maximal and minimal roots of $V(M(\cdot))$ for our Example 2 that has a reducible input-output pair (A, B)

```
α_0, x, p = n2.expansion()
print(f'α_0 = {α_0}')
print(f'x_0 = {x}')
print(f'The corresponding p from the dual = {p}')
```

```
α_0 = 1.259921052493155
x_0 = [5.27e-10 0.00e+00 3.27e-01 2.60e-01 4.13e-01]
The corresponding p from the dual = [0.   0.21 0.33 0.26 0.21 0.  ]
```

```
β_0, x, p = n2.interest()
print(f'β_0 = {β_0}')
print(f'p_0 = {p}')
print(f'The corresponding x from the primal = {x}')
```

```
β_0 = 1.0000000009313226
p_0 = [ 5.00e-01  5.00e-01 -1.55e-09 -1.24e-09 -9.31e-10  0.00e+00]
The corresponding x from the primal = [-0.    0.    0.25  0.25  0.5 ]
```

As we can see, with a reducible (A, B), the roots found by the bisection algorithms might differ, so there might be multiple γ^* that make the value of the game with $M(\gamma^*)$ zero. (see the figure above).

Indeed, although the von Neumann theorem assures existence of the equilibrium, *Assumption 41.2.1* and *Assumption 41.2.2* are not sufficient for uniqueness. Nonetheless, Kemeny et al. (1967) show that there are at most finitely many economic solutions, meaning that there are only finitely many γ^* that satisfy $V(M(\gamma^*)) = 0$ and $x_0^\top B p_0 > 0$ and that for each such γ_i^*, there is a self-contained part of the economy (a sub-economy) that in equilibrium can expand independently with the expansion coefficient γ_i^*.

The following theorem (see Theorem 9.10. in Gale [Gale, 1989]) asserts that imposing irreducibility is sufficient for uniqueness of (γ^*, x_0, p_0).

Theorem 41.5.1

Adopt the conditions of *Theorem 41.4.1*. If the economy (A, B) is irreducible, then $\gamma^* = \alpha_0 = \beta_0$.

41.5.4 A Special Case

There is a special (A, B) that allows us to simplify the solution method significantly by invoking the powerful Perron-Frobenius theorem for non-negative matrices.

Definition 41.5.2

We call an economy *simple* if it satisfies

- $n = m$
- Each activity produces exactly one good
- Each good is produced by one and only one activity.

These assumptions imply that $B = I_n$, i.e., that B can be written as an identity matrix (possibly after reshuffling its rows and columns).

The simple model has the following special property (Theorem 9.11. in Gale [Gale, 1989]): if x_0 and $\alpha_0 > 0$ solve the TEP with (A, I_n), then

$$x_0^\top = \alpha_0 x_0^\top A \qquad \Leftrightarrow \qquad x_0^\top A = \left(\frac{1}{\alpha_0}\right) x_0^\top$$

The latter shows that $1/\alpha_0$ is a positive eigenvalue of A and x_0 is the corresponding non-negative left eigenvector.

The classic result of *Perron and Frobenius* implies that a non-negative matrix has a non-negative eigenvalue-eigenvector pair.

Moreover, if A is irreducible, then the optimal intensity vector x_0 is positive and *unique* up to multiplication by a positive scalar.

Suppose that A is reducible with k irreducible subsets $S_1, \ldots, S_k$. Let A_i be the submatrix corresponding to S_i and let α_i and β_i be the associated expansion and interest factors, respectively. Then we have

$$\alpha_0 = \max_i \{\alpha_i\} \qquad \text{and} \qquad \beta_0 = \min_i \{\beta_i\}$$

```

42.1 Overview

Markov chains are one of the most useful classes of stochastic processes, being

- simple, flexible and supported by many elegant theoretical results
- valuable for building intuition about random dynamic models
- central to quantitative modeling in their own right

You will find them in many of the workhorse models of economics and finance.

In this lecture, we review some of the theory of Markov chains.

We will also introduce some of the high-quality routines for working with Markov chains available in QuantEcon.py.

Prerequisite knowledge is basic probability and linear algebra.

Let's start with some standard imports:

```
import matplotlib.pyplot as plt
import quantecon as qe
import numpy as np
from mpl_toolkits.mplot3d import Axes3D
```

42.2 Definitions

The following concepts are fundamental.

42.2.1 Stochastic Matrices

A **stochastic matrix** (or **Markov matrix**) is an $n \times n$ square matrix P such that

1. each element of P is nonnegative, and
2. each row of P sums to one

Each row of P can be regarded as a probability mass function over n possible outcomes.

It is too not difficult to check[1] that if P is a stochastic matrix, then so is the k-th power P^k for all $k \in \mathbb{N}$.

42.2.2 Markov Chains

There is a close connection between stochastic matrices and Markov chains.

To begin, let S be a finite set with n elements $\{x_1, \ldots, x_n\}$.

The set S is called the **state space** and $x_1, \ldots, x_n$ are the **state values**.

A **Markov chain** $\{X_t\}$ on S is a sequence of random variables on S that have the **Markov property**.

This means that, for any date t and any state $y \in S$,

$$\mathbb{P}\{X_{t+1} = y \,|\, X_t\} = \mathbb{P}\{X_{t+1} = y \,|\, X_t, X_{t-1}, \ldots\} \tag{42.1}$$

In other words, knowing the current state is enough to know probabilities for future states.

In particular, the dynamics of a Markov chain are fully determined by the set of values

$$P(x, y) := \mathbb{P}\{X_{t+1} = y \,|\, X_t = x\} \qquad (x, y \in S) \tag{42.2}$$

By construction,

- $P(x, y)$ is the probability of going from x to y in one unit of time (one step)
- $P(x, \cdot)$ is the conditional distribution of X_{t+1} given $X_t = x$

We can view P as a stochastic matrix where

$$P_{ij} = P(x_i, x_j) \qquad 1 \leq i, j \leq n$$

Going the other way, if we take a stochastic matrix P, we can generate a Markov chain $\{X_t\}$ as follows:

- draw X_0 from a marginal distribution ψ
- for each $t = 0, 1, \ldots$, draw X_{t+1} from $P(X_t, \cdot)$

By construction, the resulting process satisfies (42.2).

[1] Hint: First show that if P and Q are stochastic matrices then so is their product — to check the row sums, try post multiplying by a column vector of ones. Finally, argue that P^n is a stochastic matrix using induction.

42.2.3 Example 1

Consider a worker who, at any given time t, is either unemployed (state 0) or employed (state 1).

Suppose that, over a one month period,

1. An unemployed worker finds a job with probability $\alpha \in (0, 1)$.
2. An employed worker loses her job and becomes unemployed with probability $\beta \in (0, 1)$.

In terms of a Markov model, we have

- $S = \{0, 1\}$
- $P(0, 1) = \alpha$ and $P(1, 0) = \beta$

We can write out the transition probabilities in matrix form as

$$P = \begin{pmatrix} 1 - \alpha & \alpha \\ \beta & 1 - \beta \end{pmatrix} \tag{42.3}$$

Once we have the values α and β, we can address a range of questions, such as

- What is the average duration of unemployment?
- Over the long-run, what fraction of time does a worker find herself unemployed?
- Conditional on employment, what is the probability of becoming unemployed at least once over the next 12 months?

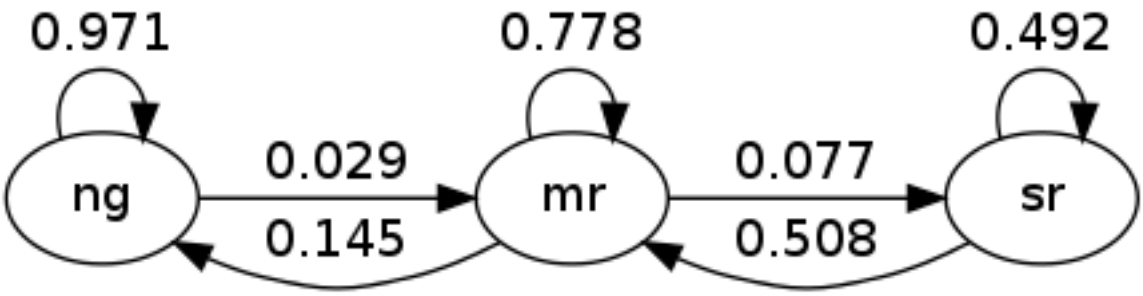
We'll cover such applications below.

42.2.4 Example 2

From US unemployment data, Hamilton [Hamilton, 2005] estimated the stochastic matrix

$$P = \begin{pmatrix} 0.971 & 0.029 & 0 \\ 0.145 & 0.778 & 0.077 \\ 0 & 0.508 & 0.492 \end{pmatrix}$$

where



- the frequency is monthly
- the first state represents "normal growth"
- the second state represents "mild recession"
- the third state represents "severe recession"

For example, the matrix tells us that when the state is normal growth, the state will again be normal growth next month with probability 0.97.

In general, large values on the main diagonal indicate persistence in the process $\{X_t\}$.

This Markov process can also be represented as a directed graph, with edges labeled by transition probabilities

Here "ng" is normal growth, "mr" is mild recession, etc.

42.3 Simulation

One natural way to answer questions about Markov chains is to simulate them.

(To approximate the probability of event E, we can simulate many times and count the fraction of times that E occurs).

Nice functionality for simulating Markov chains exists in QuantEcon.py.

- Efficient, bundled with lots of other useful routines for handling Markov chains.

However, it's also a good exercise to roll our own routines — let's do that first and then come back to the methods in QuantEcon.py.

In these exercises, we'll take the state space to be $S = 0, \ldots, n-1$.

42.3.1 Rolling Our Own

To simulate a Markov chain, we need its stochastic matrix P and a marginal probability distribution ψ from which to draw a realization of X_0.

The Markov chain is then constructed as discussed above. To repeat:

1. At time $t = 0$, draw a realization of X_0 from ψ.
2. At each subsequent time t, draw a realization of the new state X_{t+1} from $P(X_t, \cdot)$.

To implement this simulation procedure, we need a method for generating draws from a discrete distribution.

For this task, we'll use `random.draw` from QuantEcon, which works as follows:

```
ψ = (0.3, 0.7)           # probabilities over {0, 1}
cdf = np.cumsum(ψ)       # convert into cummulative distribution
qe.random.draw(cdf, 5)   # generate 5 independent draws from ψ
```

```
array([1, 1, 0, 1, 0])
```

We'll write our code as a function that accepts the following three arguments

- A stochastic matrix `P`
- An initial state `init`
- A positive integer `sample_size` representing the length of the time series the function should return

```
def mc_sample_path(P, ψ_0=None, sample_size=1_000):

    # set up
```

(continues on next page)

(continued from previous page)

```
    P = np.asarray(P)
    X = np.empty(sample_size, dtype=int)

    # Convert each row of P into a cdf
    n = len(P)
    P_dist = [np.cumsum(P[i, :]) for i in range(n)]

    # draw initial state, defaulting to 0
    if ψ_0 is not None:
        X_0 = qe.random.draw(np.cumsum(ψ_0))
    else:
        X_0 = 0

    # simulate
    X[0] = X_0
    for t in range(sample_size - 1):
        X[t+1] = qe.random.draw(P_dist[X[t]])

    return X
```

Let's see how it works using the small matrix

```
P = [[0.4, 0.6],
     [0.2, 0.8]]
```

As we'll see later, for a long series drawn from `P`, the fraction of the sample that takes value 0 will be about 0.25.

Moreover, this is true, regardless of the initial distribution from which X_0 is drawn.

The following code illustrates this

```
X = mc_sample_path(P, ψ_0=[0.1, 0.9], sample_size=100_000)
np.mean(X == 0)
```

```
np.float64(0.24912)
```

You can try changing the initial distribution to confirm that the output is always close to 0.25, at least for the `P` matrix above.

42.3.2 Using QuantEcon's Routines

As discussed above, QuantEcon.py has routines for handling Markov chains, including simulation.

Here's an illustration using the same P as the preceding example

```
from quantecon import MarkovChain

mc = qe.MarkovChain(P)
X = mc.simulate(ts_length=1_000_000)
np.mean(X == 0)
```

```
np.float64(0.248881)
```

The QuantEcon.py routine is JIT compiled and much faster.

```
%time mc_sample_path(P, sample_size=1_000_000) # Our homemade code version
```

```
CPU times: user 2.51 s, sys: 1.85 ms, total: 2.51 s
Wall time: 2.51 s
```

```
array([0, 1, 1, ..., 1, 1, 1], shape=(1000000,))
```

```
%time mc.simulate(ts_length=1_000_000) # qe code version
```

```
CPU times: user 16.3 ms, sys: 3.02 ms, total: 19.4 ms
Wall time: 19.1 ms
```

```
array([0, 1, 1, ..., 1, 1, 1], shape=(1000000,))
```

Adding State Values and Initial Conditions

If we wish to, we can provide a specification of state values to `MarkovChain`.

These state values can be integers, floats, or even strings.

The following code illustrates

```
mc = qe.MarkovChain(P, state_values=('unemployed', 'employed'))
mc.simulate(ts_length=4, init='employed')
```

```
array(['employed', 'employed', 'unemployed', 'employed'], dtype='<U10')
```

```
mc.simulate(ts_length=4, init='unemployed')
```

```
array(['unemployed', 'employed', 'unemployed', 'employed'], dtype='<U10')
```

```
mc.simulate(ts_length=4)  # Start at randomly chosen initial state
```

```
array(['employed', 'employed', 'employed', 'employed'], dtype='<U10')
```

If we want to see indices rather than state values as outputs as we can use

```
mc.simulate_indices(ts_length=4)
```

```
array([1, 1, 1, 1])
```

42.4 Marginal Distributions

Suppose that

1. $\{X_t\}$ is a Markov chain with stochastic matrix P
2. the marginal distribution of X_t is known to be ψ_t

What then is the marginal distribution of X_{t+1}, or, more generally, of X_{t+m}?

To answer this, we let ψ_t be the marginal distribution of X_t for $t = 0, 1, 2, ...$

Our first aim is to find ψ_{t+1} given ψ_t and P.

To begin, pick any $y \in S$.

Using the law of total probability, we can decompose the probability that $X_{t+1} = y$ as follows:

$$\mathbb{P}\{X_{t+1} = y\} = \sum_{x \in S} \mathbb{P}\{X_{t+1} = y \,|\, X_t = x\} \cdot \mathbb{P}\{X_t = x\}$$

In words, to get the probability of being at y tomorrow, we account for all ways this can happen and sum their probabilities.

Rewriting this statement in terms of marginal and conditional probabilities gives

$$\psi_{t+1}(y) = \sum_{x \in S} P(x, y)\psi_t(x)$$

There are n such equations, one for each $y \in S$.

If we think of ψ_{t+1} and ψ_t as *row vectors*, these n equations are summarized by the matrix expression

$$\psi_{t+1} = \psi_t P \tag{42.4}$$

Thus, to move a marginal distribution forward one unit of time, we postmultiply by P.

By postmultiplying m times, we move a marginal distribution forward m steps into the future.

Hence, iterating on (42.4), the expression $\psi_{t+m} = \psi_t P^m$ is also valid — here P^m is the m-th power of P.

As a special case, we see that if ψ_0 is the initial distribution from which X_0 is drawn, then $\psi_0 P^m$ is the distribution of X_m.

This is very important, so let's repeat it

$$X_0 \sim \psi_0 \quad \Longrightarrow \quad X_m \sim \psi_0 P^m \tag{42.5}$$

and, more generally,

$$X_t \sim \psi_t \quad \Longrightarrow \quad X_{t+m} \sim \psi_t P^m \tag{42.6}$$

42.4.1 Multiple Step Transition Probabilities

We know that the probability of transitioning from x to y in one step is $P(x, y)$.

It turns out that the probability of transitioning from x to y in m steps is $P^m(x, y)$, the (x, y)-th element of the m-th power of P.

To see why, consider again (42.6), but now with a ψ_t that puts all probability on state x so that the transition probabilities are

- 1 in the x-th position and zero elsewhere

Inserting this into (42.6), we see that, conditional on $X_t = x$, the distribution of X_{t+m} is the x-th row of P^m.

In particular

$$\mathbb{P}\{X_{t+m} = y \,|\, X_t = x\} = P^m(x, y) = (x, y)\text{-th element of } P^m$$

42.4.2 Example: Probability of Recession

Recall the stochastic matrix P for recession and growth *considered above*.

Suppose that the current state is unknown — perhaps statistics are available only at the *end* of the current month.

We guess that the probability that the economy is in state x is $\psi(x)$.

The probability of being in recession (either mild or severe) in 6 months time is given by the inner product

$$\psi P^6 \cdot \begin{pmatrix} 0 \\ 1 \\ 1 \end{pmatrix}$$

42.4.3 Example 2: Cross-Sectional Distributions

The marginal distributions we have been studying can be viewed either as probabilities or as cross-sectional frequencies that a Law of Large Numbers leads us to anticipate for large samples.

To illustrate, recall our model of employment/unemployment dynamics for a given worker *discussed above*.

Consider a large population of workers, each of whose lifetime experience is described by the specified dynamics, with each worker's outcomes being realizations of processes that are statistically independent of all other workers' processes.

Let ψ be the current *cross-sectional* distribution over $\{0, 1\}$.

The cross-sectional distribution records fractions of workers employed and unemployed at a given moment.

- For example, $\psi(0)$ is the unemployment rate.

What will the cross-sectional distribution be in 10 periods hence?

The answer is ψP^{10}, where P is the stochastic matrix in (42.3).

This is because each worker's state evolves according to P, so ψP^{10} is a marginal distibution for a single randomly selected worker.

But when the sample is large, outcomes and probabilities are roughly equal (by an application of the Law of Large Numbers).

So for a very large (tending to infinite) population, ψP^{10} also represents fractions of workers in each state.

This is exactly the cross-sectional distribution.

42.5 Irreducibility and Aperiodicity

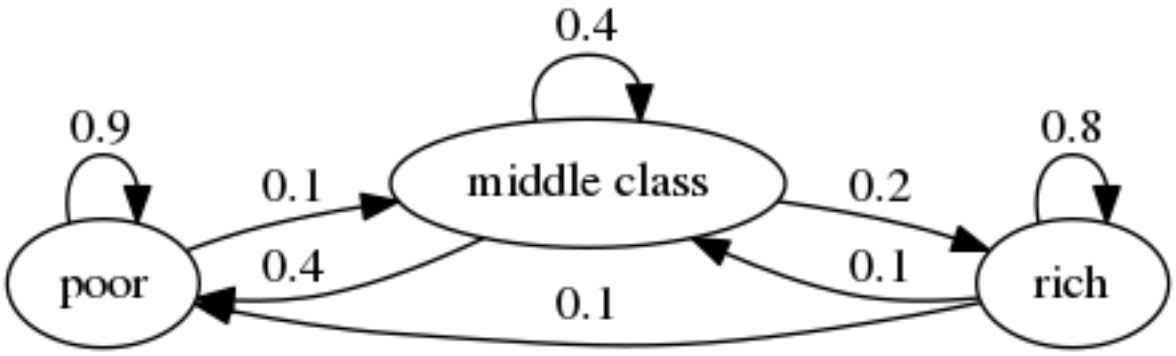
Irreducibility and aperiodicity are central concepts of modern Markov chain theory.

Let's see what they're about.

42.5.1 Irreducibility

Let P be a fixed stochastic matrix.

Two states x and y are said to **communicate** with each other if there exist positive integers j and k such that



$$P^j(x, y) > 0 \quad \text{and} \quad P^k(y, x) > 0$$

In view of our discussion *above*, this means precisely that

- state x can eventually be reached from state y, and
- state y can eventually be reached from state x

The stochastic matrix P is called **irreducible** if all states communicate; that is, if x and y communicate for all (x, y) in $S \times S$.

For example, consider the following transition probabilities for wealth of a fictitious set of households

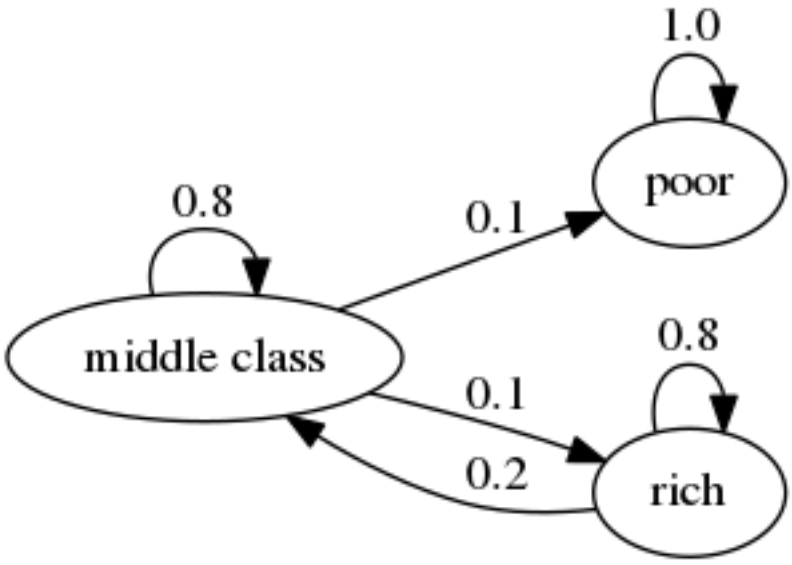
We can translate this into a stochastic matrix, putting zeros where there's no edge between nodes

$$P := \begin{pmatrix} 0.9 & 0.1 & 0 \\ 0.4 & 0.4 & 0.2 \\ 0.1 & 0.1 & 0.8 \end{pmatrix}$$

It's clear from the graph that this stochastic matrix is irreducible: we can eventually reach any state from any other state.

We can also test this using QuantEcon.py's MarkovChain class

```
P = [[0.9, 0.1, 0.0],
     [0.4, 0.4, 0.2],
     [0.1, 0.1, 0.8]]



mc = qe.MarkovChain(P, ('poor', 'middle', 'rich'))
mc.is_irreducible
```

```
True
```

Here's a more pessimistic scenario in which poor people remain poor forever

This stochastic matrix is not irreducible, since, for example, rich is not accessible from poor.

Let's confirm this

```
P = [[1.0, 0.0, 0.0],
     [0.1, 0.8, 0.1],
     [0.0, 0.2, 0.8]]

mc = qe.MarkovChain(P, ('poor', 'middle', 'rich'))
mc.is_irreducible
```

```
False
```

We can also determine the "communication classes"

```
mc.communication_classes
```

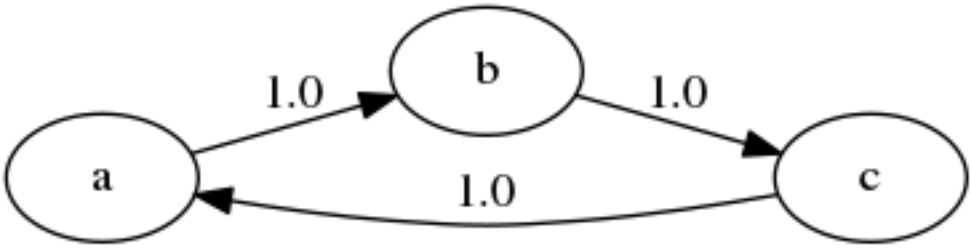
```
[array(['poor'], dtype='<U6'), array(['middle', 'rich'], dtype='<U6')]
```

It might be clear to you already that irreducibility is going to be important in terms of long run outcomes.

For example, poverty is a life sentence in the second graph but not the first.

We'll come back to this a bit later.

42.5.2 Aperiodicity



Loosely speaking, a Markov chain is called **periodic** if it cycles in a predictable way, and **aperiodic** otherwise.

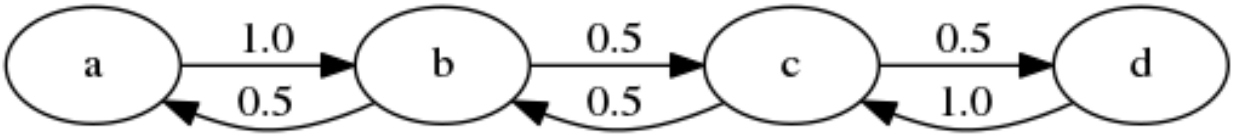
Here's a trivial example with three states

The chain cycles with period 3:

```
P = [[0, 1, 0],
     [0, 0, 1],
     [1, 0, 0]]

mc = qe.MarkovChain(P)
mc.period
```

```
3
```



More formally, the **period** of a state x is the largest common divisor of a set of integers

$$D(x) := \{j \geq 1 : P^j(x, x) > 0\}$$

In the last example, $D(x) = \{3, 6, 9, ...\}$ for every state x, so the period is 3.

A stochastic matrix is called **aperiodic** if the period of every state is 1, and **periodic** otherwise.

For example, the stochastic matrix associated with the transition probabilities below is periodic because, for example, state a has period 2

We can confirm that the stochastic matrix is periodic with the following code

```
P = [[0.0, 1.0, 0.0, 0.0],
     [0.5, 0.0, 0.5, 0.0],
     [0.0, 0.5, 0.0, 0.5],
     [0.0, 0.0, 1.0, 0.0]]

mc = qe.MarkovChain(P)
mc.period
```

```
2
```

```
mc.is_aperiodic
```

```
False
```

42.6 Stationary Distributions

As seen in (42.4), we can shift a marginal distribution forward one unit of time via postmultiplication by P.

Some distributions are invariant under this updating process — for example,

```
P = np.array([[0.4, 0.6],
              [0.2, 0.8]])
```

(continues on next page)

(continued from previous page)

```
ψ = (0.25, 0.75)
ψ @ P
```

```
array([0.25, 0.75])
```

Such distributions are called **stationary** or **invariant**.

Formally, a marginal distribution ψ^* on S is called **stationary** for P if $\psi^* = \psi^* P$.

(This is the same notion of stationarity that we learned about in the lecture on AR(1) processes applied to a different setting.)

From this equality, we immediately get $\psi^* = \psi^* P^t$ for all t.

This tells us an important fact: If the distribution of X_0 is a stationary distribution, then X_t will have this same distribution for all t.

Hence stationary distributions have a natural interpretation as **stochastic steady states** — we'll discuss this more soon.

Mathematically, a stationary distribution is a fixed point of P when P is thought of as the map $\psi \mapsto \psi P$ from (row) vectors to (row) vectors.

Theorem. Every stochastic matrix P has at least one stationary distribution.

(We are assuming here that the state space S is finite; if not more assumptions are required)

For proof of this result, you can apply Brouwer's fixed point theorem, or see EDTC, theorem 4.3.5.

There can be many stationary distributions corresponding to a given stochastic matrix P.

- For example, if P is the identity matrix, then all marginal distributions are stationary.

To get uniqueness an invariant distribution, the transition matrix P must have the property that no nontrivial subsets of the state space are **infinitely persistent**.

A subset of the state space is infinitely persistent if other parts of the state space cannot be accessed from it.

Thus, infinite persistence of a non-trivial subset is the opposite of irreducibility.

This gives some intuition for the following fundamental theorem.

Theorem. If P is both aperiodic and irreducible, then

1. P has exactly one stationary distribution ψ^*.
2. For any initial marginal distribution ψ_0, we have $\|\psi_0 P^t - \psi^*\| \to 0$ as $t \to \infty$.

For a proof, see, for example, theorem 5.2 of [Häggström, 2002].

(Note that part 1 of the theorem only requires irreducibility, whereas part 2 requires both irreducibility and aperiodicity)

A stochastic matrix that satisfies the conditions of the theorem is sometimes called **uniformly ergodic**.

A sufficient condition for aperiodicity and irreducibility is that every element of P is strictly positive.

- Try to convince yourself of this.

42.6.1 Example

Recall our model of the employment/unemployment dynamics of a particular worker *discussed above*.

Assuming $\alpha \in (0, 1)$ and $\beta \in (0, 1)$, the uniform ergodicity condition is satisfied.

Let $\psi^* = (p, 1 - p)$ be the stationary distribution, so that p corresponds to unemployment (state 0).

Using $\psi^* = \psi^* P$ and a bit of algebra yields

$$p = \frac{\beta}{\alpha + \beta}$$

This is, in some sense, a steady state probability of unemployment — more about the interpretation of this below.

Not surprisingly it tends to zero as $\beta \to 0$, and to one as $\alpha \to 0$.

42.6.2 Calculating Stationary Distributions

As discussed above, a particular Markov matrix P can have many stationary distributions.

That is, there can be many row vectors ψ such that $\psi = \psi P$.

In fact if P has two distinct stationary distributions ψ_1, ψ_2 then it has infinitely many, since in this case, as you can verify, for any $\lambda \in [0, 1]$

$$\psi_3 := \lambda \psi_1 + (1 - \lambda) \psi_2$$

is a stationary distribution for P.

If we restrict attention to the case in which only one stationary distribution exists, one way to finding it is to solve the system

$$\psi (I_n - P) = 0 \tag{42.7}$$

for ψ, where I_n is the $n \times n$ identity.

But the zero vector solves system (42.7), so we must proceed cautiously.

We want to impose the restriction that ψ is a probability distribution.

There are various ways to do this.

One option is to regard solving system (42.7) as an eigenvector problem: a vector ψ such that $\psi = \psi P$ is a left eigenvector associated with the unit eigenvalue $\lambda = 1$.

A stable and sophisticated algorithm specialized for stochastic matrices is implemented in QuantEcon.py.

This is the one we recommend:

```
P = [[0.4, 0.6],
     [0.2, 0.8]]

mc = qe.MarkovChain(P)
mc.stationary_distributions  # Show all stationary distributions
```

```
array([[0.25, 0.75]])
```

42.6.3 Convergence to Stationarity

Part 2 of the Markov chain convergence theorem *stated above* tells us that the marginal distribution of X_t converges to the stationary distribution regardless of where we begin.

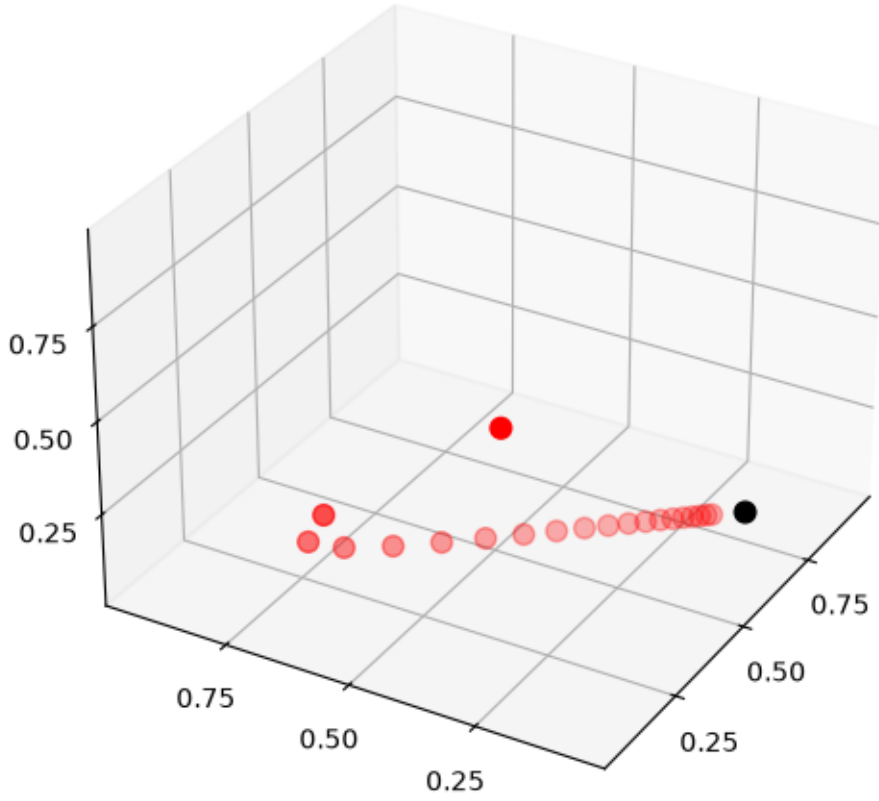
This adds considerable authority to our interpretation of ψ^* as a stochastic steady state.

The convergence in the theorem is illustrated in the next figure

```
P = ((0.971, 0.029, 0.000),
     (0.145, 0.778, 0.077),
     (0.000, 0.508, 0.492))
P = np.array(P)

ψ = (0.0, 0.2, 0.8)        # Initial condition

fig = plt.figure(figsize=(8, 6))
ax = fig.add_subplot(111, projection='3d')



ax.set(xlim=(0, 1), ylim=(0, 1), zlim=(0, 1),
       xticks=(0.25, 0.5, 0.75),
       yticks=(0.25, 0.5, 0.75),
       zticks=(0.25, 0.5, 0.75))

x_vals, y_vals, z_vals = [], [], []
for t in range(20):
    x_vals.append(ψ[0])
    y_vals.append(ψ[1])
    z_vals.append(ψ[2])
    ψ = ψ @ P

ax.scatter(x_vals, y_vals, z_vals, c='r', s=60)
ax.view_init(30, 210)

mc = qe.MarkovChain(P)
ψ_star = mc.stationary_distributions[0]
ax.scatter(ψ_star[0], ψ_star[1], ψ_star[2], c='k', s=60)

plt.show()
```

Here

- P is the stochastic matrix for recession and growth *considered above*.
- The highest red dot is an arbitrarily chosen initial marginal probability distribution ψ, represented as a vector in $\mathbb{R}^3$.
- The other red dots are the marginal distributions ψP^t for $t = 1, 2, ...$
- The black dot is ψ^*.

You might like to try experimenting with different initial conditions.

42.7 Ergodicity

Under irreducibility, yet another important result obtains: for all $x \in S$,

$$\frac{1}{m} \sum_{t=1}^{m} \mathbf{1}\{X_t = x\} \to \psi^*(x) \quad \text{as } m \to \infty \tag{42.8}$$

Here

- $\mathbf{1}\{X_t = x\} = 1$ if $X_t = x$ and zero otherwise
- convergence is with probability one
- the result does not depend on the marginal distribution of X_0

The result tells us that the fraction of time the chain spends at state x converges to $\psi^*(x)$ as time goes to infinity.

This gives us another way to interpret the stationary distribution — provided that the convergence result in (42.8) is valid.

The convergence asserted in (42.8) is a special case of a law of large numbers result for Markov chains — see EDTC, section 4.3.4 for some additional information.

42.7.1 Example

Recall our cross-sectional interpretation of the employment/unemployment model *discussed above*.

Assume that $\alpha \in (0, 1)$ and $\beta \in (0, 1)$, so that irreducibility and aperiodicity both hold.

We saw that the stationary distribution is $(p, 1 - p)$, where

$$p = \frac{\beta}{\alpha + \beta}$$

In the cross-sectional interpretation, this is the fraction of people unemployed.

In view of our latest (ergodicity) result, it is also the fraction of time that a single worker can expect to spend unemployed.

Thus, in the long-run, cross-sectional averages for a population and time-series averages for a given person coincide.

This is one aspect of the concept of ergodicity.

42.8 Computing Expectations

We sometimes want to compute mathematical expectations of functions of X_t of the form

$$\mathbb{E}[h(X_t)] \tag{42.9}$$

and conditional expectations such as

$$\mathbb{E}[h(X_{t+k}) \mid X_t = x] \tag{42.10}$$

where

- $\{X_t\}$ is a Markov chain generated by $n \times n$ stochastic matrix P
- h is a given function, which, in terms of matrix algebra, we'll think of as the column vector

$$h = \begin{pmatrix} h(x_1) \\ \vdots \\ h(x_n) \end{pmatrix}$$

Computing the unconditional expectation (42.9) is easy.

We just sum over the marginal distribution of X_t to get

$$\mathbb{E}[h(X_t)] = \sum_{x \in S} (\psi P^t)(x) h(x)$$

Here ψ is the distribution of X_0.

Since ψ and hence ψP^t are row vectors, we can also write this as

$$\mathbb{E}[h(X_t)] = \psi P^t h$$

For the conditional expectation (42.10), we need to sum over the conditional distribution of X_{t+k} given $X_t = x$.

We already know that this is $P^k(x, \cdot)$, so

$$\mathbb{E}[h(X_{t+k}) \mid X_t = x] = (P^k h)(x) \tag{42.11}$$

The vector $P^k h$ stores the conditional expectation $\mathbb{E}[h(X_{t+k}) \mid X_t = x]$ over all x.

42.8.1 Iterated Expectations

The **law of iterated expectations** states that

$$\mathbb{E}\left[\mathbb{E}[h(X_{t+k}) \mid X_t = x]\right] = \mathbb{E}[h(X_{t+k})]$$

where the outer $\mathbb{E}$ on the left side is an unconditional distribution taken with respect to the marginal distribution ψ_t of X_t (again see equation (42.6)).

To verify the law of iterated expectations, use equation (42.11) to substitute $(P^k h)(x)$ for $E[h(X_{t+k}) \mid X_t = x]$, write

$$\mathbb{E}\left[\mathbb{E}[h(X_{t+k}) \mid X_t = x]\right] = \psi_t P^k h,$$

and note $\psi_t P^k h = \psi_{t+k} h = \mathbb{E}[h(X_{t+k})]$.

42.8.2 Expectations of Geometric Sums

Sometimes we want to compute the mathematical expectation of a geometric sum, such as $\sum_t \beta^t h(X_t)$.

In view of the preceding discussion, this is

$$\mathbb{E}\Big[\sum_{j=0}^{\infty} \beta^j h(X_{t+j}) \mid X_t = x\Big] = [(I - \beta P)^{-1} h](x)$$

where

$$(I - \beta P)^{-1} = I + \beta P + \beta^2 P^2 + \cdots$$

Premultiplication by $(I - \beta P)^{-1}$ amounts to "applying the **resolvent operator**".

42.9 Exercises

Exercise 42.9.1

According to the discussion *above*, if a worker's employment dynamics obey the stochastic matrix

$$P = \begin{pmatrix} 1 - \alpha & \alpha \\ \beta & 1 - \beta \end{pmatrix}$$

with $\alpha \in (0, 1)$ and $\beta \in (0, 1)$, then, in the long-run, the fraction of time spent unemployed will be

$$p := \frac{\beta}{\alpha + \beta}$$

In other words, if $\{X_t\}$ represents the Markov chain for employment, then $\bar{X}_m \to p$ as $m \to \infty$, where

$$\bar{X}_m := \frac{1}{m} \sum_{t=1}^{m} \mathbf{1}\{X_t = 0\}$$

This exercise asks you to illustrate convergence by computing $\bar{X}_m$ for large m and checking that it is close to p.

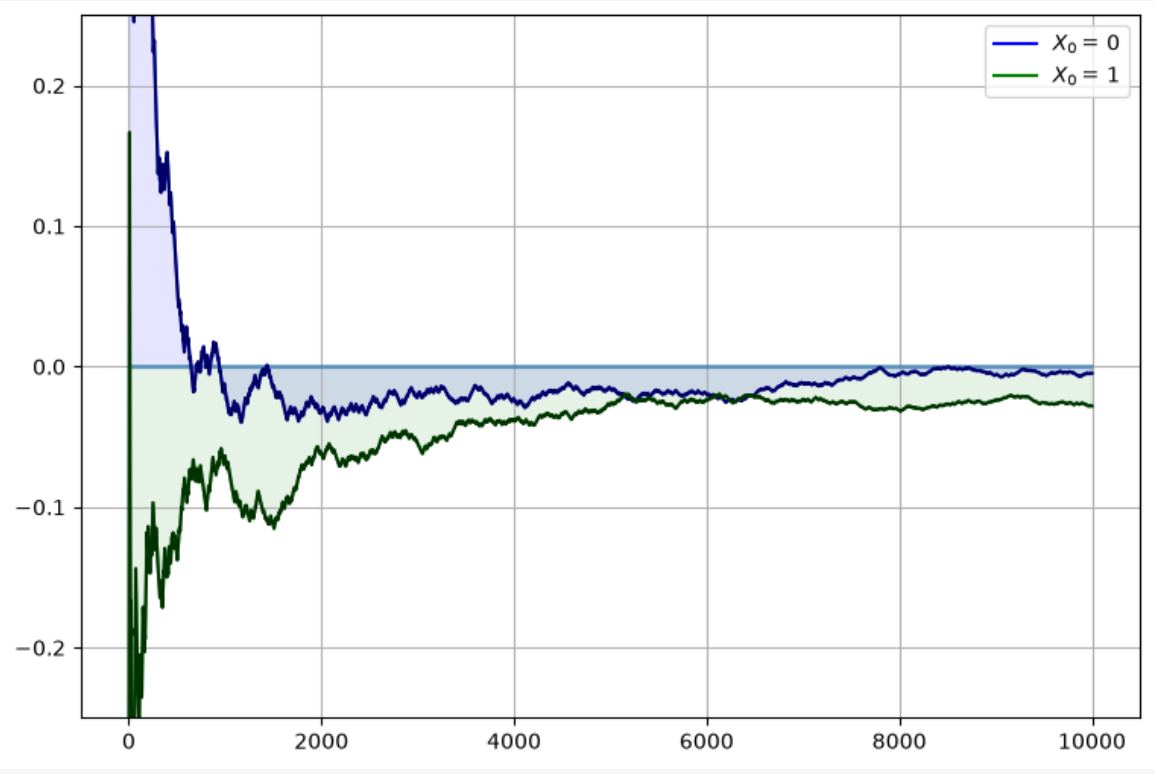
You will see that this statement is true regardless of the choice of initial condition or the values of α, β, provided both lie in $(0, 1)$.

Solution

We will address this exercise graphically.

The plots show the time series of $\bar{X}_m - p$ for two initial conditions.

As m gets large, both series converge to zero.



```
α = β = 0.1
N = 10000
p = β / (α + β)

P = ((1 - α,        α),               # Careful: P and p are distinct
     (    β,    1 - β))
mc = MarkovChain(P)

fig, ax = plt.subplots(figsize=(9, 6))
ax.set_ylim(-0.25, 0.25)
ax.grid()
ax.hlines(0, 0, N, lw=2, alpha=0.6)   # Horizonal line at zero

for x0, col in ((0, 'blue'), (1, 'green')):
    # Generate time series for worker that starts at x0
    X = mc.simulate(N, init=x0)
    # Compute fraction of time spent unemployed, for each n
    X_bar = (X == 0).cumsum() / (1 + np.arange(N, dtype=float))
    # Plot
    ax.fill_between(range(N), np.zeros(N), X_bar - p, color=col, alpha=0.1)
    ax.plot(X_bar - p, color=col, label=fr'$X_0 = \, {x0} $')
    # Overlay in black--make lines clearer
    ax.plot(X_bar - p, 'k-', alpha=0.6)

ax.legend(loc='upper right')
plt.show()
```

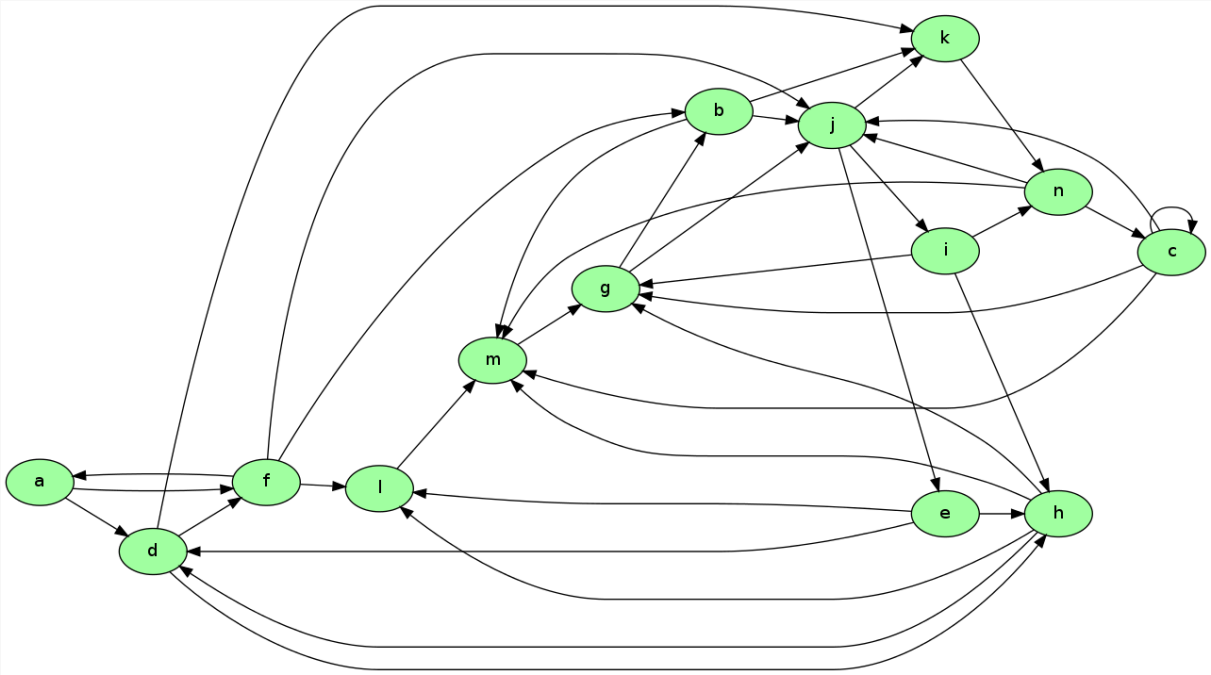
Exercise 42.9.2

A topic of interest for economics and many other disciplines is *ranking*.

Let's now consider one of the most practical and important ranking problems — the rank assigned to web pages by search engines.

(Although the problem is motivated from outside of economics, there is in fact a deep connection between search ranking systems and prices in certain competitive equilibria — see [Du *et al.*, 2013].)

To understand the issue, consider the set of results returned by a query to a web search engine.



For the user, it is desirable to

1. receive a large set of accurate matches
2. have the matches returned in order, where the order corresponds to some measure of "importance"

Ranking according to a measure of importance is the problem we now consider.

The methodology developed to solve this problem by Google founders Larry Page and Sergey Brin is known as PageRank.

To illustrate the idea, consider the following diagram

Imagine that this is a miniature version of the WWW, with

- each node representing a web page
- each arrow representing the existence of a link from one page to another

Now let's think about which pages are likely to be important, in the sense of being valuable to a search engine user.

One possible criterion for the importance of a page is the number of inbound links — an indication of popularity.

By this measure, `m` and `j` are the most important pages, with 5 inbound links each.

However, what if the pages linking to `m`, say, are not themselves important?

Thinking this way, it seems appropriate to weight the inbound nodes by relative importance.

The PageRank algorithm does precisely this.

A slightly simplified presentation that captures the basic idea is as follows.

Letting j be (the integer index of) a typical page and r_j be its ranking, we set

$$r_j = \sum_{i \in L_j} \frac{r_i}{\ell_i}$$

where

- ℓ_i is the total number of outbound links from i
- L_j is the set of all pages i such that i has a link to j

This is a measure of the number of inbound links, weighted by their own ranking (and normalized by $1/\ell_i$).

There is, however, another interpretation, and it brings us back to Markov chains.

Let P be the matrix given by $P(i, j) = \mathbf{1}\{i \to j\}/\ell_i$ where $\mathbf{1}\{i \to j\} = 1$ if i has a link to j and zero otherwise.

The matrix P is a stochastic matrix provided that each page has at least one link.

With this definition of P we have

$$r_j = \sum_{i \in L_j} \frac{r_i}{\ell_i} = \sum_{\text{all } i} \mathbf{1}\{i \to j\} \frac{r_i}{\ell_i} = \sum_{\text{all } i} P(i,j) r_i$$

Writing r for the row vector of rankings, this becomes $r = rP$.

Hence r is the stationary distribution of the stochastic matrix P.

Let's think of $P(i,j)$ as the probability of "moving" from page i to page j.

The value $P(i,j)$ has the interpretation

- $P(i,j) = 1/k$ if i has k outbound links and j is one of them
- $P(i,j) = 0$ if i has no direct link to j

Thus, motion from page to page is that of a web surfer who moves from one page to another by randomly clicking on one of the links on that page.

Here "random" means that each link is selected with equal probability.

Since r is the stationary distribution of P, assuming that the uniform ergodicity condition is valid, we *can interpret* r_j as the fraction of time that a (very persistent) random surfer spends at page j.

Your exercise is to apply this ranking algorithm to the graph pictured above and return the list of pages ordered by rank.

There is a total of 14 nodes (i.e., web pages), the first named `a` and the last named `n`.

A typical line from the file has the form

```
d -> h;
```

This should be interpreted as meaning that there exists a link from `d` to `h`.

The data for this graph is shown below, and read into a file called `web_graph_data.txt` when the cell is executed.

```
%%file web_graph_data.txt
a -> d;
a -> f;
b -> j;
b -> k;
b -> m;
c -> c;
c -> g;
c -> j;
c -> m;
d -> f;
d -> h;
d -> k;
e -> d;
e -> h;
e -> l;
f -> a;
f -> b;
f -> j;
f -> l;
g -> b;
g -> j;
h -> d;
h -> g;
h -> l;
```

```
h -> m;
i -> g;
i -> h;
i -> n;
j -> e;
j -> i;
j -> k;
k -> n;
l -> m;
m -> g;
n -> c;
n -> j;
n -> m;
```

```
Writing web_graph_data.txt
```

To parse this file and extract the relevant information, you can use regular expressions.

The following code snippet provides a hint as to how you can go about this

```
import re
re.findall(r'\w', 'x +++ y ****** z')  # \w matches alphanumerics
```

```
['x', 'y', 'z']
```

```
re.findall(r'\w', 'a ^^ b &&& $$ c')
```

```
['a', 'b', 'c']
```

When you solve for the ranking, you will find that the highest ranked node is in fact `g`, while the lowest is `a`.

Solution

Here is one solution:

```
"""
Return list of pages, ordered by rank
"""
import re
from operator import itemgetter

infile = 'web_graph_data.txt'
alphabet = 'abcdefghijklmnopqrstuvwxyz'

n = 14 # Total number of web pages (nodes)

# Create a matrix Q indicating existence of links
#  * Q[i, j] = 1 if there is a link from i to j
#  * Q[i, j] = 0 otherwise
Q = np.zeros((n, n), dtype=int)
with open(infile) as f:
    edges = f.readlines()
for edge in edges:
    from_node, to_node = re.findall(r'\w', edge)
    i, j = alphabet.index(from_node), alphabet.index(to_node)
    Q[i, j] = 1
# Create the corresponding Markov matrix P
P = np.empty((n, n))
```

```
for i in range(n):
    P[i, :] = Q[i, :] / Q[i, :].sum()
mc = MarkovChain(P)
# Compute the stationary distribution r
r = mc.stationary_distributions[0]
ranked_pages = {alphabet[i] : r[i] for i in range(n)}
# Print solution, sorted from highest to lowest rank
print('Rankings\n ***')
for name, rank in sorted(ranked_pages.items(), key=itemgetter(1), reverse=1):
    print(f'{name}: {rank:.4}')
```

```
Rankings
 ***
g: 0.1607
j: 0.1594
m: 0.1195
n: 0.1088
k: 0.09106
b: 0.08326
e: 0.05312
i: 0.05312
c: 0.04834
h: 0.0456
l: 0.03202
d: 0.03056
f: 0.01164
a: 0.002911
```

Exercise 42.9.3

In numerical work, it is sometimes convenient to replace a continuous model with a discrete one.

In particular, Markov chains are routinely generated as discrete approximations to AR(1) processes of the form

$$y_{t+1} = \rho y_t + u_{t+1}$$

Here u_t is assumed to be IID and $N(0, \sigma_u^2)$.

The variance of the stationary probability distribution of $\{y_t\}$ is

$$\sigma_y^2 := \frac{\sigma_u^2}{1 - \rho^2}$$

Tauchen's method [Tauchen, 1986] is the most common method for approximating this continuous state process with a finite state Markov chain.

A routine for this already exists in QuantEcon.py but let's write our own version as an exercise.

As a first step, we choose

- n, the number of states for the discrete approximation
- m, an integer that parameterizes the width of the state space

Next, we create a state space $\{x_0, \ldots, x_{n-1}\} \subset \mathbb{R}$ and a stochastic $n \times n$ matrix P such that

- $x_0 = -m\,\sigma_y$
- $x_{n-1} = m\,\sigma_y$

- $x_{i+1} = x_i + s$ where $s = (x_{n-1} - x_0)/(n-1)$

Let F be the cumulative distribution function of the normal distribution $N(0, \sigma_u^2)$.

The values $P(x_i, x_j)$ are computed to approximate the AR(1) process — omitting the derivation, the rules are as follows:

1. If $j = 0$, then set

$$P(x_i, x_j) = P(x_i, x_0) = F(x_0 - \rho x_i + s/2)$$

2. If $j = n - 1$, then set

$$P(x_i, x_j) = P(x_i, x_{n-1}) = 1 - F(x_{n-1} - \rho x_i - s/2)$$

3. Otherwise, set

$$P(x_i, x_j) = F(x_j - \rho x_i + s/2) - F(x_j - \rho x_i - s/2)$$

The exercise is to write a function `approx_markov(rho, sigma_u, m=3, n=7)` that returns $\{x_0, \ldots, x_{n-1}\} \subset \mathbb{R}$ and $n \times n$ matrix P as described above.

- Even better, write a function that returns an instance of QuantEcon.py's MarkovChain class.

Solution

A solution from the QuantEcon.py library can be found here.

CHAPTER

FORTYTHREE

INVENTORY DYNAMICS

Contents

- *Inventory Dynamics*
  - *Overview*
  - *Sample paths*
  - *Marginal distributions*
  - *Exercises*

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install jax
```

43.1 Overview

In this lecture, we will study the time path of inventories for firms that follow so-called s-S inventory dynamics.

Such firms

1. wait until inventory falls below some level s and then
2. order sufficient quantities to bring their inventory back up to capacity S.

These kinds of policies are common in practice and are also optimal in certain circumstances.

A review of early literature and some macroeconomic implications can be found in [Caplin, 1985].

Here, our main aim is to learn more about simulation, time series, and Markov dynamics.

While our Markov environment and many of the concepts we consider are related to those found in our *lecture on finite Markov chains*, the state space is a continuum in the current application.

Let's start with some imports

```
from functools import partial
from typing import NamedTuple
import jax
import jax.numpy as jnp
from jax import random
```

(continues on next page)

(continued from previous page)

```
import matplotlib.pyplot as plt
from sklearn.neighbors import KernelDensity
```

43.2 Sample paths

Consider a firm with inventory X_t.

The firm waits until $X_t \leq s$ and then restocks up to S units.

It faces stochastic demand $\{D_t\}$, which we assume is IID.

With notation $a^+ := \max\{a, 0\}$, inventory dynamics can be written as

$$X_{t+1} = \begin{cases} (S - D_{t+1})^+ & \text{if } X_t \leq s \\ (X_t - D_{t+1})^+ & \text{if } X_t > s \end{cases}$$

In what follows, we will assume that each D_t is lognormal, so that

$$D_t = \exp(\mu + \sigma Z_t)$$

where μ and σ are parameters and $\{Z_t\}$ is IID and standard normal.

Here's a class that stores parameters and generates time paths for inventory.

```
class Firm(NamedTuple):
    s: int    # restock trigger level
    S: int    # capacity
    μ: float  # shock location parameter
    σ: float  # shock scale parameter
```

```
@partial(jax.jit, static_argnames="sim_length")
def sim_inventory_path(firm, x_init, key, sim_length):
    """
    Simulate an inventory path of length sim_length from a single key.

    A fresh shock is generated each period by folding the period index
    into key, so callers pass one key per path rather than a whole array.

    Args:
        firm: Firm object
        x_init: Initial inventory level
        key: A single JAX random key
        sim_length: Number of periods to simulate

    Returns:
        Array of inventory levels [X_0, X_1, ..., X_{sim_length-1}]
    """

    def update(t, X):
        x = X[t - 1]
        Z = random.normal(random.fold_in(key, t))    # fresh shock for period t
        D = jnp.exp(firm.μ + firm.σ * Z)
        x_new = jnp.where(
            x <= firm.s,
```

(continues on next page)

(continued from previous page)

```
            jnp.maximum(firm.S - D, 0.0),    # restock to S, then meet demand
            jnp.maximum(x - D, 0.0),         # just meet demand
        )
        return X.at[t].set(x_new)

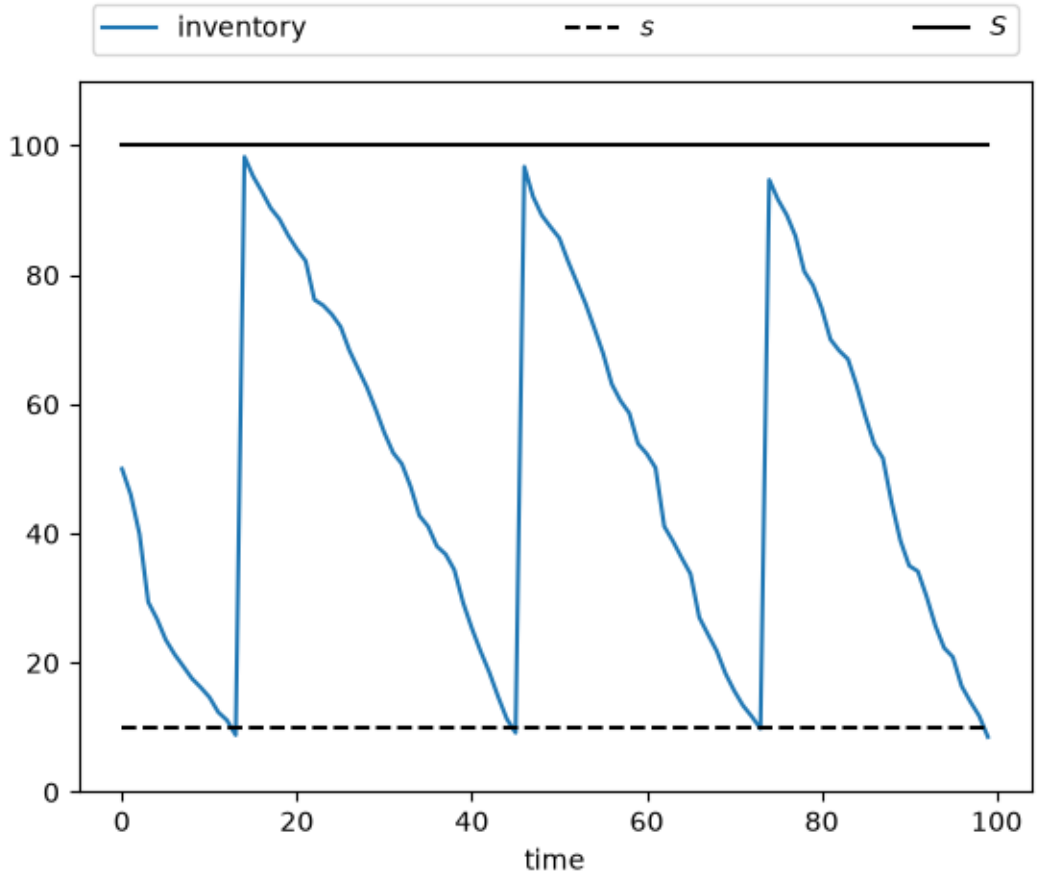
    X = jnp.zeros(sim_length).at[0].set(x_init)
    return jax.lax.fori_loop(1, sim_length, update, X)
```

Note

Writing `X.at[t].set(x_new)` returns a *new* array rather than mutating `X` in place, in keeping with JAX's functional style. This is not as wasteful as it looks: inside a `jax.jit`-compiled function the XLA compiler sees that the old array is no longer needed and performs the update in place, so no fresh array is allocated each period.

```
firm = Firm(s=10, S=100, μ=1.0, σ=0.5)
```

```
sim_length = 100
x_init = 50
X = sim_inventory_path(firm, x_init, random.key(21), sim_length)
```



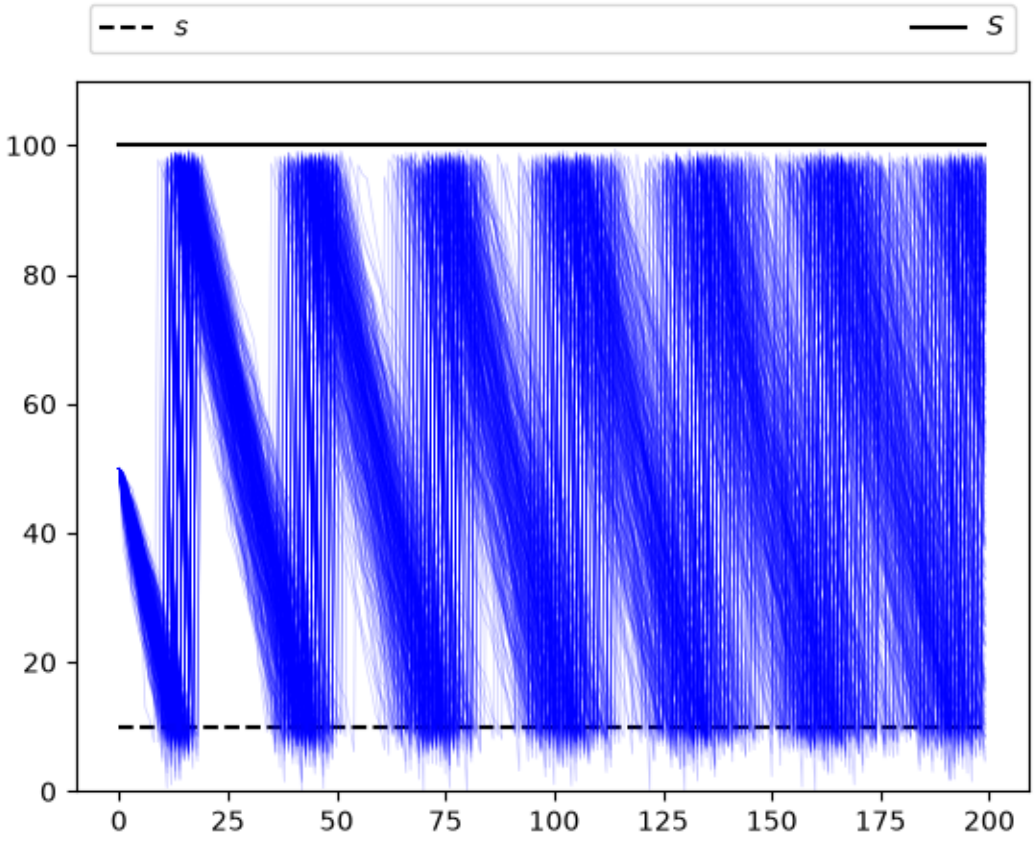
Let's run a first simulation, of a single path:

```
s, S = firm.s, firm.S

fig, ax = plt.subplots()
bbox = (0.0, 1.02, 1.0, 0.102)
legend_args = {"ncol": 3, "bbox_to_anchor": bbox, "loc": 3, "mode": "expand"}

ax.plot(X, label="inventory")
ax.plot(jnp.full(sim_length, s), "k--", label="$s$")
ax.plot(jnp.full(sim_length, S), "k-", label="$S$")
ax.set_ylim(0, S + 10)
ax.set_xlabel("time")
ax.legend(**legend_args)

plt.show()
```



Now let's simulate multiple paths in order to build a more complete picture of the probabilities of different outcomes:

```
sim_length = 200
fig, ax = plt.subplots()

ax.plot(jnp.full(sim_length, s), "k--", label="$s$")
ax.plot(jnp.full(sim_length, S), "k-", label="$S$")
ax.set_ylim(0, S + 10)
ax.legend(**legend_args)

for i in range(400):
    X = sim_inventory_path(firm, x_init, random.key(i), sim_length)
    ax.plot(X, "b", alpha=0.2, lw=0.5)

plt.show()
```

43.3 Marginal distributions

Now let's look at the marginal distribution ψ_T of X_T for some fixed T.

We will do this by generating many draws of X_T given initial condition X_0.

With these draws of X_T we can build up a picture of its distribution ψ_T.

Here's one visualization, with $T = 50$.

```
T = 50
M = 200  # Number of draws

ymin, ymax = 0, S + 10

fig, axes = plt.subplots(1, 2, figsize=(11, 6))

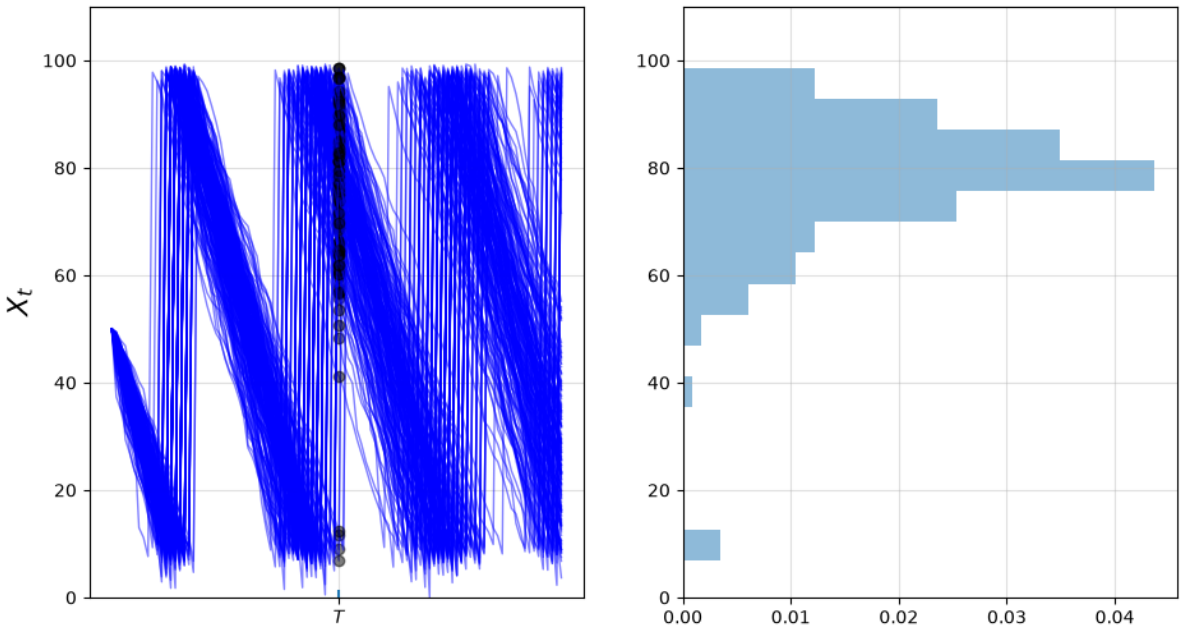
for ax in axes:
    ax.grid(alpha=0.4)

ax = axes[0]

ax.set_ylim(ymin, ymax)
ax.set_ylabel("$X_t$", fontsize=16)
ax.vlines((T,), -1.5, 1.5)
```

(continues on next page)

(continued from previous page)



```
ax.set_xticks((T,))
ax.set_xticklabels((r"$T$",))

sample = []
for m in range(M):
    X = sim_inventory_path(firm, x_init, random.key(m), 2 * T)
    ax.plot(X, "b-", lw=1, alpha=0.5)
    ax.plot((T,), (X[T],), "ko", alpha=0.5)
    sample.append(X[T])

axes[1].set_ylim(ymin, ymax)

axes[1].hist(
    sample,
    bins=16,
    density=True,
    orientation="horizontal",
    histtype="bar",
    alpha=0.5,
)

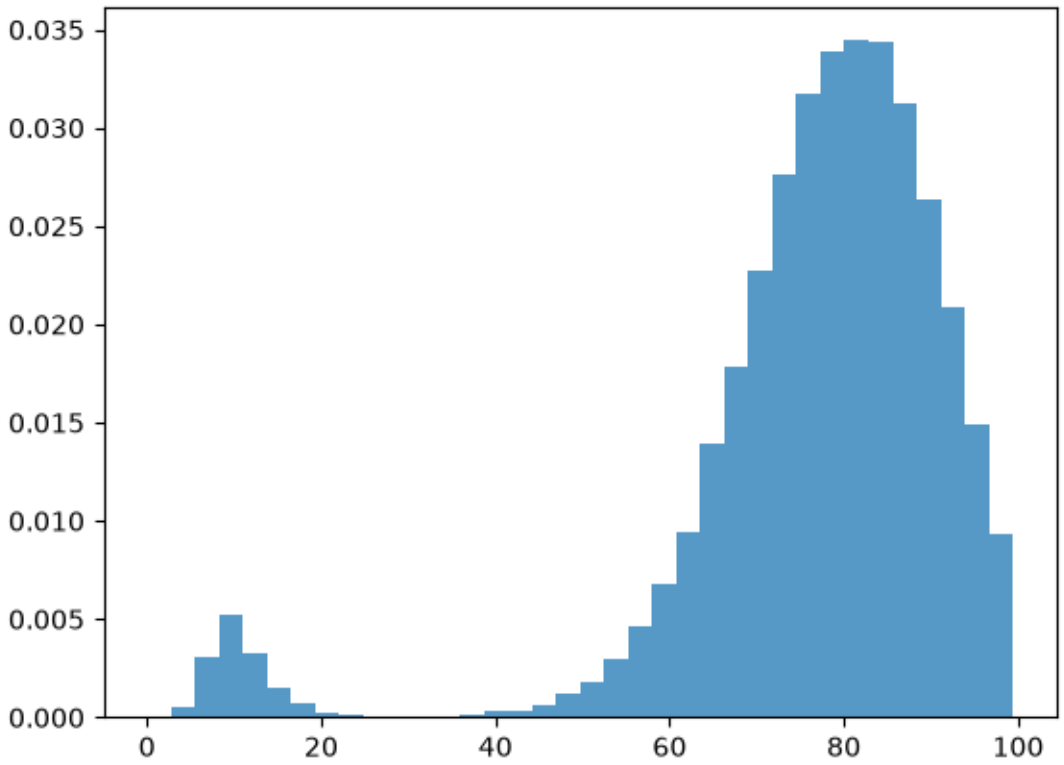
plt.show()
```

We can build up a clearer picture by drawing more samples

```
T = 50
M = 50_000

fig, ax = plt.subplots()

# Draw all M paths at once by vectorizing over one key per path
keys = random.split(random.key(0), M)
paths = jax.vmap(
    sim_inventory_path, in_axes=(None, None, 0, None)
```



(continues on next page)

(continued from previous page)

```
)(firm, x_init, keys, T + 1)
sample = paths[:, T]

ax.hist(sample, bins=36, density=True, histtype="bar", alpha=0.75)

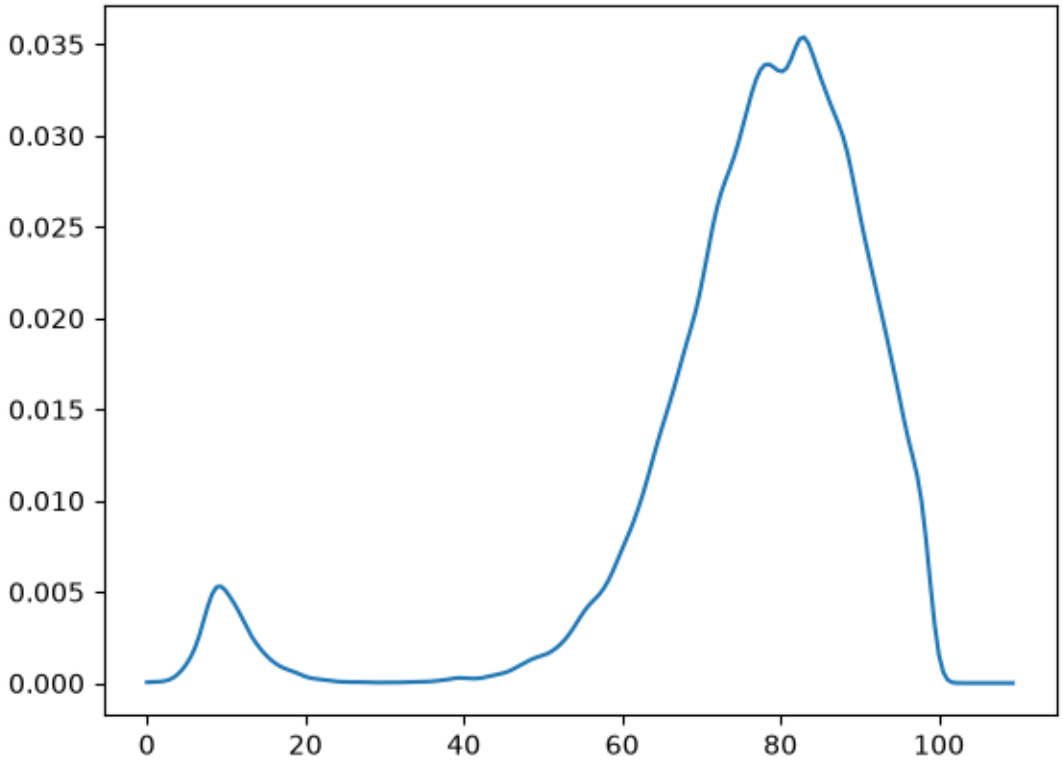
plt.show()
```

Note that the distribution is bimodal

- Most firms have restocked twice but a few have restocked only once (see figure with paths above).
- Firms in the second category have lower inventory.

We can also approximate the distribution using a kernel density estimator.

Kernel density estimators can be thought of as smoothed histograms.



They are preferable to histograms when the distribution being estimated is likely to be smooth.

We will use a kernel density estimator from scikit-learn

```
def plot_kde(sample, ax, label=""):
    xmin, xmax = 0.9 * sample.min(), 1.1 * sample.max()
    xgrid = jnp.linspace(xmin, xmax, 200)
    kde = KernelDensity(kernel="gaussian").fit(sample[:, None])
    log_dens = kde.score_samples(xgrid[:, None])

    ax.plot(xgrid, jnp.exp(log_dens), label=label)
```

```
fig, ax = plt.subplots()
plot_kde(sample, ax)
plt.show()
```

The allocation of probability density is similar to what was shown by the histogram just above.

43.4 Exercises

Exercise 43.4.1

This model is asymptotically stationary, with a unique stationary distribution.

(See the discussion of stationarity in our lecture on AR(1) processes for background — the fundamental concepts are the same.)

In particular, the sequence of marginal distributions $\{\psi_t\}$ is converging to a unique limiting distribution that does not depend on initial conditions.

Although we will not prove this here, we can investigate it using simulation.

Your task is to generate and plot the sequence $\{\psi_t\}$ at times $t = 10, 50, 250, 500, 750$ based on the discussion above.

(The kernel density estimator is probably the best way to present each distribution.)

You should see convergence, in the sense that differences between successive distributions are getting smaller.

Try different initial conditions to verify that, in the long run, the distribution is invariant across initial conditions.

Solution

Below is one possible solution:

The computations involve a lot of CPU cycles so we have tried to write the code efficiently using `jax.jit` and `jax.vmap` to run on CPU/GPU.

```
@jax.jit
def simulate_firm_forward(firm, x_init, key, num_periods):
    """
    Simulate a single firm num_periods steps forward and return its
    final inventory level. A fresh shock is drawn each period from key.
    """

    def update(t, x):
        Z = random.normal(random.fold_in(key, t))
        D = jnp.exp(firm.μ + firm.σ * Z)
        return jnp.where(
            x <= firm.s,
            jnp.maximum(firm.S - D, 0.0),
            jnp.maximum(x - D, 0.0),
        )

    return jax.lax.fori_loop(0, num_periods, update, x_init * 1.0)

# Vectorize over firms: each has its own initial level and its own key
simulate_firms_forward = jax.vmap(
    simulate_firm_forward, in_axes=(None, 0, 0, None)
)
```

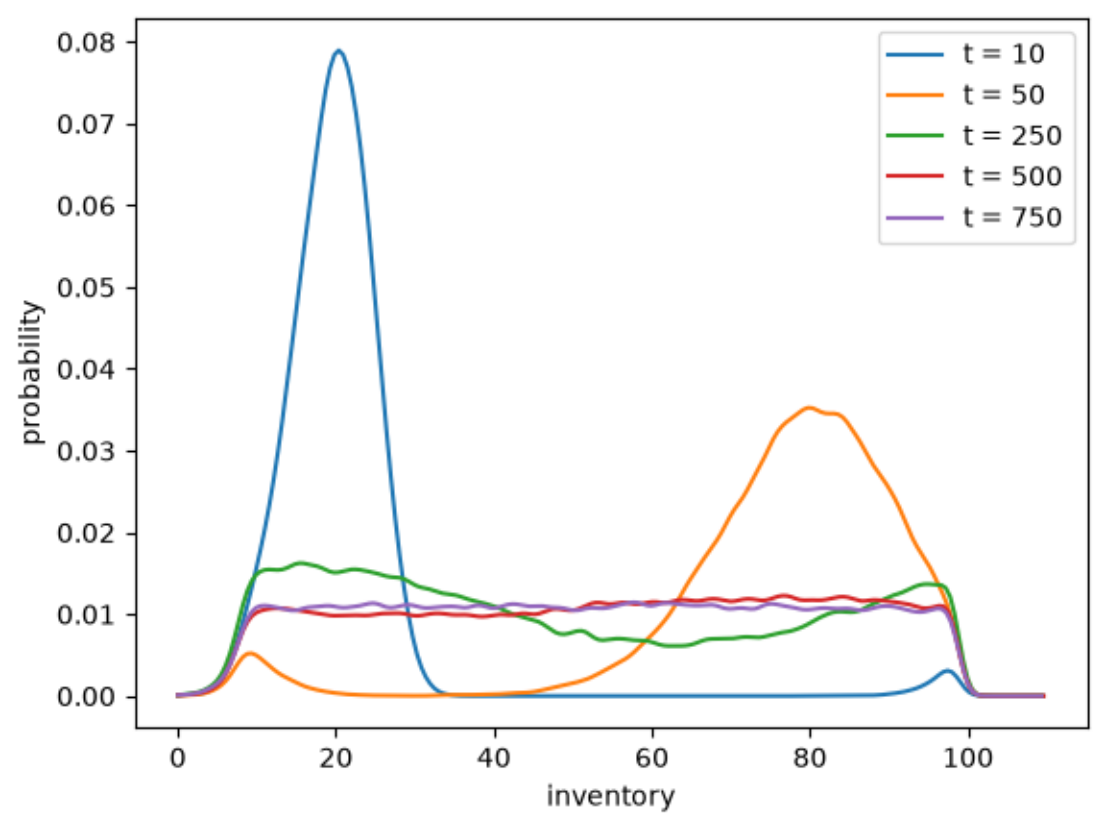
```
def shift_firms_forward(firm, current_inventory_levels, num_periods, key):
    """
    Shift multiple firms forward by num_periods using JAX vectorization.
    Returns:
        Array of new inventory levels after num_periods
    """

    # Generate one independent random key per firm
    num_firms = len(current_inventory_levels)
    firm_keys = random.split(key, num_firms)
    # Run simulation for all firms in parallel
    new_inventory_levels = simulate_firms_forward(
        firm, current_inventory_levels, firm_keys, num_periods
    )

    return new_inventory_levels
```

```
x_init = 50
num_firms = 50_000

sample_dates = 0, 10, 50, 250, 500, 750



first_diffs = jnp.diff(jnp.array(sample_dates))

fig, ax = plt.subplots()

X = jnp.full(num_firms, x_init)

current_date = 0
for d in first_diffs:
    X = shift_firms_forward(firm, X, d, random.key(current_date + 1))
    current_date += d
    plot_kde(X, ax, label=f"t = {current_date}")

ax.set_xlabel("inventory")
```

Notice that by $t = 500$ or $t = 750$ the densities are barely changing.

We have reached a reasonable approximation of the stationary density.

You can convince yourself that initial conditions don't matter by testing a few of them.

For example, try rerunning the code above with all firms starting at $X_0 = 20$ or $X_0 = 80$.

Exercise 43.4.2

Using simulation, calculate the probability that firms that start with $X_0 = 70$ need to order twice or more in the first 50 periods.

You will need a large sample size to get an accurate reading.

Solution

Here is one solution.

Again, the computations are relatively intensive so we have written a specialized JAX-jitted function and using `jax.vmap` to use parallelization across firms.

Note the time the routine takes to run, as well as the output.

```
@jax.jit
def simulate_firm_restocks(firm, x_init, key, num_periods):
    """
```

```
    Simulate a single firm for num_periods and report whether it
    restocked more than once. A fresh shock is drawn each period from key.

    Returns:
        1 if the firm restocks > 1 times, 0 otherwise
    """

    def update(t, carry):
        x, restock_count = carry
        Z = random.normal(random.fold_in(key, t))
        D = jnp.exp(firm.μ + firm.σ * Z)
        restock = x <= firm.s
        x_new = jnp.where(
            restock,
            jnp.maximum(firm.S - D, 0.0),
            jnp.maximum(x - D, 0.0),
        )
        return x_new, restock_count + restock

    # Carry the inventory level and a running restock count
    _, total_restocks = jax.lax.fori_loop(
        0, num_periods, update, (x_init * 1.0, 0)
    )
    return (total_restocks > 1).astype(jnp.int32)

# Vectorize the simulation across all firms (one key each)
simulate_firms_restocks = jax.vmap(
    simulate_firm_restocks, in_axes=(None, None, 0, None)
)

def compute_freq(
    firm, x_init=70, sim_length=50, num_firms=1_000_000, key=random.key(2)
):
    """
    Compute the frequency of firms that restock 2 or more times using JAX.

    Args:
        firm: Firm dataclass
        x_init: Initial inventory level for all firms
        sim_length: Length of simulation for each firm
        num_firms: Number of firms to simulate
        key: JAX random key

    Returns:
        Fraction of firms that restock 2 or more times
    """
    # Generate one independent random key per firm
    firm_keys = random.split(key, num_firms)
    # Run simulation for all firms
    restock_indicators = simulate_firms_restocks(
        firm, x_init, firm_keys, sim_length
    )
    # Compute frequency (fraction of firms that restocked > 1 times)
    frequency = jnp.mean(restock_indicators)
    return frequency
```

```
%%time

freq = compute_freq(firm)
print(f"Frequency of at least two stock outs = {freq}")
```

```
Frequency of at least two stock outs = 0.44668900966644287
CPU times: user 1.27 s, sys: 93.9 ms, total: 1.36 s
Wall time: 721 ms
```

> "We may regard the present state of the universe as the effect of its past and the cause of its future" – Marquis de Laplace

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

44.1 Overview

This lecture introduces the **linear state space** dynamic system.

The linear state space system is a generalization of the scalar AR(1) process we studied before.

This model is a workhorse that carries a powerful theory of prediction.

Its many applications include:

- representing dynamics of higher-order linear systems
- predicting the position of a system j steps into the future
- predicting a geometric sum of future values of a variable like
  - non-financial income

  - dividends on a stock
  - the money supply
  - a government deficit or surplus, etc.
- key ingredient of useful models
  - Friedman's permanent income model of consumption smoothing.
  - Barro's model of smoothing total tax collections.
  - Rational expectations version of Cagan's model of hyperinflation.
  - Sargent and Wallace's "unpleasant monetarist arithmetic," etc.

Let's start with some imports:

```
import matplotlib.pyplot as plt
import numpy as np
from quantecon import LinearStateSpace
from scipy.stats import norm
import random
```

44.2 The Linear State Space Model

The objects in play are:

- An $n \times 1$ vector x_t denoting the **state** at time $t = 0, 1, 2, \ldots$.
- An IID sequence of $m \times 1$ random vectors $w_t \sim N(0, I)$.
- A $k \times 1$ vector y_t of **observations** at time $t = 0, 1, 2, \ldots$.
- An $n \times n$ matrix A called the **transition matrix**.
- An $n \times m$ matrix C called the **volatility matrix**.
- A $k \times n$ matrix G sometimes called the **output matrix**.

Here is the linear state-space system

$$
\begin{aligned}
x_{t+1} &= Ax_t + Cw_{t+1} \\
y_t &= Gx_t \\
x_0 &\sim N(\mu_0, \Sigma_0)
\end{aligned}
$$

44.2.1 Primitives

The primitives of the model are

1. the matrices A, C, G
2. shock distribution, which we have specialized to $N(0, I)$
3. the distribution of the initial condition x_0, which we have set to $N(\mu_0, \Sigma_0)$

Given A, C, G and draws of x_0 and $w_1, w_2, \ldots$, the model (44.1) pins down the values of the sequences $\{x_t\}$ and $\{y_t\}$.

Even without these draws, the primitives 1–3 pin down the **probability distributions** of $\{x_t\}$ and $\{y_t\}$.

Later we'll see how to compute these distributions and their moments.

Martingale Difference Shocks

We've made the common assumption that the shocks are independent standardized normal vectors.

But some of what we say will be valid under the assumption that $\{w_{t+1}\}$ is a **martingale difference sequence**.

A martingale difference sequence is a sequence that is zero mean when conditioned on past information.

In the present case, since $\{x_t\}$ is our state sequence, this means that it satisfies

$$\mathbb{E}[w_{t+1}|x_t, x_{t-1}, ...] = 0$$

This is a weaker condition than that $\{w_t\}$ is IID with $w_{t+1} \sim N(0, I)$.

44.2.2 Examples

By appropriate choice of the primitives, a variety of dynamics can be represented in terms of the linear state space model.

The following examples help to highlight this point.

They also illustrate the wise dictum *finding the state is an art*.

Second-order Difference Equation

Let $\{y_t\}$ be a deterministic sequence that satisfies

$$y_{t+1} = \phi_0 + \phi_1 y_t + \phi_2 y_{t-1} \quad \text{s.t.} \quad y_0, y_{-1} \text{ given} \tag{44.1}$$

To map (44.1) into our state space system (44.1), we set

$$x_t = \begin{bmatrix} 1 \\ y_t \\ y_{t-1} \end{bmatrix} \qquad A = \begin{bmatrix} 1 & 0 & 0 \\ \phi_0 & \phi_1 & \phi_2 \\ 0 & 1 & 0 \end{bmatrix} \qquad C = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \qquad G = \begin{bmatrix} 0 & 1 & 0 \end{bmatrix}$$

You can confirm that under these definitions, (44.1) and (44.1) agree.

The next figure shows the dynamics of this process when $\phi_0 = 1.1, \phi_1 = 0.8, \phi_2 = -0.8, y_0 = y_{-1} = 1$.

```
def plot_lss(A,
             C,
             G,
             n=3,
             ts_length=50):

    ar = LinearStateSpace(A, C, G, mu_0=np.ones(n))
    x, y = ar.simulate(ts_length)

    fig, ax = plt.subplots()
    y = y.flatten()
    ax.plot(y, 'b-', lw=2, alpha=0.7)
    ax.grid()
    ax.set_xlabel('time', fontsize=12)
    ax.set_ylabel('$y_t$', fontsize=12)
    plt.show()
```

```
ϕ_0, ϕ_1, ϕ_2 = 1.1, 0.8, -0.8

A = [[1,     0,     0  ],
     [ϕ_0,   ϕ_1,   ϕ_2],
     [0,     1,     0  ]]

C = np.zeros((3, 1))
G = [0, 1, 0]

plot_lss(A, C, G)
```

Later you'll be asked to recreate this figure.

Univariate Autoregressive Processes

We can use (44.1) to represent the model

$$y_{t+1} = \phi_1 y_t + \phi_2 y_{t-1} + \phi_3 y_{t-2} + \phi_4 y_{t-3} + \sigma w_{t+1} \tag{44.2}$$

where $\{w_t\}$ is IID and standard normal.

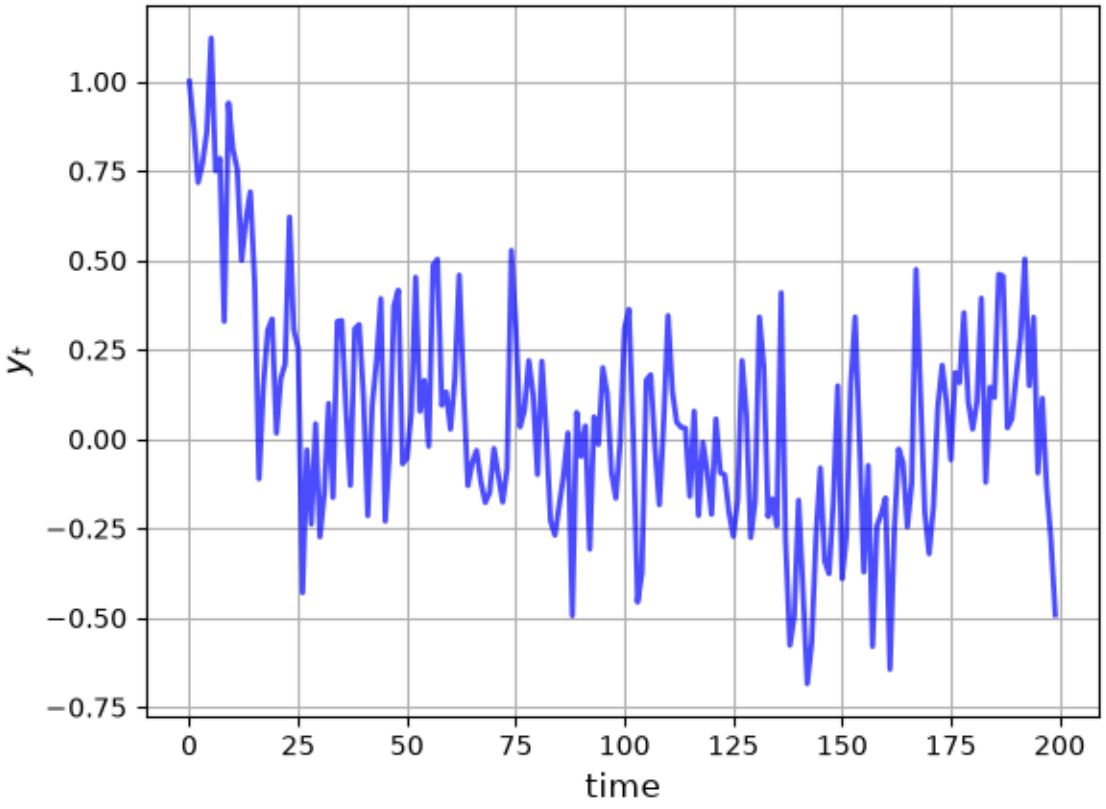
To put this in the linear state space format we take $x_t = \begin{bmatrix} y_t & y_{t-1} & y_{t-2} & y_{t-3} \end{bmatrix}'$ and

$$A = \begin{bmatrix} \phi_1 & \phi_2 & \phi_3 & \phi_4 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \qquad C = \begin{bmatrix} \sigma \\ 0 \\ 0 \\ 0 \end{bmatrix} \qquad G = \begin{bmatrix} 1 & 0 & 0 & 0 \end{bmatrix}$$

The matrix A has the form of the **companion matrix** to the vector $\begin{bmatrix}\phi_1 & \phi_2 & \phi_3 & \phi_4\end{bmatrix}$.

The next figure shows the dynamics of this process when

$$\phi_1 = 0.5, \phi_2 = -0.2, \phi_3 = 0, \phi_4 = 0.5, \sigma = 0.2, y_0 = y_{-1} = y_{-2} = y_{-3} = 1$$



```
ϕ_1, ϕ_2, ϕ_3, ϕ_4 = 0.5, -0.2, 0, 0.5
σ = 0.2

A_1 = [[ϕ_1,   ϕ_2,   ϕ_3,   ϕ_4],
       [1,     0,     0,     0  ],
       [0,     1,     0,     0  ],
       [0,     0,     1,     0  ]]

C_1 = [[σ],
       [0],
       [0],
       [0]]

G_1 = [1, 0, 0, 0]

plot_lss(A_1, C_1, G_1, n=4, ts_length=200)
```

Vector Autoregressions

Now suppose that

- y_t is a $k \times 1$ vector
- ϕ_j is a $k \times k$ matrix and
- w_t is $k \times 1$

Then (44.2) is termed a **vector autoregression**.

To map this into (44.1), we set

$$x_t = \begin{bmatrix} y_t \\ y_{t-1} \\ y_{t-2} \\ y_{t-3} \end{bmatrix} \quad A = \begin{bmatrix} \phi_1 & \phi_2 & \phi_3 & \phi_4 \\ I & 0 & 0 & 0 \\ 0 & I & 0 & 0 \\ 0 & 0 & I & 0 \end{bmatrix} \quad C = \begin{bmatrix} \sigma \\ 0 \\ 0 \\ 0 \end{bmatrix} \quad G = \begin{bmatrix} I & 0 & 0 & 0 \end{bmatrix}$$

where I is the $k \times k$ identity matrix and σ is a $k \times k$ matrix.

Seasonals

We can use (44.1) to represent

1. the **deterministic seasonal** $y_t = y_{t-4}$
2. the **indeterministic seasonal** $y_t = \phi_4 y_{t-4} + w_t$

In fact, both are special cases of (44.2).

With the deterministic seasonal, the transition matrix becomes

$$A = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}$$

It is easy to check that $A^4 = I$, which implies that x_t is strictly periodic with period 4:[1]

$$x_{t+4} = x_t$$

Such an x_t process can be used to model deterministic seasonals in quarterly time series.

The *indeterministic* seasonal produces recurrent, but aperiodic, seasonal fluctuations.

Time Trends

The model $y_t = at + b$ is known as a **linear time trend**.

We can represent this model in the linear state space form by taking

$$A = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix} \qquad C = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \qquad G = \begin{bmatrix} a & b \end{bmatrix} \tag{44.3}$$

and starting at initial condition $x_0 = \begin{bmatrix} 0 & 1 \end{bmatrix}'$.

In fact, it's possible to use the state-space system to represent polynomial trends of any order.

[1] The eigenvalues of A are $(1, -1, i, -i)$.

For instance, we can represent the model $y_t = at^2 + bt + c$ in the linear state space form by taking

$$A = \begin{bmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{bmatrix} \qquad C = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \qquad G = \begin{bmatrix} 2a & a+b & c \end{bmatrix}$$

and starting at initial condition $x_0 = \begin{bmatrix} 0 & 0 & 1 \end{bmatrix}'$.

It follows that

$$A^t = \begin{bmatrix} 1 & t & t(t-1)/2 \\ 0 & 1 & t \\ 0 & 0 & 1 \end{bmatrix}$$

Then $x_t' = \begin{bmatrix} t(t-1)/2 & t & 1 \end{bmatrix}$. You can now confirm that $y_t = Gx_t$ has the correct form.

44.2.3 Moving Average Representations

A nonrecursive expression for x_t as a function of $x_0, w_1, w_2, \ldots, w_t$ can be found by using (44.1) repeatedly to obtain

$$\begin{aligned} x_t &= Ax_{t-1} + Cw_t \\ &= A^2 x_{t-2} + ACw_{t-1} + Cw_t \\ &\quad \vdots \\ &= \sum_{j=0}^{t-1} A^j C w_{t-j} + A^t x_0 \end{aligned}$$

Representation (44.4) is a **moving average** representation.

It expresses $\{x_t\}$ as a linear function of

1. current and past values of the process $\{w_t\}$ and
2. the initial condition x_0

As an example of a moving average representation, let the model be

$$A = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix} \qquad C = \begin{bmatrix} 1 \\ 0 \end{bmatrix}$$

You will be able to show that $A^t = \begin{bmatrix} 1 & t \\ 0 & 1 \end{bmatrix}$ and $A^j C = \begin{bmatrix} 1 & 0 \end{bmatrix}'$.

Substituting into the moving average representation (44.4), we obtain

$$x_{1t} = \sum_{j=0}^{t-1} w_{t-j} + \begin{bmatrix} 1 & t \end{bmatrix} x_0$$

where x_{1t} is the first entry of x_t.

The first term on the right is a cumulated sum of martingale differences and is therefore a martingale.

The second term is a translated linear function of time.

For this reason, x_{1t} is called a **martingale with drift**.

44.3 Distributions and Moments

44.3.1 Unconditional Moments

Using (44.1), it's easy to obtain expressions for the (unconditional) means of x_t and y_t.

We'll explain what *unconditional* and *conditional* mean soon.

Letting $\mu_t := \mathbb{E}[x_t]$ and using linearity of expectations, we find that

$$\mu_{t+1} = A\mu_t \quad \text{with} \quad \mu_0 \text{ given} \tag{44.4}$$

Here μ_0 is a primitive given in (44.1).

The variance-covariance matrix of x_t is $\Sigma_t := \mathbb{E}[(x_t - \mu_t)(x_t - \mu_t)']$.

Using $x_{t+1} - \mu_{t+1} = A(x_t - \mu_t) + Cw_{t+1}$, we can determine this matrix recursively via

$$\Sigma_{t+1} = A\Sigma_t A' + CC' \quad \text{with} \quad \Sigma_0 \text{ given} \tag{44.5}$$

As with μ_0, the matrix Σ_0 is a primitive given in (44.1).

As a matter of terminology, we will sometimes call

- μ_t the **unconditional mean** of x_t
- Σ_t the **unconditional variance-covariance matrix** of x_t

This is to distinguish μ_t and Σ_t from related objects that use conditioning information, to be defined below.

However, you should be aware that these "unconditional" moments do depend on the initial distribution $N(\mu_0, \Sigma_0)$.

Moments of the Observables

Using linearity of expectations again we have

$$\mathbb{E}[y_t] = \mathbb{E}[Gx_t] = G\mu_t \tag{44.6}$$

The variance-covariance matrix of y_t is easily shown to be

$$\text{Var}[y_t] = \text{Var}[Gx_t] = G\Sigma_t G' \tag{44.7}$$

44.3.2 Distributions

In general, knowing the mean and variance-covariance matrix of a random vector is not quite as good as knowing the full distribution.

However, there are some situations where these moments alone tell us all we need to know.

These are situations in which the mean vector and covariance matrix are all of the **parameters** that pin down the population distribution.

One such situation is when the vector in question is Gaussian (i.e., normally distributed).

This is the case here, given

1. our Gaussian assumptions on the primitives
2. the fact that normality is preserved under linear operations

In fact, it's well-known that

$$u \sim N(\bar{u}, S) \quad \text{and} \quad v = a + Bu \implies v \sim N(a + B\bar{u}, BSB') \tag{44.8}$$

In particular, given our Gaussian assumptions on the primitives and the linearity of (44.1) we can see immediately that both x_t and y_t are Gaussian for all $t \geq 0$[2].

Since x_t is Gaussian, to find the distribution, all we need to do is find its mean and variance-covariance matrix.

But in fact we've already done this, in (44.4) and (44.5).

Letting μ_t and Σ_t be as defined by these equations, we have

$$x_t \sim N(\mu_t, \Sigma_t) \tag{44.9}$$

By similar reasoning combined with (44.6) and (44.7),

$$y_t \sim N(G\mu_t, G\Sigma_t G') \tag{44.10}$$

44.3.3 Ensemble Interpretations

How should we interpret the distributions defined by (44.9)–(44.10)?

Intuitively, the probabilities in a distribution correspond to relative frequencies in a large population drawn from that distribution.

Let's apply this idea to our setting, focusing on the distribution of y_T for fixed T.

We can generate independent draws of y_T by repeatedly simulating the evolution of the system up to time T, using an independent set of shocks each time.

The next figure shows 20 simulations, producing 20 time series for $\{y_t\}$, and hence 20 draws of y_T.

The system in question is the univariate autoregressive model (44.2).

The values of y_T are represented by black dots in the left-hand figure

```
def cross_section_plot(A,
                       C,
                       G,
                       T=20,                 # Set the time
                       ymin=-0.8,
                       ymax=1.25,
                       sample_size = 20,     # 20 observations/simulations
                       n=4):                 # The number of dimensions for the initial x0

    ar = LinearStateSpace(A, C, G, mu_0=np.ones(n))

    fig, axes = plt.subplots(1, 2, figsize=(16, 5))

    for ax in axes:
        ax.grid(alpha=0.4)
        ax.set_ylim(ymin, ymax)

    ax = axes[0]
    ax.set_ylim(ymin, ymax)
    ax.set_ylabel('$y_t$', fontsize=12)
```

(continues on next page)

[2] The correct way to argue this is by induction. Suppose that x_t is Gaussian. Then (44.1) and (44.8) imply that x_{t+1} is Gaussian. Since x_0 is assumed to be Gaussian, it follows that every x_t is Gaussian. Evidently, this implies that each y_t is Gaussian.

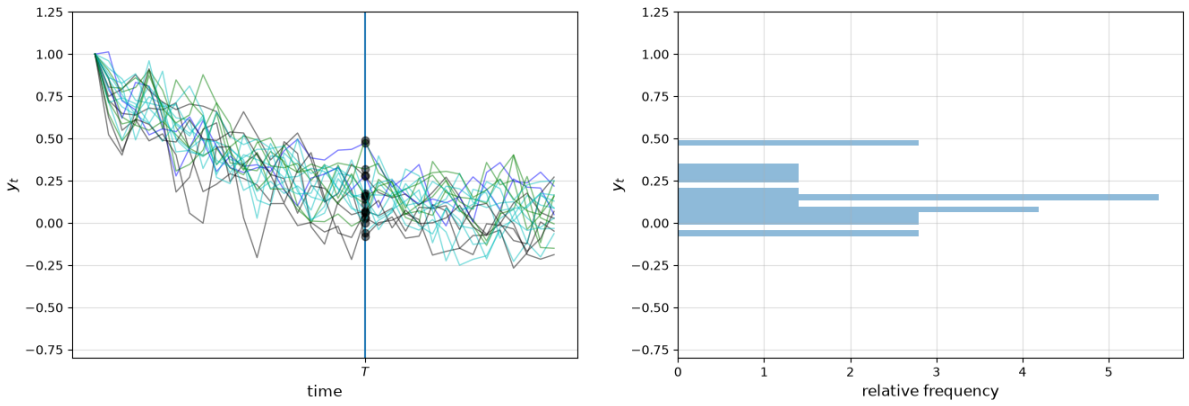
(continued from previous page)

```
    ax.set_xlabel('time', fontsize=12)
    ax.vlines((T,), -1.5, 1.5)

    ax.set_xticks((T,))
    ax.set_xticklabels(('$T$',))

    sample = []
    for i in range(sample_size):
        rcolor = random.choice(('c', 'g', 'b', 'k'))
        x, y = ar.simulate(ts_length=T+15)
        y = y.flatten()
        ax.plot(y, color=rcolor, lw=1, alpha=0.5)
        ax.plot((T,), (y[T],), 'ko', alpha=0.5)
        sample.append(y[T])

    y = y.flatten()
    axes[1].set_ylim(ymin, ymax)
    axes[1].set_ylabel('$y_t$', fontsize=12)
    axes[1].set_xlabel('relative frequency', fontsize=12)
    axes[1].hist(sample, bins=16, density=True, orientation='horizontal', alpha=0.5)
    plt.show()
```

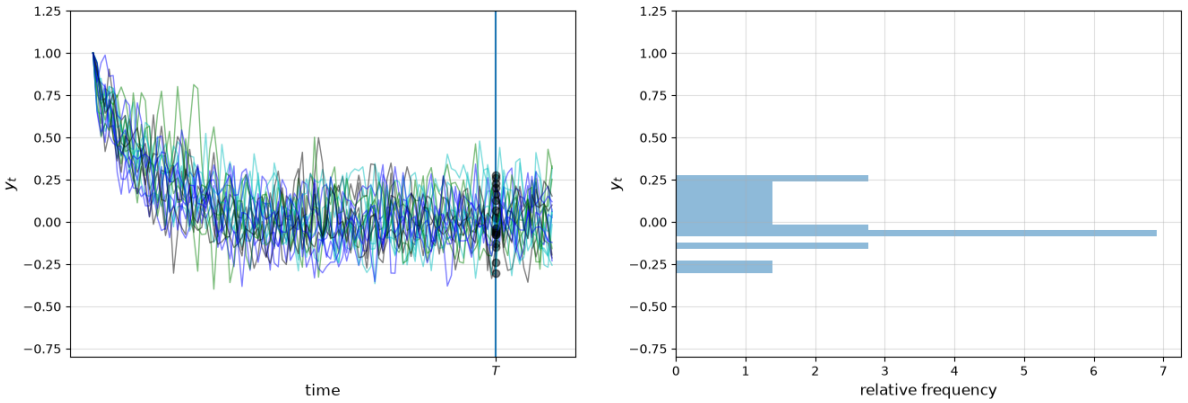


```
ϕ_1, ϕ_2, ϕ_3, ϕ_4 = 0.5, -0.2, 0, 0.5
σ = 0.1

A_2 = [[ϕ_1, ϕ_2, ϕ_3, ϕ_4],
       [1,     0,     0,     0],
       [0,     1,     0,     0],
       [0,     0,     1,     0]]

C_2 = [[σ], [0], [0], [0]]

G_2 = [1, 0, 0, 0]

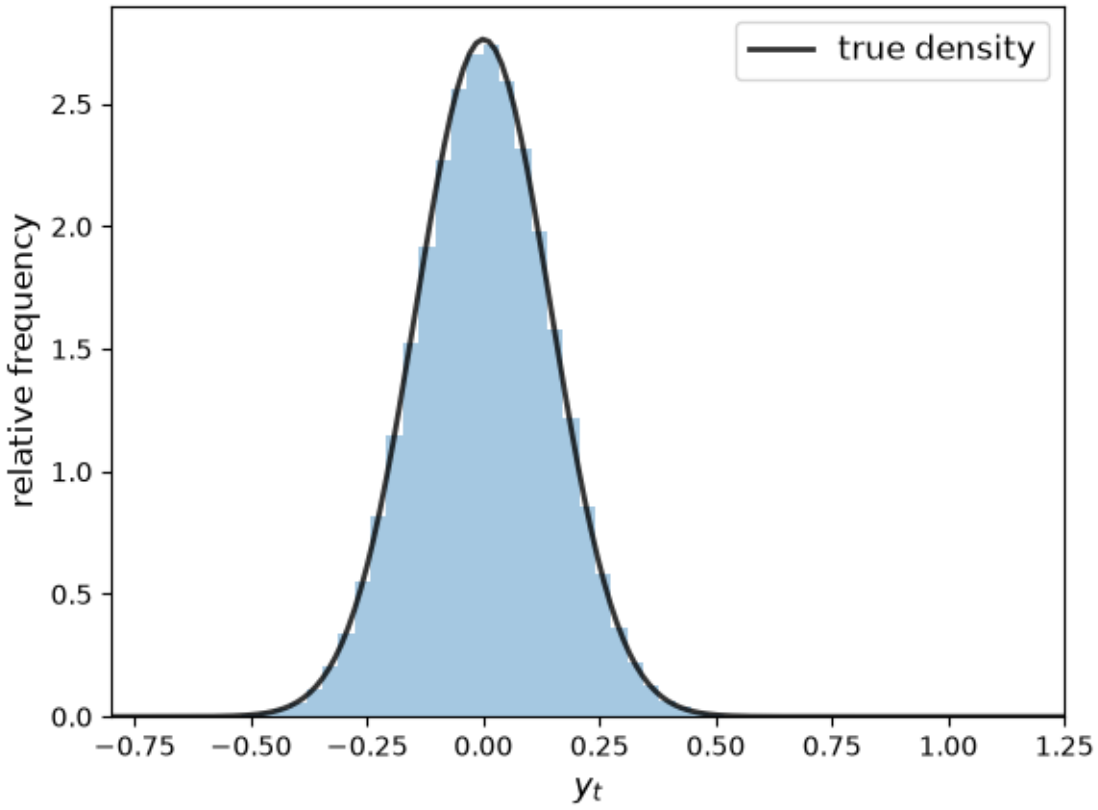


cross_section_plot(A_2, C_2, G_2)
```

In the right-hand figure, these values are converted into a rotated histogram that shows relative frequencies from our sample of 20 y_T's.

Here is another figure, this time with 100 observations

```
t = 100
cross_section_plot(A_2, C_2, G_2, T=t)
```



Let's now try with 500,000 observations, showing only the histogram (without rotation)

```
T = 100
ymin=-0.8
ymax=1.25
sample_size = 500_000

ar = LinearStateSpace(A_2, C_2, G_2, mu_0=np.ones(4))
fig, ax = plt.subplots()
x, y = ar.simulate(sample_size)
mu_x, mu_y, Sigma_x, Sigma_y, Sigma_yx = ar.stationary_distributions()
f_y = norm(loc=float(mu_y.item()), scale=float(np.sqrt(Sigma_y.item())))
y = y.flatten()
ygrid = np.linspace(ymin, ymax, 150)

ax.hist(y, bins=50, density=True, alpha=0.4)
ax.plot(ygrid, f_y.pdf(ygrid), 'k-', lw=2, alpha=0.8, label='true density')
ax.set_xlim(ymin, ymax)
ax.set_xlabel('$y_t$', fontsize=12)
ax.set_ylabel('relative frequency', fontsize=12)
ax.legend(fontsize=12)
plt.show()
```

The black line is the population density of y_T calculated from (44.10).

The histogram and population distribution are close, as expected.

By looking at the figures and experimenting with parameters, you will gain a feel for how the population distribution depends on the model primitives *listed above*, as intermediated by the distribution's parameters.

Ensemble Means

In the preceding figure, we approximated the population distribution of y_T by

1. generating I sample paths (i.e., time series) where I is a large number
2. recording each observation y_T^i
3. histogramming this sample

Just as the histogram approximates the population distribution, the **ensemble** or **cross-sectional average**

$$\bar{y}_T := \frac{1}{I} \sum_{i=1}^{I} y_T^i$$

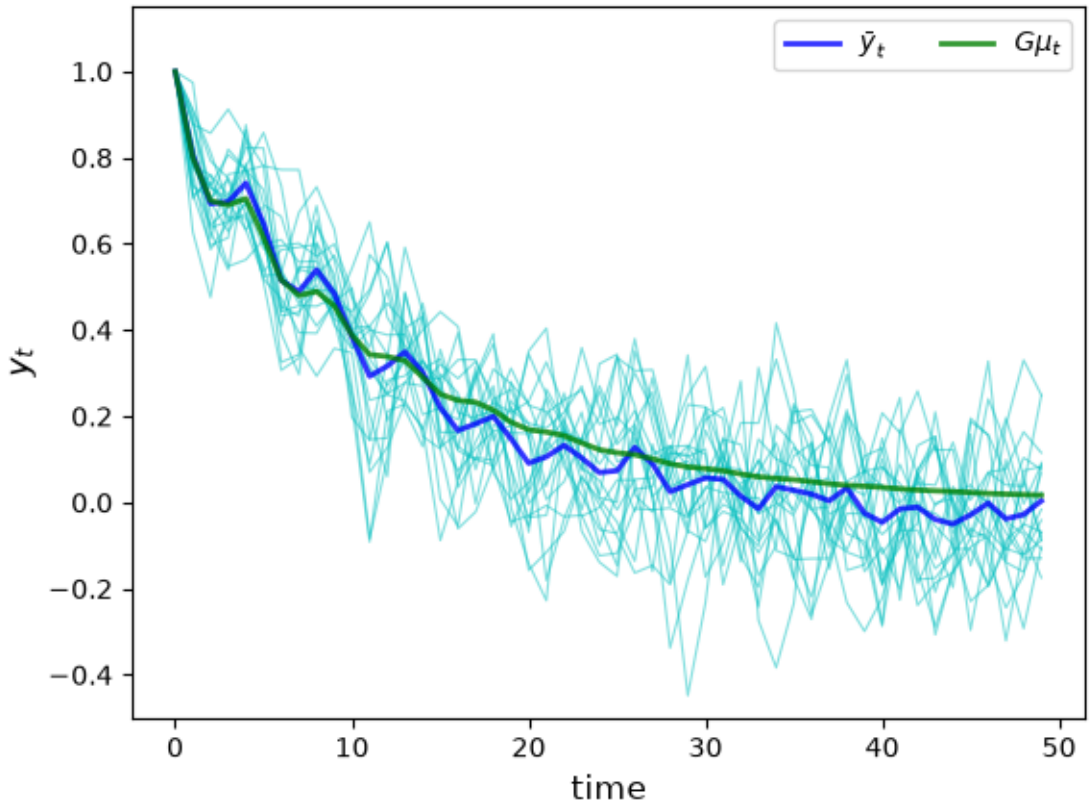
approximates the expectation $\mathbb{E}[y_T] = G\mu_T$ (as implied by the law of large numbers).

Here's a simulation comparing the ensemble averages and population means at time points $t = 0, \ldots, 50$.

The parameters are the same as for the preceding figures, and the sample size is relatively small ($I = 20$).

```
I = 20
T = 50
ymin = -0.5
ymax = 1.15

ar = LinearStateSpace(A_2, C_2, G_2, mu_0=np.ones(4))



fig, ax = plt.subplots()

ensemble_mean = np.zeros(T)
for i in range(I):
    x, y = ar.simulate(ts_length=T)
    y = y.flatten()
    ax.plot(y, 'c-', lw=0.8, alpha=0.5)
    ensemble_mean = ensemble_mean + y

ensemble_mean = ensemble_mean / I
ax.plot(ensemble_mean, color='b', lw=2, alpha=0.8, label='$\\bar y_t$')
m = ar.moment_sequence()

population_means = []
for t in range(T):
    μ_x, μ_y, Σ_x, Σ_y = next(m)
    population_means.append(float(μ_y.item()))

ax.plot(population_means, color='g', lw=2, alpha=0.8, label=r'$G\mu_t$')
ax.set_ylim(ymin, ymax)
ax.set_xlabel('time', fontsize=12)
ax.set_ylabel('$y_t$', fontsize=12)
ax.legend(ncol=2)
plt.show()
```

The ensemble mean for x_t is

$$\bar{x}_T := \frac{1}{I}\sum_{i=1}^{I} x_T^i \to \mu_T \qquad (I \to \infty)$$

The limit μ_T is a "long-run average".

(By *long-run average* we mean the average for an infinite ($I = \infty$) number of sample x_T's)

Another application of the law of large numbers assures us that

$$\frac{1}{I}\sum_{i=1}^{I}(x_T^i - \bar{x}_T)(x_T^i - \bar{x}_T)' \to \Sigma_T \qquad (I \to \infty)$$

44.3.4 Joint Distributions

In the preceding discussion, we looked at the distributions of x_t and y_t in isolation.

This gives us useful information but doesn't allow us to answer questions like

- what's the probability that $x_t \geq 0$ for all t?
- what's the probability that the process $\{y_t\}$ exceeds some value a before falling below b?
- etc., etc.

Such questions concern the *joint distributions* of these sequences.

To compute the joint distribution of $x_0, x_1, \ldots, x_T$, recall that joint and conditional densities are linked by the rule

$$p(x, y) = p(y \,|\, x)p(x) \qquad \text{(joint} = \text{conditional} \times \text{marginal)}$$

From this rule we get $p(x_0, x_1) = p(x_1 \mid x_0)p(x_0)$.

The Markov property $p(x_t \mid x_{t-1}, \ldots, x_0) = p(x_t \mid x_{t-1})$ and repeated applications of the preceding rule lead us to

$$p(x_0, x_1, \ldots, x_T) = p(x_0) \prod_{t=0}^{T-1} p(x_{t+1} \mid x_t)$$

The marginal $p(x_0)$ is just the primitive $N(\mu_0, \Sigma_0)$.

In view of (44.1), the conditional densities are

$$p(x_{t+1} \mid x_t) = N(Ax_t, CC')$$

Autocovariance Functions

An important object related to the joint distribution is the **autocovariance function**

$$\Sigma_{t+j,t} := \mathbb{E}[(x_{t+j} - \mu_{t+j})(x_t - \mu_t)'] \tag{44.11}$$

Elementary calculations show that

$$\Sigma_{t+j,t} = A^j \Sigma_t \tag{44.12}$$

Notice that $\Sigma_{t+j,t}$ in general depends on both j, the gap between the two dates, and t, the earlier date.

44.4 Stationarity and Ergodicity

Stationarity and ergodicity are two properties that, when they hold, greatly aid analysis of linear state space models.

Let's start with the intuition.

44.4.1 Visualizing Stability

Let's look at some more time series from the same model that we analyzed above.

This picture shows cross-sectional distributions for y at times T, T', T''

```
def cross_plot(A,
               C,
               G,
               steady_state='False',
               T0 = 10,
               T1 = 50,
               T2 = 75,
               T4 = 100):

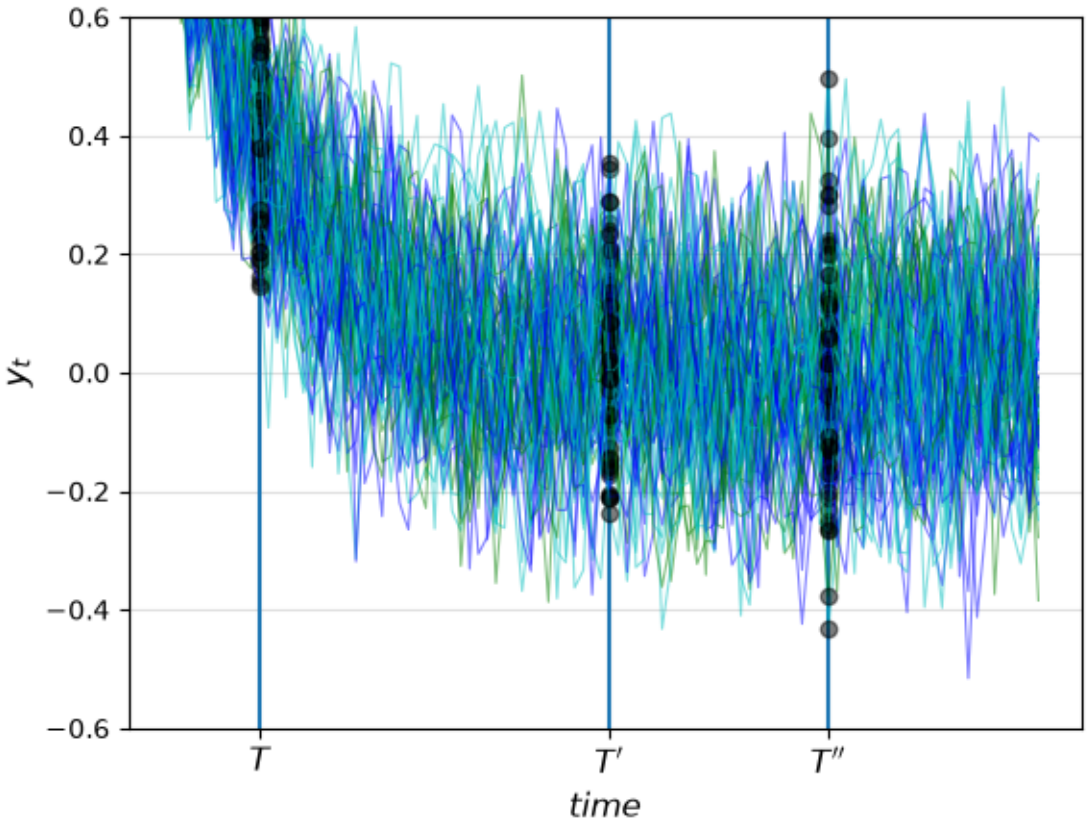
    ar = LinearStateSpace(A, C, G, mu_0=np.ones(4))

    if steady_state == 'True':
        μ_x, μ_y, Σ_x, Σ_y, Σ_yx = ar.stationary_distributions()
        ar_state = LinearStateSpace(A, C, G, mu_0=μ_x, Sigma_0=Σ_x)

    ymin, ymax = -0.6, 0.6
    fig, ax = plt.subplots()
```

(continues on next page)

(continued from previous page)



```
    ax.grid(alpha=0.4)
    ax.set_ylim(ymin, ymax)
    ax.set_ylabel('$y_t$', fontsize=12)
    ax.set_xlabel('$time$', fontsize=12)

    ax.vlines((T0, T1, T2), -1.5, 1.5)
    ax.set_xticks((T0, T1, T2))
    ax.set_xticklabels(("$T$", "$T'$", "$T''$"), fontsize=12)
    for i in range(80):
        rcolor = random.choice(('c', 'g', 'b'))

        if steady_state == 'True':
            x, y = ar_state.simulate(ts_length=T4)
        else:
            x, y = ar.simulate(ts_length=T4)

        y = y.flatten()
        ax.plot(y, color=rcolor, lw=0.8, alpha=0.5)
        ax.plot((T0, T1, T2), (y[T0], y[T1], y[T2],), 'ko', alpha=0.5)
    plt.show()
```

```
cross_plot(A_2, C_2, G_2)
```

Note how the time series "settle down" in the sense that the distributions at T' and T'' are relatively similar to each other — but unlike the distribution at T.

Apparently, the distributions of y_t converge to a fixed long-run distribution as $t \to \infty$.

When such a distribution exists it is called a **stationary distribution**.

44.4.2 Stationary Distributions

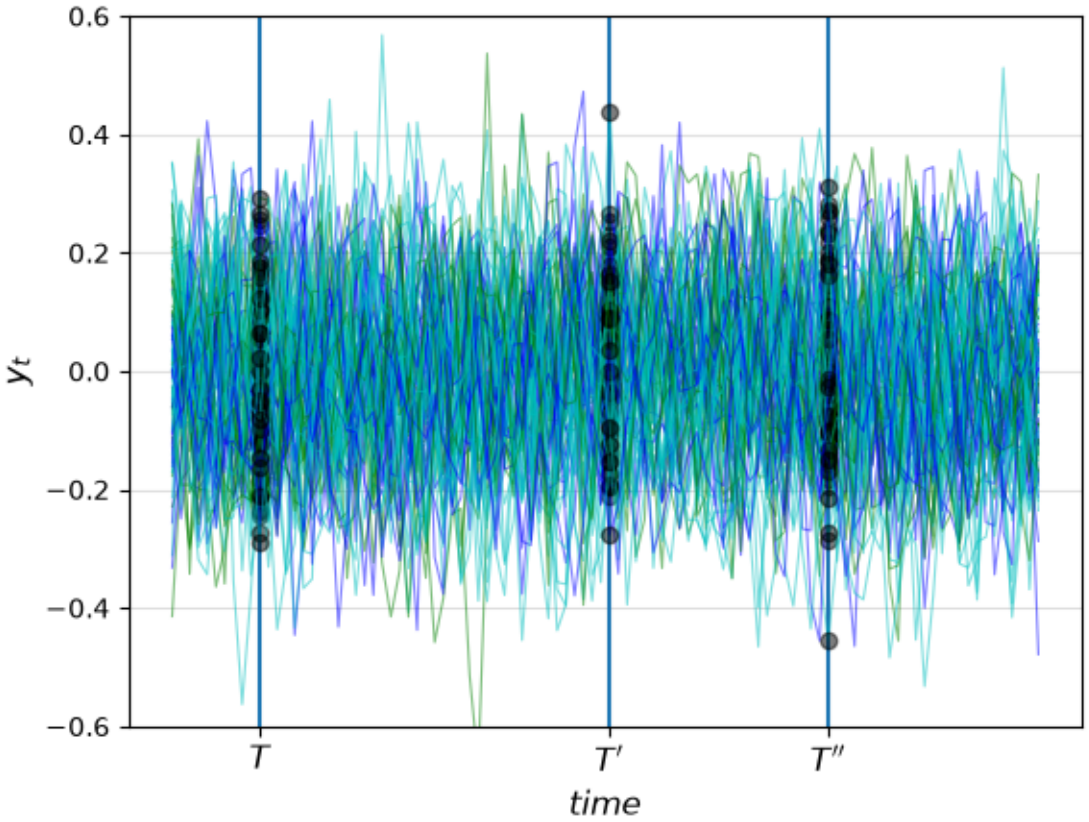
In our setting, a distribution ψ_∞ is said to be **stationary** for x_t if

$$x_t \sim \psi_\infty \quad \text{and} \quad x_{t+1} = Ax_t + Cw_{t+1} \quad \Longrightarrow \quad x_{t+1} \sim \psi_\infty$$

Since

1. in the present case, all distributions are Gaussian
2. a Gaussian distribution is pinned down by its mean and variance-covariance matrix

we can restate the definition as follows: ψ_∞ is stationary for x_t if



$$\psi_\infty = N(\mu_\infty, \Sigma_\infty)$$

where μ_∞ and Σ_∞ are fixed points of (44.4) and (44.5) respectively.

44.4.3 Covariance Stationary Processes

Let's see what happens to the preceding figure if we start x_0 at the stationary distribution.

```
cross_plot(A_2, C_2, G_2, steady_state='True')
```

Now the differences in the observed distributions at T, T' and T'' come entirely from random fluctuations due to the finite sample size.

By

- our choosing $x_0 \sim N(\mu_\infty, \Sigma_\infty)$
- the definitions of μ_∞ and Σ_∞ as fixed points of (44.4) and (44.5) respectively

we've ensured that

$$\mu_t = \mu_\infty \quad \text{and} \quad \Sigma_t = \Sigma_\infty \quad \text{for all } t$$

Moreover, in view of (44.12), the autocovariance function takes the form $\Sigma_{t+j,t} = A^j \Sigma_\infty$, which depends on j but not on t.

This motivates the following definition.

A process $\{x_t\}$ is said to be **covariance stationary** if

- both μ_t and Σ_t are constant in t
- $\Sigma_{t+j,t}$ depends on the time gap j but not on time t

In our setting, $\{x_t\}$ will be covariance stationary if μ_0, Σ_0, A, C assume values that imply that none of $\mu_t, \Sigma_t, \Sigma_{t+j,t}$ depends on t.

44.4.4 Conditions for Stationarity

The Globally Stable Case

The difference equation $\mu_{t+1} = A\mu_t$ is known to have *unique* fixed point $\mu_\infty = 0$ if all eigenvalues of A have moduli strictly less than unity.

That is, if `(np.absolute(np.linalg.eigvals(A)) < 1).all() == True`.

The difference equation (44.5) also has a unique fixed point in this case, and, moreover

$$\mu_t \to \mu_\infty = 0 \quad \text{and} \quad \Sigma_t \to \Sigma_\infty \quad \text{as} \quad t \to \infty$$

regardless of the initial conditions μ_0 and Σ_0.

This is the *globally stable case* — see these notes for more a theoretical treatment.

However, global stability is more than we need for stationary solutions, and often more than we want.

To illustrate, consider *our second order difference equation example*.

Here the state is $x_t = \begin{bmatrix} 1 & y_t & y_{t-1} \end{bmatrix}'$.

Because of the constant first component in the state vector, we will never have $\mu_t \to 0$.

How can we find stationary solutions that respect a constant state component?

Processes with a Constant State Component

To investigate such a process, suppose that A and C take the form

$$A = \begin{bmatrix} A_1 & a \\ 0 & 1 \end{bmatrix} \qquad C = \begin{bmatrix} C_1 \\ 0 \end{bmatrix}$$

where

- A_1 is an $(n-1) \times (n-1)$ matrix
- a is an $(n-1) \times 1$ column vector

Let $x_t = \begin{bmatrix} x_{1t}' & 1 \end{bmatrix}'$ where x_{1t} is $(n-1) \times 1$.

It follows that

$$x_{1,t+1} = A_1 x_{1t} + a + C_1 w_{t+1}$$

Let $\mu_{1t} = \mathbb{E}[x_{1t}]$ and take expectations on both sides of this expression to get

$$\mu_{1,t+1} = A_1 \mu_{1,t} + a \tag{44.13}$$

Assume now that the moduli of the eigenvalues of A_1 are all strictly less than one.

Then (44.13) has a unique stationary solution, namely,

$$\mu_{1\infty} = (I - A_1)^{-1} a$$

The stationary value of μ_t itself is then $\mu_\infty := \begin{bmatrix} \mu_{1\infty}' & 1 \end{bmatrix}'$.

The stationary values of Σ_t and $\Sigma_{t+j,t}$ satisfy

$$\begin{aligned} \Sigma_\infty &= A \Sigma_\infty A' + CC' \\ \Sigma_{t+j,t} &= A^j \Sigma_\infty \end{aligned}$$

Notice that here $\Sigma_{t+j,t}$ depends on the time gap j but not on calendar time t.

In conclusion, if

- $x_0 \sim N(\mu_\infty, \Sigma_\infty)$ and
- the moduli of the eigenvalues of A_1 are all strictly less than unity

then the $\{x_t\}$ process is covariance stationary, with constant state component.

Note

If the eigenvalues of A_1 are less than unity in modulus, then (a) starting from any initial value, the mean and variance-covariance matrix both converge to their stationary values; and (b) iterations on (44.5) converge to the fixed point of the *discrete Lyapunov equation* in the first line of (44.14).

44.4.5 Ergodicity

Let's suppose that we're working with a covariance stationary process.

In this case, we know that the ensemble mean will converge to μ_∞ as the sample size I approaches infinity.

Averages over Time

Ensemble averages across simulations are interesting theoretically, but in real life, we usually observe only a *single* realization $\{x_t, y_t\}_{t=0}^T$.

So now let's take a single realization and form the time-series averages

$$\bar{x} := \frac{1}{T}\sum_{t=1}^{T} x_t \quad \text{and} \quad \bar{y} := \frac{1}{T}\sum_{t=1}^{T} y_t$$

Do these time series averages converge to something interpretable in terms of our basic state-space representation?

The answer depends on something called *ergodicity*.

Ergodicity is the property that time series and ensemble averages coincide.

More formally, ergodicity implies that time series sample averages converge to their expectation under the stationary distribution.

In particular,

- $\frac{1}{T}\sum_{t=1}^{T} x_t \to \mu_\infty$
- $\frac{1}{T}\sum_{t=1}^{T} (x_t - \bar{x}_T)(x_t - \bar{x}_T)' \to \Sigma_\infty$
- $\frac{1}{T}\sum_{t=1}^{T} (x_{t+j} - \bar{x}_T)(x_t - \bar{x}_T)' \to A^j\Sigma_\infty$

In our linear Gaussian setting, any covariance stationary process is also ergodic.

44.5 Noisy Observations

In some settings, the observation equation $y_t = Gx_t$ is modified to include an error term.

Often this error term represents the idea that the true state can only be observed imperfectly.

To include an error term in the observation we introduce

- An IID sequence of $\ell \times 1$ random vectors $v_t \sim N(0, I)$.
- A $k \times \ell$ matrix H.

and extend the linear state-space system to

$$\begin{aligned} x_{t+1} &= Ax_t + Cw_{t+1} \\ y_t &= Gx_t + Hv_t \\ x_0 &\sim N(\mu_0, \Sigma_0) \end{aligned}$$

The sequence $\{v_t\}$ is assumed to be independent of $\{w_t\}$.

The process $\{x_t\}$ is not modified by noise in the observation equation and its moments, distributions and stability properties remain the same.

The unconditional moments of y_t from (44.6) and (44.7) now become

$$\mathbb{E}[y_t] = \mathbb{E}[Gx_t + Hv_t] = G\mu_t \tag{44.14}$$

The variance-covariance matrix of y_t is easily shown to be

$$\text{Var}[y_t] = \text{Var}[Gx_t + Hv_t] = G\Sigma_t G' + HH' \tag{44.15}$$

The distribution of y_t is therefore

$$y_t \sim N(G\mu_t, G\Sigma_t G' + HH')$$

44.6 Prediction

The theory of prediction for linear state space systems is elegant and simple.

44.6.1 Forecasting Formulas – Conditional Means

The natural way to predict variables is to use conditional distributions.

For example, the optimal forecast of x_{t+1} given information known at time t is

$$\mathbb{E}_t[x_{t+1}] := \mathbb{E}[x_{t+1} \mid x_t, x_{t-1}, \ldots, x_0] = Ax_t$$

The right-hand side follows from $x_{t+1} = Ax_t + Cw_{t+1}$ and the fact that w_{t+1} is zero mean and independent of $x_t, x_{t-1}, \ldots, x_0$.

That $\mathbb{E}_t[x_{t+1}] = \mathbb{E}[x_{t+1} \mid x_t]$ is an implication of $\{x_t\}$ having the **Markov property**.

The one-step-ahead forecast error is

$$x_{t+1} - \mathbb{E}_t[x_{t+1}] = Cw_{t+1}$$

The covariance matrix of the forecast error is

$$\mathbb{E}[(x_{t+1} - \mathbb{E}_t[x_{t+1}])(x_{t+1} - \mathbb{E}_t[x_{t+1}])'] = CC'$$

More generally, we'd like to compute the j-step ahead forecasts $\mathbb{E}_t[x_{t+j}]$ and $\mathbb{E}_t[y_{t+j}]$.

With a bit of algebra, we obtain

$$x_{t+j} = A^j x_t + A^{j-1} Cw_{t+1} + A^{j-2} Cw_{t+2} + \cdots + A^0 Cw_{t+j}$$

In view of the IID property, current and past state values provide no information about future values of the shock.

Hence $\mathbb{E}_t[w_{t+k}] = \mathbb{E}[w_{t+k}] = 0$.

It now follows from linearity of expectations that the j-step ahead forecast of x is

$$\mathbb{E}_t[x_{t+j}] = A^j x_t$$

The j-step ahead forecast of y is therefore

$$\mathbb{E}_t[y_{t+j}] = \mathbb{E}_t[Gx_{t+j} + Hv_{t+j}] = GA^j x_t$$

44.6.2 Covariance of Prediction Errors

It is useful to obtain the covariance matrix of the vector of j-step-ahead prediction errors

$$x_{t+j} - \mathbb{E}_t[x_{t+j}] = \sum_{s=0}^{j-1} A^s C w_{t-s+j} \tag{44.16}$$

Evidently,

$$V_j := \mathbb{E}_t[(x_{t+j} - \mathbb{E}_t[x_{t+j}])(x_{t+j} - \mathbb{E}_t[x_{t+j}])'] = \sum_{k=0}^{j-1} A^k C C' A^{k'} \tag{44.17}$$

V_j defined in (44.17) can be calculated recursively via $V_1 = CC'$ and

$$V_j = CC' + AV_{j-1}A', \quad j \geq 2 \tag{44.18}$$

V_j is the **conditional covariance matrix** of the errors in forecasting x_{t+j}, conditioned on time t information x_t.

Under particular conditions, V_j converges to

$$V_\infty = CC' + AV_\infty A' \tag{44.19}$$

Equation (44.19) is an example of a **discrete Lyapunov** equation in the covariance matrix V_∞.

A sufficient condition for V_j to converge is that the eigenvalues of A be strictly less than one in modulus.

Weaker sufficient conditions for convergence associate eigenvalues equaling or exceeding one in modulus with elements of C that equal 0.

44.7 Code

Our preceding simulations and calculations are based on code in the file lss.py from the QuantEcon.py package.

The code implements a class for handling linear state space models (simulations, calculating moments, etc.).

One Python construct you might not be familiar with is the use of a generator function in the method `moment_sequence()`.

Go back and read the relevant documentation if you've forgotten how generator functions work.

Examples of usage are given in the solutions to the exercises.

44.8 Exercises

Exercise 44.8.1

In several contexts, we want to compute forecasts of geometric sums of future random variables governed by the linear state-space system (44.1).

We want the following objects

- Forecast of a geometric sum of future x's, or $\mathbb{E}_t\left[\sum_{j=0}^{\infty} \beta^j x_{t+j}\right]$.
- Forecast of a geometric sum of future y's, or $\mathbb{E}_t\left[\sum_{j=0}^{\infty} \beta^j y_{t+j}\right]$.

These objects are important components of some famous and interesting dynamic models.

For example,

- if $\{y_t\}$ is a stream of dividends, then $\mathbb{E}\left[\sum_{j=0}^{\infty} \beta^j y_{t+j} | x_t\right]$ is a model of a stock price
- if $\{y_t\}$ is the money supply, then $\mathbb{E}\left[\sum_{j=0}^{\infty} \beta^j y_{t+j} | x_t\right]$ is a model of the price level

Show that:

$$\mathbb{E}_t \left[\sum_{j=0}^{\infty} \beta^j x_{t+j}\right] = [I - \beta A]^{-1} x_t$$

and

$$\mathbb{E}_t \left[\sum_{j=0}^{\infty} \beta^j y_{t+j}\right] = G[I - \beta A]^{-1} x_t$$

what must the modulus for every eigenvalue of A be less than?

Solution

Suppose that every eigenvalue of A has modulus strictly less than $\frac{1}{\beta}$.

It *then follows* that $I + \beta A + \beta^2 A^2 + \cdots = [I - \beta A]^{-1}$.

This leads to our formulas:

- Forecast of a geometric sum of future x's

$$\mathbb{E}_t \left[\sum_{j=0}^{\infty} \beta^j x_{t+j}\right] = [I + \beta A + \beta^2 A^2 + \cdots] x_t = [I - \beta A]^{-1} x_t$$

- Forecast of a geometric sum of future y's

$$\mathbb{E}_t \left[\sum_{j=0}^{\infty} \beta^j y_{t+j}\right] = G[I + \beta A + \beta^2 A^2 + \cdots] x_t = G[I - \beta A]^{-1} x_t$$

  - *Summary*

In addition to what's in Anaconda, this lecture will need the following libraries:

```
!pip install quantecon
```

45.1 Overview

This lecture creates non-stochastic and stochastic versions of Paul Samuelson's celebrated multiplier accelerator model [Samuelson, 1939].

In doing so, we extend the example of the Solow model class in our second OOP lecture.

Our objectives are to

- provide a more detailed example of OOP and classes
- review a famous model
- review linear difference equations, both deterministic and stochastic

Let's start with some standard imports:

```
import matplotlib.pyplot as plt
import numpy as np
```

We'll also use the following for various tasks described below:

```
from quantecon import LinearStateSpace
import cmath
import math
import sympy
from sympy import Symbol, init_printing
from cmath import sqrt
```

45.1.1 Samuelson's model

Samuelson used a *second-order linear difference equation* to represent a model of national output based on three components:

- a *national output identity* asserting that national output or national income is the sum of consumption plus investment plus government purchases.
- a Keynesian *consumption function* asserting that consumption at time t is equal to a constant times national output at time $t-1$.
- an investment *accelerator* asserting that investment at time t equals a constant called the *accelerator coefficient* times the difference in output between period $t-1$ and $t-2$.

Consumption plus investment plus government purchases constitute *aggregate demand,* which automatically calls forth an equal amount of *aggregate supply*.

(To read about linear difference equations see here or chapter IX of [Sargent, 1987].)

Samuelson used the model to analyze how particular values of the marginal propensity to consume and the accelerator coefficient might give rise to transient **business cycles** in national output.

Possible dynamic properties include

- smooth convergence to a constant level of output
- damped business cycles that eventually converge to a constant level of output
- persistent business cycles that neither dampen nor explode

Later we present an extension that adds a random shock to the right side of the national income identity representing random fluctuations in aggregate demand.

This modification makes national output become governed by a second-order **stochastic linear difference equation** that, with appropriate parameter values, gives rise to recurrent irregular business cycles.

(To read about stochastic linear difference equations see chapter XI of [Sargent, 1987].)

45.2 Details

Let's assume that

- $\{G_t\}$ is a sequence of levels of government expenditures – we'll start by setting $G_t = G$ for all t.
- $\{C_t\}$ is a sequence of levels of aggregate consumption expenditures, a key endogenous variable in the model.
- $\{I_t\}$ is a sequence of rates of investment, another key endogenous variable.
- $\{Y_t\}$ is a sequence of levels of national income, yet another endogenous variable.
- α is the marginal propensity to consume in the Keynesian consumption function $C_t = \alpha Y_{t-1} + \gamma$.
- β is the "accelerator coefficient" in the "investment accelerator" $I_t = \beta(Y_{t-1} - Y_{t-2})$.
- $\{\epsilon_t\}$ is an IID sequence standard normal random variables.
- $\sigma \geq 0$ is a "volatility" parameter — setting $\sigma = 0$ recovers the non-stochastic case that we'll start with.

The model combines the consumption function

$$C_t = \alpha Y_{t-1} + \gamma \tag{45.1}$$

with the investment accelerator

$$I_t = \beta(Y_{t-1} - Y_{t-2}) \tag{45.2}$$

and the national income identity

$$Y_t = C_t + I_t + G_t \tag{45.3}$$

- The parameter α is peoples' **marginal propensity to consume** out of income - equation (45.1) asserts that people consume a fraction of $\alpha \in (0, 1)$ of each additional dollar of income.
- The parameter $\beta > 0$ is the investment accelerator coefficient - equation (45.2) asserts that people invest in physical capital when income is increasing and disinvest when it is decreasing.

Equations (45.1), (45.2), and (45.3) imply the following second-order linear difference equation for national income:

$$Y_t = (\alpha + \beta)Y_{t-1} - \beta Y_{t-2} + (\gamma + G_t)$$

or

$$Y_t = \rho_1 Y_{t-1} + \rho_2 Y_{t-2} + (\gamma + G_t) \tag{45.4}$$

where $\rho_1 = (\alpha + \beta)$ and $\rho_2 = -\beta$.

To complete the model, we require two *initial conditions*.

If the model is to generate time series for $t = 0, \ldots, T$, we require initial values

$$Y_{-1} = \bar{Y}_{-1}, \quad Y_{-2} = \bar{Y}_{-2}$$

We'll ordinarily set the parameters (α, β) so that starting from an arbitrary pair of initial conditions $(\bar{Y}_{-1}, \bar{Y}_{-2})$, national income Y_t converges to a constant value as t becomes large.

We are interested in studying

- the transient fluctuations in Y_t as it converges to its **steady state** level
- the *rate* at which it converges to a steady state level

The deterministic version of the model described so far — meaning that no random shocks hit aggregate demand — has only transient fluctuations.

We can convert the model to one that has persistent irregular fluctuations by adding a random shock to aggregate demand.

45.2.1 Stochastic version of the model

We create a *random* or *stochastic* version of the model by adding a random process of *shocks* or *disturbances* $\{\sigma\epsilon_t\}$ to the right side of equation (45.4), leading to the *second-order scalar linear stochastic difference equation*:

$$Y_t = (\alpha + \beta)Y_{t-1} - \beta Y_{t-2} + (\gamma + G_t) + \sigma\epsilon_t \tag{45.5}$$

45.2.2 Mathematical analysis of the model

To get started, let's set $G_t \equiv 0$, $\sigma = 0$, and $\gamma = 0$.

Then we can write equation (45.5) as

$$Y_t = \rho_1 Y_{t-1} + \rho_2 Y_{t-2}$$

or

$$Y_{t+2} - \rho_1 Y_{t+1} - \rho_2 Y_t = 0 \tag{45.6}$$

To discover the properties of the solution of (45.6), it is useful first to form the **characteristic polynomial** for (45.6):

$$z^2 - \rho_1 z - \rho_2 \tag{45.7}$$

where z is possibly a complex number.

We want to find the two **zeros** (a.k.a. **roots**) – namely λ_1, λ_2 – of the characteristic polynomial.

These are two special values of z, say $z = \lambda_1$ and $z = \lambda_2$, such that if we set z equal to one of these values in expression (45.7), the characteristic polynomial (45.7) equals zero:

$$z^2 - \rho_1 z - \rho_2 = (z - \lambda_1)(z - \lambda_2) = 0 \tag{45.8}$$

Equation (45.8) is said to *factor* the characteristic polynomial.

When the roots are complex, they will occur as a complex conjugate pair.

When the roots are complex, it is convenient to represent them in the polar form

$$\lambda_1 = re^{i\omega}, \ \lambda_2 = re^{-i\omega}$$

where r is the *amplitude* of the complex number and ω is its *angle* or *phase*.

These can also be represented as

$$\lambda_1 = r(cos(\omega) + i \sin(\omega))$$

$$\lambda_2 = r(cos(\omega) - i \sin(\omega))$$

(To read about the polar form, see here)

Given *initial conditions* Y_{-1}, Y_{-2}, we want to generate a *solution* of the difference equation (45.6).

It can be represented as

$$Y_t = \lambda_1^t c_1 + \lambda_2^t c_2$$

where c_1 and c_2 are constants that depend on the two initial conditions and on ρ_1, ρ_2.

When the roots are complex, it is useful to pursue the following calculations.

Notice that

$$\begin{aligned} Y_t &= c_1(re^{i\omega})^t + c_2(re^{-i\omega})^t \\ &= c_1 r^t e^{i\omega t} + c_2 r^t e^{-i\omega t} \\ &= c_1 r^t [\cos(\omega t) + i \sin(\omega t)] + c_2 r^t [\cos(\omega t) - i \sin(\omega t)] \\ &= (c_1 + c_2) r^t \cos(\omega t) + i(c_1 - c_2) r^t \sin(\omega t) \end{aligned}$$

The only way that Y_t can be a real number for each t is if $c_1 + c_2$ is a real number and $c_1 - c_2$ is an imaginary number.

This happens only when c_1 and c_2 are complex conjugates, in which case they can be written in the polar forms

$$c_1 = ve^{i\theta}, \quad c_2 = ve^{-i\theta}$$

So we can write

$$\begin{aligned} Y_t = &\quad ve^{i\theta} r^t e^{i\omega t} + ve^{-i\theta} r^t e^{-i\omega t} \\ = &\quad vr^t [e^{i(\omega t + \theta)} + e^{-i(\omega t + \theta)}] \\ = &\quad 2vr^t \cos(\omega t + \theta) \end{aligned}$$

where v and θ are constants that must be chosen to satisfy initial conditions for Y_{-1}, Y_{-2}.

This formula shows that when the roots are complex, Y_t displays oscillations with *period* $\breve{p} = \frac{2\pi}{\omega}$ and *damping factor* r.

We say that $\breve{p}$ is the *period* because in that amount of time the cosine wave $\cos(\omega t + \theta)$ goes through exactly one complete cycles.

(Draw a cosine function to convince yourself of this please)

Remark: Following [Samuelson, 1939], we want to choose the parameters α, β of the model so that the absolute values (of the possibly complex) roots λ_1, λ_2 of the characteristic polynomial are both strictly less than one:

$$|\lambda_j| < 1 \qquad \text{for } j = 1, 2$$

Remark: When both roots λ_1, λ_2 of the characteristic polynomial have absolute values strictly less than one, the absolute value of the larger one governs the rate of convergence to the steady state of the non stochastic version of the model.

45.2.3 Things this lecture does

We write a function to generate simulations of a $\{Y_t\}$ sequence as a function of time.

The function requires that we put in initial conditions for Y_{-1}, Y_{-2}.

The function checks that α, β are set so that λ_1, λ_2 are less than unity in absolute value (also called "modulus").

The function also tells us whether the roots are complex, and, if they are complex, returns both their real and complex parts.

If the roots are both real, the function returns their values.

We use our function written to simulate paths that are stochastic (when $\sigma > 0$).

We have written the function in a way that allows us to input $\{G_t\}$ paths of a few simple forms, e.g.,

- one time jumps in G at some time
- a permanent jump in G that occurs at some time

We proceed to use the Samuelson multiplier-accelerator model as a laboratory to make a simple OOP example.

The "state" that determines next period's Y_{t+1} is now not just the current value Y_t but also the once lagged value Y_{t-1}.

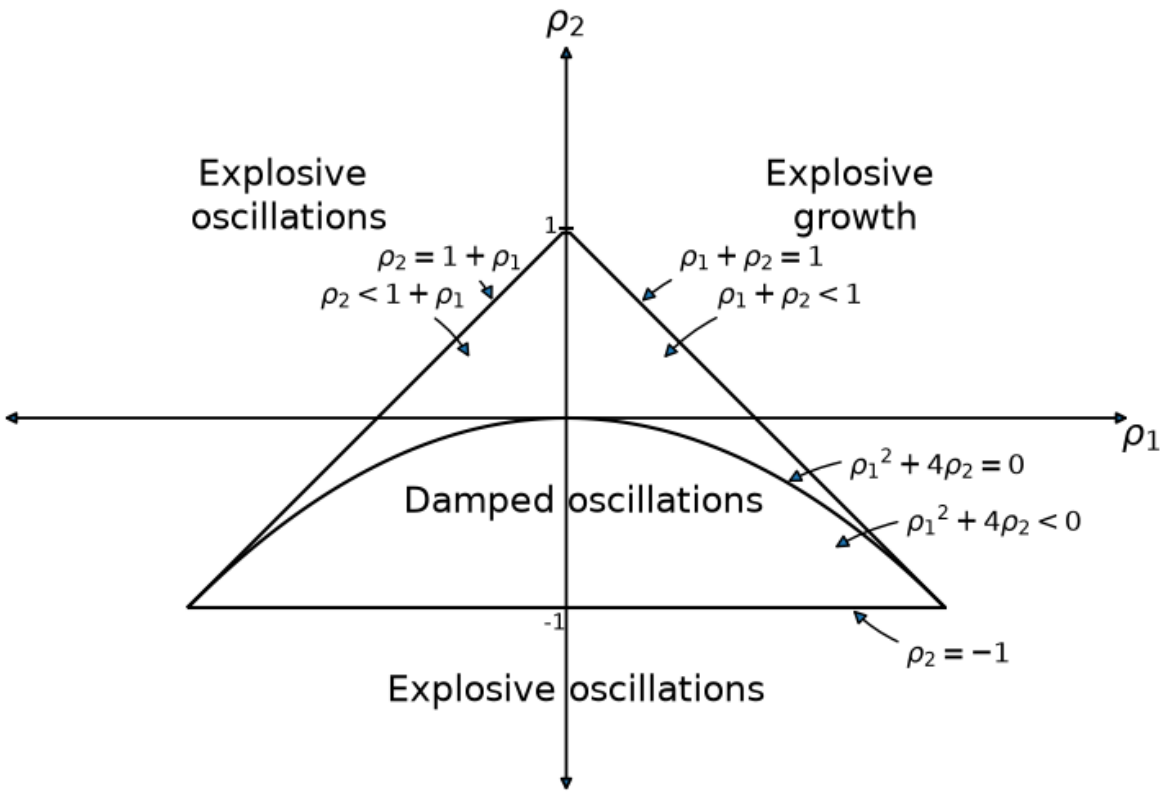
This involves a little more bookkeeping than is required in the Solow model class definition.

We use the Samuelson multiplier-accelerator model as a vehicle for teaching how we can gradually add more features to the class.

We want to have a method in the class that automatically generates a simulation, either non-stochastic ($\sigma = 0$) or stochastic ($\sigma > 0$).

We also show how to map the Samuelson model into a simple instance of the `LinearStateSpace` class described here.

We can use a `LinearStateSpace` instance to do various things that we did above with our homemade function and class.



Among other things, we show by example that the eigenvalues of the matrix A that we use to form the instance of the `LinearStateSpace` class for the Samuelson model equal the roots of the characteristic polynomial (45.7) for the Samuelson multiplier accelerator model.

Here is the formula for the matrix A in the linear state space system in the case that government expenditures are a constant G:

$$A = \begin{bmatrix} 1 & 0 & 0 \\ \gamma + G & \rho_1 & \rho_2 \\ 0 & 1 & 0 \end{bmatrix}$$

45.3 Implementation

We'll start by drawing an informative graph from page 189 of [Sargent, 1987]

The graph portrays regions in which the (λ_1, λ_2) root pairs implied by the $(\rho_1 = (\alpha + \beta), \rho_2 = -\beta)$ difference equation parameter pairs in the Samuelson model are such that:

- (λ_1, λ_2) are complex with modulus less than 1 - in this case, the $\{Y_t\}$ sequence displays damped oscillations.
- (λ_1, λ_2) are both real, but one is strictly greater than 1 - this leads to explosive growth.
- (λ_1, λ_2) are both real, but one is strictly less than -1 - this leads to explosive oscillations.
- (λ_1, λ_2) are both real and both are less than 1 in absolute value - in this case, there is smooth convergence to the steady state without damped cycles.

Later we'll present the graph with a red mark showing the particular point implied by the setting of (α, β).

45.3.1 Function to describe implications of characteristic polynomial

```
def categorize_solution(ρ1, ρ2):
    """
    This function takes values of ρ1 and ρ2 and uses them
    to classify the type of solution.
    """
    discriminant = ρ1**2 + 4 * ρ2
    if ρ2 > 1 + ρ1 or ρ2 < -1:
        return "Explosive oscillations"
    elif ρ1 + ρ2 > 1:
        return "Explosive growth"
    elif discriminant < 0:
        return "Damped oscillations"
    else:
        return "Steady state convergence"

def analyze_roots(α, β, verbose=True):
    """
    Unified function to calculate roots and analyze their properties.
    """
    ρ1 = α + β
    ρ2 = -β

    # Compute characteristic polynomial roots
    roots = np.roots([1, -ρ1, -ρ2])

    # Classify solution type
    solution_type = categorize_solution(ρ1, ρ2)

    # Determine root properties
    is_complex = all(isinstance(root, complex) for root in roots)
    is_stable = all(abs(root) < 1 for root in roots)

    if verbose:
        print(f"ρ1 = {ρ1:.2f}, ρ2 = {ρ2:.2f}")
        print(f"Roots: {[f'{root:.2f}' for root in roots]}")
        print(f"Root type: {'Complex' if is_complex else 'Real'}")
        print(f"Stability: {'Stable' if is_stable else 'Unstable'}")
        print(f"Solution type: {solution_type}")

    return {
        'roots': roots,
        'rho1': ρ1,
        'rho2': ρ2,
        'is_complex': is_complex,
        'is_stable': is_stable,
```

(continues on next page)

(continued from previous page)

```
        'solution_type': solution_type
    }
```

We also write a unified simulation function that can handle both non-stochastic and stochastic versions of the model.

It allows for government spending paths of a few simple forms which we specify via a dictionary `g_params`

```
def simulate_samuelson(
    y_0, y_1, α, β, γ=10, n=100, σ=0, g_params=None, seed=0
):
    """
    Unified simulation function for Samuelson model.

    Parameters:
    g_params: dict with keys 'g', 'g_t', 'duration' for government spending
    seed: random seed for reproducible results
    """
    analysis = analyze_roots(α, β, verbose=False)
    ρ1, ρ2 = analysis['rho1'], analysis['rho2']

    # Initialize time series
    y_t = [y_0, y_1]

    # Generate shocks if stochastic
    if σ > 0:
        rng = np.random.default_rng(seed)
        ϵ = rng.normal(0, 1, n)

    # Simulate forward
    for t in range(2, n):

        # Determine government spending
        g = 0
        if g_params:
            g_val, g_t_val = g_params.get('g', 0), g_params.get('g_t', 0)
            duration = g_params.get('duration', None)
            if duration == 'permanent' and t >= g_t_val:
                g = g_val
            elif duration == 'one-off' and t == g_t_val:
                g = g_val
            elif duration is None:
                g = g_val

        # Calculate next value
        y_next = ρ1 * y_t[t-1] + ρ2 * y_t[t-2] + γ + g
        if σ > 0:
            y_next += σ * ϵ[t]

        y_t.append(y_next)

    return y_t, analysis
```

We will use this function to run simulations of the model.

But before doing that, let's test the analysis function

```
analysis = analyze_roots(α=1.3, β=0.4)
```

```
ρ1 = 1.70, ρ2 = -0.40
Roots: ['1.42', '0.28']
Root type: Real
Stability: Unstable
Solution type: Explosive growth
```

45.3.2 Function for plotting paths

A useful function for our work below is

```
def plot_y(function=None):
    """Function plots path of Y_t"""

    plt.subplots(figsize=(10, 6))
    plt.plot(function)
    plt.xlabel("$t$")
    plt.ylabel("$Y_t$")
    plt.show()
```

45.3.3 Manual or "by hand" root calculations

The following function calculates roots of the characteristic polynomial using high school algebra.

(We'll calculate the roots in other ways later using `analyze_roots`.)

The function also plots a Y_t starting from initial conditions that we set

```
def y_nonstochastic(y_0=100, y_1=80, α=0.92, β=0.5, γ=10, n=80):
    """
    This function calculates the roots of the characteristic polynomial
    by hand and returns a path of y_t starting from initial conditions
    """
    roots = []

    ρ1 = α + β
    ρ2 = -β

    print(f"ρ_1 is {ρ1:.2f}")
    print(f"ρ_2 is {ρ2:.2f}")

    discriminant = ρ1**2 + 4 * ρ2

    if discriminant == 0:
        roots.append(ρ1 / 2)
        print("Single real root: ")
        print("".join(f"{r:.2f}" for r in roots))
    elif discriminant > 0:
        roots.append((ρ1 + sqrt(discriminant).real) / 2)
        roots.append((ρ1 - sqrt(discriminant).real) / 2)
        print("Two real roots: ")
        print(" ".join(f"{r:.2f}" for r in roots))
    else:
        roots.append((ρ1 + sqrt(discriminant)) / 2)
        roots.append((ρ1 - sqrt(discriminant)) / 2)
        print("Two complex roots: ")
```

(continues on next page)

(continued from previous page)

```
        print(" ".join(f"{r.real:.2f}{r.imag:+.2f}j" for r in roots))

    if all(abs(root) < 1 for root in roots):
        print("Absolute values of roots are less than one")
    else:
        print("Absolute values of roots are not less than one")

    def transition(x, t):
        return ρ1 * x[t - 1] + ρ2 * x[t - 2] + y

    y_t = [y_0, y_1]

    for t in range(2, n):
        y_t.append(transition(y_t, t))

    return y_t

plot_y(y_nonstochastic())
```

```
ρ_1 is 1.42
ρ_2 is -0.50
Two real roots:
0.77 0.65
Absolute values of roots are less than one
```

45.3.4 Reverse-engineering parameters to generate damped cycles

The next cell writes code that takes as inputs the modulus r and phase ϕ of a conjugate pair of complex numbers in polar form

$$\lambda_1 = r\exp(i\phi), \quad \lambda_2 = r\exp(-i\phi)$$

- The code assumes that these two complex numbers are the roots of the characteristic polynomial
- It then reverse-engineers (α, β) and (ρ_1, ρ_2), pairs that would generate those roots

```
def f(r, ϕ):
    """
    Takes modulus r and angle ϕ of complex number r exp(j ϕ)
    and creates ρ1 and ρ2 of characteristic polynomial for which
    r exp(j ϕ) and r exp(- j ϕ) are complex roots.

    Returns the multiplier coefficient $\alpha$
    and the accelerator coefficient $\beta$
    that verifies those roots.
    """
    # Create complex conjugate pair from polar coordinates
    g1 = cmath.rect(r, ϕ)
    g2 = cmath.rect(r, -ϕ)

    # Calculate corresponding ρ1, ρ2 parameters
    ρ1 = g1 + g2
    ρ2 = -g1 * g2

    # Derive α and β coefficients from ρ parameters
    β = -ρ2
    α = ρ1 - β
    return ρ1, ρ2, α, β
```

Now let's use the function in an example.

Here are the example parameters

```
r = 0.95

# Cycle period in time units
period = 10
ϕ = 2 * math.pi / period

# Apply the reverse-engineering function
ρ1, ρ2, α, β = f(r, ϕ)

print(f"α, β = {α:.2f}, {β:.2f}")
print(f"ρ1, ρ2 = {ρ1:.2f}, {ρ2:.2f}")
```

```
α, β = 0.63+0.00j, 0.90-0.00j
ρ1, ρ2 = 1.54+0.00j, -0.90+0.00j
```

The real parts of the roots are

```
print(f"ρ1 = {ρ1.real:.2f}, ρ2 = {ρ2.real:.2f}")
```

```
ρ1 = 1.54, ρ2 = -0.90
```

45.3.5 Root finding using numpy

Here we'll use numpy to compute the roots of the characteristic polynomial

```
r1, r2 = np.roots([1, -ρ1, -ρ2])

p1 = cmath.polar(r1)
p2 = cmath.polar(r2)

print(f"r, ϕ = {r:.2f}, {ϕ:.2f}")
print(f"p1, p2 = ({p1[0]:.2f}, {p1[1]:.2f}), ({p2[0]:.2f}, {p2[1]:.2f})")

print(f"α, β = {α:.2f}, {β:.2f}")
print(f"ρ1, ρ2 = {ρ1:.2f}, {ρ2:.2f}")
```

```
r, ϕ = 0.95, 0.63
p1, p2 = (0.95, 0.63), (0.95, -0.63)
α, β = 0.63+0.00j, 0.90-0.00j
ρ1, ρ2 = 1.54+0.00j, -0.90+0.00j
```

```
def y_nonstochastic(y_0=100, y_1=80, α=0.9, β=0.8, γ=10, n=80):
    """
    This function enlists numpy to calculate the roots of the characteristic
    polynomial.
    """

    y_series, analysis = simulate_samuelson(y_0, y_1, α, β, γ, n, 0, None, 42)

    print(f"Solution type: {analysis['solution_type']}")
    print(f"Roots are {analysis['roots']}")
    print(f"Root type: {'Complex' if analysis['is_complex'] else 'Real'}")
    print(f"Stability: {'Stable' if analysis['is_stable'] else 'Unstable'}")

    return y_series

plot_y(y_nonstochastic())
```

```
Solution type: Damped oscillations
Roots are [0.85+0.27838822j 0.85-0.27838822j]
Root type: Complex
Stability: Stable
```

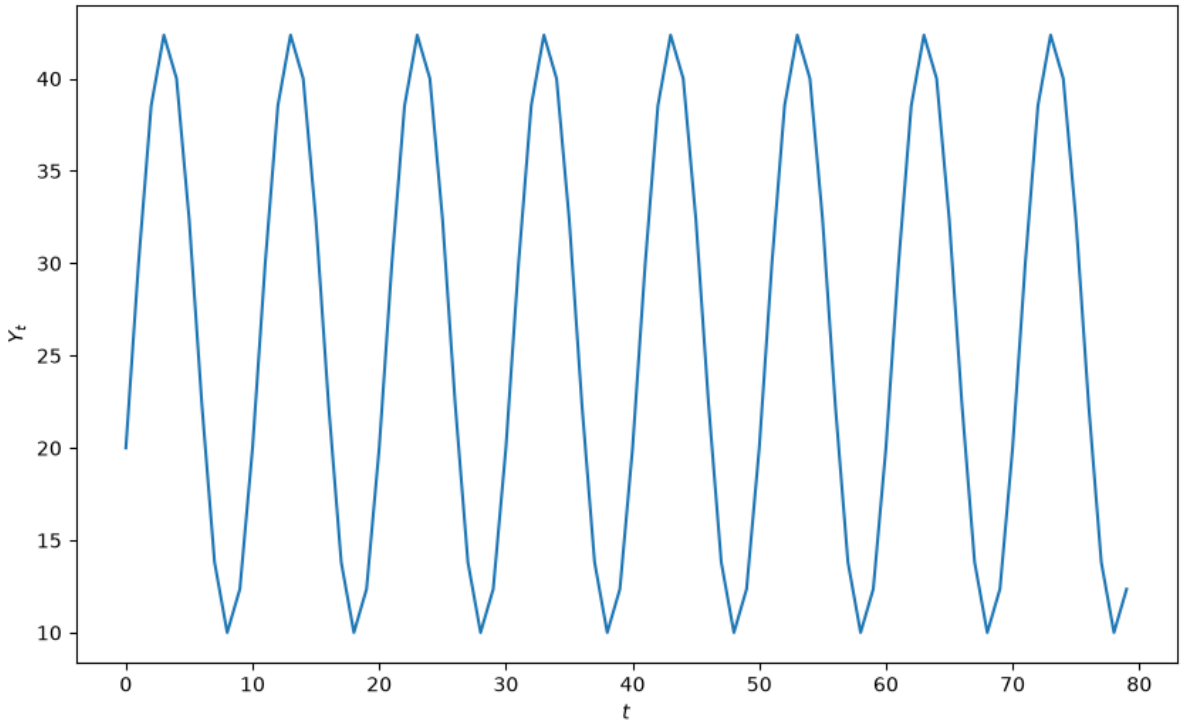
45.3.6 Reverse-engineered complex roots: Example

The next cell studies the implications of reverse-engineered complex roots.

We'll generate an *undamped* cycle of period 10

```
r = 1  # Generates undamped, nonexplosive cycles

period = 10  # Length of cycle in units of time
ϕ = 2 * math.pi / period



# Apply the reverse-engineering function f
ρ1, ρ2, α, β = f(r, ϕ)

# Extract real parts for numerical computation
α = α.real
β = β.real

print(f"α, β = {α:.2f}, {β:.2f}")

ytemp = y_nonstochastic(α=α, β=β, y_0=20, y_1=30)
plot_y(ytemp)
```

```
α, β = 0.62, 1.00
Solution type: Damped oscillations
Roots are [0.80901699+0.58778525j 0.80901699-0.58778525j]
Root type: Complex
Stability: Stable
```

45.3.7 Digression: Using Sympy to find roots

We can also use sympy to compute analytic formulas for the roots

```
init_printing()

r1 = Symbol("ρ_1")
r2 = Symbol("ρ_2")
z = Symbol("z")

sympy.solve(z**2 - r1 * z - r2, z)
```

$$\left[\rho_1/2 - \sqrt{\rho_1^2 + 4\rho_2}/2,\ \rho_1/2 + \sqrt{\rho_1^2 + 4\rho_2}/2\right]$$

```
α = Symbol("α")
β = Symbol("β")
r1 = α + β
r2 = -β

sympy.solve(z**2 - r1 * z - r2, z)
```

$$\left[\alpha/2 + \beta/2 - \sqrt{\alpha^2 + 2\alpha\beta + \beta^2 - 4\beta}/2,\ \alpha/2 + \beta/2 + \sqrt{\alpha^2 + 2\alpha\beta + \beta^2 - 4\beta}/2\right]$$

45.4 Stochastic shocks

Now we'll construct some code to simulate the stochastic version of the model that emerges when we add a random shock process to aggregate demand

```
def y_stochastic(y_0=0, y_1=0, α=0.8, β=0.2, γ=10, n=100, σ=5):
    """
    This function takes parameters of a stochastic version of
    the model, analyzes the roots of the characteristic
    polynomial and generates a simulation.
    """

    y_series, analysis = simulate_samuelson(y_0, y_1, α, β, γ, n, σ, None, 42)

    print(f"Solution type: {analysis['solution_type']}")
    print(f"Roots are {[f'{root:.2f}' for root in analysis['roots']]}")
    print(f"Root type: {'Complex' if analysis['is_complex'] else 'Real'}")
    print(f"Stability: {'Stable' if analysis['is_stable'] else 'Unstable'}")

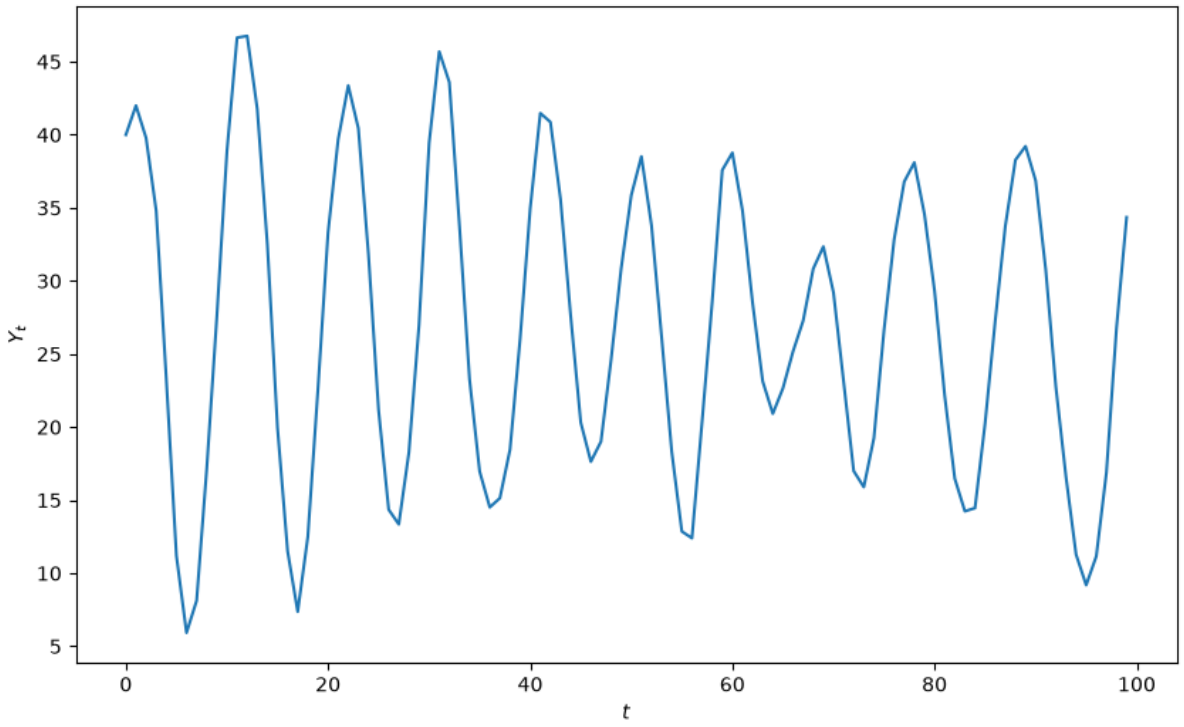
    return y_series

plot_y(y_stochastic())
```

```
Solution type: Steady state convergence
Roots are ['0.72', '0.28']
Root type: Real
Stability: Stable
```

Let's do a simulation in which there are shocks and the characteristic polynomial has complex roots

```
r = 0.97



period = 10  # Length of cycle in units of time
ϕ = 2 * math.pi / period

# Apply the reverse-engineering function f
ρ1, ρ2, α, β = f(r, ϕ)

# Extract real parts for numerical computation
α = α.real
β = β.real

print(f"α, β = {α:.2f}, {β:.2f}")
plot_y(y_stochastic(y_0=40, y_1=42, α=α, β=β, σ=2, n=100))
```

```
α, β = 0.63, 0.94
Solution type: Damped oscillations
Roots are ['0.78+0.57j', '0.78-0.57j']
Root type: Complex
Stability: Stable
```

45.5 Government spending

This function computes a response to either a permanent or one-off increase in government expenditures

```
def y_stochastic_g(
    y_0=20, y_1=20, α=0.8, β=0.2, γ=10,
    n=100, σ=2, g=0, g_t=0, duration="permanent"
):
    """
    This program computes a response to a permanent increase
    in government expenditures that occurs at time 20
    """

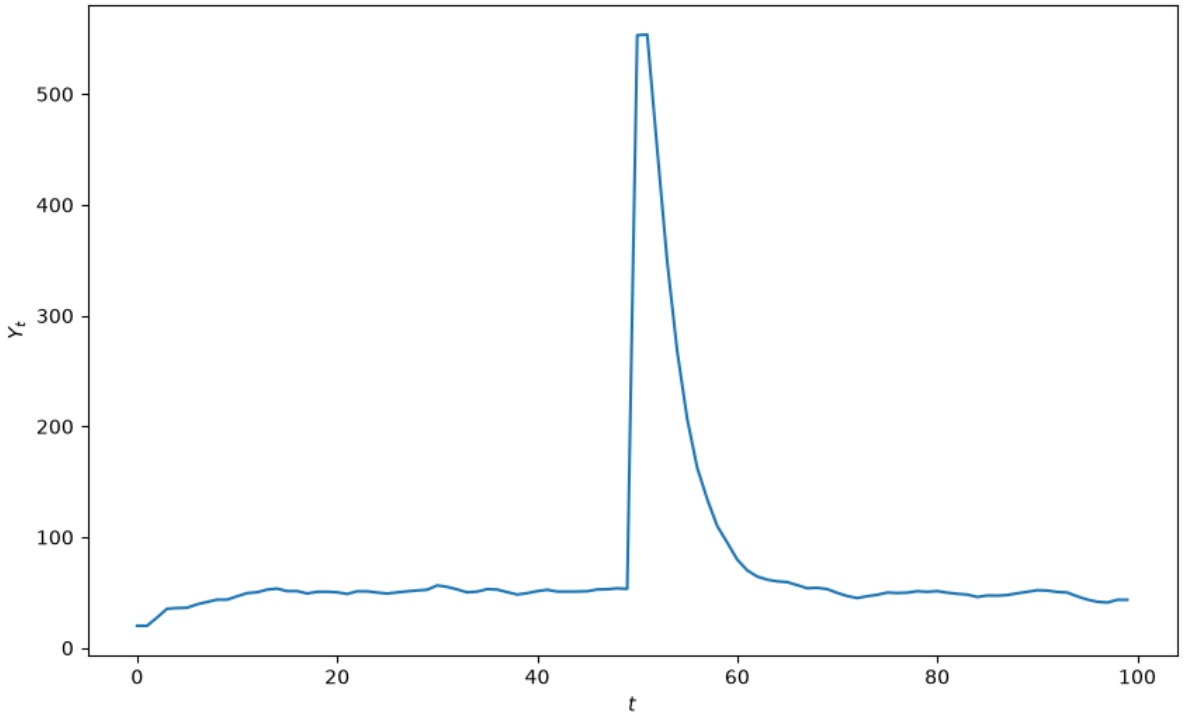
    g_params = (
        {'g': g, 'g_t': g_t, 'duration': duration} if g != 0 else None
    )
    y_series, analysis = simulate_samuelson(
        y_0, y_1, α, β, γ, n, σ, g_params, 42
    )

    print(f"Solution type: {analysis['solution_type']}")
    print(f"Roots: {analysis['roots']}")
    print(f"Root type: {'Complex' if analysis['is_complex'] else 'Real'}")
    print(f"Stability: {'Stable' if analysis['is_stable'] else 'Unstable'}")

    return y_series
```

A permanent government spending shock can be simulated as follows

```
plot_y(y_stochastic_g(g=10, g_t=20, duration="permanent"))
```



```
Solution type: Steady state convergence
Roots: [0.7236068 0.2763932]
Root type: Real
Stability: Stable
```

We can also see the response to a one time jump in government expenditures

```
plot_y(y_stochastic_g(g=500, g_t=50, duration="one-off"))
```

```
Solution type: Steady state convergence
Roots: [0.7236068 0.2763932]
Root type: Real
Stability: Stable
```

45.6 Wrapping everything into a class

Up to now, we have written functions to do the work.

Now we'll roll up our sleeves and write a Python class called `Samuelson` for the Samuelson model

```
class Samuelson:
    r"""
    This class represents the Samuelson model, otherwise known as the
    multiplier-accelerator model.
    The model combines the Keynesian multiplier
    with the accelerator theory of investment.

    The path of output is governed by a linear
    second-order difference equation

    .. math::

        Y_t = (\alpha + \beta) Y_{t-1} - \beta Y_{t-2} + (\gamma + G_t) + \sigma \
↪epsilon_t

    Parameters
    ----------
    y_0 : scalar
        Initial condition for Y_0
    y_1 : scalar
        Initial condition for Y_1
    α : scalar
        Marginal propensity to consume
    β : scalar
```

(continues on next page)

(continued from previous page)

```
        Accelerator coefficient
    n : int
        Number of iterations
    σ : scalar
        Volatility parameter. It must be greater than or equal to 0. Set
        equal to 0 for a non-stochastic model.
    g : scalar
        Government spending shock
    g_t : int
        Time at which government spending shock occurs. Must be specified
        when duration != None.
    duration : {None, 'permanent', 'one-off'}
        Specifies type of government spending shock. If none, government
        spending equal to g for all t.

    """

    def __init__(
        self, y_0=100, y_1=50,
        α=1.3, β=0.2, γ=10, n=100, σ=0, g=0, g_t=0, duration=None
    ):

        self.y_0, self.y_1, self.α, self.β = y_0, y_1, α, β
        self.n, self.g, self.g_t, self.duration = n, g, g_t, duration

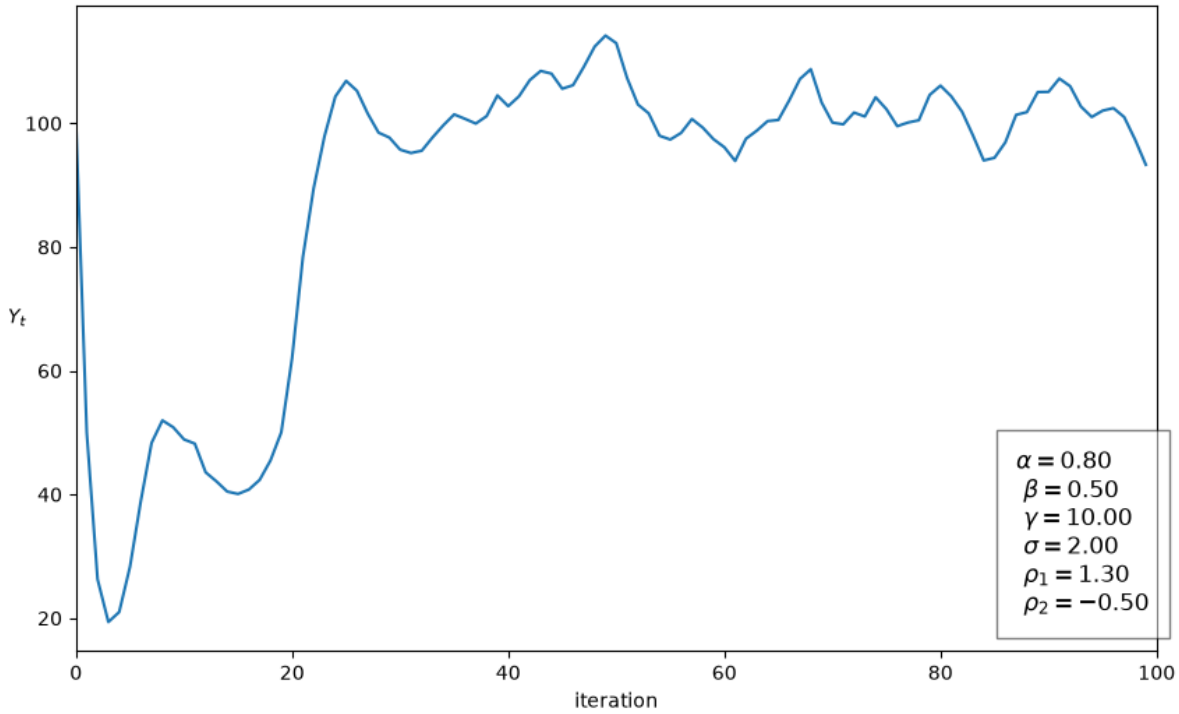
            label=r"$(\rho_1, \rho_2)$",
            zorder=5,
        )

        plt.legend(fontsize=12, loc=3)

        return fig
```



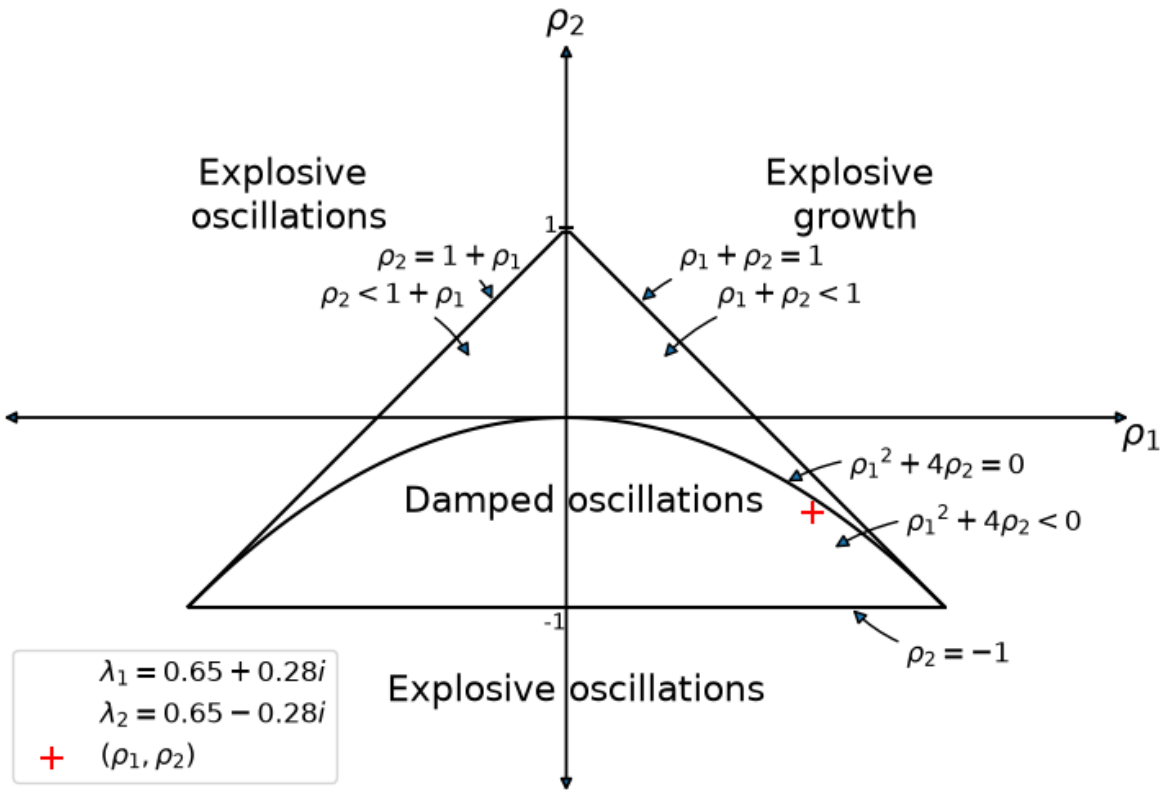
45.6.1 Illustration of Samuelson class

Now we'll put our Samuelson class to work on an example

```
sam = Samuelson(α=0.8, β=0.5, σ=2, g=10, g_t=20, duration="permanent")
sam.summary()
```

```
Summary
-----------------------------------------------
Root type: Complex conjugate
Solution type: Damped oscillations
Roots: [0.65+0.27838822j 0.65-0.27838822j]
Absolute value of roots is less than one
Stochastic series with σ = 2
Government spending equal to 10
Permanent government spending shock at t = 20
```

```
sam.plot()
plt.show()
```



45.6.2 Using the graph

We'll use our graph to show where the roots lie and how their location is consistent with the behavior of the path just graphed.

The red + sign shows the location of the roots

```
sam.param_plot()
plt.show()
```

45.7 Using the LinearStateSpace class

It turns out that we can use the QuantEcon.py LinearStateSpace class to do much of the work that we have done from scratch above.

Here is how we map the Samuelson model into an instance of a `LinearStateSpace` class

```
α = 0.8
β = 0.9
ρ1 = α + β
ρ2 = -β
γ = 10
σ = 1
g = 10
n = 100

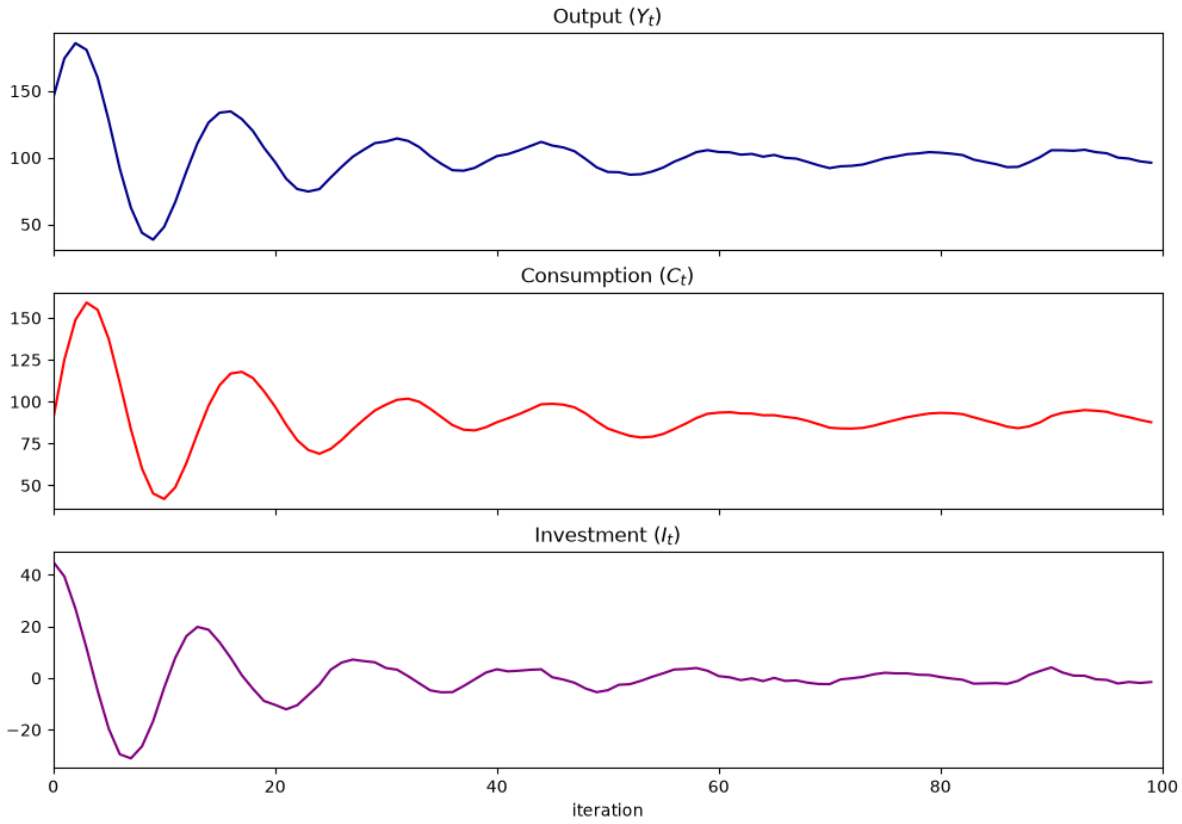
A = [[1, 0, 0], [γ + g, ρ1, ρ2], [0, 1, 0]]

G = [
    [γ + g, ρ1, ρ2],   # Y_{t+1}
    [γ, α, 0],         # C_{t+1}
    [0, β, -β],        # I_{t+1}
]

μ_0 = [1, 100, 50]
C = np.zeros((3, 1))
C[1] = σ  # Shock variance
```

(continues on next page)

(continued from previous page)



```
sam_t = LinearStateSpace(A, C, G, mu_0=μ_0)

rng = np.random.default_rng()
x, y = sam_t.simulate(ts_length=n, random_state=rng)

fig, axes = plt.subplots(3, 1, sharex=True, figsize=(12, 8))
titles = ["Output ($Y_t$)", "Consumption ($C_t$)", "Investment ($I_t$)"]
colors = ["darkblue", "red", "purple"]
for ax, series, title, color in zip(axes, y, titles, colors):
    ax.plot(series, color=color)
    ax.set(title=title, xlim=(0, n))

axes[-1].set_xlabel("iteration")

plt.show()
```

45.7.1 Other methods in the `LinearStateSpace` class

Let's plot *impulse response functions* for the instance of the Samuelson model using a method in the `LinearStateSpace` class

```
imres = sam_t.impulse_response()
imres = np.asarray(imres)
y1 = imres[:, :, 0]
y2 = imres[:, :, 1]
y1.shape
```

$$(2,\ 6,\ 1)$$

Now let's compute the zeros of the characteristic polynomial by simply calculating the eigenvalues of A

```
A = np.asarray(A)
w, v = np.linalg.eig(A)
print(np.round(w, 2))
```

```
[0.85+0.42j 0.85-0.42j 1.  +0.j  ]
```

45.7.2 Inheriting methods from `LinearStateSpace`

We could also create a subclass of `LinearStateSpace` (inheriting all its methods and attributes) to add more functions to use

```
class SamuelsonLSS(LinearStateSpace):
    """
    This subclass creates a Samuelson multiplier-accelerator model
    as a linear state space system.
    """

    def __init__(self, y_0=100, y_1=50, α=0.8, β=0.9, γ=10, σ=1, g=10):

        self.α, self.β = α, β
        self.y_0, self.y_1, self.g = y_0, y_1, g
        self.γ, self.σ = γ, σ

        # Set initial state vector
        self.initial_μ = [1, y_0, y_1]

        self.ρ1 = α + β
        self.ρ2 = -β

        # Construct state transition matrix
        self.A = [[1, 0, 0], [γ + g, self.ρ1, self.ρ2], [0, 1, 0]]

        # Construct observation matrix
        self.G = [
            [γ + g, self.ρ1, self.ρ2],  # Y_{t+1}
            [γ, α, 0],                  # C_{t+1}
            [0, β, -β],                 # I_{t+1}
        ]

        self.C = np.zeros((3, 1))
```

(continues on next page)

(continued from previous page)

```
        self.C[1] = σ  # Shock variance

        # Initialize the LinearStateSpace instance
        LinearStateSpace.__init__(
            self, self.A, self.C, self.G, mu_0=self.initial_μ
        )

    # Create unicode aliases for mu_0 and Sigma_0 in the parent class
    @property
    def μ_0(self):
        return self.mu_0

    @μ_0.setter
    def μ_0(self, value):
        self.mu_0 = value

    @property
    def Σ_0(self):
        return self.Sigma_0

    @Σ_0.setter
    def Σ_0(self, value):
        self.Sigma_0 = value

    def plot_simulation(self, ts_length=100, stationary=True, seed=0):

        # Store original distribution parameters
        temp_μ = self.μ_0
        temp_Σ = self.Σ_0

        # Use stationary distribution for simulation
        if stationary == True:
            try:
                (self.μ_x, self.μ_y, self.Σ_x, self.Σ_y, self.Σ_yx
                ) = self.stationary_distributions()
                self.μ_0 = self.μ_x
                self.Σ_0 = self.Σ_x

            # Handle case where stationary distribution doesn't exist
            except ValueError:
                print("Stationary distribution does not exist")

        rng = np.random.default_rng(seed)
        x, y = self.simulate(ts_length, random_state=rng)

        fig, axes = plt.subplots(3, 1, sharex=True, figsize=(12, 8))
        titles = ["Output ($Y_t$)",
                  "Consumption ($C_t$)",
                  "Investment ($I_t$)"]
        colors = ["darkblue", "red", "purple"]
        for ax, series, title, color in zip(axes, y, titles, colors):
            ax.plot(series, color=color)
            ax.set(title=title, xlim=(0, n))

        axes[-1].set_xlabel("iteration")
        plt.show()
```

(continues on next page)

(continued from previous page)

```
        # Restore original distribution parameters
        self.μ_0 = temp_μ
        self.Σ_0 = temp_Σ

    def plot_irf(self, j=5):

        x, y = self.impulse_response(j)

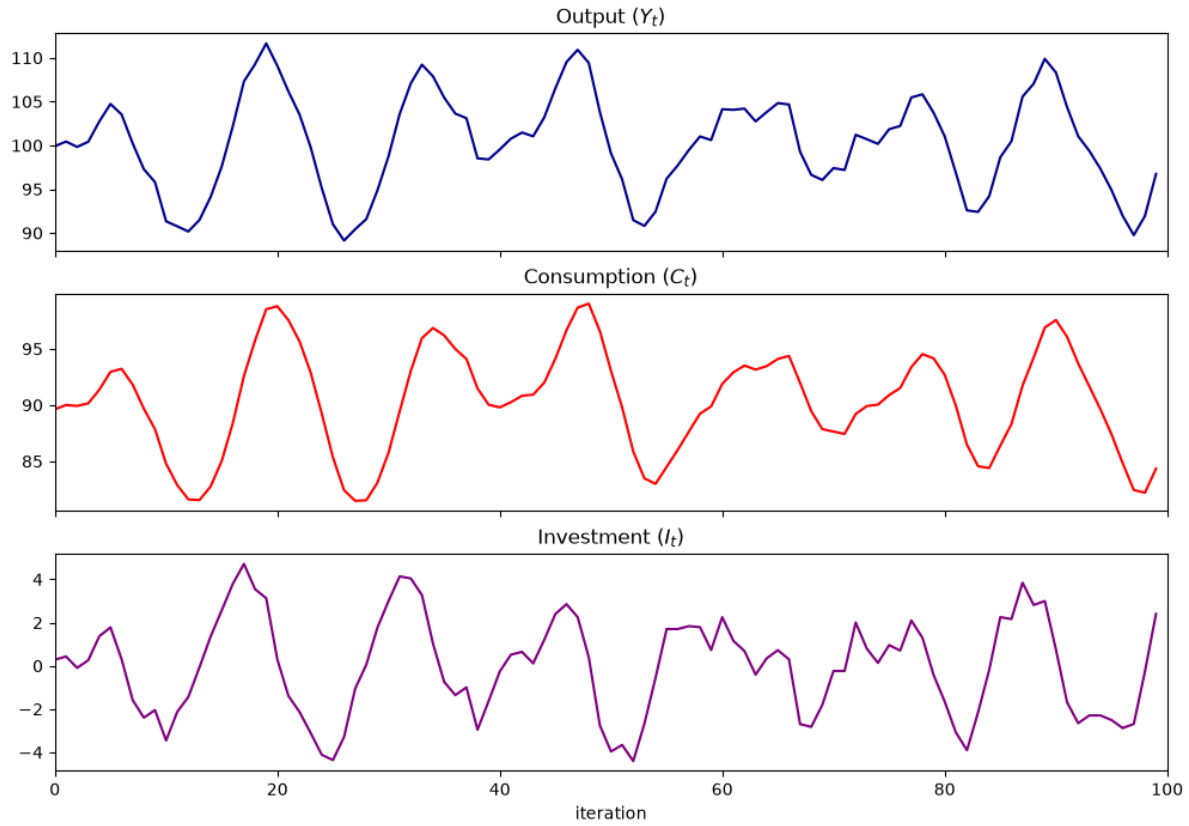
        # Reshape impulse responses for plotting
        yimf = np.array(y).flatten().reshape(j + 1, 3).T

        fig, axes = plt.subplots(3, 1, sharex=True, figsize=(12, 8))
        labels = ["$Y_t$", "$C_t$", "$I_t$"]
        colors = ["darkblue", "red", "purple"]
        for ax, series, label, color in zip(axes, yimf, labels, colors):
            ax.plot(series, color=color)
            ax.set(xlim=(0, j))
            ax.set_ylabel(label, rotation=0, fontsize=14, labelpad=10)

        axes[0].set_title("Impulse response functions")
        axes[-1].set_xlabel("iteration")
        plt.show()

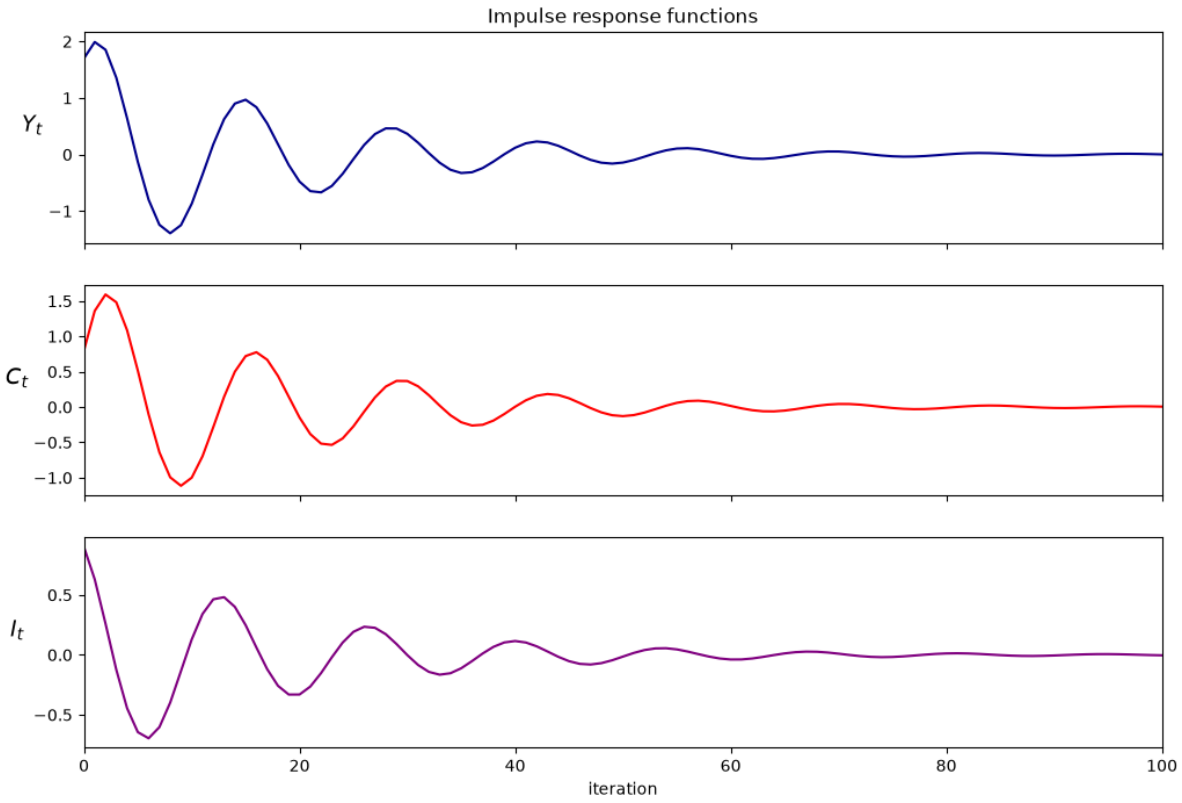
    def multipliers(self, j=5):
        x, y = self.impulse_response(j)
        return np.sum(np.array(y).flatten().reshape(j + 1, 3), axis=0)
```

45.7.3 Illustrations



Let's show how we can use the `SamuelsonLSS`

```
samlss = SamuelsonLSS()
```



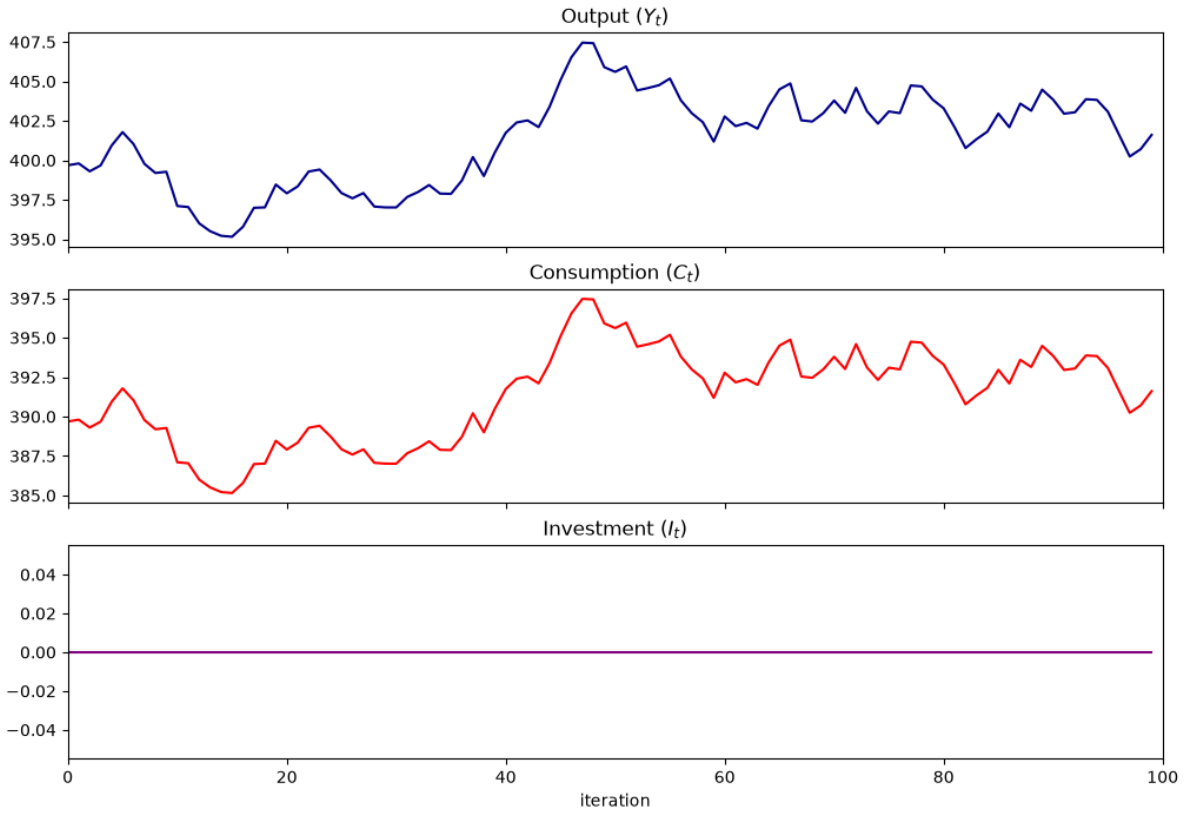
```
samlss.plot_simulation(100, stationary=False)
plt.show()
```

```
samlss.plot_simulation(100, stationary=True)
plt.show()
```

```
samlss.plot_irf(100)
plt.show()
```

```
samlss.multipliers()
```

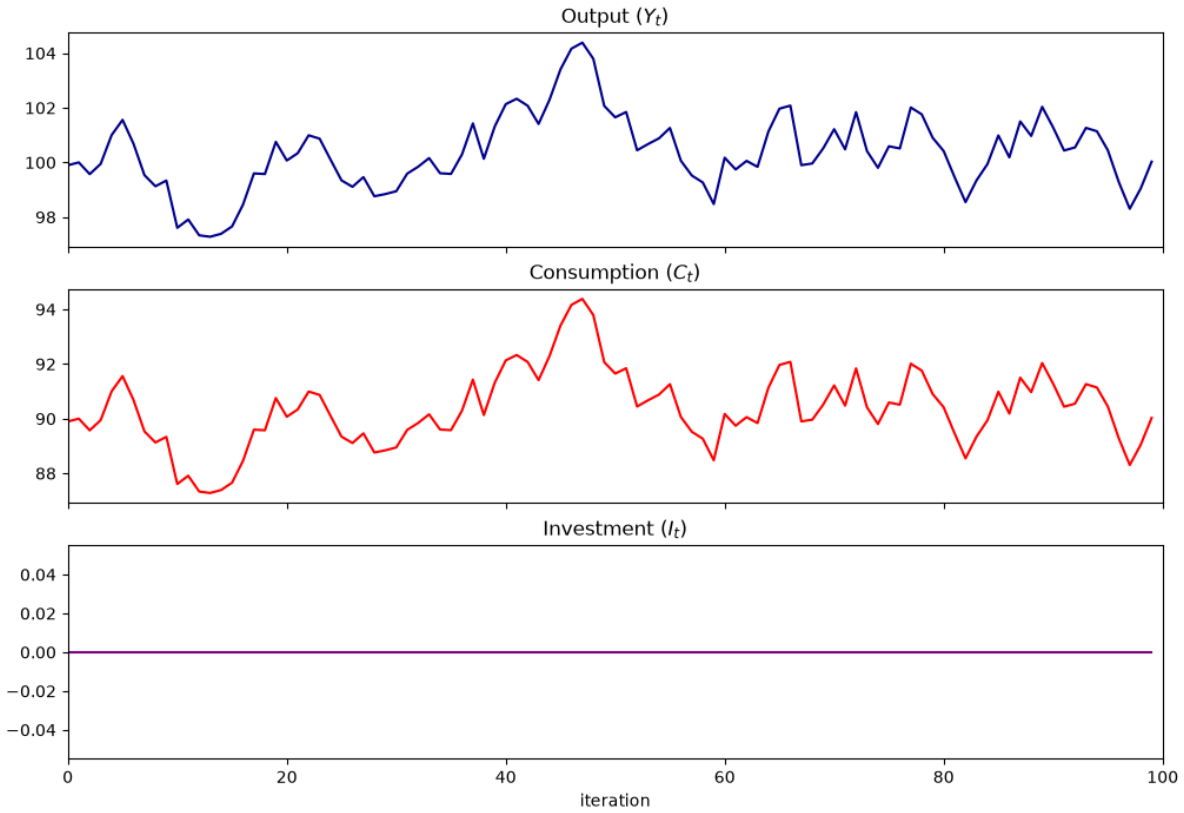
```
array([7.414389, 6.835896, 0.578493])
```



45.8 Pure multiplier model

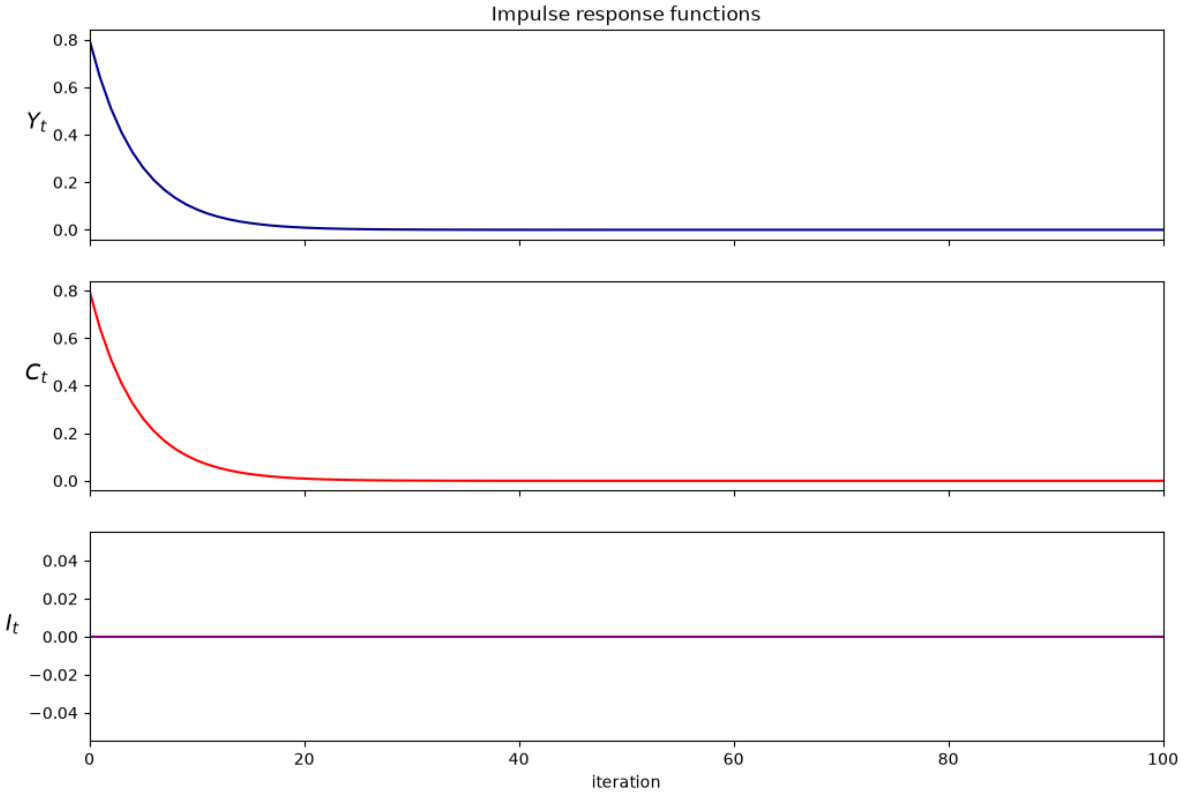
Let's shut down the accelerator by setting $b = 0$ to get a pure multiplier model

- the absence of cycles gives an idea about why Samuelson included the accelerator



```
pure_multiplier = SamuelsonLSS(α=0.95, β=0)
```

```
pure_multiplier.plot_simulation()
```



```
pure_multiplier = SamuelsonLSS(α=0.8, β=0)
```

```
pure_multiplier.plot_simulation()
```

```
pure_multiplier.plot_irf(100)
```

45.9 Summary

In this lecture, we wrote functions and classes to represent non-stochastic and stochastic versions of the Samuelson (1939) multiplier-accelerator model, described in [Samuelson, 1939].

We saw that different parameter values led to different output paths, which could either be stationary, explosive, or oscillating.

We also were able to represent the model using the QuantEcon.py LinearStateSpace class.

46.1 Overview

This lecture studies two classic papers by Gregory Chow:

- Chow [1968] presents empirical evidence for the acceleration principle, describes how acceleration promotes oscillations, and analyzes conditions for the emergence of spectral peaks in linear difference equation subjected to random shocks
- Chow and Levitan [1969] presents a spectral analysis of a calibrated US macroeconometric model and teaches about spectral gains, coherences, and lead–lag patterns

These papers are related to ideas in the following lectures:

- The multiplier–accelerator mechanism in *Samuelson Multiplier-Accelerator*
- Linear stochastic difference equations and autocovariances in *Linear State Space Models*
- Eigenmodes of multivariate dynamics in *VARs and DMDs*

- Fourier ideas in *Circulant Matrices* (and, for empirical estimation, the advanced lecture Estimation of Spectra)

Chow [1968] builds on earlier empirical work testing the acceleration principle on US investment data.

We start with that empirical evidence before developing the theoretical framework.

We will keep returning to three ideas:

- In deterministic models, oscillations indicate complex eigenvalues of a transition matrix.
- In stochastic models, a "cycle" shows up as a local peak in a (univariate) spectral density.
- Spectral peaks depend on eigenvalues, but also on how shocks enter and on how observables load on eigenmodes.

Let's start with some standard imports:

```
import numpy as np
import matplotlib.pyplot as plt
```

We will use the following helper functions throughout the lecture

```
def spectral_density_var1(A, V, ω_grid):
    """Spectral density matrix for VAR(1): y_t = A y_{t-1} + u_t."""
    A, V = np.asarray(A), np.asarray(V)
    n = A.shape[0]
    I = np.eye(n)
    F = np.empty((len(ω_grid), n, n), dtype=complex)
    for k, ω in enumerate(ω_grid):
        H = np.linalg.inv(I - np.exp(-1j * ω) * A)
        F[k] = (H @ V @ H.conj().T) / (2 * np.pi)
    return F

def spectrum_of_linear_combination(F, b):
    """Spectrum of x_t = b'y_t given the spectral matrix F(ω)."""
    b = np.asarray(b).reshape(-1, 1)
    return np.array([np.real((b.T @ F[k] @ b).item())
                                for k in range(F.shape[0])])

def simulate_var1(A, V, T, burn=200, seed=1234):
    r"""Simulate y_t = A y_{t-1} + u_t with u_t \sim N(0, V)."""
    rng = np.random.default_rng(seed)
    A, V = np.asarray(A), np.asarray(V)
    n = A.shape[0]
    chol = np.linalg.cholesky(V)
    y = np.zeros((T + burn, n))

    for t in range(1, T + burn):
        y[t] = A @ y[t - 1] + chol @ rng.standard_normal(n)

    return y[burn:]

def sample_autocorrelation(x, max_lag):
    """Sample autocorrelation of a 1d array from lag 0 to max_lag."""
    x = np.asarray(x)
    x = x - x.mean()
    denom = np.dot(x, x)
    acf = np.empty(max_lag + 1)
    for k in range(max_lag + 1):
        acf[k] = np.dot(x[:-k] if k else x, x[k:]) / denom
    return acf
```

46.2 Empirical foundation for the acceleration principle

Chow [1968] opens by reviewing empirical evidence for the acceleration principle from earlier macroeconometric work.

Using annual observations for 1931–40 and 1948–63, Chow tested the acceleration equation on three investment categories:

- new construction
- gross private domestic investment in producers' durable equipment combined with change in business inventories
- the last two variables separately

In each case, when the regression included both Y_t and Y_{t-1} (where Y is gross national product minus taxes net of transfers), the coefficient on Y_{t-1} was of *opposite sign* and slightly smaller in absolute value than the coefficient on Y_t.

Equivalently, when expressed in terms of ΔY_t and Y_{t-1}, the coefficient on Y_{t-1} was a small fraction of the coefficient on ΔY_t.

46.2.1 An example: automobile demand

Chow presents a clean illustration using data on net investment in automobiles from his earlier work on automobile demand.

Using annual data for 1922–41 and 1948–57, he estimates by least squares:

$$y_t^n = \underset{(0.0022)}{0.0155} Y_t \; \underset{(0.0020)}{-0.0144}\, Y_{t-1} \; \underset{(0.0056)}{-0.0239}\, p_t \; \underset{(0.0040)}{+0.0199}\, p_{t-1} + \underset{(0.101)}{0.351} y_{t-1}^n + \text{const.} \tag{46.1}$$

where:

- Y_t is real disposable personal income per capita
- p_t is a relative price index for automobiles
- y_t^n is per capita net investment in passenger automobiles
- standard errors appear in parentheses

The key observation: the coefficients on Y_{t-1} and p_{t-1} are *the negatives* of the coefficients on Y_t and p_t.

This pattern is exactly what the acceleration principle predicts.

46.2.2 From stock adjustment to acceleration

The empirical support for acceleration should not be surprising once we accept a stock-adjustment demand equation for capital:

$$s_{it} = a_i Y_t + b_i s_{i,t-1} \tag{46.2}$$

where s_{it} is the stock of capital good i.

The acceleration equation (46.1) is essentially the *first difference* of (46.2).

Net investment is the change in stock, $y_{it}^n = \Delta s_{it}$, and differencing (46.2) gives:

$$y_{it}^n = a_i \Delta Y_t + b_i y_{i,t-1}^n \tag{46.3}$$

The coefficients on Y_t and Y_{t-1} in the level form are a_i and $-a_i(1 - b_i)$ respectively.

They are opposite in sign and similar in magnitude when b_i is not too far from unity.

This connection between stock adjustment and acceleration is central to Chow's argument about why acceleration matters for business cycles.

46.3 Acceleration enables oscillations

Having established the empirical evidence for acceleration, we now examine why it matters theoretically for generating oscillations.
